Introduction xv
Tracey A. Revenson and Andrew Baum

Part I. Basic Processes

1 Factors Influencing Behavior and Behavior Change 3
*Martin Fishbein, Harry C. Triandis, Frederick H. Kanfer, Marshall Becker,
Susan E. Middlestadt, and Anita Eichler*

2 Representations, Procedures, and Affect in Illness Self-Regulation:
A Perceptual-Cognitive Model 19
Howard Leventhal, Elaine A. Leventhal, and Linda Cameron

3 Conceptualization and Operationalization of Perceived Control 49
Kenneth A. Wallston

4 On Who Gets Sick and Why: The Role of Personality and Stress 59
Richard J. Contrada and Max Gyll

5 Visceral Learning 85
Bernard T. Engel

6 Biofeedback and Self-Regulation of Physiological Activity:
A Major Adjunctive Treatment Modality in Health Psychology 95
Robert J. Gatchel

- 7** Behavioral Conditioning of the Immune System 105
Alexander W. Kusnecov
- 8** Physiological and Psychological Bases of Pain 117
Dennis C. Turk
- 9** Personality Traits as Risk Factors for Physical Illness 139
Timothy W. Smith and Linda C. Gallo
- 10** Personality's Role in the Protection and Enhancement of Health:
Where the Research Has Been, Where It Is Stuck, How It Might Move 175
Suzanne C. Ouellette and Joanne DiPlacido
- 11** Social Comparison Processes in the Physical Health Domain 195
Jerry Suls and René Martin
- 12** Social Networks and Social Support 209
Thomas Ashby Wills and Marnie Filer
- 13** Self-Efficacy and Health 235
Brenda M. DeVellis and Robert F. DeVellis
- 14** The Psychobiology of Nicotine Self-Administration 249
Neil E. Grunberg, Martha M. Faraday, and Matthew A. Rahman
- 15** Obesity 263
Rena R. Wing and Betsy A. Polley
- 16** Alcohol Use and Misuse 280
Mark D. Wood, Daniel C. Vinson, and Kenneth J. Sher

Part II. Crosscutting Issues

- 17** Stress, Health, and Illness 321
Angela Liegey Dougall and Andrew Baum
- 18** What Are the Health Effects of Disclosure? 339
Joshua M. Smyth and James W. Pennebaker
- 19** Preventive Management of Work Stress: Current Themes
and Future Challenges 349
Debra L. Nelson, James Campbell Quick, and Bret L. Simmons

Preface

This volume was conceived during the waning stages of initial, rapid growth of health psychology. In the preceding years the field had defined itself, identified important contributions and targets of opportunity, and had achieved a remarkable degree of influence within its parent field as well as the larger behavioral medicine arena. Behavioral treatments and adjunctive treatments for palliation and cure were developed, prevention that relied on behavior and behavior change was expanded, and psychological variables were more routinely included in models of the etiology of disease and promotion or maintenance of good health. Public health conceptions of air-borne or water-borne diseases or disease vectors had been supplemented by “lifestyle-borne diseases” and the expansion of medical psychology practice with patients and at-risk individuals had occurred. Clearly this was a time of great accomplishment that required a pause and an opportunity to reflect and integrate all that had been learned and done.

As with all Handbooks, preparation and finalization of chapters and contributions took longer than was initially expected, and the pause in the rapid growth of health psychology was brief (if, indeed, there was a pause). As the volume was being put together, important new research and theory in areas like cancer, women’s health, and socioeconomic or sociocultural phenomena appeared and new emphases on community involvement, prevention, and survivorship

evolved. The field was continuing to grow and mature at a rate that made it difficult to keep up. Consequently, this volume had to do more than summarize previous work and chart new directions. It also had to integrate new work often as related chapters were being completed. The Handbook has incorporated these new and breaking developments for the most part and represents a comprehensive summary and integration of current research and theory in health psychology. It should serve as a valuable resource for many years, containing the roots and seeds of future discoveries and accomplishments as well as the more established and enduring bases, applications, and implications of our work over the past 30 years.

There are many people who have contributed to the development of health psychology and to this book over the years, far too many to thank in this preface. One who should be singled out, for his rare vision, wit, and patience, and for his support, friendship, and enthusiasm for health psychology is Larry Erlbaum. As a friend, colleague, publisher, and *mentsch* he has been and continues to be a pillar of the health psychology community. We would also like to thank Michele Hayward for her patience, outstanding organizational and editorial skills and stewardship of this project from its inception, and to production and editorial folks at LEA, most notably Art Lizza. Most of all, we thank the contributors to this volume and to the field of health psychology for their hard work, dedication, and vision.

Introduction

Tracey A. Revenson

Andrew Baum

The woods are lovely, dark and deep,
But I have promises to keep,
And miles to go before I sleep,
And miles to go before I sleep.
(Frost, 1923)

Over the past two decades, health psychology researchers have grappled with critical behavioral, biological, and social science questions: How do personality and behavior contribute to the pathophysiology of cardiovascular disease? What do women gain from screening mammography if it creates anxiety and avoidance of regular screening? Why do we expect individuals to take responsibility for condom use to prevent HIV transmission when using condoms is an interpersonal negotiation? When are social relationships supportive and when are they detrimental to health? Only some of these questions have been answered adequately, many findings have been refuted, and many questions have been reframed along the way. The chapters in this volume address the central questions (still) of interest for Health Psychology, and pose many more for the next decade of research and theory.

Although this is a first edition, one could argue that there are two precursors of this volume. In 1979, *Health Psychology—A Handbook*, edited by George Stone, Frances Cohen, and Nancy Adler, was published by Jossey-Bass, Inc. At that time the term *health psychology* was a fairly new one; only a handful of doctoral programs in psychology specifically trained health psychologists, and the Division of Health Psychology (Division 38) had just been established within the American Psychological Association (Wallston, 1997). In the mid-1980s, a series of five edited volumes were published by Lawrence Erlbaum Associates under the title, *Handbook of Psychology*

and *Health* (Baum & Singer, 1982, 1987; Baum, Taylor, & Singer, 1984; Gatchel, Baum, & Singer, 1982; Krantz, Baum, & Singer, 1983). In contrast to the Stone et al. volume, the books in this series focused on specific topic areas, such as child and adolescent health, cardiovascular disorders, coping and stress, or on subdisciplines within psychology (clinical, social). This series was published over several years just as Health Psychology became firmly established in its own right. Although there has been a number of textbooks and edited volumes in the area of health psychology published since then, there has been no other comprehensive “handbook”.¹ As there have been great advances in knowledge about health-behavior relationships in the past decade, the time seemed right for a handbook. Although many publications bear the designation of “handbook”, the New Shorter Oxford English Dictionary offers the following definition, “A book containing concise in-

¹ There have been other handbooks in specialty areas, for example, *Handbook of Stress: Theoretical and Clinical Aspects* (Goldberger & Breznitz, 1983, second edition, 1993); *Behavioral Health: A Handbook of Health Enhancement and Disease Prevention* (Matarazzo et al., 1984); *Handbook of Behavioral Medicine* (Gentry, 1984); *Health Psychology: A Psychobiological Perspective* (Feurestein, Labbe, & Kuczmierczyk, 1986); *Behavioral Medicine & Women: A Comprehensive Handbook* (Blechman & Brownell, 1988, revised 1998); and *Handbook of Diversity Issues in Health Psychology* (Kato & Mann, 1996).

formation on a particular subject; a guidebook" (1997, E 19). At nearly 900 pages, one could argue that this Handbook is not concise, but the chapters do synthesize current theory and knowledge on many substantive areas in the field, taking us through the development of a concept to its future directions.

The preface to Stone, Cohen, and Adler's handbook is just as fitting today as it was 21 years ago: "*In recent years there has been a growing concern about problems of health and illness and about the state and cost of the current health care delivery system. There has also been increasing awareness of the significance of psychological factors in the etiology, course, and treatment of disease and in the maintenance of health*" (1979, p. ix).

Let us use these two sentences as a springboard to report on the progress of health psychology, place current challenges in sociopolitical context, and guide our work for the future.

THE CURRENT SOCIOPOLITICAL CONTEXT OF HEALTH PSYCHOLOGY

An article published a decade ago in the *New England Journal of Medicine* illustrated one important aspect of the current health care crisis when it concluded that a black man in Harlem was less likely to reach 65 years of age than was a man in Bangladesh (McCord & Freeman, 1990). Americans spend more of their gross domestic product on health services than any other major industrialized country; in 1998, national health care expenditures totaled \$1.15 trillion, or 13.5% of the gross domestic product (U.S. Health Care Financing Administration, 1999). Yet, the quality of healthcare and its availability to our citizens is more limited than in many nations that spend less. These enormous health expenditures do not assure better quality care or better health for all Americans. Despite overall declines in mortality, disparities among racial/ethnic groups in mortality and morbidity remain substantial: a White female child born in 1997 can expect to live 79.9 years, a black female child 74.7 years; the comparable figures for males are 74.3 and 67.2 (Hoyert, Kochanek, & Murphy, 1999). In 1997, overall mortality was 55 percent higher for Black Americans than for White Americans (National Center for Health Statistics, 1999). Many causes of mortality that may explain this differential include behaviorally-linked conditions, such as HIV infection, homicide, firearm-related deaths, unintentional injuries, and stroke. Stage-specific survival rates among women with breast cancer have increased overall in the past quarter-century, but the overall 5-year survival rates for women from 1989–1994 were 87% for White women and 71% for Black women (National Center for Health Statistics, 1999). Explanations for these disparities include the fact that, on average, white women receive prenatal care more often and earlier in their pregnancies, and seek medical care for breast cancer at an earlier stage of the disease.

Chronic diseases often affect those people who have the least access to health care and the fewest financial resources to pay for it. In 1998 an estimated 44.3 million Americans (16.3% of the population) were not covered by health insurance at any time during the year, and the percentage was dou-

ble (32.3%) for poor people (National Center for Health Statistics, 1999). The uninsured rate among Hispanics was three times higher than that of non-Hispanic Whites (National Center for Health Statistics, 1999). Ethnic minority and elderly individuals, families living in poverty, and people living in rural areas or inner cities are often in the poorest health, have multiple risk factors for serious illness, receive the poorest health care, have little or no insurance coverage, and are less likely to receive preventive care. Despite medical progress in the past quarter-century that has led to reductions in the major causes of death (cancer, heart disease, and stroke), many underserved and ethnic minority groups are lagging behind (Macera, Armstead, & Anderson, chap. 24; Landrine & Klonoff, chap. 51). For example, the age-adjusted mortality rate (for all causes) for Blacks is approximately one and a half-times that of Whites (Macera et al., chap. 24). Approximately 31% of this excess mortality can be accounted for by six well-established risk factors related to behavior: smoking, alcohol intake, total serum cholesterol, blood pressure, obesity, and diabetes. An additional 38% can be accounted for by family income, despite the fact that income and the prevalence of risk factors co-vary. On a disease-specific level, coronary heart disease as a cause of death among Blacks far exceeds that of Whites, with both physiological factors (e.g., hypertension, cardiovascular reactivity) and social environmental factors (e.g., racial stress, socioeconomic status) playing a role. HIV/AIDS has disproportionately affected certain ethnic minority groups in this country as well as people in poverty, with behavioral mediating processes including intravenous drug injection and unprotected sex (Catania, Binson, Dolcini, Moskowitz, & van der Straten, chap. 47; Mays, So, Cochran, Detels, Benjamin, Allen, & Kwon, chap. 48). The research these examples reflect suggests we look more closely at the interaction of person, situation, and social-structural factors in understanding these health differentials. Important social structural factors include education and the economics of health care, which are mutually influential and which both influence health practices.

There are other factors that argue for the approach generally taken by health psychology and related disciplines like behavioral medicine, medical sociology, and medical anthropology. Perhaps the most important is that the medical model of disease and health that has dominated the prevention, treatment, and scientific study of these phenomena simply cannot account for nor explain the onset and progression of illness—who becomes ill, why people get particular diseases at a certain time in their life, and how these diseases respond to treatment. Where major diseases were once caused by microorganisms that could be controlled or eradicated with wonder drugs, improved sanitation, and other biological interventions, the diseases that dominate health care today are not. Rather, they are diseases of lifestyle, aging, or behavior interacting with genetic predisposition and biological changes. Most cardiovascular diseases have substantial genetic origins, reflect biological processes in their pathophysiology, and respond to medications and medical treatments. However, considerable variance in their development and course is explained by behavior: diet, exercise, tobacco use, and

stress appear to contribute directly and indirectly to these diseases. Other major health threats in this modern era also appear to arise at least in part because of these factors, and cancer, diabetes, HIV disease, and other major diseases may be more readily controlled through thoughtful and systematic application of biobehavioral principles and the sociocultural context (e.g., Amaro, 1995). The confluence of the changing face of healthcare, the unequal burden of disease across our society, and the dominance of chronic diseases with substantial behavioral components has been key in the development of health psychology.

CURRENT APPROACHES IN HEALTH PSYCHOLOGY

At the time it was established, the discipline of health psychology brought together psychologists trained in traditional areas of psychology who shared a common interest in problems of health and illness and a common conceptual approach—but who brought their own disciplinary paradigms and methodologies to the table. Not surprisingly, this cacophony of scientific jargons, models, and approaches was confusing at times. It also brought a breadth and eclecticism to the study of health and behavior that has been partly responsible for its success.

The common approach was labeled the *biopsychosocial model* (Engel, 1977; Schwartz, 1982). In contrast to the biobehavioral model it replaced, this eponymously named approach suggests a transaction of *psyche* and *soma*—that physiological, psychological and social factors are braided together in health and illness. The biopsychosocial model does not give primacy to biological indices; they are not the ultimate criteria for defining health and illness. Instead, the model argues, it is impossible to understand disease processes by knowing about only one component of the model. The biopsychosocial model was inclusive enough to be applied to risk estimates for particular diseases as well as health-promoting behaviors and environments, to disease progression as well as psychosocial adaptation to illness, and to individually-oriented therapeutic and behavior change interventions as well as broader community-based and media approaches. The biopsychosocial model stimulated more effective theories and research designs; facilitated multi-disciplinary thinking and, most importantly, suggested a multi-cause multi-effect approach to health and illness, rather than the limiting single-cause, single-effect approach.

Although the strength of experimental evidence is not consistent across all diseases or all psychological variables implicated in disease, research of the past 20 years strongly supports the biopsychosocial model. In a recent *Annual Review* chapter, Baum and Posluszny (1999) specify three pathways in which psychosocial or behavioral factors affect, and are affected by, health and illness: (1) direct biological changes that cause or are caused by emotional or behavioral processes; (2) behaviors that convey health risks; and (3) behaviors associated with illness or the possibility of becoming ill. Behavioral conditioning of the immune system (Kusnecov, chap. 7), pain processes (Turk, chap. 8), and the

effects of stress on physiology (Dougall & Baum, chap. 17; G. Evans, chap. 20; Dunkel-Schetter, Gurung, Lobel, & Wadhwa, chap. 30; Kop, Gottdiener, & Krantz, chap. 40; Marsland, Bachen, Cohen, & Manuck, chap. 41; Delahanty & Baum, chap. 45) all exemplify direct influences—sometimes reciprocal, sometimes parallel—of psychological and physiological processes.

Many other phenomena of interest to health psychologists illustrate the second and third pathways: cognitive appraisals of control, abilities or others' situations (Fishbein, Triandis, Kanfer, Becker, Middlestadt, & Eichler, chap. 1; Leventhal, Leventhal, & Cameron, chap. 2; Wallston, chap. 3; Suls & Martin, chap. 11; DeVellis & DeVellis, chap. 13); personality (Conrada & Gyll, chap. 4; Smith & Gallo, chap. 9; Ouellette & DiPlacido, chap. 10; Williams, chap. 39); coping (Stanton, Collins, & Sworowski, chap. 21); interpersonal relationships (Wills & Filer, chap. 12; Smyth & Pennebaker, chap. 18; Evans, chap. 27) screening (Rimer, McBride, & Crump, chap. 31; Aiken, Gerend, & Jackson, chap. 44;) and adherence (Dunbar-Jacob & Schlenk, chap. 34). Well-established behavioral risk factors (pathway 2) include: smoking (Grunberg, Faraday, & Rahman, chap. 14.) alcohol intake (Wood, Vinson, & Sher, chap. 16), and weight control (Wing & Polley, chap. 15).

The role of biological, psychological and social factors in health and illness is not hard to accept. What has been more difficult to understand, and to translate into testable theories, is how health is affected by the *interplay* of those physiological, psychological, sociological and cultural factors. Previously, card-carrying health psychologists were trained in one of the more “traditional” areas of psychology (developmental, social, clinical, experimental) and, they tended to define problems through the paradigmatic lenses of that area. More recently, the field has seen a concerted attempt to blend approaches, conduct “translational” research, and develop more synergistic models. For example, the area of psychoneuroimmunology not only connects areas *within* psychology, but links them to a subdiscipline of biology/medicine (Andersen, Golden-Kretz, & DiLillo, chap. 43; Andersen, Kiecolt-Glaser, & Glaser, 1994). A recent focus in cancer control and prevention examines how the presence of disease biomarkers affects treatment choices, screening behavior, and mental health (Lerman, 1997). In 1995, this emphasis on multidisciplinary knowledge found “legs” in the creation of the Office of Behavioral and Social Science Research at NIH in 1995. The mission of this office is, “to enhance and accelerate scientific advances in the understanding, treatment, and prevention of disease by greater attention to behavioral and social factors and their interaction with biomedical variables” (Anderson, 1999).

Other notable changes have occurred in the way health-behavior processes are studied. First, we have seen more and more research set in the world of everyday experience, linked to the social problems we face. For example, the pressing problems of violence against women (Koss, Ingram, & Pepper, chap. 32), alcohol and drug use (Grunberg et al., chap. 14; Wing & Polley, chap. 15); and workplace stress (Nelson, Quick, & Simmons, chap. 19;

Leiter & Maslach, chap. 23) fall under the rubric of health psychology because of their health-damaging consequences.

Second, health psychology (like its mother-field) has gone beyond individual-level processes to examine phenomena within social systems: the family (Martire & Schulz, chap. 29; Pasch, chap. 33); workplace (Nelson et al., chap. 19); school (G. Evans, chap. 20) and community (Obeidallah, Hauser, & Jacobson, chap. 25; Altman & Goodman, chap. 36; Butterfoss, Wandersman, & Goodman, chap. 37). Ecological approaches that examine the transactional relationships among individuals and the environments they live in, as well as inter-relationships among these settings, have received much theoretical attention and offer promise for understanding disease processes within cultural groups and for designing effective interventions (Anderson & McNeilly, 1991; Revenson, 1990; Smith & Anderson, 1986; Taylor, Repetti, & Seeman, 1997; Winnett, King, & Altman, 1989). These models have been applied to understanding health phenomena such as the effects of environmental stress (G. Evans, chap. 20), HIV infection among women (Amaro, 1995; Ickovics, Thayaparan, & Ethier, chap. 49); and social inequalities in health outcomes (Anderson, 1995; Macera et al., chap. 24). An ecological approach also recognizes the fact that health-behavior processes are developmental, and that we must understand the specific linkages at different stages of the life cycle (Melamed, Roth, & Fogel, chap. 26; Siegler, Bastian, & Bosworth, chap. 28; Martire & Schulz, chap. 29; Pasch, chap. 33; Ickovics et al., chap. 49).

Third, health psychologists look to health-promoting behaviors as well as health-damaging ones (Rimer et al., chap. 31). Health is clearly more than the absence of the signs and symptoms of physical disease. The inclusive definition offered by the World Health Organization defines health as a state of complete physical, mental and social well-being, and not as the mere absence of disease and infirmity (symptoms). For example, regular exercise may be one of the most powerful determinants of overall health, as well as a deterrent for many diseases (Phillips, Kiernan, & King, chap. 38). Early detection of breast and cervical cancers (as well as many other cancers) has resulted in lowered mortality rates among women of all ages (Rimer et al., chap. 31; Aiken et al., chap. 44).

All three of these changes have been shadowed by a call to bring cultural differences in health front and center when understanding the behavioral and social factors in health and illness (Amaro, 1995; Landrine & Klonoff, chap. 51). This may be the area where health psychology has had the least success but has the potential for the greatest contribution. Although it has been a central tenet of medical sociology and epidemiology for years, only recently have psychologists acknowledged the strong direct and indirect influences of socioeconomic status on health (e.g., Adler et al., 1994), whether conceptualized in terms of income, education or social class. For example, people with less than a high school education have death rates that are twice those for people with education beyond high school (National Center for Health Statistics, 1999). In a similar fashion, health psychology has increased attention to within group health-behavior processes for women (Stanton & Gallant, 1995), people of color (Anderson, 1995; Anderson & Eisner,

1997); and older persons (Manuck, Jennings, & Baum, 2000; Resnick & Rozensky, 1996).

Finally, there has been a willingness to blur the boundaries between what is termed "basic" and "applied" science, and to work to integrate knowledge and practice. Exemplars of this work are described in the chapters in the third section of this volume, as scholars translate research findings into effective and cost-effective techniques for individual treatment (Shapiro, chap. 42; Redd, & Jacobsen, chap. 46) and community-based interventions (Altman & Goodman, chap. 36; Butterfoss et al., chap. 37).

TRANSLATING HEALTH PSYCHOLOGY RESEARCH INTO PRACTICE AND POLICY

With the exception of AIDS, the nature and patterns of disease over this century have changed from acute, infectious, and often fatal diseases to chronic disabling illnesses.

Heart disease, cancer, and stroke account for the greatest number of deaths in the United States, for both men and women, and, with other chronic conditions, account for increased disability, hospitalization days, and lowered quality of life. Much of this illness and disability—the preventable portion—has been linked to behavioral or lifestyle factors (Healthy People 2000, 1990; Matarazzo et al., 1994). A prime example is cigarette smoking, which has been implicated in the development of lung cancer, stroke, coronary artery disease, and low-birthweight babies.

The dramatic drop in mortality from infectious diseases such as tuberculosis, diphtheria, and polio over the past century was largely a result of advances in public health, accomplished by changes in the physical environment or through the use of preventive or therapeutic measures such as vaccines and antibiotics. No single exposure preventive interventions comparable to vaccines can "remove" the behavioral and lifestyle factors that are involved in the onset and progression of chronic disease. And, although recent emphases on disease prevention and health promotion among the medical and public health sectors provide a welcome contrast to the traditional biomedical model, most disease prevention efforts have been defined and practiced by the medical community in ways that seriously limit their utility.

Health psychology's contribution to decreasing the prevalence of illness has revolved primarily around individual behavior change, consistent with the foundations and history of the discipline. Similarly, most research in health psychology (translated into practice by its cousin, behavioral medicine) has been directed toward individual or group differences in health status indicators, risk factors, and habits (Rodin & Salovey, 1989). While recognizing the importance of primary prevention, health psychologists have concentrated their efforts on secondary prevention at the individual or small group level, to increase early detection of disease (for example, by encouraging routine screening for cancer). The successes of secondary prevention can be seen clearly in the area of cancer prevention and control—for example, the ability of mammography to identify breast cancer at an early stage improves the opportunity for effective treatment and survival (Aiken et al., chap. 44;

MMWR, 2000). Psychological interventions such as support groups and information hotlines have minimized the incidence of mental health problems as a consequence of illness (Stanton et al., chap. 21; Wills & Filer, chap. 12).

Most behavioral interventions focus on the individual as the target of change (or on aggregates of individuals). In contrast, Stokols (1992), among others, urges us "to provide environmental resources and interventions that promote enhanced well-being among occupants of an area" (1992, pp. 6–7). We are only beginning to understand the effects of living in neighborhoods that lack basic environmental resources—neighborhoods with extreme poverty, high crime rates, inadequate housing, public transportation or schools—on health and well-being (Fullilove, 1999). The case study detailed by Butterfoss et al. (chap. 37) in this handbook provides a blueprint for how researchers and health educators allied with community coalitions can improve community health outcomes. Altman and Goodman (chap. 36) describe a broader range of community-wide or policy strategies that can lead to community-wide change in health behaviors, such as changing the community's social norms regarding health behaviors such as smoking, nutrition or exercise (see also Revenson & Schiaffino, 2000). They stress the importance of including community members in health-promoting programs from their inception, and devising culturally-sensitive health promotion strategies in order for health interventions to be incorporated by the community once researchers have moved on. Clearly, "translating" our knowledge of biobehavioral mechanisms in health and illness to more widespread efforts will be a challenge for the next decade of community psychology.

CONCLUSION

The exponential growth in brain and behavioral sciences over the past decade is mirrored in the field of health psychology. But rapid growth also begets growing pains. Health psychologists have taken stock, many times, to assess our progress and our pitfalls (Coyne, 1997; Landrine & Klonoff, 1992; Taylor, 1984; 1987; 1990). As recently as March, 2000, when APA's division of Health Psychology sponsored a conference on the future of health psychology, a unified definition or vision for the field still did not exist. Despite this—or perhaps as a result of it—health psychologists have managed to make great progress in our understanding of the cognitive, behavioral, cognitive-behavioral, physiological, social, environmental, social environmental, personality, and developmental factors underlying health and illness processes over the past quarter-century. But there are many miles to go before we sleep.

We are now nearing the end of the second decade of the AIDS epidemic. Although major advances in treatment have prolonged and improved the quality of life of those infected with HIV, there is still no cure for, or a vaccine to prevent, this deadly disease. Perhaps most important, it has become increasingly clear that primary prevention must focus on behavior and behavior change. AIDS is first and foremost a consequence of behavior. It is not who people are, but what people do that determines whether or not they expose themselves or others to HIV, the virus that causes AIDS. As Kelly, Murphy, Sikkema, and Kalichman (1993) pointed out, the task confronting the behavioral sciences is to develop theory-based intervention programs to reduce "risky" behaviors and increase "healthy" behaviors.

In order to change behavior, however, it is first necessary to understand why people behave the way they do. The more that is known about the variables underlying a person's decision to perform or not to perform a given behavior, the more likely it is that successful behavioral intervention programs can be developed. Given the severity of the AIDS epidemic, it seemed appropriate to bring together the developers and/or leading proponents of five major behavioral theories in order to identify a finite set of variables to be considered in any behavioral analysis. To this end, the National Institute of Mental Health (NIMH) organized a theorists workshop.

The participants at the workshop were Albert Bandura (social cognitive theory), Marshall Becker (health belief model), Martin Fishbein (reasoned action), Frederick Kanfer

(self-regulation, self-control), and Harry Triandis (Subjective Culture and Interpersonal Relations). Anita Eichler, of the NIMH AIDS program, served as chairperson, and Susan Middlestadt, research director of the Academy of Educational Development's AIDSCOM program served as AIDS research consultant. On Day 1 of the conference, each participant described his theory and discussed how it could be applied to an understanding of AIDS-related behaviors. On Day 2, the participants identified a set of key variables. On Day 3, the focus was on operationally defining the variables identified on Day 2. This chapter briefly describes the five theories; discusses some main points of consensus, including the identification of eight key variables that appear to serve as the primary determinants of any given behavior; illustrates how these variables can be assessed; and considers some unresolved issues.

THEORIES OF BEHAVIOR AND BEHAVIOR CHANGE

Although there are a number of theories of behavior and behavior change available in the literature, there are three theories that have had a major impact on much of the behavioral research in the AIDS area: the health belief model (e.g., Becker, 1974, 1988; Janz & Becker, 1984; Montgomery et al., 1989), social cognitive theory (e.g., Bandura, 1986, 1992, 1994) and the theory of reasoned action (e.g., Ajzen & Fishbein, 1980; Fishbein, 1980; Fishbein & Ajzen, 1975; Fishbein, Middlestadt, & Hitchcock, 1991).

According to the health belief model, two major factors influence the likelihood that a person will adopt a recommended health protective behavior. First, individuals must feel personally threatened by the disease (i.e., they must feel personally susceptible to a disease with serious or severe consequences). Second, they must believe the benefits of taking the preventive action outweigh the perceived barriers to (and/or costs of) preventive action.

From the perspective of social cognitive theory, the initiation and persistence of an adaptive behavior depends on beliefs of self-efficacy and outcome expectancies. That is, in order to perform a given behavior individuals must believe in their capability to perform the behavior in question under different circumstances and they must have an incentive to do so (i.e., expected positive outcomes of performing the behavior must outweigh expected negative outcomes). Incentives may involve physical outcomes, social outcomes, or self-sanctions.

According to the theory of reasoned action, performance or nonperformance of a given behavior is primarily a function of the person's intention to perform (or to not perform) that behavior. The intention is, in turn, viewed as a function of two primary determinants—the individual's attitude toward performing the behavior (based on their beliefs about the consequences of performing the behavior, i.e., beliefs about the costs and benefits of performing the behavior) and their perception of the social (or normative) pressure exerted on them to perform the behavior.

The aforementioned three theories represent a public health, a clinical, and a social psychological approach to the prediction and understanding of behavior. Although there is no real competitor to the health belief model in the public health domain, there are other, well-established, clinical and social psychological behavioral theories. For example, in the clinical domain, the theory of self-regulation and self-control (e.g., F. H. Kanfer, 1970; F. H. Kanfer & Scheffert, 1988; R. Kanfer & F. H. Kanfer, 1991), has received considerable attention. And, within social psychology, the theory of subjective culture and interpersonal relations (e.g., Triandis, 1972, 1977, 1980) is often viewed as a major competitor to the theory of reasoned action.

The theory of self-regulation and self-control describes how self-regulatory processes (i.e., self-observation, self-evaluation, and self-reinforcement) lead to satisfaction with behavioral performance and continuation of the behavior, or to dissatisfaction and either self-corrective action or termination of the behavior. Although more of a process than a predictive model, the theory identifies goal-setting (or intentions), self-efficacy, outcome expectancies, skills, and affective states (e.g., mood and emotion) as important determinants of behavior.

According to the theory of subjective culture and interpersonal relations, the likelihood of performing a given behavior is determined by intentions, habits, and facilitating factors. Intentions are, in turn, viewed as a function of perceived consequences of performing the behavior (i.e., outcome expectancies), social influences (including norms, roles and the self-concept), and emotions.

Among them, the five theories, briefly described above, have developed or contain almost all of the variables that have been utilized in attempts to understand and change a wide variety of human behaviors.

MAIN POINTS OF CONSENSUS

Early on, it became very clear that a distinction must be made between theories of behavioral prediction and theories of behavioral change. Whereas models of behavioral prediction focus on variables (or factors) that "determine" the performance or nonperformance of any behavior at a given point in time, models of behavior change focus on "states" of the organism or "stages" individuals may go through in their attempt to change behavior.

Generally speaking, there was agreement that people will continue to behave as they have in the past until some internal or external stimulus (e.g., a symptom, a mass media message) interrupts this "normal" flow of behavior. Behavioral prediction models attempt to identify variables that serve as determinants of ongoing behaviors. That is, these models focus on those variables that help to explain why some members of a given population are performing a given behavior while other members of the same population are not. In contrast, behavior change models focus first on the stimuli that "disrupt" ongoing behavior and then on the processes individuals may utilize in moving from one state or stage to another in their attempt to eliminate old or adopt new behaviors.

For example, a TV ad that informs the public about AIDS transmission (i.e., a “cue to action”) may be an important first step in getting someone to consider behavior change. But whether a person is or is not exposed to such an ad may not be a determinant (and in fact may be a very poor predictor) of whether the person is or is not performing any given AIDS protective behavior (e.g., using a condom). Similarly, recognition that people’s behavior is putting them at risk for AIDS may be, at least for some, a necessary step in a change process. Nevertheless, perceived risk may be unrelated to (and not be a determinant of) whether individuals are or are not performing a given AIDS-protective behavior.

Although behavioral prediction and behavior change theories often have different foci, they are quite complementary. Indeed, the intensity and direction of the variables identified in behavioral prediction theories often serve as markers or indicators of a state of the organism or a stage of change. For example, as is described later, there was general consensus that the intention to perform a given behavior is one of the immediate determinants of that behavior. The stronger the intention to perform a given behavior, the greater the likelihood that the person will, in fact, perform that behavior. By recognizing that intention is a continuous variable (ranging from strong intention not to perform a behavior through uncertainty to strong intentions to perform the behavior), it can be argued that the strength of a person’s intention may serve as an index of a given state of the organism or of a stage in a change process. Thus, as people move from strong negative through neutral through weak positive intentions, they may be moving from what Prochaska and DiClemente (1983, 1986) called the precontemplative to the contemplative stage. Similarly, as individuals move from weak to strong positive intentions, they may be moving from what F. H. Kanfer and Schefft (1988) called an intentional state through a decisional state to a state of commitment.

Although process models of behavioral change are important, as a first step it is helpful to explain why people behave the way they do. Thus, the focus of the workshop was on identifying key variables that would enable the prediction and understanding of behavior. Clearly, if a limited number of variables that serve as potential determinants of any given behavior can be identified, it should be possible to measure these variables and examine the strength of the associations among them as well as the strength of the associations between each of these variables and the behavior in question. These analyses should lead to the identification of the one or two variables that most strongly influence the decision to perform (or not perform) a given behavior in a given population. Once identified, these variables should then serve as the primary focus of an intervention.

Variables Underlying Behavioral Performance

After a consideration of each of the five theories, a set of eight variables was identified that appear to account for most of the variance in any given deliberate behavior: intention, environmental constraints, skills, anticipated outcomes (or attitude),

norms, self-standards, emotion, and self-efficacy. For a person to perform a given behavior, one or more of the following must be true:

1. The person has formed a strong positive intention (or made a commitment) to perform the behavior.
2. There are no environmental constraints that make it impossible for the behavior to occur.
3. The person has the skills necessary to perform the behavior.
4. The person believes that the advantages (benefits, anticipated positive outcomes) of performing the behavior outweigh the disadvantages (costs, anticipated negative outcomes); in other words, the person has a positive attitude toward performing the behavior.
5. The person perceives more social (normative) pressure to perform the behavior than to not perform the behavior.
6. The person perceives that performance of the behavior is more consistent than inconsistent with his or her self-image, or that its performance does not violate personal standards that activate negative self-sanctions.
7. The person’s emotional reaction to performing the behavior is more positive than negative.
8. The person perceives that he or she has the capabilities to perform the behavior under a number of different circumstances; in other words, the person has perceived self-efficacy to execute the behavior in question.

Generally speaking, the first three factors are viewed as necessary and sufficient for producing any behavior. That is, for behavior to occur, a person must have a strong positive intention (i.e., have a commitment) to perform the behavior in question; the individual must have the skills necessary to carry out the behavior; and the environment must provide a context of opportunity, or be free of constraints, such that the behavior can occur. Thus, for example, if a male injecting drug user (IDU) is committed to using bleach every time he shares injection equipment, has bleach available, and has the skills necessary to use the bleach, the probability is close to 1.0 that he will bleach before sharing. Similarly, if this same person has formed a strong intention to always use a condom for vaginal sex with his spouse, has a condom available, does not experience strong resistance to condom use from his spouse, and has the necessary skills to use the condom, the probability will again be close to 1.0 that he will use a condom when he engages in vaginal sex with his spouse.

The remaining five variables are viewed as influencing the strength and direction of intention. For example, it can be argued that individuals will not form a strong intention to perform a behavior unless they first believe that behavioral performance will lead to more positive than negative outcomes and/or they believe that they have the skills and abilities necessary to perform that behavior (i.e., they believe that they can perform the behavior). In other words, attitudes and/or self-efficacy may influence the strength of a person’s

intention. It is important to recognize however, that one or more of these variables may also have a direct influence on behavior. Thus, for example, by influencing the amount of effort someone expends, and by influencing an individual's persistence in the face of barriers, self-efficacy may also have a direct impact on behavior.

It should also be recognized that behavioral performance can influence one or more of these five variables. Individuals may form a positive intention to perform, and may in fact perform a given behavior, at least in part because they believe that performance of the behavior will lead to a positively valued outcome. When individuals perform the behavior, however, this outcome may not occur. Clearly, this information will influence the person's behavioral beliefs (or outcome expectations), which may in turn influence intentions and future behavioral performances.

MEASUREMENT CONSIDERATIONS

Having identified eight variables (or factors) that are assumed to underlie the performance (or nonperformance) of any behavior, it is necessary to consider how each of these variables can be assessed. First, however, it is important to distinguish between variables that have "fixed" contents and those that have "variable" contents. To a certain extent, this distinction parallels the distinction between *etic* (i.e., universal) and *emic* (i.e., population specific) considerations. That is, for some variables (e.g., intention), item content is "fixed" and the assessment question is not "what" to measure, but how to best measure the construct in a given population. For other variables, however (e.g., behavioral beliefs or outcome expectancies), item content depends on the population being considered, and it is necessary to first go to a representative sample (and/or trained observers) of the population being studied in order to determine item content.

Thus, prior to attempting to develop any fixed item assessment instrument, the use of standardized elicitation procedures (see Ajzen & Fishbein, 1980) are recommended to identify four broad classes of variables: perceived outcomes of performing the behavior; relevant referents (either individuals or groups) vis-à-vis the behavior; perceived facilitators of, and barriers to, behavioral performance; and characteristics, qualities, and attributes of people who do and do not perform the behavior. In addition, it is sometimes necessary to consider a fifth class of variables, namely, action alternatives.

As becomes clear later, outcomes are necessary for developing measures of behavioral beliefs or outcome expectancies; relevant referents are necessary for developing normative measures; barriers and facilitator are necessary for assessing both environmental constraints and self-efficacy; and personal characteristics are necessary for assessing self-image and violations of self-standards. Action alternatives help one to identify relevant behaviors that either define a behavioral category (e.g., safe sex) or identify skills or courses of action necessary for goal attainment.

Clearly, however, outcomes, referents, barriers, facilitators, personal characteristics, and action alternatives will vary from behavior to behavior as well as from population to population.

Thus, it is essential that open-ended elicitation questions be asked with respect to the specific behavior under consideration. Unfortunately, selecting this behavior is often more difficult than may first appear. Consider, for example, a situation in which a heterosexual male resists using a condom for vaginal sex with a casual partner. If the goal is to try to increase condom use in this situation, should the focus be on increasing the likelihood that the male will use a condom or on increasing the likelihood that the female will get her partner to use a condom? Although it can be argued that getting a partner to use a condom is no less a performance attainment than putting on a condom, it can also be argued that getting a partner to use a condom is a goal that may be attained only by performing one or more behaviors, such as "telling one's partner to use a condom," "refusing to have sex unless one's partner uses a condom," or "negotiating condom use with one's partner." Thus, it could also be argued that in an attempt to increase condom use in this situation, the focus should be on increasing the likelihood that the woman will perform one or more of these behaviors. Note, however, that in contrast to "telling one's partner to use a condom" or "refusing to have sex," "negotiating condom use" is not a single behavior but a behavioral category involving a number of different behaviors.

This distinction between goals (e.g., avoiding AIDS, getting a partner to use a condom), behavioral categories (e.g., practicing safe sex, negotiating condom use), and behaviors (e.g., using a condom, telling one's partner to use a condom) is discussed in more detail later. At this point, however, it is sufficient to point out that, with relatively few exceptions, the assessment of the eight variables is essentially identical whether the focus is on a goal, a behavioral category, or a specific behavior. Perhaps the major difference is that when the focus is on a behavioral category or a goal, it is also necessary to identify the behaviors comprising the category or the behaviors to be performed in the attempt to attain the goal. Given the primary concern with behavior, for illustrative purposes this chapter focuses on a specific behavior, namely, the likelihood that males will always use a condom for vaginal sex with their wives (or their main sexual partners). In addition, when appropriate, ways in which assessment procedures can be adapted for consideration of a behavioral category or a goal are illustrated. Generally speaking, however, in the examples, phrases such as "getting my husband (or main sexual partner) to always use a condom for vaginal sex," "engaging in safe sex," or "negotiating condom use for vaginal sex with my husband (or main sexual partner)," can be substituted for the phrase "always using a condom for vaginal sex with my spouse (or main sexual partner)."

Identifying Variable (Population-Specific) Content

As already indicated, the first stage in developing fixed-format assessment instruments is to identify salient outcomes, referents, facilitators, barriers, and personal characteristics with respect to the behavior in question. In addition, if the focus is on a behavioral category or a goal, it is necessary to identify the action alternatives that comprise the behavioral category and/or that lead to goal attainment. In order to obtain this information,

it is necessary to ask a representative sample of the population a series of open-ended questions.

Perceived Outcomes. Anticipated outcomes or behavioral beliefs are viewed as one of the key variables underlying behavioral performance. To identify salient outcomes associated with a male's use of condoms for vaginal sex with his spouse (or main sexual partner), a representative sample of men could be asked questions such as the following:

1. What do you see as the advantages (positive outcomes of, benefits of, good things that would happen) of your always using a condom for vaginal sex with your spouse or main sexual partner?
2. What do you see as the disadvantages (negative outcomes, costs, bad things that would happen) of your always using a condom for vaginal sex with your spouse or main sexual partner?
3. What else comes to mind when you think about always using a condom for vaginal sex with your spouse or main partner? For example, how would always using a condom for vaginal sex with your wife (or main sexual partner) make you feel? How would it make others feel? How would they react?

Content analyses of the open-ended responses to these questions should allow the identification of a set of salient (frequently mentioned) outcomes or consequences. It is important to recognize that the same outcome may be seen as an advantage by some members of the population and as a disadvantage by others. For example, some people might see "preventing pregnancy" as a "good" thing whereas others may view this same outcome negatively. The content analysis should attempt to identify salient "outcomes" irrespective of their perceived value. Once this list is developed, the set of outcomes can be categorized in any number of ways. For example, a researcher might want to distinguish "costs" from "benefits," or might want to distinguish between "long-term" and "short-term" outcomes. Similarly, it may be useful to distinguish between "physical" outcomes (e.g., will protect me from AIDS), "social" outcomes (e.g., will make my partner angry), and "self-sanctions" (e.g., would make me feel dirty). Irrespective of the particular category system used, the important point is to identify the set of outcomes or consequences that the people in the population under study are most likely to consider when they think about performing the behavior in question.

Relevant Referents. Perceived normative pressure is also expected to influence behavioral performance. It is thus necessary to identify those individuals or groups that the individual perceives as potential sources of social influence. More specifically, it is important to identify those individuals or groups who are perceived to be putting pressure on the individual to perform or not perform the behavior in question. In order to obtain this information, the representative sample of men should also be asked questions, such as:

1. Please list those individuals or groups who would support or approve of your always using a condom for vaginal sex with your spouse or main sexual partner.
2. Please list those individuals or groups who would oppose or disapprove of your always using a condom for vaginal sex with your spouse or main sexual partner.
3. Please list any other individuals or groups that come to mind when you think about always using a condom for vaginal sex with your spouse or main sexual partner.

Content analyses can be conducted to identify the most frequently mentioned referents. Once again, it is important to recognize that a given referent (e.g., friends, spouse) may be listed by some as a person who would approve of the behavior and by others as a person who would disapprove of the behavior. The purpose of the content analysis should be to identify the referents mentioned most frequently by the population, irrespective of their perceived positions.

Barriers and Facilitator. In order to identify environmental constraints as well as other internal and external circumstances that may influence behavioral performance, questions such as the following can be asked:

1. What makes it difficult or impossible for you to always use a condom for vaginal sex with your wife? (Probe: Can you think of any other barriers or circumstances that would prevent you from, or make it hard for you to always use a condom for vaginal sex with your wife or main sexual partner?)
2. What helps you or makes it easier for you to always use a condom for vaginal sex with your wife? (Probe: Can you think of anything else that would facilitate or increase the likelihood that you will always use a condom for vaginal sex with your spouse or main sexual partner?)

Content analyses of responses to these items should allow identification of a set of "circumstances" that increase or reduce the likelihood of the behavior occurring. In contrast to "outcomes" and "referents," it is unlikely that the same circumstance will be seen as a facilitator by some respondents and as a barrier by others. Nevertheless, some people may mention the presence of a given factor or circumstance as a barrier whereas others may mention its absence as a facilitator. For example, some respondents may indicate that it is "harder" for them to always use a condom with their wives if they have been drinking or using drugs, and others may say it is "easier" for them to always use a condom if they have not been drinking or using drugs. Thus, once again, attempts should be made to develop a single set of circumstances whose presence or absence may facilitate or prevent the performance of the behavior in question.

It is important to note that the purpose is to identify circumstances that influence behavioral performance, and not outcomes of that performance and/or strategies that may help a person perform the behavior. Thus, for example, if a respondent says that one of the things that makes it more difficult for him to always use a condom with his wife is that "it will make my wife angry," then he is reporting a perceived outcome

rather than a circumstance. Similarly, if the individual says it would be easier to always use a condom with my wife "if I had talked to her beforehand," then he is reporting a strategy that may be used to increase the likelihood of condom use, rather than a circumstance that can facilitate or hinder performance. Although a researcher may wish to retain a list of "strategies" (to be used in developing action alternatives and/or in identifying skills), these responses should be excluded from the analysis of barriers and facilitators. Similarly, outcomes should also be excluded in developing the set of circumstances that influence the behavior in question. However, if a respondent lists outcomes that he had not previously mentioned in response to the outcome questions, these responses should be included in the content analysis of outcomes.

In addition to asking a representative sample of the population to identify circumstances that may increase or decrease the likelihood of behavioral performance, it is often useful (and sometimes necessary) to also ask trained observers (or people familiar with the population) to identify factors that may facilitate or inhibit the behavior. As Nisbett and Ross (1980) pointed out, people are often quite inaccurate in identifying factors that influence their own behaviors. Thus, the obtained list of respondent-elicited circumstances should be supplemented with circumstances identified by independent observers.¹

Once the set of circumstances influencing behavior has been identified, it can be categorized, like the set of perceived outcomes, in a number of different ways. Most obviously, a distinction can be made between facilitators and barriers. In addition and perhaps more important, each circumstance can be categorized as one that is "internal" or "external" to the individual. As is seen later, external circumstances are used to assess environmental constraints, and the full set of circumstances contribute to the development of self-efficacy items.

Personal Characteristics. In order to determine whether performance of the behavior in question is consistent or inconsistent with individual's self-image or self-standards, it is necessary to know how they perceive people who do and do not perform the behavior in question. Thus, the respondents can be asked questions such as:

1. How would you describe a man who ALWAYS or ALMOST ALWAYS uses a condom for vaginal sex with his wife (or main sexual partner)? That is, what do you believe are the characteristics, qualities, or attributes of such a person?
2. How would you describe a man who NEVER or ALMOST NEVER uses a condom for vaginal sex with his wife (or main sexual partner)? Once again, please list what you believe to be the characteristics, qualities, and attributes of such a person.

¹The extent to which the circumstances identified by the trained observers match those identified by the sample of respondents is itself useful information that may indicate a number of internal mechanisms such as rationalizations, defenses, and so on.

Content analyses of responses to these items should allow researchers to arrive at a single set of frequently mentioned characteristics or "traits" of men who do or do not perform the behavior in question.

Action Alternatives. Although the aforementioned questions are sufficient for obtaining information necessary for developing fixed-format items to assess each of the potential variable content determinants of a given behavior, it is necessary to obtain additional information if the focus is on a behavioral category or a goal. More specifically, as already indicated, if the focus is on a behavioral category (e.g., safe sex, negotiating condom use), then it is necessary to identify those behaviors that comprise the behavioral category. Similarly, if the focus is on a goal or outcome (e.g., getting my partner to use a condom, avoiding AIDS), then it is necessary to identify the behaviors (or courses of action) that may increase the likelihood that the person will attain that goal. Note, however, that a given individual's perception of what behaviors define a behavioral category and/or of what behaviors will lead to goal attainment, may be very different from those held by a group of experts. For example, epidemiologists may include a very different set of behaviors in their definition of safe sex than will a layperson. Similarly, a clinician may see a different set of behaviors leading to goal attainment than will the patient. Thus, in identifying action alternatives, information should be obtained from knowledgeable experts as well as from a representative sample of the population under investigation.

For example, if the goal of an intervention was to increase the likelihood that women will engage in a behavioral category, such as practicing safe sex with their husbands (or main sexual partners), then a representative sample of women could be asked questions such as: What do you consider to be safe sex with your husband? That is, what sexual behaviors are safe? What sexual behaviors are dangerous?

Content analyses of responses to these types of questions should allow the identification of the behaviors that the population sees as comprising the behavioral category. In addition, they should help form an understanding of what respondents mean when they respond to questions about "safe sex" or other behavioral categories. A similar set of questions could be asked of a small sample of "experts." By looking at differences between the behaviors identified by the population and those identified by experts, an investigator can clarify and explicitly define (for the respondent) what is meant by the behavioral category. In addition, once a complete list of behaviors comprising a behavioral category is developed, one may wish to focus on one or more specific behaviors that could be studied in their own right and/or that could serve as the focus of an intervention.

Similarly, if there is interest in increasing the likelihood that women will attain a specific goal (e.g., get their husbands or main sexual partners to always use a condom for vaginal sex), a representative sample of women (as well as a small group of "experts") could be asked questions such as: What is involved in getting your husband (or main sexual partner) to always use a condom for vaginal sex? That is what would you have to do or

say to get your husband to always use a condom for vaginal sex? What other behaviors could you perform to increase the likelihood that he will use a condom for vaginal sex?

Content analysis of responses to this set of questions again identifies a more specific set of behaviors that a respondent may use to attain the behavioral goal in question. Discrepancies between action alternatives identified by the population and those identified by experts provide important information. Moreover, responses to these questions provide insight into skills that may be required to attain that goal. In addition, this information, along with information on circumstances described earlier, provides the basis for developing self-efficacy items.²

As mentioned earlier, it is important to recognize that the salient sets of outcomes, referents, circumstances, and traits (as well as action alternatives) are expected to vary as a function of both the behavior under consideration and the population of interest. Clearly, the outcomes of using a condom for vaginal sex with a spouse (or main sexual partner) may be very different from those associated with using a condom for vaginal sex with a new or occasional partner. Similarly, heterosexual males may see different consequences of using a condom for vaginal sex with their wives (or main sexual partners) than do bisexual males or men with hemophilia. Moreover, Black males may perceive different outcomes and have different referents than White or Hispanic males. Thus, to fully understand the determinants of a given behavior in a given population, it is necessary to elicit outcomes, referents, circumstances and traits vis-à-vis that behavior in that population. This information can then be used to develop closed-format assessment items.

Suggestions for Assessing Each of the Eight Key Variables

In order to illustrate how the previous information may be used to develop fixed alternative assessment items, and to illustrate how variables with "fixed" content can be assessed, the focus continues to be on men's use of condoms for vaginal sex with their wives (or main sexual partners). Once again, however, it is important to note that the same set of procedures and types of items would be developed for investigations of behavioral categories or goal attainment.

Intentions to Perform the Behavior. As described earlier, there is general consensus that men who intend to "always use a condom for vaginal sex with my main partner" are

²It is important to note that very often what will be obtained are behavioral categories rather than explicit behaviors in response to questions concerning paths to goal attainment. For example, "negotiate condom use" is a frequent response to a question such as "What would you have to do to get your spouse to always use a condom for vaginal sex?" When this is the case, it is important to identify the behaviors comprising the response category. Thus, for example, questions such as the following could be posed: What is involved in your negotiating condom use for vaginal sex with your spouse? That is, how would you negotiate condom use? What behaviors would you perform? What would you do or say as a part of this negotiation?

significantly more likely to use a condom every time they have vaginal sex with their main partners than are men who do not have this intention. Moreover, the stronger the person's intention to "always use a condom for vaginal sex with my main partner," the more likely he is to carry out this behavior.

Unfortunately, the term *intention* has been used in different ways. For some, an intention is simply a weak statement of a wish or desire to perform a given behavior; for others, intentions have been viewed as a commitment or a self-instruction to carry out the behavior. The problem is a distinction between treating "intention" as an on/off variable (i.e., the person either intends or does not intend to act) and treating intention as a continuous variable varying in strength or intensity.

In the field of social psychology, where the concept of intention has been used most widely, the concept is viewed as a continuous variable, and it is usually measured with one or more of the following scales:

I will always use a condom for vaginal sex with my main partner

likely ___:___:___:___:___:___ unlikely

I intend to always use a condom for vaginal sex with my main partner

likely ___:___:___:___:___:___ unlikely

I will try to always use a condom for vaginal sex with my main partner

likely ___:___:___:___:___:___ unlikely

These scales assess respondents' subjective probability or subjective likelihood that they will perform (or will try to perform) the behavior in question.³ Because probability or likelihood may be a difficult concept in some cultures, it is possible to substitute such scales as "agree-disagree," "certain-uncertain," or "true-false" for "likely-unlikely."

Similarly, there may be concern that respondents cannot handle 7-point (or 5-point or 9-point) scales. In these cases, this information can be obtained with a two-part question: Do you think it is likely or unlikely that you will always use a condom for vaginal sex with your main partner?

Responses of "I don't know," "neither," or "it's as likely as it is unlikely" are taken as indications that the respondent is at the midpoint of the scale. Those answering likely (or unlikely), should then be asked the following: And would you say that it was extremely likely (unlikely), quite likely (unlikely), or only slightly likely (unlikely)?

Once again, it should be recognized that both the judgment scale (i.e., Do you agree or disagree that ...) and the descriptive adverbs (do you agree strongly, moderately, or only slightly) can be changed. Needless to say, exactly how the question is asked should depend on the population being con-

³For those who view intention as self-instruction, an additional scale, such as the following should also be developed:

When I am about to have vaginal sex with my spouse or main partner, I say to myself "Use a Condom."

Always ___:___:___:___:___:___ Never

sidered. However, for the question to assess intention as it is used here, it is necessary to arrive at a continuous measure that indicates the likelihood that a person will (or the strength of the individual's commitment to) perform or try to perform the behavior in question.

Environmental Constraints Preventing Behavioral Performance. Although often overlooked, there may be a number of environmental constraints that make performance of the behavior virtually impossible. With respect to condom use for vaginal sex with a spouse or main sexual partner, one environmental constraint that would prevent this behavior is the absence of condoms. Clearly, if a condom is not available, or the person does not have the money to buy one, this behavior cannot occur. Similarly, if a spouse (or main sexual partner) refuses to have vaginal sex if the individual uses a condom, then condom use is quite unlikely. Note that the concern here is with circumstances or factors that are external to the individual.

Unfortunately, there is no standardized procedure for assessing the degree to which such environmental constraints are present. However, it seems reasonable to assume that such a measure could be developed by considering the set of external circumstances identified during the elicitation phase of the research. That is, a measure could be developed by considering those "external" circumstances that serve as barriers to behavioral performance. For example, respondents could be asked questions, such as the following, to indicate the extent to which each external circumstance was usually present or absent:

When you are about to have vaginal sex with your spouse (or main sexual partner), how often do each of the following occur?

Each item could be scored from 1(Never) to 5(Always), and the sum of the items could serve as an index of the degree to which environmental constraints were present.⁴

1. Condoms are NOT available

Never	Almost Never	Sometimes	Almost Always	Always
-------	-----------------	-----------	------------------	--------

2. Your spouse (or main sexual partner) resists your use of condoms

Never	Almost Never	Sometimes	Almost Always	Always
-------	-----------------	-----------	------------------	--------

Skills Necessary for Behavioral Performance. It is becoming increasingly clear that those interested in understanding behavioral performance must pay attention to skill dimensions. With respect to a male's use of a condom for vaginal sex with his spouse or main sexual partner, the skills involved are those related to buying (or otherwise obtaining) and using a

condom. Clearly, if the person does not know what a condom is, where to get it, or how to use it, then one will not be used. Moreover, as already described, if a partner is opposed to, or resists, condom use, additional skills, such as those involved in negotiating condom use, may also be necessary. Needless to say, such social negotiation skills become particularly relevant and important when the focus is on a woman's attempt to get her partner to use a condom.

It is therefore necessary to develop skill measures. Fortunately, some measures are already available. For example, Cleghorn et al. (1991) developed a highly reliable, observational test of condom use skills. More specifically, respondents are given a packaged condom and are asked to put the condom on a dildo. Trained observers then record the extent to which the person does or does not perform a number of specific actions such as "unrolling the condom," "holding the tip of the condom," and "covering 100% of the shaft of the penis."

With respect to negotiation skills, Kelly, St. Lawrence, Hood, and Brasfield (1989) constructed a set of eight role-play scenes following standard paradigms for assertion assessment (cf. Eisler, Miller, & Hersen, 1973; Hersen & Bellack, 1976). Each role play consisted of a scene narration in which a sexual partner attempts to pressure subjects to engage in a high risk practice or another person proposes a sexual encounter. The narrations were presented on audiotape, with each narration being followed by three prompts delivered live by a trained assistant who simulated the verbal conduct of the coercive partner. Subjects' responses were audiotape recorded and were later coded for overall effectiveness (on a scale from 1 = very ineffective to 7 = very effective), as well as for discrete components of skill. For example, in scenes depicting coercions to engage in high risk behavior, respondents were coded for acknowledging the partner's request, specifically refusing the high risk behavior, providing the reason for the refusal, noting the need to be safer, and suggesting a specific low risk alternative.

Generally speaking, the set of action alternatives identified during the elicitation phase of the research should provide guidelines and serve as the basis for developing skill measures. More specifically, by knowing the actions a person would have to perform to reach a given goal and/or by knowing what behaviors are included in a behavioral category, it should be possible to develop skill measures.

Behavioral Beliefs, Outcome Expectancies, Costs and Benefits, Perceived Consequences. In almost every behavioral theory, there is some recognition of the proposition that people will not perform a given behavior unless they believe (or anticipate) that the advantages (benefits, positive outcomes) of performing the behavior outweigh the disadvantages (costs, negative outcomes). That is, all theories agree that, at some level, people consider the possible outcomes of behavioral performance. Moreover, there is general consensus that it is not possible to simply generate a set of outcomes or consequences, but rather it is necessary to go to the population of interest and find out what the individuals believe to be the outcomes or consequences of engaging in a given behavior.

⁴Alternatively, a group of trained observers could be asked to indicate the degree to which each of these circumstances were present or absent for the population being considered.

The previous section described procedures for identifying a set of salient outcomes with respect to the performance of a given behavior in a given population. This set of salient outcomes can then serve as the basis for developing fixed alternative assessment items.

The assessment instrument should contain two questions for each outcome: One assessing the respondent's belief that performing the behavior will lead to the outcome; and another assessing the value the respondent places on the outcome. For example, among men, two frequently mentioned outcomes of using a condom for vaginal sex with a spouse (or main sexual partner) are that this behavior will "prevent pregnancy" and "reduce my sexual pleasure." Given these outcomes, item pairs such as the following can be developed:

(1a) My always using a condom for vaginal sex with my main partner will prevent her from becoming pregnant.

likely ___:___:___:___:___:___:___ unlikely

(1b) Preventing my main partner from becoming pregnant is:

good ___:___:___:___:___:___:___ bad

(2a) My always using a condom for vaginal sex with my main partner will reduce my sexual pleasure.

likely ___:___:___:___:___:___:___ unlikely

(2b) Reducing my sexual pleasure is:

good ___:___:___:___:___:___:___ bad

Individuals are positively motivated when they believe that behavioral performance leads to positive outcomes or prevents negative ones. They are negatively motivated (i.e., motivated not to engage in the behavior) when they believe that behavioral performance leads to negative outcomes or prevents positive ones. In order to capture the psychology of the "double negative" (i.e., in order to insure that the prevention of a bad outcome will be seen as a positive motivator), it is essential to score both beliefs and outcome evaluations in a bipolar fashion (i.e., from -3 to +3). When this scoring system is used, it is possible to determine whether a given belief is serving as a positive or negative motivator (for performance of the behavior in question) by multiplying each belief (1a) by its corresponding outcome evaluation (1b). These products can then be summed algebraically across the set of salient outcomes to arrive at a single score that can be seen as an index of propensity or motivation to perform (or not perform) the behavior in question.

Within social psychology, such a cost-benefit or expectancy-value index has often been viewed as an indirect measure of the respondent's attitude toward performing the behavior in question (see, e.g., Fishbein & Ajzen, 1975). More specifically, the process already described uses a compensatory expectancy-value model to arrive at an indirect assessment of attitude.⁵ The recognition that "outcome expectancy scores," "perceived consequent scores" and "cost-benefit analyses" are related to (or underlie) attitudes toward performing the behavior in question, suggests that, in

addition to utilizing such an indirect estimate, it is also possible to measure the relevant attitude more directly.

Most people would agree that attitude is indexed along a bipolar evaluative (good/bad) or affective (I like/I dislike) dimension. It is important to note, however, that when a person evaluates something as "good" or says "I like something," that person can mean one or more of the following:

1. The behavior is "wise," "beneficial" and "safe."
2. The behavior is "pleasant," "enjoyable" and "easy."
3. The behavior is "moral," "correct," and "appropriate."

Thus, it is important that a direct measure of attitude capture these potentially different meanings of the attitude concept. In order to do this, a semantic differential measure of attitude is recommended. The *semantic differential* is, by far, the most widely used attitude measurement instrument, and when properly constructed, there is considerable evidence to support its reliability and validity. Generally speaking, the process begins with a large number of bipolar adjective scales, relevant to the concept (or behavior) under consideration. By using factor analyses or other standardized item selection procedures, it is possible to identify the set of items that are the best indicators of the underlying attitudinal dimension. In order to insure that the three potential meanings of attitude are represented, items such as the following can be used:

My always using a condom for vaginal sex with my spouse or main partner

wise ___:___:___:___:___:___:___ foolish

pleasant ___:___:___:___:___:___:___ unpleasant

correct ___:___:___:___:___:___:___ incorrect

easy ___:___:___:___:___:___:___ difficult

safe ___:___:___:___:___:___:___ dangerous

enjoyable ___:___:___:___:___:___:___ unenjoyable

moral ___:___:___:___:___:___:___ immoral

beneficial ___:___:___:___:___:___:___ harmful

I like ___:___:___:___:___:___:___ I dislike

good ___:___:___:___:___:___:___ bad

A preliminary "attitude" score can be obtained by summing responses (scored from +3 [wise, enjoyable, good] to -3 [foolish, unenjoyable, bad]) on each bipolar adjective scale. Item total correlations can then be computed and used to eliminate scales unrelated to the underlying attitude dimension. The final set of items can then serve as a relatively direct measure of atti-

⁵As described earlier, there are a number of ways in which a set of outcomes can be categorized. More specifically, it might be desirable to distinguish between short- and long-term outcomes or between physical outcomes, social outcomes, and self-sanctions. Consistent with this, it may be useful to disaggregate the overall expectancy-value score into a number of subscores. From a social-psychological perspective, however, the individual's attitude toward performing a given behavior is based on all of their salient outcome expectancies or behavioral beliefs.

tude. The sum over these scales is the attitude score. The higher the score, the more favorable the respondent's attitude toward performing the behavior in question. This direct measure should be highly correlated with, and may be used to validate, the indirect expectancy-value estimate.

Perceived Normative Pressure. As described earlier, some outcomes of performing a given behavior may be "social" in nature (e.g., My using a condom for vaginal sex with my spouse will make her think I don't trust her; will make her angry). Like other outcomes, these social outcomes enter into expectancy-value considerations and thus should be included in the analysis of outcome expectancies. It is important to recognize, however, that norms can influence behavior independent of outcome expectancies. That is, there is considerable evidence that individuals and groups may influence behavior even when they are not perceived as sources of positive or negative reinforcements. As Fishbein and Ajzen (1975) pointed out, people may often perform a behavior because they believe that an important other thinks they should perform that behavior, even though the important other may never know whether they have or have not performed the behavior. To fully understand why a person does or does not perform a given behavior, it is necessary to assess the extent to which the individual perceives social pressure to perform or not perform the behavior in question.

The first step in developing a measure of social pressure is to identify those individuals or groups that may be exerting pressure on the individual to perform or not perform the behavior. Once again, this cannot be done by simply making up a list of potential referents, but instead, as described earlier, it is necessary to go to the population of interest to identify a set of relevant individuals or groups. Thus, for example, when males are asked to list individuals or groups who would approve or disapprove of their always using condoms for vaginal sex with their wives or main sexual partners, two frequently mentioned referents are "my wife (or main sexual partner)" and "my friends." Although individuals may believe that a given referent thinks they should (or should not) perform a given behavior, this belief may have little impact on behavior unless they are motivated to comply with that referent. Note that that concern is with assessing the degree to which a person is motivated to comply with a given referent rather than the degree to which the person is motivated to comply with the specific behavioral proscription of that referent. Recognize, however, that a given referent may exert social pressure in some behavioral domains but not in others. Thus, in order to assess the social pressure exerted by a given referent, item pairs such as the following are necessary:

(1a) My wife (or main sexual partner) thinks

I should ___:___:___:___:___:___ I should not
always use a condom when we have vaginal sex

(1b) When it comes to AIDS prevention,

I want to do ___:___:___:___:___:___ I do not
want to do what my wife thinks I should do

(2a) Most of my friends think:

I should ___:___:___:___:___:___ I should not
always use a condom when I have vaginal sex with my
spouse (or main partner)

(2b) When it comes to AIDS prevention,

I want to do ___:___:___:___:___:___ I do not
want to do what most of my friends think I should do

In order to capture the normative pressure exerted by a given referent, each normative belief should be weighted (i.e., multiplied) by people's motivation to comply with the referent. In contrast to an expectancy-value estimate, however, the psychologic of the "double negative" does not apply to social influence. That is, when individuals say they are not motivated to comply with a given referent, this does not imply that they perceive social pressure to do the opposite of what that referent thinks they should do. Thus, although normative beliefs (i.e., items 1a and 2a) may be scored from -3 to +3, motivation to comply (i.e., items 1b and 2b) should be scored from 1 (I do not want to do what the referent thinks I should do) to 7 (I want to do what the referent thinks I should do). Summing these products across all relevant referents leads to an index of perceived normative pressure.

A more direct assessment of perceived social pressure can be obtained by using measures such as the following:

(1) Most people who are important to me think

I should ___:___:___:___:___:___ I should not
always use a condom when I have vaginal sex with my
spouse (or main partner)

(2) People I respect and admire

want me to ___:___:___:___:___:___ do not want me
to always use a condom when I have vaginal sex with my
spouse (or main partner)

This direct measure should be highly correlated with, and may be used to validate, the indirect index of perceived social pressure to perform (or not perform) the behavior in question.

In addition to the social pressure created by individuals' perceptions (or beliefs) that specific referents think they should or should not perform a given behavior, their behavior is often also influenced by the behavior of others. For example, although parents often tell their children to "do what I say, not what I do," children often emulate their parents' behaviors. That is, parents often serve as "models" for their children's behaviors. As French and Raven (1959) pointed out, people often behave like others not because they believe that their behavior will "please" or "displease" the referent, or because they believe that the referent will "reward" or "punish" them, but because they want to be like the referent. Although there is no known standardized procedure for assessing this aspect of normative pressure, it seems reasonable to assume that an instrument analogous to the one already described

could be developed. For example, it might be useful to employ item pairs such as the following:

(1a) Most of my friends always use a condom when they have vaginal sex with their wives (or main sexual partners)

likely ___:___:___:___:___:___unlikely

(1b) When it comes to AIDS prevention,

I want to be ___:___:___:___:___:___I do not want to be like most of my friends

In addition, this aspect of social pressure could be directly assessed with items such as:

(1) Most of the people who are important to me always use a condom when they have vaginal sex with their wives (or main sexual partners)

likely ___:___:___:___:___:___unlikely

(2) Most of the people I respect and admire

Always ___:___:___:___:___:___never

Use a condom when they have vaginal sex with their wives (or main sexual partners)

Self-Standards and Sanctions. As Bandura (1986) and Kanfer (1970) pointed out, although people may respond to social pressures, they do not constantly shift their behavior to conform to whatever others might want. Rather, they adopt certain standards of behavior for themselves; they do things that give them a sense of self-pride and they refrain from behaving in ways that violate their self-standards. Indeed, as described earlier, some outcome expectancies may refer to feelings of self-worth and self-censure (e.g., My always using a condom for vaginal sex with my wife or main sexual partner is the responsible thing to do, makes me feel dirty). Like other outcome expectancies, these positive and negative self-sanctions enter into expectancy-value considerations, and thus they should be included in the analysis of outcome expectancies.⁶

It is important to recognize, however, that perceptions of the self may influence behavior even in the absence of explicit outcome expectancies. That is, individuals may not consider whether performing (or not performing) a given behavior will make them feel “good” or “bad” about themselves, but rather, they may simply consider whether performance of the behavior is consistent or inconsistent with their self-image. As

⁶Within the social cognitive framework, positive and negative self-sanctions are measured by having subjects rate their reactions to their own conduct on a scale ranging from highly self-satisfied, through neutral, to highly self-dissatisfied. For example:
How would you feel about always using a condom for vaginal sex with your spouse (or main sexual partner)?

-3	-2	-1	0	+1	+2	+3
Highly Self- Dissatisfied			Neutral			Highly Self- Satisfied

Triandis (1977) argued, the more individuals perceive that they are the type of person who would perform the behavior in question, the more likely they are to intend to, and to actually perform that behavior. Thus, to fully understand why people do or do not perform a given behavior, it is necessary to consider the degree to which performance of the behavior is consistent with their self-image. For example, an item, such as the following could be used:

I'm the kind of person who always uses a condom when I have vaginal sex with my wife (or main partner).

agree ___:___:___:___:___:___disagree

Alternatively, a more indirect measure could be developed. As already described, a set of characteristics or traits can be identified that are associated with performance and nonperformance of the behavior. Then either an adjective check list or a semantic differential format could be used to assess the discrepancy between a person's self-image and his or her perception of a person who does (or does not) perform the behavior in question. For example, the following characteristics or traits are often mentioned when men are asked to describe men who do and do not always use condoms for vaginal sex with their wives or main sexual partners: cautious, responsible, caring, macho, foolish.

Respondents could first be asked to rate themselves on scales such as the following:

I am

cautious ___:___:___:___:___:___a risk taker

responsible ___:___:___:___:___:___irresponsible

caring ___:___:___:___:___:___self-centered

macho ___:___:___:___:___:___wimpy

wise ___:___:___:___:___:___foolish

Respondents could then be asked to rate “A man who always uses a condom when he has vaginal sex with his wife (or main sexual partner)” on the same set of scales. An absolute discrepancy score could be calculated for each item, and the sum of the discrepancies would then serve as an index of the degree to which people's self-image deviated from their perception of a man who performed the behavior in question. The larger the discrepancy, the more the behavior is inconsistent with a person's self-image. This indirect measure should be highly correlated with the more direct measure suggested earlier.

Emotional Reactions. As already described, a behavioral performance that is consistent or inconsistent with a person's self-image may lead to feelings of pride or shame. Behavioral performance may also result in strong emotional reactions, such as feelings of elation, depression, delight, disgust, fear, anxiety, and repulsion. Again, when anticipating these positive and negative self-sanctions, they are best viewed as outcome expectancies and should be included in expectancy-value or cost-benefit analyses. In addition, however, people may experience emotional reactions when they

merely think about performing the behavior. Emotional reactions of this type may also influence a person's decision to perform or not perform a given behavior.

It is important to distinguish between these emotional reactions and what was earlier described as affective feelings vis-à-vis the behavior in question. Although clearly related to "affect," this concept is conceptualized as a much stronger, classically conditioned positive or negative "gut" reaction to the "thought" of performing the behavior in question. Although no standardized set of items has been developed to assess emotional response, it appears that a semantic differential such as the following could be used to assess one's emotional reactions to a given behavior:

When I think about always using a condom for vaginal sex with my spouse (or main sexual partner), I feel

delighted ___:___:___:___:___:___:___disgusted

happy ___:___:___:___:___:___:___angry

joyful ___:___:___:___:___:___:___depressed

anxious ___:___:___:___:___:___:___calm

nauseated ___:___:___:___:___:___:___exhilarated

frightened ___:___:___:___:___:___:___relaxed

Self-Efficacy. The concept of perceived self-efficacy refers to individuals' beliefs in their capability to perform the behavior in question under different circumstances. The stronger the perceived self-efficacy, the stronger the intention to perform the behavior, and the greater the likelihood that a person will perform the behavior, given some incentive to do so.

Perceived self-efficacy with respect to a given behavior (or behavioral category, or a course of action directed at goal attainment) is always measured in relation to task demands that vary in difficulty, threat, complexity, or some other type of challenge or obstacle. In short, measurement of perceived self-efficacy demands gradations of challenge. In addition, people should be asked to judge their perceived self-efficacy as of now, and not for some future time. To put this somewhat differently, efficacy items should measure current perceived capabilities and not future hypothetical capabilities. Finally, items should measure individuals' efficacy to perform the behavior regularly or always. It is often easy to perform a behavior (e.g., using a condom for vaginal sex with a spouse) occasionally but difficult to perform this same behavior routinely or regularly, unless the behavior becomes habitual or automatic.

In devising self-efficacy items, the first step is to identify internal or external conditions that make performance difficult. Procedures for arriving at such a set of conditions or circumstances vis-à-vis any given behavior (or set of behaviors) were described earlier. With respect to the behavior of "always using a condom for vaginal sex with my spouse (or main sexual partner)," internal challenges may include high sexual arousal, and being high on alcohol or drugs. External challenges might include not having a condom available, or they might describe difficult circumstances such as having a resis-

tant partner who is argumentative, inebriated, or high on drugs. If the focus is shifted from a male's condom use to a female's attempt to get her partner to use a condom, then circumstances in which a partner is abusive, threatening, and/or coercive one must also be considered. Based on this information, a scale such as the following may be constructed to assess a male's self-efficacy with respect to using a condom for vaginal sex with his spouse (or main sexual partner):⁷

Rate how confident you are that you can regularly do the things described below. Rate your degree of confidence as of now by recording a number from 0 to 100 using the scale given below:

0	10	20	30	40	50	60	70	80	90	100
Cannot do at all				Moderately				Certain can do		
				certain can do						

___ I can use a condom for vaginal sex with my wife (or main sexual partner) while under the influence of alcohol or drugs.

___ If my wife (or main sexual partner) didn't want me to use a condom for vaginal sex, I can convince her that it is necessary for me to do so.

___ I can delay vaginal sex with my wife (or main sexual partner) if a condom is not available.

___ I can use a condom for vaginal sex with my wife (or main sexual partner) while I am very sexually aroused.

The estimate of self-efficacy is obtained by summing responses (from 0 to 100) over the set of items. The higher the score, the greater the perceived self-efficacy.

SOME UNRESOLVED ISSUES

Although there is consensus that the previous eight variables serve as the major determinants of behavior, at present there is no consensus concerning the causal model linking these variables to behavior. Indeed, each of the theorists have essentially proposed an explicit causal ordering of some (or all) of these variables in their theories and there was no agreement on the strength of interrelationships among these variables or on where each variable would be located in a causal chain. For example, although some see considerable theoretical and/or empirical overlap between some variables (e.g., intention and self-efficacy; attitude and emotion), others would argue that these concepts are relatively independent. As another example, some see perceived normative pressure as directly influencing intention, and others argue that norms only have force when they lead to (or are backed up by) anticipated consequences. A third example of disagreement concerns the mediating role of intention. That is, whereas some would argue

⁷Studies that try to measure numerous variables place constraints on the number of items that can be used to measure any one of them. Researchers, therefore, have to sacrifice wide gradations of challenge and try to pick optimal levels of challenge for the population being studied.

that some variables (e.g., attitude, perceived norms) influence behavior only indirectly (i.e., through their influence on intention), others would argue for both a direct and an indirect effect of a given variable on behavior.

In general, however, there is agreement that intentions are most proximal to behavior, and the other seven variables may best be seen as either influencing the formation and strength of intentions and/or as influencing the likelihood that people will act on their intentions.

One implication of this is that it points out the necessity of measuring intentions prior to developing an intervention. Clearly, very different interventions will be necessary if a person (or group) has not yet developed a strong intention (or made a commitment) to perform a given behavior, than if the person has formed a strong intention, but is unable to act upon it.

Recall that we assume that a person will perform a given behavior if (a) he or she has a strong intention to do so, (b) he or she has the necessary skills to perform the behavior, and (c) there are no environmental constraints (or "external" barriers) to prevent behavioral performance. Thus, if one has formed a strong intention to perform a given behavior but is not acting upon that intention, the intervention should probably be focused upon improving skills and/or removing or helping one to overcome environmental constraints.

In contrast, if a person has not yet formed a strong intention to perform a given behavior, the goal of the intervention should be to strengthen the person's intention to perform that behavior. And, as indicated above, this could be accomplished by changing self-efficacy, outcome expectancies (or attitudes), perceived norms, self-standards, or emotions vis-à-vis that behavior. But what intentions should such interventions address?

Clearly, it is possible to try to change people's intentions to reach goals (e.g., to avoid AIDS), to engage in a category of behaviors (e.g., to practice safe sex), or to perform a given behavior (e.g., to always use a condom for vaginal sex with my spouse). Since there was general agreement that intentions to reach goals are often poor predictors of goal attainment or of the behaviors individuals may perform in their attempt to reach the goal, it was agreed that interventions should focus on behaviors rather than on goals or outcomes. For example, it was agreed that although little would be accomplished by strengthening someone's intention to "avoid AIDS," it would be appropriate to direct an intervention at strengthening a woman's intention to tell her partner to use a condom or at increasing a male's intention to use a condom. What was less clear, however, was whether it was appropriate to direct interventions at intentions to engage in behavioral categories such as "practicing safe sex," or "negotiating condom use with my partner." Unfortunately, intentions to engage in behavioral categories are not always good predictors (or determinants) of whether a person will (or will not) perform a given behavior within that category. For example, a young man may form a strong intention to engage in "safe sex," yet he may have little or no intention to "always use a condom." Similarly, a young woman may form a strong intention to "negotiate condom use with my partner," yet she may have little or no intention to

"tell my partner to use a condom." Thus, if there is an interest in increasing the likelihood that men will use condoms or the likelihood that women will tell their partners to use condoms, it may be better to change intentions to use condoms and intentions to tell a partner to use condoms than to change intentions to practice "safe sex" or intentions to "negotiate condom use with my partner."

To complicate the issue even further, although condom use is a behavior for men, it is a goal for women. Women do not use condoms; at best, a woman can try to get her partner to use a condom. But is "getting my partner to use a condom" a goal or a behavioral category? As has been pointed out, in order to get a partner to use a condom, an individual may perform several specific behaviors (e.g., telling one's partner to use a condom, refusing to have sex unless one's partner uses a condom), at least some of which may reflect the behavioral category of "negotiating condom use with one's partner." Thus, once again, there is the question of whether it is more appropriate to try to increase a woman's intention to "get my partner to use a condom" or to increase her intention to perform one or more specific behaviors whose performance might increase the likelihood that a partner will use a condom. The way an individual answers this question has important implications for identifying the intention that the intervention should address. The question of what is or is not a goal, a behavior or a behavioral category, and the parallel question of what are appropriate intentions for interventions to address, are unresolved issues that require further attention.

Generally speaking, however, interventions that are not directed at increasing skills or removing environmental constraints should attempt to reinforce and strengthen intentions to engage in "desirable" (e.g., safe, healthy) behaviors and/or to weaken intentions to engage in "undesirable" (e.g., dangerous, unhealthy) behaviors.

By utilizing measures such as those already described, each of the eight potential determinants of behavior can be assessed and this information can be used to empirically identify the one or two variables that most strongly influence intentions to perform, and actual performance of, a given behavior in a given population. These empirically determined variables should then serve as the primary focus of an intervention.

For example, if norms are found to be most highly related to intentions and behavior, the intervention should focus on increasing perceived normative pressure to perform the behavior in question. In contrast, if self-efficacy is found to be most highly related to intentions and behavior, then the intervention should focus on increasing the person's self-efficacy with respect to that behavior. Because it is recognized that the relative importance of a given variable as a determinant of intention and/or behavior will depend on both the behavior under consideration and the population being studied, interventions should be based on empirical research. Little will be accomplished by directing an intervention at a given variable (e.g., outcome expectancies, norms, or self-standards) if the variable is unrelated (or only weakly related) to the behavior that needs to be changed. Given the limited resources available for prevention and change programs, it is essential that

interventions focus on changing those variables that have the greatest probability of influencing the likelihood that members of a given population will engage in the behavior in question.⁸

ACKNOWLEDGMENTS

This chapter is dedicated to Marshall Becker, a true pioneer in health psychology. His contributions and humanity will be greatly missed. The chapter is a slightly revised version of M. Fishbein, A. Bandura, H. C. Triandis, F. H. Kanfer, M. H. Becker, S. E. Middlestadt, & A. Eichler (1992), *Factors Influencing Behavior and Behavior Change: Final Report—Theorist's Workshop*. Bethesda: NIMH. We are grateful to Dr. Bandura for his input on social cognitive theory, and in particular, for the definition, description and assessment of self-efficacy. Because of his strong belief that science is best advanced by developing a single theory (rather than by integrating parts of different theories), Dr. Bandura chose not to be a coauthor of the present chapter.

⁸The theorists workshop that produced this paper was held in 1991. At that time, most AIDS psychosocial research was directed at identifying factors that put people at risk for acquiring or transmitting AIDS or at understanding the determinants of "safer" or "riskier" behaviors. There were few, if any, theory-based behavioral interventions to prevent the acquisition or transmission of HIV. Since that time, many of the ideas presented in this paper have served as the theoretical underpinnings for a number of successful behavior change interventions. For illustrations of how the concepts and measures described in the paper have been used to design, implement, and evaluate multi-site behavior change interventions at both the community and individual level, see Fishbein et al. (1996), the CDC AIDS Community Demonstartion Projects Research Group (1999), and Kamb et al. (1998).

Representations, Procedures, and Affect in Illness Self-Regulation: A Perceptual-Cognitive Model

Howard Leventhal

Elaine A. Leventhal
Robert Wood Johnson School of Medicine

Linda Cameron
University of Auckland

The explosion of research in health psychology over the past 40 years has been accompanied by the proliferation of a variety of theoretical models to help find a better understanding of the reciprocal relations between health and behavior. One set of models that has been used for the analysis of behaviors to promote health and treat and adapt to disease (e.g., utility theories and social learning models) has focused on five types of variables: The cognitive processes involved in the perceptions of vulnerability to disease (Becker, 1974; Hochbaum, 1958; Janz & Becker, 1984; Rogers, 1983; Rosenstock, 1966); the availability of actions to manage threat and/or emotional reactions to it (Lazarus & Launier, 1978); intentions to act based on the perceptions of the barriers and benefits of particular actions for threat avoidance (Fishbein & Ajzen, 1974; Janz & Becker, 1984; Rosenstock, 1966); the views held by valued others respecting specific healthy and risky behaviors (Fishbein & Ajzen, 1974); and perceptions of self-competence or self-efficacy to perform these actions (Ajzen, 1988; Bandura, 1977; Clark & Zimmerman, 1990). To a substantial degree, these constructs are the inventions of the investigators (see Krasnegor, Ep-

stein, Bennett-Johnson, & Yaffe, 1993; Leventhal & Cameron, 1987; Leventhal, Zimmerman, & Gutmann, 1984). This contrasts with a second set of models with names such as “self-regulation and adaptation” (Kanfer, 1977), “illness cognition” (Croyle & Barger, 1993), “mental representation in health and illness” (Skelton & Croyle, 1991), and “common-sense representation of illness danger” (Leventhal, Meyer, & Nerenz, 1980). These models, the focus of this chapter, make extensive use of constructs generated by their subjects (i.e., they incorporate the subjects’ phenomenology into their scientific vocabulary). The approach reflects a long-standing tradition in social and personality psychology (e.g., Kelly, 1955; Lewin, 1935), and in studies of “folk illness” by medical anthropologists (e.g., Chrisman, 1977; Kleinman, 1980; Pachter, 1993; Simons, 1993). The variation in their names reflects differential emphasis on various features of self-regulation in acting to prevent, treat, cure, or adjust to acute or chronic illnesses. All of the models are driven by three fundamental themes:

1. Individuals are conceptualized as active problem solvers trying to make sense of potential or existent changes in

their somatic state and to act to avoid or control those changes perceived as signs of illness or physical disorder; in effect, individuals are self-regulating systems. In this framework, adaptation is a product of a problem-solving process in which decisions to take specific actions reflect the understanding (representation) of an illness threat, the availability of procedures for its management, and experience with the outcomes (costs and benefits) of specific procedures.

2. The adaptive process is based on common sense beliefs and appraisals. That is, the representation of a disease threat, the coping procedures selected for its management, and the appraisal of outcomes is a product of the individual's understanding and skills. Thus, these representations and procedures may not reflect the objective, biomedical nature of the threat or the medical procedures optimal for its control.

3. The notion of "folk-illness," which distinguishes the biomedical concept of disease from its social concept of illness, emphasizes the role of the sociocultural environment in shaping the self-regulation process. Thus, the individuals' representation of a threat and their selection and evaluation of coping procedures will reflect their perceptions (i.e., representation) of the attitudes and beliefs of their social and cultural environment. This environment includes family, friends, health practitioners (biomedical and traditional), mass media, socially defined roles (such as the passive versus active patient), and the linguistic terms used to label and describe specific diseases and treatments. Each of these factors constrains and shapes the substance and behavior of the self-regulation system. Because a wide range of factors shape the content (or "software") of the self-regulatory behavioral system, assessments across persons within a common socio-cultural domain, and assessments across cultural domains, will reveal both common and unique features of illness representations, coping strategies, and appraisals.

The first of the following sections describes the *commonsense model of self-regulation*, which was designed to capture both the common and the unique features of the adaptation process. This section defines the actor's phenomenological view of health threats and the procedures for their management; in effect, it describes both the *structure* and the *content* of the problem-solving system. The second section describes the *system dynamics*, or the processes involved in self-regulation. The focus here is on the rules governing the interactions among the system's perceptual, cognitive, and affective components as individuals construct representations of threats and procedures for threat control. The self system is central to the discussion of system dynamics as the meaning of specific illness episodes arises from their impact on the self. The third section focuses on the role of the social context in shaping behavior during illness episodes. The views exposed here concerning the ways in which the self and social environment influence health-related problem solving differ in important respects from the views espoused by utility and social learning approaches. The fourth section gives special

attention to comparisons between self-regulation approaches and the utility and social learning models of the first set. The citations are designed to integrate the diverse literature relevant to the self-regulation approach here adopted. Exhaustive reviews are available elsewhere (Petrie & Weinman, 1997; Skelton & Croyle, 1991).

THE STRUCTURE AND CONTENT OF THE COMMONSENSE MODEL OF SELF-REGULATION

A psychological model of the processes involved in coping with specific episodes of illness and/or illness threats must depict the structure of the problem-solving system and its content (the cognitive and emotional material within it). Social-psychological research often considers the identification of mental contents as a task that is, at best, of secondary concern. Content is ignored, however, at the researcher's peril because it affects both structure and process. The content (e.g., ideas about the indicators, duration, causes, and ways of preventing and curing specific diseases) is the software or commonsense feature of the system as it reflects the declarative and procedural knowledge of the people under study. The categories in which these commonsense ideas are cast (e.g., the attributes of illness representations, the procedures in implicit memory, as well as the various rules governing the behavior of the system) are constructions of the investigator (Leventhal & Nerenz, 1985).

Although there is considerable diversity among self-regulation models of adaptation to health threats (e.g., Carver & Scheier, 1981, 1982, 1990, 1998; Lazarus & Folkman, 1984; Leventhal, 1970; Miller, Shoda, & Hurley, 1996; Prochaska, DiClemente, & Norcross, 1992), all share the following, specific features. First, the ongoing self-regulation process, or *episodic, problem solving*, is their primary focus. Second, the problem-solving process involves at least three sets of factors: (a) The individual actor's view, or *representation*, of the status of the health problem during the current, ongoing episode; (b) the actor's *procedures*, or plans and tactics, for the control of the threat; and (c) the actor's *appraisal* of the consequences of the coping efforts. The separation of the representation of the health threat from the procedures for threat management is a critical feature of the parallel model first presented in 1970 (see Fig. 2.1). The separation emerged from the repeated findings that messages about health threats did not lead to behavior unless they were combined with information depicting a plan for action. Whether it was the simple act of taking a tetanus shot (Leventhal, Singer, & Jones, 1965; Leventhal, Jones, & Trembly, 1966), or the more complex act of quitting smoking (Leventhal, Watts, & Pagano, 1967), the data showed that concrete information that defined a plan for action was necessary for the occurrence and maintenance of behavior. Although action plans did not generate behaviors by themselves, they were essential for connecting attitudes to behavior. These three factors—*representations, procedures for action, and appraisals*—along with feedback, are the basic constituents of a TOTE (test-operate-test-exit) unit in control

theory (Carver & Scheier, 1981, 1982, 1990; Miller, Galanter, & Pribram, 1960; see Fig. 2.2). The TOTE representation suggests that the three components may be closely interrelated and less independent of one another than suggested by the stages represented in the parallel model (Fig. 2.1). This issue is discussed in more detail during the discussion of dynamics.

Figure 2.1 shows that health threats are processed as two parallel arms; the processing of information for *controlling danger*, upper arm, and the processing of information for *controlling the emotional responses* elicited by the danger, lower arm. The independence of the processing of danger and the processing of affect was seen in early studies of people's response to fear arousing communications. These studies showed that messages depicting the threat of diseases such as lung cancer or tetanus had three effects: They aroused fear, changed attitudes, and at times, influenced overt behavior. But neither the presence of fear nor its level had a consistent relation to behavioral outcomes. For example, messages arousing high levels of fear, in comparison to those arousing low levels, did not increase the frequency of behaviors such as taking tetanus inoculations (Leventhal et al., 1966; Leventhal et al., 1965). Outcome measures showed that fear had two, character-

istic effects: It was temporary, and it produced attitudinal and behavioral "avoidance." Thus, intentions to drive safely (Leventhal & Trembly, 1968) and reports of decreases in cigarette smoking were enhanced by fear (Leventhal et al., 1967), whereas acts that could increase fear (e.g., taking a chest x-ray and discovering, perhaps lung cancer) were inhibited by fear (Leventhal & Watts, 1966). Recent studies support the hypothesis that fear facilitates behaviors to prevent disease and inhibits behaviors to detect or approach disease (Millar & Millar, 1996). The temporary quality of fear effects—they were visible for only 1 or 2 days following exposure to threat messages—contrasted with the promotion of health protective actions that lasted over weeks and sometimes months for subjects exposed to communications combining either a strong or weak threat message with action plans. This contrast created a problem for conceptualizing the effects of threat messages. Specifically, if the presence of an active state of fear or the intensity of this state was irrelevant for converting action plans into behavior, some type of "cognitive" change induced by the threat messages must be responsible for moving plans into action. These factors were labeled as the *representation* of the health threat, and the label defined a specific task, namely, identifying the content and structure of "representations."

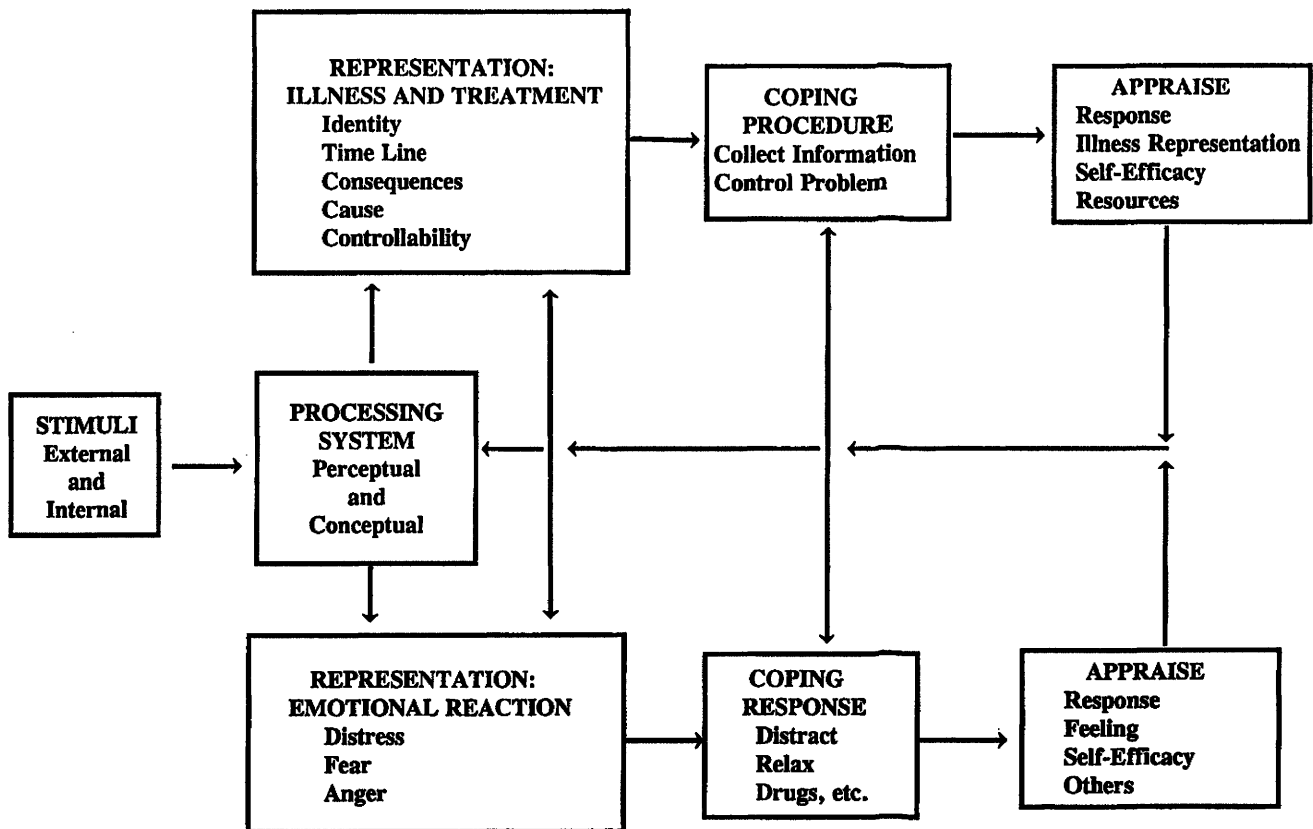

FIG. 2.1. The top arm of the parallel response model depicts the processing of the individual's phenomenal reality, or the representation of somatic experience and the plans, procedures, and outcome appraisals generated by the representation. A similar sequence for the emotional processes is represented by the lower arm. Arrows represent feedback and interactions among the processing levels (from Leventhal, Leventhal, & Schaefer, 1991).

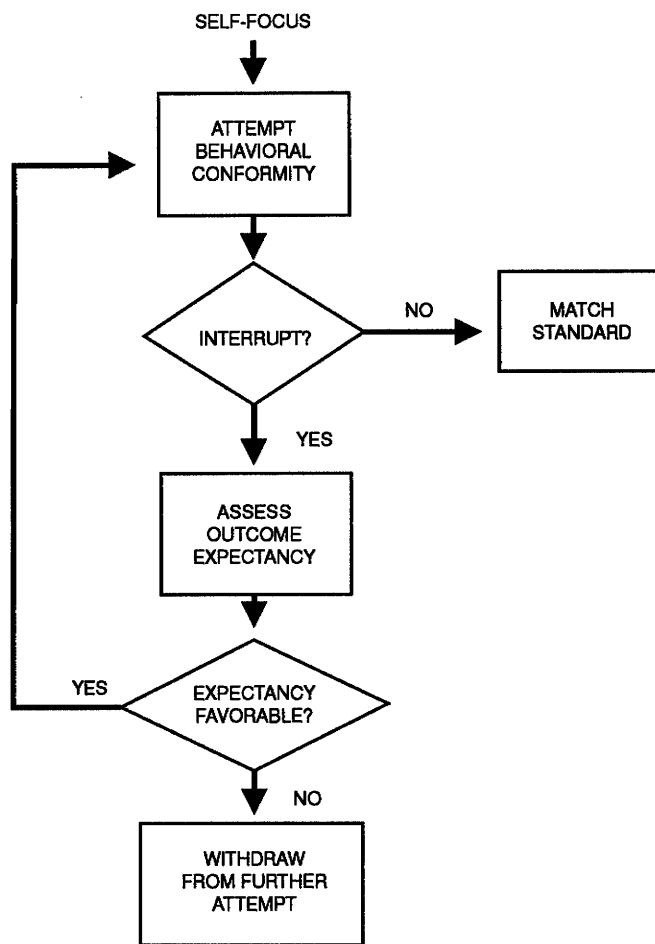

FIG. 2.2. A schematic depiction of a feedback loop, the basic unit of cybernetic control. In such a loop a sensed value is compared to a reference value or standard, and adjustments are made in an output function (if necessary) to shift the sensed value in the direction of the standard. Loops of this type may be arranged in parallel, hierarchies, the upper level loops in a hierarchy providing reference values for lower level ones, and loops in adjacent hierarchies providing reference values useful for shifting the ongoing process in new directions when obstructions are encountered (courtesy of Carver & Scheier, 1998).

The Problem-Solving Episodes: Illness Representations

The approach to the identification of the content of the illness representation (i.e., the substance that establishes goals and creates plans and actions for goal attainment and criteria for appraising action outcomes) was influenced by a decision to study illness behavior. In illness behavior (Kasl & Cobb, 1966), the *problem-solving episodes* are initiated by somatic stimuli (i.e., changes produced by a disease) or by disease labels. The objective was defined, therefore, as the investigation of the ways in which people understood and/or interpreted somatic symptoms and how they represented and

coped with disease threats (Leventhal & Leventhal, 1993; Leventhal, Nerenz, & Strauss, 1982). It was assumed, incorrectly perhaps, that it would be possible to identify the same features of the representation of health threats whether by studying how people interpreted somatic symptoms or by studying health-related actions that are undertaken by persons who are asymptomatic or healthy.

The Content of Illness Representations. Data generated by open- and close-ended interviews with patients, and data from studies using multidimensional scaling of illness labels with undergraduates, identified five sets of attributes of illness representations (Fig. 2.1):

1. The *identity* of the threat, or the symptoms and labels that define it (Dempsey, Dracup, & Moser, 1995; Lau, Bernard, & Hartmann, 1989; Meyer, Leventhal, & Gutmann, 1985).
2. The *time line*, which can include beliefs regarding the time lines for development and duration of a disease, the point in time to use a treatment regimen, the time needed for cure or control, and the time from disease onset to death when no treatment is possible (Heidrich, Forsthoff, & Ward, 1994; Klohn & Rogers, 1991; Meyer et al., 1985).
3. The *causes* of the threat, which may involve external agents (e.g., bacteria, virus, job stress, or even bewitchment), internal susceptibilities (e.g., genetic factors), and behavioral causes (e.g., a bump causing breast cancer; Baumann, Cameron, Zimmerman, & Leventhal, 1989).
4. The anticipated and experienced *consequences* of the disease, which may involve physical, emotional, social, and economic outcomes (Cella, Tulsky, Gray, et al., 1993; Croyle & Jemmott, 1991; Klohn & Rogers, 1991; Leventhal, Easterling, Coons, Luchterhand, & Love, 1986; McGee, O'Boyle, Hickey, O'Malley, & Joyce, 1991).
5. Its *controllability*, which pertains to the anticipated and perceived responsiveness of the condition to self-treatment and expert intervention (Lau & Hartmann, 1983).

These representational attributes form the basis of lay models of illness as they have been described from the time of Hippocrates and Galen to the present (Schober & Lacroix, 1991); they are the attributes that guide the selection of coping procedures and shape their execution. For example, symptoms represented as a coronary threat typically stimulate rapid care-seeking and the cessation of other activities (Matthews, Siegel, Kuller, Thompson, & Varat, 1983); those of a possible cancer may lead to care-seeking if they fall within the set of symptoms typically attributed to cancer (e.g., a lump in the breast; Facione, 1993), or to a "wait and see" strategy to determine whether they are getting worse (Cameron, Leventhal, & Leventhal, 1993; Hackett & Cassen, 1969). The symptoms of a common cold may stimulate self-care procedures such as getting extra sleep, taking aspirins, taking vitamin C, and drinking fluids.

Illness Representations Have Structure. Representations also have structure. Structure is of two types: The attributes of representations are represented in both abstract and concrete form (e.g., identity is represented as the disease label and its symptoms, and time-line is represented as conceptual, clock time and perceptual, "felt" time). And representations are constructed from underlying schemata or patterns of attributes that may reflect beliefs about specific diseases or specific classes of disease.

The bilevel nature of attributes is critical for behavior as it is the concrete, symptomatic level of illness that is a consistent and powerful predictor of utilization of health care (Berkanovic, Hurwicz, & Landsverk, 1988; Berkanovic, Telesky, & Reeder, 1981; McKinlay & Dutton, 1974; Pescosolido, 1992). The more interesting examples of the abstract and concrete nature of representations are those in which knowledge of both abstract and concrete cognition is necessary for understanding behavior. For example, Yoder and Hornik (1996) examined mothers' use of oral rehydration treatment of infant diarrhea from six large surveys conducted in Africa and Asia, and found that the mothers' observation of concrete symptoms (vomiting, fever, reduced play) predicted use of treatment after controls were entered for the mothers' judgments of the severity of the child's illness. Thus, concrete experience had direct as well as indirect (mediated by severity judgments) effects on behavior. More dramatic evidence appears when abstract and concrete levels of processing generate conflicting goals and different criteria for appraising coping efficacy. Diabetes and hypertension provide well-studied examples. Diabetic patients rely on symptoms to vary their insulin and food intake to avoid hypoglycemia even though they are trained and active users of far more accurate, objective devices for assessment of blood glucose levels; subjective cues win out over the procedures guided by abstract knowledge (Gonder-Frederick & Cox, 1986, 1991). Hypertensive patients behave similarly. Meyer, Leventhal, and Gutmann (1985) found that 80% of the patients in their study who were in ongoing treatment for hypertension agreed with the statement that "People can't tell when their blood pressure is elevated." These patients agreed with this statement because their doctors told them that elevated base levels of blood pressure, the numbers that define chronic hypertension, are silent or asymptomatic. Later in the same interview, however, 90% of these patients reported they could tell whether their blood pressure was elevated on the basis of a variety of somatic cues such as heart palpitations, warm face, and headache. More importantly, patients were compliant and had better blood pressure control if they believed their medications were reducing their symptoms: If the medications were seen as ineffective in controlling symptoms, both adherence and blood pressure control were poor.

The belief that hypertension is symptomatic is unsurprising on three counts. First, the label, hypertension, suggests that specific somatic experiences accompany elevated blood pressure (Blumhagen, 1980). Second, unlike basal blood pressure levels, acute or phasic shifts in blood pressure induced by intense exertion (e.g., exercise) produce palpable somatic change (Pennebaker & Watson, 1988). Third, medi-

cal practitioners may inadvertently suggest that hypertension is symptomatic when they conduct a review of systems, the "head to toe" symptom based inquiry designed to detect comorbidities and/or unfavorable sequelae of hypertension. While these three factors play an important role in linking specific symptoms to the hypertension label, that they do so is likely a reflection of a fourth, more fundamental factor: the tendency of the cognitive system to connect or to define abstractions with concrete instances (Quinn & Eimas, 1997; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). This linkage reflects what we have called the *symmetry rule*: the experience of symptoms will lead to a search for labels and the presence of labels will lead to a search for symptoms. The effect of symptoms on the search for labels is demonstrated by Schachter and Singer's (1962) classic study of emotional contagion. The search for symptoms given the presence of labels, is seen in studies where false feedback on elevations in blood pressure lead to increases in the reporting of symptoms identical to those reported by hypertensives (Baumann, Cameron, Zimmerman, & Leventhal, 1989; Croyle, 1990).

These matching of symptoms and labels to form disease representations reflects the integration of somatic sensations with underlying disease *schemata* or disease *prototypes*. The integration gives the self-diagnosis its implicit cause, time line, anticipated consequences, assumptions about controllability, and associated affective reactions. At any point in time, however, the individual may be conscious of only some of these factors. Investigators differ, however, concerning whether the process of matching a somatic input to memory involves a match to a prototype or a match to a specific, episodic memory (Croyle & Barger, 1993). This issue is dealt with in greater detail during a discussion of system dynamics.

Problem-Solving Episodes: Coping Procedures and Appraisals

Sensing a threat, the individual is faced with the problem of defining and controlling it, that is, preventing, curing, and/or halting its progression (Cioffi, 1991). The representation plays a central role in the selection, performance, and maintenance of procedures. A key proposition of our model is that "the representation of the disease affects the plausibility or choice of a procedure for threat control, defines a goal for the procedure, and sustains the performance of the procedure until the threat is removed" (Leventhal, Diefenbach, & Leventhal, 1992). In more familiar terms, the representations of the illness and the selected procedure create outcome expectations and a time frame for goal attainment. For example, individuals suffering from a runny nose and a headache may assume that they have an acute cold (identity and symptoms) that will last for a day or two (time frame), is uncomfortable but not life threatening (minimal consequences), and whose symptoms can be managed (control). The procedure for control, taking an over-the-counter medication such as aspirin or tylenol, has an identity, a label and expected somatic "side effects" (removal of headache and if aspirin, possible stomach acid), an expected time frame for efficacy (half hour to an

hour to work with duration of 4 to 6 hours), with no serious consequences, expected control of any of its side effects (take an antacid with the aspirin), and so on.

The variety of coping procedures is enormous. They range from short-term actions such as using one or another of the vast number of over-the-counter medications, to participation in one of many procedures for the prevention or early detection of cancer or cardiovascular disease, to repetitive and longer term actions such as obtaining an annual check-up, adopting a low-fat diet, avoiding risk by quitting smoking, or adopting any of the wide variety of procedures used for months and years to minimize dysfunction and live with an incurable, chronic condition. It seems likely that the extraordinary variety of coping procedures is due in part to the perception that different, specific procedures are needed to deal with particular threats. For example, topical antibacterial agents are used for wounds but not for gastric distress.

In addition to their enormous variety and specificity, procedures for controlling threat have multiple objectives, and the very same procedure may have different objectives at varying points in time. For example, social comparison, one of a larger set of procedures defined by a search for information, may be useful for self-diagnosis of the *identity* of a symptom and simultaneously, for the reduction of fear. For example, if both you and a friend suffer from stomach pains, vomiting, and diarrhea 12 hours after eating the same dessert at lunch, it is more plausible to assume that you are both suffering from food poisoning rather than an ulcer or stomach cancer (Leventhal, Hudson, & Robitaille, 1997). Thus, a procedure may be used for both problem solution and emotion control at the very same point in time. Indeed, coping procedures have complex meanings. Unlike utility and social-learning frameworks, which assign two attributes to coping procedures, *response efficacy*, or the effectiveness of the response in meeting its goal, and *self-efficacy*, or the individual's ability to perform the response (Bandura, 1977), self-regulation models posit complex, multiattribute representations for procedures. Horne and his associates (Horne, 1997) revealed that individuals possess a range of strongly held beliefs regarding the identity, potential consequences, causes or modes of operation, and timelines for medications. For example, people hold specific beliefs about the risks of medications (e.g., that they can be addictive and have harmful as well as beneficial consequences). Thus, response efficacies include a causal route and a time line for efficacy, somatic effects in addition to symptom removal (identity or side effects), and a variety of consequences in addition to cure and/or control of disease. Procedures can be viewed within the same framework as illnesses: Their representations possess a full set of attributes and they reliably predict adherence to medication regimens (Horne, 1997). The variety, flexibility, and variation in functional utility of specific procedures belies the value of factorially derived classifications of coping responses as problem focused or emotion focused (Lazarus & Launier, 1978; H. Leventhal, 1970).

The contrast formed between the complexity of procedures when observed at the episodic level and the simplicity resulting from factorial studies of coping has led investigators

to propose hierarchical models (Krohne, 1993; Leventhal, Suls, & Leventhal, 1993), with generalized strategies defining commonalities across broad classes of coping responses (e.g., risk aversion and energy conservation [Leventhal & Crouch, 1997; Leventhal, Leventhal, & Schaefer, 1991]), middle-level strategies for timing problem-solving responses and controlling emotional reactions (e.g., monitoring or blunting; Miller, 1996; Miller, Combs, & Kruus, 1993; Miller & Mangan, 1983), and specific, lower level procedures such as taking aspirins, exercise, and/or seeking medical care to manage or ward off particular somatic conditions (Klohn & Rogers, 1991; Stoller, 1993, 1997). The modest predictive power of currently used coping instruments, the inconsistent outcomes from study to study, and the failure of coping theory as a basis for interventions to improve adherence to preventive and treatment behaviors reflects the absence of solid empirical data on different levels of analysis. Exceptions are mentioned later (see Stone, Helder, & Schneider, 1988; Stone & Neale, 1984).

Although conscious deliberation enters into the planning and performance of many coping procedures, a substantial number of coping reactions are performed automatically. In fact, automatic behaviors for controlling a health threat may occur at all levels of coping. Consider, for example, a woman who thinks she may have a lump under her right arm. She may automatically and unintentionally execute specific coping tactics, such as searching for parallel, somatic features by touching and exploring the area under her left arm to determine whether a parallel feature is present, suggesting perhaps that both are permanent parts of herself rather than something caused by disease. Automaticity adds to the difficulty of investigating the coping process.

The Episode and Affective Reactions

A wide range of emotional responses appear at various points and in varying intensities in response to warnings, diagnoses, and treatment for disease threats. Examples abound: (a) Exposure to vivid motion pictures depicting the consequences of automotive accidents provokes a mixture of fear, anger, and depression (Leventhal & Trembly, 1968); (b) Exposure to vivid images of lung cancer surgery evokes fear responses and avoidance of chest x-rays (Leventhal & Watts, 1966); (c) Anecdotal reports often describe the diagnosis of breast cancer as equivalent to a "blow on the head"; (d) Diagnoses of recurrent gynecological cancer may arouse a sense of devastation (Andersen, 1999); (e) Emotional distress, characterized as anxiety and fear, fluctuate during hospitalization for medical treatment, rising as the day of surgery nears, peaking following recovery from anesthesia, and gradually declining over the days to discharge (Johnston, 1980); (f) Patients differ in the number of symptoms and level of distress reported in response to the "same" pharmacological agents during cancer chemotherapy (Love, Leventhal, Easterling, & Nerenz, 1989; Manne et al., 1994); (g) Anxiety and distress change with repeated treatment. Some patients show reductions of distress over chemotherapy cycles as they become in-

creasingly familiar with the procedure and show fewer emotional responses (Nerenz, Leventhal, Easterling, & Love, 1986), whereas others show dramatic increases when a later treatment produces unexpected effects that high levels of uncertainty (Nerenz, Leventhal, & Love, 1982); 8) Associative learning may sustain nausea and anxiety over treatment trials, condition to formerly neutral cues, and contribute to a steady rise in distress levels over the course of treatment (Andrykowski, 1990; Bovbjerg et al., 1992; Leventhal, Easterling, Nerenz, & Love, 1988).

Bidirectionality of Emotion and Representations.

The variation in emotional distress between persons and over time within the same person, in response to warnings of health threats and during medical treatment, indicates that affective reactions are highly dependent on the meaning individuals assign them. It appears that the affective tail is wagged by the cognitive dog (Lazarus, 1982, 1984). "Meaning" is an amalgam of the representation of the danger and its treatment, the perceived availability of resources to manage the consequences of both, and the outcome of these management efforts (Folkman, 1984; Lazarus, 1966; Lazarus & Folkman, 1984; Scherer, 1984, 1993).

The interplay between emotional reactions and cognition is not, however, uniformly from cognition to affect: It is bidirectional and affective reactions can precede or follow, and in either case, influence both cognition and behavior (Leventhal & Scherer, 1987). Physiological changes induced by exercise (Clark, 1982), sexual excitement or anger (Zillman, 1979), and physical illness can elicit a range of emotional states (Aneshensel, Frerichs, & Huba, 1984), and exacerbate fears of illness and death. Physical illnesses elicit emotional reactions through multiple indirect paths, such as their meaning or threat value or their impact on physical function (Brown, 1990; Zeiss, Lewinsohn, Rhode, & Seeley, 1996), and through a variety of direct paths. For example, the body's immune defenses have direct effects on the central nervous system (Hart, 1988) and diseases can cause cell death and/or depletion of neurotransmitter leading to depressed affect (Cummings, 1992; Leventhal, Patrick-Miller, Leventhal, & Burns, 1997).

The complexity of links between emotion and cognitive representations of illness is precisely what should be expected given that both emotion and cognition involve complex mental and physiological systems; they are not simple entities. Thus, it is expected that emotional reactions, and the individual's success in regulating these reactions, will have multiple effects on the cognitive side of the equation. Emotions can affect illness representations and coping by generating and/or amplifying somatic sensations, increasing feelings of vulnerability (Johnson & Tversky, 1983), or enhancing or minimizing perceptions of illness severity (Ditto, Jemmott, & Darley, 1988), by paralyzing action and lowering expectations of successful outcomes, and by damaging perceptions of self-efficacy (Leventhal, 1970; Seligman, 1975). These issues focus on process and are discussed in the following section.

THE DYNAMICS OF COMMON-SENSE SELF-REGULATION

The processes underlying the construction of illness representations, the selection and execution of coping procedures and their interaction with affective processes, represent the dynamics of self-regulation. These processes are at work in the evolution of episodes for both the prevention and management of illness. This constructive process takes place in the context of the self, that is, the individual's actual and (self) perceived characteristics (cognitive and emotional). A theme that is raised and repeated throughout this section is that coping procedures are guided by questions concerning the implications of illness for the self-system (Hooker & Kaus, 1994; Marcus & Nurius, 1986). Farmer and Good (1991) articulated a similar approach in medical anthropology. The meaning of cancer or cardiovascular disease for an individual emerges from an interaction of the individual's representations of the disease, its treatment and prevention, with the individual's self and with his or her daily function. People act on disease threats, and these actions provide important information about the threat as well as their resources and ability to regulate and protect their physical and psychological integrity.

Theoretical constructions of this interactive process can be made at multiple levels. The moment-by-moment problem-solving processes taking place during ongoing illness episodes involve interactions of concrete and abstract features of illness representations with concrete and abstract features of the self. At the concrete level, the symptomatic identity of the disease, anticipated symptoms, or somatic experiences of treatment, and experienced duration specific treatment side effects derive meaning from interactions with concrete aspects of the self, that is, with the "working" or functional self (e.g., energy to complete treatment, perception about one's ability to tolerate the pain and injury of treatment, etc.). Abstract components of the representation (e.g., beliefs about time until death, expectations regarding possible injury from aversive treatments such as surgery, chemotherapy, etc.) interact with higher order factors of the self-system such as optimism-pessimism or feelings of vulnerability to harm, and self-efficacy at performing specific self-treatment regimens. These meanings generated from the interaction of these higher order variables are presumed to be important for initiating and sustaining goal-directed, episodic behaviors. For example, feelings of vulnerability to a life-threatening disease creates motivation to adopt procedures for prevention (avoidance of death), and willingness to adopt and endure noxious medical treatments is generated by beliefs about the efficacy of the treatment, the intensity and duration of its noxious effects, and beliefs about the self such as perceiving oneself as able to endure distress and possessing an optimistic outlook on the likelihood of cure.

The procedures used to control threat elucidate the interactions among the illness models and representations of the self. For example, identification of somatic sensations as symptoms of risk involve questions such as, "How do I know if this lump is part of my normal self or a product of a

threatening disease?" "Are my sensory experiences signs of illness or signs of stress?" When an individual performs a procedure such as taking an aspirin to control a headache, the expected outcome (i.e., the removal of the headache in a defined time frame for a defined period of relief) is a product of the underlying model of the illness and a model of the self's prior response to such treatment (e.g., headaches caused by stress are cured, headaches from nasal-respiratory inflammation recur after 3 or 4 hours, etc.). The response to treatment facilitates the identification of its source, and labeling its source spells out the implications of the headache episode for the self. Defining the questions raised in efforts to define the meaning and establish goals during illness episodes, and identifying the schemata underlying them, will be a major objective of self-regulation theory.

The discussion begins at a more atomistic level (i.e., the interaction of somatic sensations with memory structures in the construction of representations). It moves to questions involved in the dynamics of coping and to interactions of representations and coping procedures with affective processes. Interactions of these factors with the social environment are deferred to the following section.

Constructing Illness Representations

Figure 2.1 suggests that the self-regulation process is linear (i.e., that somatic or external stimuli generate illness representations that are followed by coping procedures and their appraisal). Although the backward pointing arrows in Fig. 2.1 indicate that a loop is created by postappraisal feedback, and feedback can alter any or all of the prior components including the stimulus inputs, these arrows do not overcome the overall linear view implied by the figure. It is worth stating, therefore, that procedures can create stimuli that generate representations as can affective responses. For example, the physically expected cardiac acceleration associated with physical or sexual exertion can generate the representation of coronary disease in vigilant persons. The discussion, however, follows a linear order and begins with the processes involved in the conversion of somatic stimuli to symptoms and health representations, and moves from there to the role of procedures in disambiguating stimuli (i.e., in converting ambiguous somatic sensations into health threats). The ability to distinguish nonself from self (i.e., pathogenic processes from normal and nonthreatening departures from baseline) is an integral part of this process. The interaction of affective processes, representations, coping, and the self-system are discussed last.

Converting Sensations to Symptoms: The Matching Process. Lazarus (1966) labeled the interpretive step of translating somatic sensations into symptoms, "primary appraisal." Use of the word "appraisal" is unfortunate, however, because it implies that decoding is a conscious process when it is known that much of the decoding process takes place outside awareness. The bilevel nature of the attributes of representations described earlier (e.g., identity as label symptoms,

time lines as clock time and felt time) are consistent with the suggestion that the knowledge base used to transform a somatic sensation into a symptom includes both semantic memories (e.g., memories of labels such as heart disease, cancer, and colds) and concrete, perceptual memories of personal somatic experiences (e.g., memory of painful sensations in specific parts of the body during specific illness episodes; Millstein & Irwin, 1987). The semantic structures appear to be heavily involved in guiding how people think and talk about symptoms and in structuring long-term strategies or plans for symptom management. Perceptual memories of specific episodes, on the other hand, appear to generate an immediate, sensory link to appraisals of health status and treatment efficacy and they play a central role in the elicitation and maintenance of emotional reactions and automatic procedures for emotional control (Cameron & Leventhal, 1995; Easterling & Leventhal, 1989; Johnson, 1975).

As somatic sensations activate both types of process more or less simultaneously, the representation and procedures will reflect both types of memory store, as seen in the symmetry of symptoms and labels. In the majority of instances, representations and procedures are generated by matching of a set of somatic events rather than a single somatic sensation to an underlying schema. Bishop (1991) used a variety of clustering techniques to identify sets of symptoms that generate specific representations (see also, D'Andrade, Quinn, Nerlove, & Romney, 1972). For example, (a) headache, face flushing and chest pain; (b) hard or tender growths in various parts of the body accompanied by fatigue and general malaise; and (c) coughs, running noses, and fatigue, may lead to self-diagnoses of heart attack, cancer, and flu, respectively (Bishop, 1991; Bishop & Converse, 1986). The specificity of the interpretive process has considerable practical importance as multiple studies show that the nature of symptoms are related to delay in care seeking. For example, in her review of delay in care seeking by women with breast cancer, Facione (1993) noted that seven of nine studies showed longer delays for symptoms other than a lump in the breast (e.g., pain, bleeding or discharge, dimpling, etc.). Delay is understandable as symptoms are inherently ambiguous (i.e., they do not advertise their cause). Not surprisingly, delay is also common among primary care providers (Facione, 1993).

Croyle and Barger (1993) pointed out that two views of this matching process have been suggested by different investigators. Bishop and Converse (1986) viewed the process as matching a set of symptoms to a generalized prototype. This interpretation is supported by data showing that a set of symptoms is more quickly labeled and more likely to be recalled if it is constructed to match a prototype than if it is constructed randomly. On the other hand, Leventhal and colleagues (Leventhal, 1982, 1986; Leventhal & Diefenbach, 1991) described the process as an integration of current symptoms with the schema of specific illness episodes. The initial formulation of the hypothesis that an episode specific memory schema could underlie the decoding of somatic sensations and the formation of illness representations was based on clinical reports of phantom pain. Phantoms are most often reported following limb amputation, and the pain embedded in

the phantom is typically identical to that experienced in an episode immediately prior to amputation (Melzack, 1973). The somatic sensations of limb and pain appear to be stored in perceptual memory (Melzack, 1992), and the complexity of the memory is highlighted by the manner in which the pain can ebb and flow as the phantom limb changes its apparent position. Observations congruent with the episodic hypothesis include reports that coronary patients may misdiagnose chest pains and delay care seeking in response to a second coronary attack because the symptomatology is not identical to that of their first episode. Croyle and Barger's (1993) suggestion that "only frequently experienced illness, such as the flu, stimulate the development of prototypes" and that "severe or unusual episodes, however, may serve as a direct basis for comparison" (p. 34) appears a reasonable resolution of these two viewpoints.

Person and Situation Factors Facilitate the Matching Process. Both person and environmental factors can enhance the availability of disease-specific schemata and enhance the likelihood of illness interpretation of symptoms. A compelling example of a personal factor is seen in a study of women who had been successfully treated for breast cancer (Easterling & Leventhal, 1989). Some of these women felt highly vulnerable to recurrence, and they expressed high levels of worry about cancer (an indicant of the activation of the representation of cancer) if they were experiencing vague, noncancer specific, symptoms (e.g., fatigue). Women who believed recurrence was unlikely did not express worry in response to these ambiguous symptoms. Similarly, a recent study of women who volunteered for a clinical trial on the effects of tamoxifen on blood lipids and bone density, revealed that symptom reports were associated with increased worry about breast cancer up to 6 months after entering the trial, even though the symptomatic side effects (e.g., hot flashes and vaginal irritation) were recognized as induced by the chemoprevention therapy and not by disease recurrence (Cameron, Leventhal, & Love, 1998). Not only did the tamoxifen side effects appear to generate worry about cancer, they also prompted increases in breast self-examinations to detect the possible appearance of new lumps. Importantly, a control group of placebo users did not exhibit these increases in cancer worry or breast self-examination use over time. In both studies, breast cancer representations (and, in the latter study, protective action) were activated by symptoms associated with the breast cancer experience even though these symptoms were not interpreted as signs of illness. Person factors have important consequences for the use of medical care, as data show that factors such as "hypochondriacal" attitudes are strong predictors of total utilization after accounting for the contribution of total number of illness conditions and the presence of symptoms (Barsky, Wyshak, & Klerman, 1986).

Situational factors have a similar effect in sensitizing illness schemata and facilitating a match to symptoms. For example, Salovey and Birnbaum (1989) found that the induction of negative moods increased feelings of vulnerability to serious diseases for subjects who were well; mood had no effect on vulnerability judgments by subjects who

were ill. Thus, everyday illnesses activated illness schemata and stimulated feelings of vulnerability to more serious illness, overriding any additional sense of vulnerability that might be created by negative moods. The activation of illness schemata by the induction of negative mood and its associated increase in feelings of vulnerability to serious illness was visible, however, in healthy subjects. These laboratory data are consistent with field observations such as the flood of phone calls for cancer check ups that follow mass media reports of cancer in highly visible public personalities and the high rates of genetic testing for breast cancer among women who report a history of breast cancer among close family members (Chaliki et al., 1995).

The Interdependence of Representations and Coping Procedures. The initial formulation of the self-regulation model defined separate representation and procedural stages (Leventhal, 1970). The separation was consistent with the data showing that different types of information influenced representations and coping. More recent data point to a more integral or Gestalt-like relation between representations and procedures (Garner, 1962). The integral nature of the relation reflects findings showing that representations shape procedures (i.e., procedures that "fit" the presumed physical and physiological nature of the threat are preferred; Lacroix, Martin, Avendano, & Goldstein, 1991). For example, drinking liquid to treat gastric distress is integral because it fits the locus and nature of the stimulus, just as applying a soothing liquid or creams is integral to the treatment of surface irritations. The concrete component of the representation plays a central role in the selection and maintenance of procedures (Palatano & Seifert, 1997). The temporal expectations for these highly available procedures are also extremely clear. One should experience change instantaneously.

Anthropological studies provide numerous examples of the integrality of representations and coping procedures. Weller, Pachter, Trotter, and Baer (1993) described the symptoms of *empacho*, (vomiting, stomach pain, and swollen stomach), its presumed causes (intestinal obstructions caused by "eating too much, the wrong type or poorly prepared food, or eating at the wrong time"), and the procedures for its treatment. The procedures include "massage, rolling an egg on the stomach, ingesting olive oil or tea, etc.," all of which are designed to dislodge the presumed obstruction. Kaye (1993) provided a similarly graphic description of integrality for a disease called *mollera caida*. Symptoms of *mollera caida* include a sunken fontanelle (from which it derives its name), diarrhea, and sunken eyes, resulting from dehydration caused by gastroenteritis that can lead to infant death. Folk beliefs attribute it to falls or the abrupt withdrawal of the nipple during nursing, and treat it by holding the infant by the heels, sucking on the fontanelle or pressing on the soft palate, procedures designed to force the fontanelle to its original position. The treatments for both illnesses are integrally related to their symptoms and perceived cause.

Both *empacho* and *mollera caida* illustrate that common-sense, cultural constructions build on observable indicators

of a biologically definable condition. As the biology of a disease such as *molera caida* is constant over time and cultures, its key symptoms can shape similar treatments over hundreds of years, for example, from the time of the early Greeks and Romans, through the middle ages, to the Renaissance and 16th-century Aztec writing that blend European and new world views of the condition (Kaye, 1993). It would be a mistake, however, to assign such behaviors as anomalies of less developed cultures, as similar practices are readily identified in the United States in the few studies searching for them. For example, the self-care procedures reported for women with symptoms of breast cancer range from use of antibiotic ointments to cure ulcerations, washing to clear secretions, rubbing to soften tissue, applying heat and pulling to change the physical contour of the breast (Facione, 1993). The need to redefine a symptom emerges when such procedures fail to affect their target.

If-Then Rules and Questions for the Self. The proposed integrality of representational beliefs and coping procedures led us to borrow the formulation of cognitive theorists that representations and procedure are bound together as “if-then” rules (Anderson, 1983, 1993; Miller et al., 1996; Mischel & Shoda, 1995). The “if” refers to the cognitive definition of the stimulus pattern, the “then” to associated cognition regarding expected consequences and behavioral responses appropriate for its control. “If-then” rules are also activated by feedback from the outcomes of action. In the latter case, “if” refers to the stimulus pattern generated by the coping procedure and “then” corresponds to modifications in representational beliefs.

The questions initiating and sustaining a sequence of if-then rules emerge from the implications of illness for the self-system. Representations of illness, the timelines, anticipated physical indicators (symptoms and functional), as well as social and economic consequences, and beliefs about control, have important implications for the physical, emotional, and functional integrity of the self, and the time frame (i.e., existence) of the self. This has been described as a literal “collision” of illness and self-representations (Leventhal, Leventhal, & Carr, in press). A recent study by Heidrich, Forsthoft, and Ward (1994) illustrated how this impact affects emotional and interpersonal adjustment of women with breast cancer. Two major aspects of the representation of breast cancer, a chronic time line and physical dysfunction, had negative impact on emotional adjustment and anticipated satisfaction in close, interpersonal relationships. These effects were mediated, however, by the discrepancies created between the individual’s current, cancer impacted self, and desired self characteristics. To move from a general proposition (i.e., that “if-then rules emerge from the collision of illness and self representations”) to specific theoretical hypotheses, it is essential to identify the specific types of questions that emerge from this “collision.”

Two Examples of If-Then Rules. Investigators have identified two, specific, schema-related questions that underlie “if-then” rules: the *stress-illness* question and the *aging-*

illness question. The stress-illness question is resolved by what appear to be automatic, environmental searches designed to discriminate underlying, implicit schemata of illness and stress (Pennebaker, 1982). A search of individuals’ life situation permit them to attribute ambiguous somatic symptoms (e.g., fatigue, headache, joint pains.) to current stressors or to illness. For example, when students were given a list of ambiguous symptoms and asked whether they would believe they were ill or stressed if they experienced them when awakening the next morning, they endorsed a stress attribution if a midterm was scheduled for the following day, and they endorsed an illness attribution if the question was asked the day before a class-free weekend. Symptoms that defined a clear picture of a known, physical illness were attributed to illness for both the exam and weekend days (Baumann et al., 1989). A similar effect appeared in the analysis of care seeking by a sample of elderly adults. When symptoms presented a clear sign of a health problem, life stressors had no effect on seeking medical care (Cameron, Leventhal, & Leventhal, 1995). Ambiguous symptoms, however, were attributed to stress and did not lead to use of medical care if they appeared soon after the occurrence of a new (less than a month) life stressor. If, however, the life stressor was old, respondents sought care for ambiguous symptoms, presumably because they believed that long-lasting stressors could cause illness (Cameron et al., 1995). Thus, commonsense has a “1-month rule” or temporal criterion for answering the stress-illness question and disambiguating a symptom set. It is interesting to note that the “1-month rule” matches the data on the relation of stressor duration for contracting colds following viral exposure (Cohen et al., 1998).

Where the stress-illness question appears to involve a quick, implicit search of the individual’s life situation, the aging-illness question evokes searches of the properties of symptoms and the individual’s physical self (Alonzo, 1980). Symptoms that are slow to appear and slow to change, and advanced chronological age of the person experiencing them, can encourage attributions of somatic changes to age rather than to illness (Prohaska, Keller, Leventhal, & Leventhal, 1987), although these effects can change due to historical conditions that alter people’s perceptions of the risk and/or curability of different diseases (Facione, 1993). It seems unlikely that a great deal of conscious cogitation is necessary to answer the stress-illness or age-illness questions. In many, if not most, instances, the criteria or rules are applied automatically with little thought. Both cases, however, involve more than an underlying schemata of illness: The stress-illness question clearly involves emotion schemata (Pennebaker, 1982), and the age-illness question involves a schema of the physical self (Epstein, 1973). The attachment of affect to the self schema—for example, negative views of the body are more common among women than men (Muth & Cash, 1997)—may differ with age, and is likely to interact with disease-specific representations and to affect willingness to seek care for diseases that threaten changes in body image. It is also likely that a stress response to the stress-illness question addresses beliefs about the vulnerability of the self to emotional distress, and in particular, the ability to control distress.

Such beliefs may minimize illness attributions in response to ambiguous symptoms.

Just as there are stereotypes or beliefs about age, so too are there stereotypes about the victims of disease. These stereotypes then influence the processes of symptom labeling and attribution. For example, Martin, Gordon, and Lounsbury (1998) explored the impact of gender-related stereotypes regarding heart disease on the interpretation of cardiac-related symptoms. In samples of undergraduates, community dwelling adults, and physicians, they found that cardiac symptoms were discounted or minimized—not for women in general—but specifically for female victims who reported concurrent life stressors. Thus, a stereotype linking female gender to stress leads to the discounting of life threatening symptoms.

Differentiation of Illness Representations. Representations change as disease episodes unfold. For example, as their treatments go forward, patients with hypertension and patients with metastatic breast cancer show a shift from acute to chronic time lines in their illness representations (Leventhal et al., 1986; Meyer et al., 1985). Ongoing involvement with a chronic disease can generate important changes in the representation of specific disease attributes, and these changes can have important effects for adjustment and self-regulation. A change that has proven of special importance in predicting adjustment is breaking the symmetry of disease identity, that is, separating the label (concept of the underlying disease) from the symptoms that jointly define its identity.

The evidence is most clear in studies of adaptation to rheumatoid arthritis. Data show increasingly depressive mood over time for patients with rheumatoid arthritis (Affleck, Tennen, Pfeiffer, & Fifield, 1987; Brown, 1990; Zeiss et al., 1996). This increase is mediated by disruptions in physical function (Zeiss et al., 1996). The physical disruption appears to reflect losses to the self (e.g., arthritis “makes me feel that I am falling apart,” and “When I think of myself, pain comes to mind”). These appraisals of loss of personal control (Felton & Revenson, 1984) reflect feelings of helplessness with regard to controlling the illness and its manifestations. Some patients, however, differentiate the underlying disease (its label and chronic time line) from its symptomatic manifestations (Schiaffino & Revenson, 1992). Having done so, they can focus their coping and outcome appraisals on their success in controlling the duration of episodes of symptom-induced dysfunction rather than their success in eliminating disease (Schiaffino, Shawaryn, & Blum, 1998). A positive correlation is found between coping and positive mood for patients who have made the differentiation and are coping with symptoms, but a negative correlation between coping and adjustment has been found for patients who have not made the differentiation; patients in the latter group experience failure as they appraise their coping with respect to their ability to control the underlying disease (Affleck et al., 1987). Pimm (1997) reviewed these data and described ongoing trials in which he and his collaborators hoped to confirm the finding that patients who differentiate their chronic rheumatoid condition from its symptoms of stiffness and pain, and made use of procedures (stretching and exercise) that allow them to lead

more active and less dysfunctional lives, regardless of the degree of physical disease. The separation of the underlying, chronic (time line) condition from its manifestations (symptoms with variable, episodic time-lines) and engaging in coping reactions that produce positive effects in the controllable manifestations of the disease (e.g., reducing the extent and duration of symptom induced dysfunction) appears to be the key to self-management that generates a sense of control and positive affect (Schiaffino & Revenson, 1992). In sum, the alteration in the representation, which may be stored as a prototype or episodic image, focuses attention and procedures on controllable symptomatology. Propositional, if-then questions are framed by and test the validity of the underlying illness schema.

Updating Representations and Procedures. Appraisals of self-selected and medically prescribed diagnostic and treatment procedures are constantly modifying and updating illness representations. For example, a middle-aged male may experience a burning pain in the esophagus that can be represented either as gastric distress or cardiac pain. If the gastric distress interpretation holds sway, the choice of coping might be one or another home remedy such as drinking extra fluid, taking an antacid, or resting. If the coronary interpretation holds sway, then the choice of coping procedures might be the cessation of activities and consultation with a physician. The feedback from each of these procedures will serve to validate or invalidate its efficacy and update the representation. If the gastric distress diminishes following use of antacid, it confirms the initial self-diagnosis; if it does not, it opens new questions, the answers to which will be sought depending on factors such as the severity and duration of the symptoms and the affective responses elicited by alternative hypotheses.

A representation may be updated incorrectly regardless of whether a procedure is performed consciously or automatically. At least four different factors may contribute to error. First, the feedback may be ambiguous and open to a variety of conflicting interpretations. Second, the feedback may be familiar (e.g., change in gastric distress) and validate the most available hypothesis rather than that which is correct. Third, the threat associated with the correct interpretation may activate defensive minimization (e.g., is far more comfortable to think one has gastric upset than a life threatening coronary event; Ditto et al., 1988). Fourth, the desirable change in somatic activity may be incorrectly attributed to the most salient component of a complex procedure (e.g., drinking tea) rather than to a less salient and effective component (e.g., sitting and resting, which reduced the demand for cardiac output and reduced the esophageal pain).

Emotions, Representations, Procedures and Symptoms

Having separated the processing of cognitive and emotional experiences (See also Epstein, 1994; LeDoux, 1993), it is essential to address how the two interact. As stated earlier, both factors in this equation (i.e., emotional reactions and cognitive

representations of illness) reflect the action of complex systems. It is impossible, therefore, to address all facets of this interaction because chapters can be written on the ways in which different patterns of physiological activity evoke episodic memories, and others on how matches of the cognitive or mood components at learning and recall affect memory retrievals (Bower, 1981). The focus here is on two, simpler issues. The first concerns how health and illness behaviors are affected by "hot" emotion (states) as distinct from "hot cognition." The second concerns how the processes involved in "hot emotion" and "hot cognition" differ from those in "cold" cognition. In addressing each of these issues, emotion is treated as a unified construct (i.e., as a factor in experience) and the many complexities of the system generating it are ignored.

Affect and Illness Cognition: Separate Process and Inseparable Outcomes

Although reasonably clear distinctions can be drawn between "hot emotion," "hot cognition," and "cold cognition," it is important to recognize that the boundaries separating them are fuzzy (Abelson, Kinder, Peters, & Fiske, 1982). "Hot emotion" refers, as might be expected, to states of emotional activation, to those times when a person is experiencing affect (i.e., is afraid, angry, or depressed) is having affect related thoughts, is showing facial and bodily expressions of affect, and is showing emotionally relevant somatic activation. "Hot cognition" refers to perceptions, images, and thoughts with emotional significance, that is, cognitive material associated with and capable of arousing emotion.

Hot Emotion and the Inhibition of Action. The disruption of coping (i.e., the inhibition of action) is the aspect of active fear emotion most frequently documented in the domain of health and illness behaviors. Numerous examples of coping inhibition were presented in the first section of the chapter, which reviewed the importance of studies of fear communication for the formulation of the parallel response model (Leventhal, 1970). Active levels of fear inhibited taking of chest x-rays (Leventhal & Watts, 1966) produced a 1-day delay by low esteem subjects in taking inoculations to protect against tetanus (Kornzweig, 1967; reviewed in Leventhal, 1970), and facilitated reports of short-term efforts to quit smoking (Leventhal et al., 1967). The conclusion merits repeating: Fear encourages avoidance of stimuli capable of increasing emotional activation by inhibiting approach behaviors. The consequence may be failure to engage in a threatening, but health-protective behavior (e.g., failure to take chest x-rays), or the facilitation of a health-promoting behavior (e.g., inhibition of cigarette smoking). In both cases, however, the effects of hot emotion are confined to the period during which emotion is activated (i.e., emotion must be present to produce inhibitory effects). These results and the self-regulatory model representing them, suggest that emotional distress has its greatest impact on the procedural component of the problem-solving process, and has little impact on the representation of the threat. Fear and its somatic

sequelae (e.g., feeling shaky or down) communicate to individuals experiencing it that he or she may lack the competence to manage a danger (Leventhal, 1970; Leventhal & Mosbach, 1983), yet these reductions in feelings of self-competence may last only as long as the fear is present (see also Rescorla & Solomon, 1967).

Although fear, such as the fear of surgical treatment, may inhibit autonomous, health promotive actions, such as seeking diagnosis for symptoms of breast cancer, the very same state of fear can activate external resources and thereby overcome barriers created by the breakdown of autonomous action. Active fear encourages affiliation (Schachter, 1959) and creates an impulse to communicate and seek help to cope with both the emotion and its source (Shaver, Schwartz, Kirson, & O'Conner, 1987). Seeking out others activates social support and the support network is likely to compensate for the breakdown in internal resources by creating external pressures and assistance for care seeking (Cameron et al., 1993). Failure to consider the role of supportive others in the presence of threat, and failure to consider whether the behavior at issue approaches or avoids the source of threat, are likely responsible for the substantial inconsistency noted in studies relating fear to seeking diagnosis and care for risks of cancer (Croyle & Lerman, 1999; Facione, 1993). On the other hand, when fear is combined with the need to present oneself as strong and unconcerned with danger, it may encourage a rigid level of avoidance that threatens personal well-being by delaying interpersonal contacts essential for threat control.

Hot Cognition: Affect Integrated With Illness Cognition. Associative processes can create a tight link between affective and cognitive processes, the two acting as a single, integral unit (Leventhal, 1984). When cancer or heart disease are described as "dreaded and feared diseases," people are recognizing that they are not only negatively evaluated and perceived as painful, and a lethal threat, but that the cognitive elements defining them are powerful stimuli for fear. Thus, cancer and cardiovascular disease represent *hot cognition* (i.e., the cognition defining them are tightly linked with fear and signs of either disease must be avoided to prevent being overwhelmed by fear). A recent study by Cameron and Leventhal (1995) provided evidence for differentiating "hot emotion" from hot cognition. Young adults who perceived themselves as highly vulnerable to heart disease showed no increase in intentions to engage in regular exercise to protect their cardiovascular system when they were exposed to either a highly threatening message about heart disease or an exercise task that induced somatic sensations of cardiac arousal. By contrast, a reassuring "wellness" message about heart disease had an immediate enhancing effect on exercise intentions. But whereas the threat messages and somatic experience of cardiovascular arousal failed to produce an immediate effect, participants in both of these groups as well as participants in the wellness groups reported increases in exercise rates over the long term in comparison to a control group unexposed to threat or wellness information. The temporary inhibition of intended action by

the threatening health information is consistent with inhibition by an active state of fear, but the improvement in exercise over the longer term (i.e., after the state of fear had declined) suggests that the cognitive representation of cardiovascular risk was imbued with motivating potential—that is, that the cognition of cause, (insufficient exercise), identity (what the disease will do functionally and experientially), time line (its effects are lasting), and consequences (it can kill) were imbued with motivational potential: These cognitions were “hot.”

Forgas (1995) proposed that emotions “infuse” cognitive processes and influence how individuals reason about and draw conclusions respecting the people around them. He reviewed data suggesting that the effects of emotions on cognition are pronounced when the cognitive, evaluative process is lengthy and drawn out rather than instantaneous. Such schema are especially likely to form either when dealing with prolonged or chronic diseases that allow for considerable rumination, providing ample opportunity to link disease imagery with affective processes. If the rumination includes active procedures for threat management, the resulting cognition will likely motivate effective, problem-focused coping. On the other hand, in situations in which exposure to a disease threat provokes very high levels of fear and procedures to control the fear or the threat are unavailable, the continuous stimulation of ruminative processes by unresolved fear will lead to the formation of well-structured cognitive-affective memories lacking problem-focused coping procedures. These conditions are similar to those for the formation of posttraumatic stress syndrome (van der Kolk, 1987). Disease schemata formed under such conditions become catastrophic as they integrate ultimate threats, loss of control, and powerful affective expectations: “Cancer can and will destroy me, there is nothing that I or anyone else can do about it, and I will suffer enormous pain and distress.” It may be necessary to disassemble such threat–fear–avoidance schemata to encourage individuals to take the steps needed for early detection of highly threatening diseases.

The need to distinguish the effects of learned, affective associations from the direct effects of emotional arousal is a familiar issue in domains such as learned helplessness (Maier & Jackson, 1979) and the treatment of fear-based phobias (Lang, Cuthbert, & Melamed, 1986). For example, when learned helplessness is involved, it is necessary to disconfirm old expectations that action in this context cannot reduce threat or avert failure, and to create new expectations that action can lead to protection or success. If a momentary state of fear or an automatic depletion of central neurotransmitter were responsible for the behavioral inhibition (Weiss, Glazer, Pohorecky, & Miller, 1975), then there would be no need for relearning because behavior would resume when fear dissipated and the neurotransmitter were replenished. Similarly, promoting adaptive behavior in response to prolonged health threats, for which individuals will have formed stable representations, requires attention both to the immediate impact of emotional arousal on disease representational attributes and to the reformulation of the cognitive and emotional associations established within the representational schemata.

A substantial number of studies have identified a variety of procedures for the regulation of emotional reactions during exposure to threatening circumstances (Carver, Scheier, & Weintraub, 1989; Lazarus & Folkman, 1984; Miller, 1996; Miller, Shoda, & Hurley, 1996). These efforts appear to have concentrated on the identification of coping traits or actions commonly used to cope with difficult life problems, and have generated a substantial amount of data suggesting that coping with feelings by means of tactics such as wishful thinking, avoidance, or mentally rehearsing painful or catastrophic outcomes are related to poorer adjustment (Lazarus & Folkman, 1984). The failure to distinguish the role of coping with respect to “affective states” versus “hot-cognition” may be the source of one of their more serious limitations (i.e., the failure to assess what actually transpires during problem solving episodes; E. A. Leventhal et al., 1993). Thus, both traitlike measures and problem-specific measures are ambiguous as to whether and when a particular response was actually performed during a threat episode, whether it was the only response performed, which responses were the most salient or most successful, and whether a response was performed to reduce a state of affective distress or to avoid thoughts or cues to affective distress. Failure to assess the ongoing sequence of procedures that unfold in the management of both the objective features of a health threat and the emotions provoked by that threat, ignores the contingencies among coping strategies and the possibility of a positive role for affectively focused coping. For example, effective management of a painful and potentially dangerous health threat that provokes intense and relatively prolonged active fear states might require periods of “time out” to allow one to recoup resources for problem management. When and how this “time out” is spent could be critical for adaptation. If it is spent in ruminative thought that amplifies emotional distress and forms hot cognition that encourages avoidance of problem solving, the time out will fail to contribute to a positive adaptation. On the other hand, if it is spent in a supportive social interchange or in distractive “rumination” designed to provide temporary surcease (e.g., engaging in a favorite hobby), which allows the individual to recover, creates a sense of control over self, and avoids the formation of cognition of uncontrollable and unapproachable dangers, then the individual can return to planning for problem management.

Suls and Fletcher (1985) postulated that this process of “dosing” is important for avoiding system breakdown and is consistent with the evidence just reviewed, suggesting that action to bring fear under control does not necessarily preclude effective problem management over the long term (Cameron & Leventhal, 1995; Leventhal & Watts, 1966). An assumption that underlies the “dosing” hypothesis is that emotions contain information about the status of information-processing and behavioral systems, that is, they can tell whether or not individuals have the energy, ability to concentrate, and skills needed to perform specific, self-protective procedures over protracted time frames, and that individuals can make conscious use of this information (Leventhal, 1970; Leventhal & Mosbach, 1983). As such, emotions serve as highly useful guides to coping efforts, as cues for an affective

rule (i.e., *If I am calm Then I can act, If I am anxious, Then I'd better wait before trying*). Coping measures that fail to assess the dynamics of emotional regulation and problem solving, or that simply construe all "emotion-focused" and "avoidance" coping efforts as maladaptive, are likely to miss important information about effective and ineffective adaptation.

Negative Emotions and Symptoms

An issue that has received a great deal of attention in the past decade is whether negative affect, as a stable trait and as an episodic state, will encourage the development of illness representations by focusing attention inward and increasing the awareness of symptoms in ways that bias somatic perceptions and lead to tendencies to overreport illness (Costa & McCrae, 1987; Watson & Pennebaker, 1989). This thesis is based on observations of a modest-sized relation between negative affect and symptom reports (most correlations are in the .25 to .35 range) that is consistently reported in cross-sectional data (Watson & Pennebaker, 1989). Experimental studies support several aspects of this formulation. Higher levels of symptom reporting are found in environments lacking external cues to attract attention (Pennebaker & Brittingham, 1982). Experimental induction of negative affect results in higher levels of symptom reporting in both healthy (Croyle & Uretsky, 1987) and ill participants (Salovey & Birnbaum, 1989). It is important to note, however, that it is arbitrary to state that it is the high- rather than the low-reporting group that is biased in symptom reporting. Indeed, the available data suggests that negative affect interacts with cognitive processes in three ways: It activates somatic vigilance and increases accurate symptom reporting; it activates illness representations encouraging attribution to illness of vague symptoms that are not specific indicators of illness; and it may increase susceptibility to pathogens and other symptom generating events. These conclusions are derived from longitudinal studies, the more recent of which provide some degree of control over somatic experience.

Observations over long time frames are inconsistent with the hypothesis that negative affectivity is associated with inaccurate, overreporting of symptoms. In their study of a large sample of middle-aged males, Spiro, Aldwin, Levenson, and Busse (1990) confirmed the typical cross sectional relation between neurotic anxiety and symptom reporting, but no relation between emotional traits and increases in reports of physical or psychological symptoms over a 20-year time frame. Using a far shorter time frame in a situation with substantial control over somatic events, Diefenbach, Leventhal, Leventhal, and Patrick-Miller (1996) compared changes in symptom reports by elderly participants in a design where one group completed their reports before inoculation and 1 and 4 days after inoculation with vaccines for flu and tetanus, and completed them again in identical fashion before and after placebo inoculations. A second group went through the very same procedures in reverse order (i.e., placebo first and active inoculant second). Analyses comparing subjects divided into high and low scores on measures of both trait and state anxiety and trait and state depression

showed baseline to postinoculation increases of local symptoms (sore arm, redness) after the active inoculations but not after the placebo inoculations. Reports of vague, flu-like symptoms declined after both active and placebo inoculation. The data showed the expected cross-sectional association of the negative affect measures with symptom reporting, but no differences between subjects scoring high on depression and/or anxiety (either trait or state) and those with low scores, with respect to increased reports of local symptoms or decreased reports of systemic, flu like symptoms. Thus, all subjects, regardless of their trait or state affects, were sensitive to increases in distinctive changes in somatic experience (redness and soreness of the arm) when these somatic changes are present, and all subjects gave less attention to somatic sensations that were vague and indifferent when they were expecting and searching for the distinctive symptoms and visible signs of vaccination.

A recent study of symptomatic side effects reported by women in a double-blind clinical trial of tamoxifen chemoprevention therapy provides strong evidence that negative affectivity is associated with greater symptom sensitivity and accurate symptom reports (Cameron et al., 1998). Postmenopausal women with breast cancer in remission were randomly assigned to take tamoxifen, a drug that induces hot flashes and other hormonally related side effects, or a placebo for a 2-year period. Assessments of symptom reports revealed that trait anxiety was associated with increases in reports of hormonally related symptoms during the first 3 months of the trial, but only among tamoxifen users and not among placebo users. Moreover, high anxiety was not associated with increases in reports of symptoms that were unrelated to tamoxifen use in either drug condition. Not only was high trait anxiety associated with greater sensitivity to symptoms, but low anxious placebo users exhibited tendencies to inaccurately underreport symptoms over the course of the trial in that their symptom reports decreased significantly over the first 6 months. Consequently, cross-sectional differences in symptom reports between high and low anxious groups may reflect a combination of greater sensitivity by high anxious individuals and inaccurate underreporting of symptoms by low anxious individuals.

These data are consistent with the hypothesis that negative affectivity is associated with an increased focus of attention to somatic activity, or a vigilance rule: *If it is an unexpected somatic change, then anticipate and test for illness danger*. This enhanced focus need not, however, lead to inaccurate symptom reports. Cameron et al. (1998) proposed that this increased vigilance is due to the activation of illness-related representations among high anxious individuals. The hypothesis is consistent with the data showing that high trait anxiety subjects given tamoxifen were more worried and ruminated more about breast cancer and exhibited a marked increase in breast self-examinations over the course of the trial, clear indications of the activation of a cancer representation. On the other hand, the vigilance generated by illness representations may bias symptom attributions even when it does not necessarily bias the quantity of symptoms reported. Wiebe and her associates (Wiebe, Alderfer, Palmer, Lindsay, & Jarrett,

1994) reported that their diabetic patients high in trait anxiety were more likely to attribute nondiabetes-related symptoms to changes in blood glucose.

Attribution and Direct Effects on Illness

The data generated in a clinical trial examining the development of colds in subjects exposed to respiratory virus produced evidence supporting the hypothesis that trait negative affect influenced symptom attribution, very likely by the activation of illness schemata, whereas state negative affect has a direct effect on illness severity (Cohen et al., 1995). These investigators found that, in comparison to subjects low in trait negative affect, subjects high on this measure reported a small but statistically reliable greater increase in reports of symptoms post viral exposure (.83 symptom). Trait negative affect was not related, however, to an "objective" postexposure measure of illness (weight of mucous discharge), which suggests that subjects high on trait negative affect reported more flu-like symptoms regardless of their level of illness. A measure of state negative affect (emotional mood at the start of the investigation) was related to the "objective" measure of illness (mucous discharge) which was related, in turn, to post-infection symptom levels. Concordant with others (Cameron et al., 1998; Wiebe et al., 1994), Cohen et al. (1995) suggested that subjects high in trait negative affect report more symptoms because they do not distinguish symptoms of flu from symptoms of emotional upset and/or irritability created by being sick. Second, they suggested that state negative mood affects symptom reporting because of its effect on disease (mucous discharge). Thus, the state measure may reflect the influence of current levels of life stress on susceptibility to illness and, therefore, to symptom reporting. This indirect path accounts, however, for only 9% of the postexposure increase in symptoms.

The studies reviewed so far suggest that trait negative affects have at best very small effects on symptom reporting when reporting is examined over time. Second, the effect seems to reflect two processes: Greater somatic attention and more accurate reporting of symptoms, and the activation of illness representations resulting in the attribution of vague (sensitive but nonspecific) symptoms to illness. This does not exhaust, however, the various paths by which negative affect can influence illness representations. Croyle and Uretsky's (1987) finding that induced negative emotion may alter the meaning of symptoms by increasing their judged severity may have more important implications for the role of affect in illness representations than that of merely increasing the number of symptoms reported. For example, Clark and Ehlers (1993) postulated that catastrophic interpretations of somatic symptoms represent the critical path for the development of panic disorders. Such interpretations heighten anxiety, intensify attention to the body and detection of somatic cues, and encourages the representations of these cues as signs of a physical catastrophe (e.g., "I'm having a heart attack" or "I'm about to faint"). These interpretations encourage the performance of self-protective procedures such as sitting and resting or leaning against the wall (Salkovskis, 1990, cited in

Clark & Ehlers, 1993), and these actions may provide the illusion of control over catastrophic outcomes and reinforce and maintain the inappropriate interpretation of the somatic event by disallowing disconfirming feedback (i.e., not having a heart attack and not fainting). There may be an *emotion-severity* rule at play: *If I am so upset, then it (the somatic sign) must be very serious and require immediate action.*

Clark and Ehlers (1993) made two additional and extremely important points. First, catastrophic interpretations are specific to somatic sensations: Individuals with panic disorder do not seem to apply negative or catastrophic interpretations to ambiguous events that are not somatic. Consistent with the bilevel processing feature of the model, the perceptual nature (visual and/or palpable) of such cues appears to lie at the base of their motivating power (Klohn & Rogers, 1991). Second, and consistent with findings in the tamoxifen symptoms study, individuals suffering from panic disorders are more accurate perceivers of their somatic reactions (judging heart rates) than other types of phobic or normal subjects. The accuracy finding suggests why it may be so difficult to find anxious individuals reporting more symptoms in response to known somatic changes, relative to the symptom reports of nonanxious persons. When anxious persons report more symptoms than their nonanxious peers, it may simply reflect that the nonanxious are less accurate and underreporting.

A final issue to consider here is the possibility that different negative emotions may have different effects on somatic health and differ, therefore, in their effects on symptom reporting. The data reported by Cohen et al. (1995) suggested that mood state can affect susceptibility to upper-respiratory infections and produce a small increase in symptoms. Data showing relations between high levels of depression and poorer responses on tests of immune function (Cohen & Williamson, 1991; Patrick-Miller, 1994) suggest a mechanism that may underlie the relationship of negative affect to increased symptom reporting for infectious illnesses. It is not clear, however, whether it is depression per se or the feeling of loss of control over daily events that is the critical factor in increasing susceptibility to infectious illness and symptom reporting (Cohen, Tyrell, & Smith, 1991). It also seems unlikely that a specific emotional process, such as depression, will have the same effect on all diseases and, therefore, on reports of all types of symptoms. Diseases differ greatly from one another in their meaning as well as in their biology, and one specific affect, such as angry hostility, may increase the risk of cardiac disease (e.g., Smith, 1992), cardiac symptom reporting, and swift responding to cardiac symptoms (see Matthews et al., 1983) and yet have little impact on susceptibility to, reporting of symptoms, or seeking treatment for infectious disease.

Life Stressors and Distress Can Facilitate or Deter Illness Decisions

Studies examining the relation of life stress, and presumably of negative affect, to the decision that a person is ill and in need of professional care show that life stress increases health

care utilization (Piliusik, Boylan, & Acredelo, 1987; Tessler, Mechanic, & Dimond, 1976). This finding is consistent with the attribution of symptoms to illness in the studies focused on negative affect and symptom reporting. Other studies, however, show no effect (Berkanovic et al., 1988; Sarason, Sarason, Potter, & Antoni, 1985). For example, in a carefully conducted study, Watson (1988) reported the usual modest association of negative affect to symptom reports for his college student subjects; the correlations held when computed across subjects and within subjects over time. There was, however, no association of negative affect with the use of health services. These findings, and others showing that negative affect is related to symptoms but not to medical care use or to objective disease indices, led Watson and Pennebaker (1989) to suggest that negative affect may be a confounding or nuisance factor in the study of the stress-illness relation.

The inconsistent relation between emotional stress and decisions to seek health care could reflect two sets of factors: inadequate conceptual analysis of the stress-decision process and methodological deficits contingent upon them. For example, Eckenrode and Gore (1981) found no effect of life stress on mothers' decisions to seek pediatric services for their symptomatic children when they used traditional cross-sectional methods of analysis that compared stressed to nonstressed mother-child pairs. An effect was visible, however, when the data were examined on a day-by-day basis, such that pediatric care seeking was more likely for symptomatic children the day following a stressful life event. The main conceptual deficit, however, is the unwarranted assumption that life stress will produce a simple main effect, such that high levels of stress increase decisions to seek medical care (Cohen & Williamson, 1991; Mechanic, 1979). The inadequacies of this model was made abundantly clear in the study by Cameron, Leventhal, and Leventhal (1995). Life stressors had quite different effects on care seeking depending on the nature of the individual's symptoms and the duration of the stressor. Symptoms that were clear and distinct signs of physical illness, such as a fever or a visible rash, led to care seeking regardless of whether a life stressor was present or absent. Care seeking increased for vague and ambiguous symptoms only when the stressor was of several weeks duration; when the stressor onset was recent, care seeking was minimal as the symptoms were attributed to stress rather than to illness. Emotional processes, in the form of rules (e.g., the stress-illness rule and the upset-serious rule) alter the meaning or representation of somatic events and the procedures generated by them.

Appetite, Impulse and Loss of Control

Positive affects have been ignored throughout this discussion, yet positive affects and appetitive states associated with them can have important effects on health and risk behaviors. This omission seems reasonable if there is agreement with the proposal that in comparison to positive affects, negative affects such as fear are far more potent determinants of behavior (Taylor, 1991). Taylor's (1991) proposal seems reasonable if the comparison is of negative

states of fear and/or anger in comparison to the everyday positive states accompanying good food, joys of friendship, humor, and so forth. The steep gradient and rapid rise of negative affects, as well as their peak levels, does indeed create the experience of intensity. The proposal seems less reasonable, however, when the passions and addictive states involved with sexuality and substance use are considered. These affectively charged states regularly override cognitive controls, although it is unclear whether they are positive states or sequences of negative and positive affect (Solomon, 1980). The point at issue is that "hot affect," both negative and positive, can override "rational" cognitive controls and generate ample justification for doing so.

THE SOCIAL-INSTITUTIONAL CONTEXT OF ILLNESS EPISODES

Illness *episodes* are nested within a larger personal, social, and cultural context. Thus, the individual's life experiences, institutional affiliations and roles, and cultural context can influence the representation of symptoms (e.g., perceived identity, causes, time-lines, consequences and control), the affective reactions they evoke, the procedures used to manage the symptoms and affects, and the criteria for appraising outcomes. Thus, the effects of contextual factors on behavioral outcomes can be mediated by any one or any number of these components (see Fig. 2.3).

Interpersonal and Personal History

No life is exempt from illness, and the individual's illness history is a major determinant of the meanings, procedures, and appraisals evoked during a specific illness episode. Seasonal upper-respiratory illnesses, occasional or recurrent headaches, and gastrointestinal upsets generate a set of "acute" illness prototypes that form the core of people's illness knowledge. These prototypes (e.g., the symptoms and labels, time lines, mild consequences, expectation for control, treatment procedures and associated affective distress) generate the most immediate and compelling interpretations and management strategies for the majority of people's illness episodes. The acute prototype is also consistent with people's need to sustain optimistic expectations (Taylor, 1983, 1991). For example, 40% of the women entering chemotherapy treatment for metastatic breast cancer believed their disease was equivalent to an acute, curable illness (Leventhal et al., 1986). The elderly experience an array of chronic musculoskeletal sensations, muscle aches and injuries, stiff and swollen joints, and chronic gastrointestinal problems, which add new prototypes and generate new rules (age-illness rule) for self-appraisal.

Repetitive, somatic experience is only one of the factors involved in prototype formation; social factors are another (Suls, Martin, & Leventhal, 1997). The social context gives meaning to undefined somatic experiences by suggesting labels, causes, time lines, procedures for self-management, and rules for treatment evaluation. For example, a parent's labeling, treatment procedures, and emotional reactions dur-

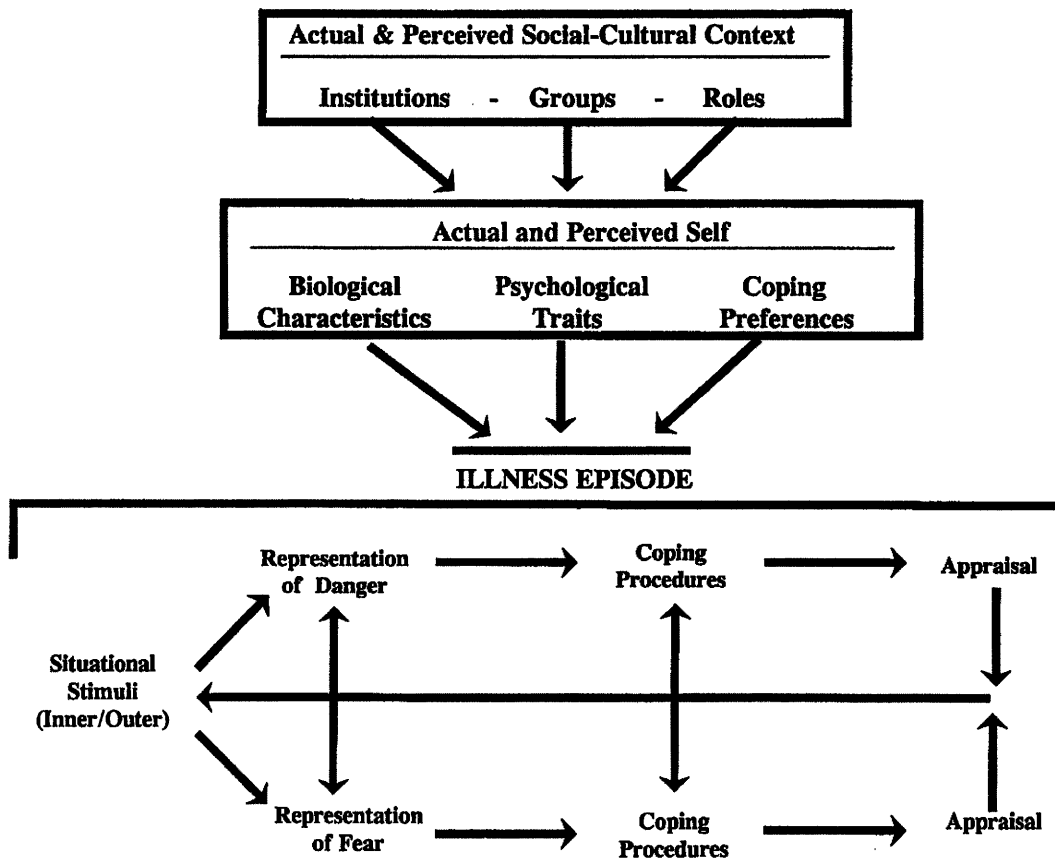

FIG. 2.3. Parallel response model set in context. The effect of contextual factors on response outcomes can be mediated by factors in any of the major components activated at the cognitive (e.g., time line, control) or affective (e.g., affect identity, procedures for control) level during an illness or health promotion episode.

ing a child's illness episodes can be more salient and more central a set of features of a child's illness prototypes than the somatic experiences initiating these episodes. The attentive, anxious parent questioning children about their symptoms and administering family remedies is (often inadvertently) shaping the children's perception of the importance of symptoms, the threat posed by them, and the possibility for their control. When a prototype or schema is activated by future symptoms, it will bring to life the meanings, emotions, coping procedures, and social expectations embedded in it (Mechanic, 1979). Little wonder, then, that "mature" and highly educated individuals (including medical specialists) feel helpless, frightened, and in need of "mothering" when severely ill (Mandel & Spiro, 1987).

The social factors shaping illness schemata extend well beyond the immediate family. Observation of sickness in others, media reports of disease and death, reports of medical advances, and discussions of the causes and consequences of illness all serve to add new labels, images, and affects to the schemata generated by personal somatic experiences. These varied social influences act throughout the life span and can play a critical role in shaping adaptation to somatic change. Imagine, for example, the experience of typical patients who

are told by their doctor that they "have" hypertension. The label, hypertension, suggests that high blood pressure is caused by tension and states of hyperactivity (Blumhagen, 1980). The appropriate treatment requires medication and follow-up visits to monitor the effects of the medication on blood pressure. At each follow-up visit, the patient is greeted by the usual, "Hello! How are you feeling?" and a review of systems, that is, a step-by-step series of questions respecting symptoms in different areas of the body, to identify medication side effects and/or comorbid conditions (e.g., "Have you had any symptoms or problems with your eyes? With your ears? Any chest pains? Any problems breathing?"). Although the opening greeting, "How are you feeling?" is unlikely to be sufficient to create the impression that hypertension is symptomatic, it in combination with the review of systems, is more than enough to imply that individuals should feel something if they "have" hypertension. As few physicians are likely to explain why they are conducting the review of systems, nothing is said to contradict this inference. In short, it is eminently reasonable for patients to assume that hypertension is symptomatic, and their suspicions are readily confirmed if their blood pressure is not fully controlled and they check it whenever they feel any symptoms (e.g., a warm face, headache, and/or

tension). As patients' are unlikely to check their blood pressure when they are asymptomatic, they will not generate evidence to disconfirm the association. In short, the medical interaction can create the conditions for biased self-assessments.

Meyer, Leventhal, and Gutmann (1985) supported the hypothesis that the doctor-patient exchange can influence patients to represent hypertension as a symptomatic condition. In addition to the data mentioned earlier (i.e., that 90% of the patients in a continuous treatment group believed they could tell when their blood pressure was elevated), a separate sample of patients showed a substantial increase in the belief that they could use symptoms to monitor their blood pressure from the time of their initial treatment until 6 months later after several visits: The proportion changed from 71% at the initial treatment to over 90% at the later point in time. Tape recordings of the patients' interactions with the practitioners were in accord with the interpretation that the medical encounter caused the change in beliefs as the bulk of the practitioners' questions were focused on symptoms and strongly implied that symptoms were possible indicators of blood pressure.

The Consequences of Unshared Representations

Patients' beliefs that they can use symptoms to monitor their hypertension is clearly at variance both with the practitioners' models of this disease and with data on the accuracy of people's ability to estimate their basal blood pressure levels. With regard to the accuracy issue, it is noteworthy that the average within-subject correlations of blood pressure with symptom reports of insurance company employees was only .14 (Baumann & Leventhal, 1985). The same average within-subject correlation was higher (.3) in a study that included an episode of vigorous activity (Pennebaker & Watson, 1988), although excluding this data point reduced the correlation to .14 (Pennebaker & Watson, 1988). Vigorous activity enhances accuracy as it introduces phasic cues, both external and internal, (increased rate of breathing, fatigue, etc.), related to pressure change, stable (i.e., tonic blood pressure does not).

The combination of the belief that individuals can monitor blood pressure has serious implications, however, within the context of the medical encounter. Patients who believe their blood pressure is symptomatic are in conflict with their practitioner's view that symptoms cannot be used to monitor base level blood pressure. Should they believe the explicit, medical model that hypertension is an asymptomatic disorder, or should they believe their implicit model that they can feel whether they are or are not "sick"? The Meyer et al. (1985) data showed that newly treated patients who believed they could monitor their blood pressure were more likely to drop out of treatment 6 months later than patients who concurred with the medical model. And fully 61% of the newly treated patients quit treatment 6 months later if during the first visit they told their physician they believed they could monitor their pressure. Only 24% had quit treatment among those who either did not believe they could monitor their pressure or did

not tell the doctor about their belief. Open communication appears to have established the groundwork for conflict and quitting treatment.

Problems arising from sharing or not sharing disease models are not restricted to hypertension. Practitioner-patient disagreements have been documented among diabetics and doctors (Hampson, 1997), mothers and pediatricians (Becker et al., 1977), and the severely mentally ill and their psychiatrists (Jamison, 1995). Differences in the underlying schema of a disease held by patients and medical practitioners encourage different procedures for validating experience, that is, different if-then rules confirm the validity of contrasting models and the result in many instances is nonadherence to needed treatment. Greater discrepancies between patient and medical models have also been related to poorer function in daily living (e.g., failure to return to work; Lacroix et al., 1991). Under carefully controlled conditions, patients can be taught to use symptom monitoring to regulate use of medication if there are valid associations between symptoms and fluctuations in the underlying biological condition. Kovatchev, Cox, Gonder-Frederick, and Schlundt (1998) provided an exceptional example of this approach with diabetic patients.

Social Observation-Comparison

As the meaning of symptom and effectiveness of treatments are often ambiguous, it was natural for investigators to make use of social comparison theory (Festinger, 1954; Schachter, 1959; Schachter & Singer, 1962; Suls & Miller, 1977; Suls & Wills, 1991) in their efforts to understand behavior during illness episodes (Buunk & Gibbons, 1997). Motivation for social comparison is powerful when somatic experience is ambiguous, as seen in Schachter's (1959) studies of affiliation under conditions of threat. Motivation to affiliate was so strong that Schachter's participants opted to be with others in the same situation, rather than to be alone or with others in a different situation. This effect appeared even though subjects were prohibited from talking. As neither verbal or nonverbal communication are prohibited during most illness episodes or medical treatments, the opportunity and utility of social comparison during illness is far greater than that allowed Schachter's subjects. Social comparison, or better, social influence, can vary from seeking advice or information from another about a symptom or treatment, through responses to people's expressions of anxiety in response to illness, to receiving comments about their appearance (Zola, 1973). Comparison with others in similar or dissimilar circumstances to share information about symptoms and medications, is commonplace among the elderly (e.g., Brody & Kleban, 1983).

To understand the function of social information during illness episodes, it is essential to identify the goal(s) satisfied by the comparison process. For example, Kulik and Mahler (1987) found that preoperative coronary bypass patients who were in the same room with postoperative patients were less anxious prior to their operations and recovered faster after the operation compared to patients who were assigned roommates who were also awaiting surgery. Interestingly, the outcome was the same whether the roommate was undergoing a

similar or different type of operation. Thus, unlike the laboratory setting where participants preferred and appeared to benefit from affiliation with similar others (Schachter, 1959), the data suggest that affiliation among individuals anticipating the threat of surgery sustains or even reinforces feelings of threat and fails to provide examples of successful, postoperative recovery. Kulik and Mahler (1997) suggested that social observation fulfills several important functions, such as providing reassurance and reducing fear of death and disfigurement by seeing that someone has “made it through,” observing someone having lower postoperative levels of anxiety and pain than expected, and receiving information about the experiences of surgery and specific tips for coping. Thus, a recovering roommate may enable patients to model a view of themselves from the “outside,” to envision themselves looking better than expected and improving from day to day, and not merely from the “inside” as fearful and pained. The meanings derived from these observations may increase feelings of control and prepare patients to direct their coping efforts more effectively. The apparently effortless nature of social comparison in the case examined by Kulik and Mahler contrasts with social comparisons involving substantial effort, the latter is typical of situations where practice is necessary for the acquisition of behavioral skills (Tennen & Affleck, 1997). Tennen and Affleck (1997) believed the presence of effort is a necessary criteria for the presence of social comparison, and that effort is likely essential to acquire the skills needed to manage chronic pain. Whether effort is or is not necessary, however, depends on the objective of social comparison. The identification of objectives within the self-regulation framework (e.g., Is social comparison producing information to clarify causes, consequences, and time lines, to define criteria for the appraisal of coping procedures, or to add procedures to the coping repertory?) will clarify when effort is and is not a necessary component of the social comparison process.

Culture and Language

Personal illness history and ongoing, interpersonal exchanges with illness take place within an extended cultural matrix, and representations, procedures for disease regulation, and appraisal criteria can be expected to reflect this context. Indeed, cultural beliefs and language impact virtually every attribute of the self-regulatory system. For example, the label “hypertension” suggests that physical and mental hyperactivity and tension are both signs and causes of elevated blood pressure (Blumhagen, 1980). Cultural beliefs about such causes of disease can discourage adherence to medically oriented treatment (Heurtin-Roberts & Reisin, 1992) and encourage adherence to culturally accepted treatment from traditional healers (Weller, 1984). The effects of culture-wide beliefs, both secular and religious, are both direct and indirect, and the indirect effects may be more common and less readily recognized. For example, religious beliefs regarding possession and retribution can create a background in which possession and wrongdoing can be seen as causes of disease,

and atonement and good works seen as appropriate means of cure. Similarly, secular beliefs in the power of mechanical causation and scientific cure can lead to the minimization of the role of lifestyle in disease causation and to excessive reliance on medical “magic bullets.”

The relation between culture and disease representations is, however, reciprocal. Both the biology of disease and beliefs about disease shape the medical care system, and the system in turn shapes and maintains these beliefs. For example, the representation of infectious illness as communicable, symptomatic, time limited and curable, created a care system oriented toward brief encounters with medical practitioners in a “fee for service” framework (Saward, 1977). Once in place, this service framework has encouraged and sustained the representation and treatment of both infectious and chronic illness within a common, acute disease model. It took a crisis in which chronic, life-threatening illnesses in an aging population overwhelmed the health care system and forced recognition that the acute illness model created significant problems for treatment (Knowles, 1977; White, 1973). The crisis made clear the need to revise the cultural model.

Transitions Over Illness Episodes and Over the Life Span

The one constancy in biological and behavioral systems is change. Illness episodes, both acute and chronic, are in constant flux. Symptoms vary in type, intensity, and duration, thoughts about cause and consequences dance across the stage of consciousness, and a variety of procedures are undertaken—some of which meet and others of which fail to meet hoped for outcomes. Change is the motif during any given episode and across the life span. Not only do different illnesses assail people as they age, the very same illnesses present with different symptoms in the old and young (Goodstein, 1985). A viable model of the behavioral adaptation to illness must capture this variation.

From Concrete to Abstract Representations: The Adolescent Transition. Aging adds substantially to our repertory of knowledge and skills in the health domain. This knowledge can be explicit (i.e., part of a verbalizable set of propositions and facts) and implicit (i.e., part of a set of concepts and skills that shape perception and performance, even if they cannot be accessed in consciousness; Leventhal, 1982). Disease representations and procedures for disease management fall in both classes, and with age, greater differentiation can be anticipated among diseases, and between illness and health, and movement from use of concrete, episode specific representations to the inclusion of more abstract, prototypic features (Leventhal & Crouch, 1997). Millstein and Irwin (1987) illustrated how representations may change during the adolescent transition and provides strong support for the symptomatic nature of illness representations. When asked how they would define illness, nearly all (94%) participants, both the youngest (age 11–12) and oldest (age 15–16), mentioned one or more physical symptoms. A similar effect occurred when

asked how they would define health: The absence of symptoms was mentioned by 54% of participants and a substantial number also mentioned disease prevention behaviors. The difference between the representation of illness and the representation of health was more clear among the older children. Of the younger children, 38% mentioned the absence of symptoms for health as compared to 18% of the older adolescents; the older group defined health in terms of functional ability and preventive behaviors. In short, the older adolescents differentiated the concepts of illness and health to a greater degree than the younger adolescents, and the differentiation was reflected in increased reporting of preventive action.

From Delay to Swift Care Seeking: A Later Life Transition. The differences between chronic and acute disease can generate major psychological discontinuities for an ill person. As has been suggested throughout this chapter, lifelong experience with the common cold builds prototypes of illness as short-term, self-limited affairs lacking serious consequences for the self. Expectations regarding source and type of treatment (e.g., aspirins that are self-prescribed or antibiotics given by a practitioner) and anticipated outcomes of these treatments are part of the prototype. As prototypes can operate automatically (i.e., without thought) they can facilitate adaptation to subsequent illness episodes that fit the prototype, and they can disrupt adaptation to episodes inconsistent with the prototype. The time frame and causes of chronic illness, their life threatening consequences and need for lifelong procedures for control, are inconsistent with both the explicit and implicit features of our prototypes of acute, infectious illness. The difficulty in resolving these inconsistencies was brought out by the data on patients with hypertension (only 28% of the patients new to treatment thought their disease was chronic, whereas 40% thought the problem was acute; Meyer et al., 1985), and the data on patients with metastatic breast cancer (29% believed their condition was acute at the start of chemotherapy treatment, which dropped to 11% 6 months later; Leventhal et al., 1986). Hypertensive patients holding an acute model were much more likely to drop out of treatment than those holding a chronic view. Thoughts of quitting paralleled the hypertensive data for cancer patients, but the life threat of the disease insured behavioral adherence.

A basic change appears to take place in people's views of their somatic and psychological system as they move into retirement age. This shift appears to be responsible for a change in the strategies used for avoiding and managing health threats and to reflect recognition that chronic illnesses are increasingly likely with advanced age and that physical and psychological resources are in decline. Specifically, older persons express greater interest and involvement in health promotive action (e.g., adherence to balanced diet, use of nutritional supplements, and are more adherent to treatment regimens; Prohaska et al., 1987). Older persons also report feeling substantially younger than their years and are optimistic about their ability to avoid deadly chronic illness. The pattern suggests that older persons are averse to taking health risks and eager to do what is necessary to maintain their resources (Baltes & Baltes, 1990; Carstensen, 1992; Leventhal & Crouch, 1997).

The risk aversion of the elderly is seen most clearly when we compare speed of care seeking for everyday symptoms by study participants who are over age 65 to participants who are middle aged (i.e., age 45–55). Estimates of the time elapsing from first noticing a symptom until calling for care show that both groups are quicker to seek care for symptoms they regard as serious when first noticed, and both are slower to seek care for those they regard as mild, although the elderly group delays less overall (Leventhal, Leventhal, Schaefer, & Easterling, 1993). Risk aversion is most visible when the time from first noticing to seeking care into two stages, an appraisal stage, or the duration from first noticing a symptom until deciding one is sick, and an illness stage, the duration from deciding one is sick until calling for care (E. A. Leventhal et al., 1993; Leventhal, Easterling, Leventhal, & Cameron, 1995). Compared to the middle aged, the elderly spend less time in appraisal, indicating that they are less willing to take chances with an event of uncertain implication. The elderly and the middle aged also differ once they decide they are ill. In this instance, the difference is moderated by the evaluation of symptom severity: For symptoms evaluated as very severe at onset, both groups spend little time before calling for expert advice, and for symptoms that are mild both groups are equally slow. But for symptoms that are judged possibly severe, the middle aged delay virtually six times longer than do the elderly; in fact, the middle aged actually take longer to call for an evaluation of these possibly serious symptoms than they do for their mild symptoms. Additional data suggest that lengthy illness delays by middle-aged respondents reflect avoidance, or fear of finding out they may have a life threatening illness (E. A. Leventhal et al., 1993). In summary, whereas these "stages" should not be thought of as sharply bounded periods, they do provide insight into the process underlying age difference in speed of response and support the hypothesis that older persons do adopt a help seeking strategy designed to avoid risk and conserve limited, physical resources.

Ageing-related increases in physical frailty and declines in psychological function are likely to create a sense of fragility and vulnerability of the physical and psychological self and to set the stage for the formation of chronic disease prototypes (i.e., schemata in which diseases have extended time lines, stable symptoms, reduced possibility of cure and pose a threat to life and function). The underlying sense of vulnerability and its associated, chronic disease schemata should generate clearer images of the way chronic diseases can impact the self, giving the elderly a concrete view of the way disease can affect physical and cognitive function. These changes can lead to higher order, risk-averse, strategies, (e.g., Why take chances? Go to the doctor; Leventhal & Crouch, 1997), and to images of loss that are experienced as a diminished self (i.e., a self-deprived of work and social roles), or in terms of the disease taking over the self (Nerenz & Leventhal, 1983), and the individual living the life of a cancer or cardiac patient. Diseases that are seen to encompass and usurp the self will be imaged as intruders that create loss of hope and depression (Clemmey & Nicassio, 1997), leading to multiple negative consequences including poor adherence to treatment (Carney, Freedland, Eisen, Rich, & Jaffe, 1995). As such losses are highly aversive (Kahnemann &

Tversky, 1984), they likely encourage health promotive behavior among the elderly.

REPRESENTATIONAL MEANINGS DETERMINE HEALTH OUTCOMES

Implicit in the commonsense model of self-regulation is the assumption that illness representations, by directing coping procedures and appraisals, will be critically responsible for health-related outcomes that are at least partially influenced by behavior. Research by Weinman, Petrie and their associates (Petrie, Moss-Morris, & Weinman, 1995; Petrie, Weinman, Sharpe, & Buckley, 1996) demonstrated the potential impact of representations on important illness outcomes. For example, a recent study of patients diagnosed with Chronic Fatigue Syndrome (CFS) revealed that perceptions of illness consequences significantly predicted disability status. Patients who believed that "pushing themselves" beyond their present physical stamina would lead to catastrophic consequences (e.g., "I'd probably have a stroke and die") were more disabled in terms of work activities, household responsibilities, and recreational activities in relation to patients who believed that overexertion would lead to noncatastrophic consequences (Petrie et al., 1995). These group differences in disability did not appear to be due to differences in illness severity or psychological adjustment, because the two groups were virtually identical in terms of the time since illness onset, experiences of CFS symptoms and non-CFS symptoms, number of medical visits for CFS in the recent past, and mental health scores.

Further evidence that representational beliefs influence health outcomes is provided by a study revealing that illness perceptions reported by patients hospitalized for their first myocardial infarction predicted behavioral aspects of recovery during the next 6 months, even after controlling for illness severity and psychological adjustment (Petrie et al., 1996). Beliefs that heart disease is controllable or curable were found to be associated with a greater likelihood of regularly attending a rehabilitation course, whereas beliefs that heart disease is of relatively short duration were associated with a shorter delay in returning to work. Moreover, beliefs that the disease posed serious consequences were associated with a longer time until resuming work, household, recreational, and social activities. Taken together, these studies highlight the impact of representational beliefs on critical aspects of functioning and recovery from serious illness and suggest the potential efficacy of identifying and changing maladaptive beliefs at an early stage of illness in order to facilitate adaptation and recovery.

PROMOTING HEALTHY ACTION: A COMPARISON WITH OTHER BEHAVIORAL APPROACHES

Three Traditional Approaches

Most studies of the determinants of health behavior have been guided by the health belief model (Janz & Becker, 1984;

Rosenstock, 1966), the "theory" of reasoned action (Fishbein & Ajzen, 1974) or its more recent embodiment as the "theory" of planned behavior (Ajzen, 1988), and social learning theory (Bandura, 1977). These models are in accord with the self-regulation position here presented in that all three postulate that health and illness behaviors are the product of: *motivational factors*, or cognitive-perceptual factors such as attitudes toward a health threat, perceived evaluation of the action by others in the social context ("social norms"), vulnerability perceptions, or perceptions regarding the magnitude of a health threat; and *action components*, such as an intention to act (Ajzen, 1988) or perceptions of self-efficacy, defined as the perceived ability to manage the action (Bandura, 1977; Rogers, 1983). Furthermore, the motivational and action components are regarded as integrally linked, such that intentions to perform a health promotive action (e.g., quitting smoking, reducing dietary fat, or practicing safe sex) are construed as products of the attitudes and perceptions regarding the action. The models also assume that self-efficacy is a cognitive-perceptual factor that taps an underlying willingness or motivation to engage in the action (Ajzen, 1988; Bandura, 1977; Rogers, 1983). However, many of the studies assessing self-efficacy and behavioral intentions fail to distinguish (conceptually and empirically) two uses of these constructs (i.e., as predictors of behavioral outcomes and as additional sources of motivation for action).

Differences With Traditional Theories

The self-regulation model provides a more detailed view of both the cognitive-perceptual factors affecting motivation and the connection between motivation and action in comparison to prior models. For example, whereas the other models emphasize attitudes or vulnerability perceptions as sources of motivation, the present model points to two parallel factors, emotional states and the representation of the threat. Second, the current model specifies specific components of the representation as determinants of action. Because the commonsense model identifies and assesses the representational features of threat (symptoms, labels, causes, control, timeline) from the point of view of the respondent and does not force the respondent to integrate these into a probability statement to satisfy the needs of a formal decision model, it provides a clearer set of guidelines for interventions designed to engage and modify the actor's perceptions and thoughts about a health threat. In short, the model provides a more detailed view of the actor's immediate goal representation, the cues that evoke action, and the rationale for selecting particular acts over others. The attitudes defined and assessed by the other theoretical approaches typically are not stored in memory structures; instead, individuals must access their representation of the relevant health threat in order to formulate the required attitudes that will enable them to respond to the study questions (e.g., "I am in favor of getting a mammogram").

Second, the self-regulation model contrasts with the other theories in that it differentiates between the abstract and concrete emotional features of illness representations, and the

role of abstract and concrete factors in the generation of emotional reactions. By differentiating abstract and concrete levels of processing, the current version of self-regulation theory allows for conflict among goals and procedures; that is, the abstract and concrete facets of representations may differ in their criteria for response selection and outcome success. The current model argues that the concrete or perceptual level of representations is the basis for the formulation of abstractions and that level is often the most powerful prod to action (Palatano & Seifert, 1997). The multilevel feature of the model is critical for the analysis and understanding of the influence of emotion on illness-related perceptions, appraisals, and behaviors.

Third, the self-regulation model differs from the traditional theories by giving heavy emphasis to process; that is, it focuses on the continual interactions among the variables active during behavioral episodes to prevent and or control illness and to the updating and transitions that occur over time. The model also deals with changes in the representation of health threats from that of an acute to that of a chronic threat, and the need to revise procedures, outcome expectations, and outcome appraisals as a function of changes in the illness representation. The integrality hypothesis and the "if-then" rules expressing the relation of representation and coping merit special attention because they provide a vehicle for understanding and predicting the conditions for an individual's selection and appraisal of specific coping procedures. The contrast between the self-regulation perspective and the health belief and the reasoned (planned) action models is sharpest in this area, as neither of the latter provide a detailed view of process. Health belief variables, such as vulnerability and severity beliefs and the perceived costs and benefits of action, are beliefs at a moment. Neither these concepts nor those of intention, perceived norms, or attitudes suggest ways of engaging and changing individual cognition.

Social learning theory and similar cognitive-behavioral models (Rachman, 1997; Teasdale, 1997), share a focus on process with the self-regulation model. There are potentially important differences, however. First, the cognitive behavioral models have not presented a substantively detailed picture of illness representations. Second, cognitive-behavioral models have not yet focused on the *integral* nature of the relation of coping procedures to representations and the complexity of the representation of procedures (i.e., that procedures have labels and concrete representations, time lines, requirements for their performance or control—self and expert efficacy), and causal paths for their desired and undesired consequences. It is hard to imagine efficacy expectations for any procedure in the absence of a time line. Everyone wants to know, "How long will it take" to cure symptoms or block further progression. They also want to know "How much" or "How often" the procedure can be performed to insure efficacy without risk. If the objective is to insure adherence to treatment on the part of patients entering treatment for diseases such as hypertension or diabetes, or to reduce the distress of patients in chemotherapy treatment for cancer, or to encourage adherence to

rehabilitation subsequent to coronary bypass surgery, the threat as perceived or misperceived by the patient must be addressed, these misperceptions must be corrected, and the problem representation must be linked to unbiased procedures for self-management. Thus, although many of the details of cognitive-behavioral therapy and the transactional systems approach developed by Lazarus (1966; Lazarus & Folkman, 1984) are similar to the current self-regulation model, their models lack the level of detail needed both for prediction and educational interventions. Finally, whereas all of the models identify social information as a critical determinant of action, only the self-regulation model asks whether social influence acts upon one or more features of the representation, plans, expectancies, skills for specific coping tactics, or the appraisal of coping outcomes. The self-regulation model also illustrates the effects of social influence on emotional processes (i.e., on both the type of affect experienced and the direction it provides to motivation).

Three factors have been responsible for the differences between the self-regulation model and cognitive-behavioral theories as they are applied to health problems. First, social learning and cognitive-behavioral theory developed within the framework of learning theory, which emphasized the acquisition of behaviors that were specified a priori by the investigator. Second, behavioral investigators accepted the behavioral goals specified by medical and public health authorities (e.g., stopping smoking, using safety belts, reducing dietary fat). Because the learning theory approach meshed with the acceptance of public health recommendations for the prevention and control of disease, investigators failed to examine the way their participants viewed these various health problems and health behaviors. By overlooking the ethology of health behavior, investigators have failed to recognize the large set of behaviors perceived as relevant for controlling health threats, the commonsense and cultural justifications for choosing one or another action for controlling risk, and the multiple goals creating motivation for action (Carver & Scheier, 1998). Third, unlike their academic counterparts, health researchers are under pressure to produce results that are of clinically significant magnitude. Behavioral intentions and self-efficacy expectations meet this demand because they are quick and easy to assess, they are good predictors of behavior, and they are likely to produce publishable findings.

The self-regulation model was developed from a social psychological framework that is attentive to the phenomenal world of the actor (Lewin, 1935), and was influenced by a range of themes in cognitive psychology (e.g., Anderson, 1983, 1993; Bruner, Goodnow, & Austin, 1956; Garner, 1962; Kahneman & Tversky, 1982; Nisbett & Ross, 1980). The model was also influenced at each step of its development by clinical practice. Thus, our studies have always reflected the needs of the clinician to understand the patient's perspective and to engage and involve the patient in self-management in seeking and using medical treatment (Johnson, 1975; Leventhal et al., 1991). Our self-regulation model has defined its concepts to represent the frame within which both patient and clinician operate.

Illness Cognition, Self-Regulation, and Practice

An important next step for the self-regulation model is to demonstrate its utility for the development and empirical testing of educational and therapeutic interventions. These interventions should be based on the concepts defining illness representations and should incorporate ideas as to how representations shape coping procedures. The presentations should make use of concrete (i.e., perceptual) as well as abstract material in order to fully engage participants' underlying schemata of illness and procedural strategies and tactics. The material must be skillfully designed to appeal to these cognitive structures and to meld them with the ecological and biological realities of potential or actual health threats. The participant in self-management has to learn how to determine whether specific, somatic symptoms and declines in feelings of vigor or pleasure define the presence of illness, and they must learn when to seek professional assistance in clarifying their perceived cause and meaning. Kovatchev, Cox, Gonder-Frederick and Schlundt (1998) offered a path to interventions in their analysis of the transitions involved in diabetic's use of symptoms to achieve control over blood sugar levels. When in treatment, patients must learn how to share information and develop realistic expectations about the consequences of disease and specific treatments, and they must learn how to be sensitive to the meaning of "side effects" and the time lines for effective outcomes. Professional or self-care procedures for the management of disease threats may change subjective experience and lead to increasing differentiation of the representation of a disease, (as with the separation of the symptoms from the underlying disease by patients with rheumatoid arthritis), and the differentiation of the positive and negative effects of treatment. A critical question is whether the model can be used to help patients shape these changes to enhance their ability to minimize the destructive impact of disease on their physical, emotional, and social well being; that is, can people be helped to live with chronic disease rather than be overwhelmed by it? If the self-regulation model adds to our understanding of the processes involved in avoiding and adapting to health threats and assists us in facilitating effective adaptations, it will vindicate the effort and time spent in its development.

Conceptualization and Operationalization of Perceived Control

Kenneth A. Wallston
Vanderbilt University

Personal control is being increasingly recognized as a central concept in the understanding of the relationships between stressful experience, behaviours and health. Experimental investigations indicate that control over aversive stimulation has profound effects on autonomic, endocrine and immunological responses, and may influence the pathological processes implicated in the development of cardiovascular disease, tumour rejection and proliferation, and the acquisition of gastrointestinal lesions. Clinically, control and lack of control have been identified as relevant to the experience of pain, anxiety and depression. In the field of psychosocial epidemiology, interesting observations are emerging that relate health to control over job parameters and other aspects of people's lives. (Steptoe & Appels, 1989, p. ix)

The construct of personal (or perceived) control plays an important, central role in health psychology. As exemplified by the previous quotation, it is relevant to stress-related situations and contributes to health-related behavior in individuals who are not experiencing stress. What is less clear is the way the construct of perceived control should be conceptualized and operationalized in health psychology research. This chapter first defines the construct conceptually. After pointing out a number of issues in the study of perceived control, the various ways in which health psychologists have operationalized the construct in their research are reviewed. The final section covers moderators of perceived control, thus illustrating the complex nature of the mechanisms by which perceived control operates to influence health behavior and health status.

CONCEPTUAL DEFINITIONS OF PERCEIVED CONTROL

Thompson (1981) defined personal control as "the belief that one has at one's disposal a response that can influence the

aversiveness of an event" (p. 89). Perceived control (used synonymously in this chapter with *personal* control) has been defined as "the belief that one can determine one's own internal states and behavior, influence one's environment, and/or bring about desired outcomes" (K. A. Wallston, B. S. Wallston, S. Smith, & Dobbins, 1987, p. 5). "Most authors ... view control as a belief or cognition, reflecting the extent to which people think they can influence the situation, either by altering it, by changing its meaning or by regulating their own behavioral or emotional reactions" (Ormel & Sanderman, 1992, p. 196).

The fact that perceived control is a *belief* is critical. The perception may, or may not, be based on reality (Averill, 1973). When perceived control is based on reality, it is referred to as veridical or actual control; when it is patently not based on reality, it is sometimes referred to as illusory control (see Langer, 1975; Taylor, 1989). In most instances, the truth lies somewhere in between. Veridicality is not necessary or sufficient to bring about the perception of control, although the perception of control, however illusory, may have a profound effect on the individual.

Primary Versus Secondary Control

There are at least two separate ways by which a perception or feeling of control can be accomplished (Rothbaum, Weisz, & Snyder, 1982). In primary control, individuals enhance their rewards or achieve their objectives by influencing existing realities (e.g., other people, circumstances, symptoms, or behavior problems). In secondary control, individuals enhance their outcomes by accommodating to existing realities and maximizing satisfaction or goodness of fit with things as they are.

Targets of Control

Control is almost always directed at one or more *targets*. These targets include internal states, behavior, the environment (including behaviors of other people), and outcomes. The likelihood of multiple targets suggests that any conceptualization (and operationalization) of perceived control must be multifaceted. For example, individuals may perceive control over their own behaviors but not over others' behavior. They also may believe they have control over one aspect of their behavior (e.g., the ability to understand the words in a sentence) but not over other aspects of their behavior (e.g., the ability to understand the meaning of a sentence). Not only do targets differ, but control perceptions for targets differ over time. As a result, any attempt to treat the construct of perceived control simplistically is misguided.

In health psychology, the three most prevalent targets of control are health status, health behavior, and health care treatment. These are not the only targets of interest to health psychologists, however. For instance, Baum, Cohen, and Hall (1993) discussed control over environmental stressors such as hurricanes, earthquakes, tornados, explosions, and technological support services. Brownell (1991), on the other hand, focused on control over individuals' bodies. Anything that may impact on the individual is a potential target for control.

Appraisal

In Lazarus and Folkman's (1984) theory of stress and coping, primary appraisal refers to a judgment of the threat value of a stressor, whereas secondary appraisal refers to a judgment of available resources to deal with the threat. Perceptions of control affect and are affected by the process of secondary appraisal; the more resources available, the greater the perception of control and the better the ability to cope with the stressor. Some theoreticians in this area equate perceived control with "coping potential" (Craig Smith, personal communication, 1993); the greater the perceived control, the more likely the individual will cope successfully. Perceptions of control, therefore, can be thought of as personal coping resources.

ISSUES IN THE STUDY OF PERCEIVED CONTROL

Manipulated Versus Measured Control

The overwhelming majority of research on perceived control treats it as an individual difference construct that can be as-

sessed by self-reports, usually with a paper-and-pencil instrument and sometimes by interview. In a smaller body of experimental research (e.g., Langer & Rodin, 1976; Mills & Krantz; 1979; Schulz, 1976), perceived control over some aspect of the environment, such as the health care delivery system, is manipulated in order to study the effects of perceived control on outcomes. For example, Langer and Rodin (1976) gave residents in a nursing home choice over which night they viewed a movie and whether the residents or the nursing staff had responsibility for watering plants. The investigators offered these choices to determine the effects that even a minimal amount of control has on mental and physical health.

The experimental research approach, rooted in social psychology, treats perceived control as an intervening variable. In these studies, some aspect of the situation is manipulated by the experimenter. Theoretically, the manipulation affects the subject's perception of control, which in turn helps determine the person's response to the situation (i.e., the outcome). An assumption in this type of research is that perceptions of control can be influenced by experiences.

In a series of field experiments conducted in the 1980s, Wallston and colleagues (see B. S. Wallston et al., 1987; K. A. Wallston, 1989; K. A. Wallston et al., 1991, for details) attempted to manipulate patients' perceptions of control over their health care situations by giving them enhanced choices and/or information to increase the predictability within the situations. The researchers expected that the patients' increased sense of control would lead to reduced feelings of distress and greater compliance with their medical regimens. No main effects for the control enhancing manipulations were found. Instead, the outcomes were determined by a complex interaction of the experimental conditions and patients' desire for control in those situations. The importance of taking into account individual differences such as desire for control are addressed later in this chapter.

In the aforementioned Wallston et al. studies, measures of perceived control administered after the experimental manipulations served both as an "outcome" of the manipulated independent variable (choice and/or predictability information) and as an "indicator" of the psychological process that intervened between the independent and the dependent variables. A separate set of questions served as the manipulation check in these studies. Among other things, these latter questions asked if the subject remembered being given a choice and/or predictability information. It is critical when conducting experimental manipulations of control to include both explicit manipulation checks as well as measures of perceived control as an outcome (or intervening) variable.

Levels of Specificity/Generalizability

In psychology in general, and health psychology in particular, perceived control has been assessed at three levels: *general*, cutting across many behaviors and situations faced by individuals; *midlevel*, pertaining to a given domain in people's lives (e.g., work, health, interpersonal relationships) but cutting across behaviors and situations within that domain; and *specific* to a given behavior and/or situation. Assessments at a

general level are usually treated as stable personality traits, not easily amenable to change.

Caution should be exercised in assuming that mid- or specific-level assessments of perceived control remain stable over time because beliefs can change with each new experience. Investigators must choose a level of measurement that best suits their purposes. For example, the administration of a measure designed to assess perceived control over life in general should not be used to evaluate the effectiveness of a communication designed to convince diabetics they are in control of their own condition. Instead, a measure specific to health, or even one specific to diabetes, would be a better choice. When measuring perceived control after a deliberate manipulation of control, the instrument needs to be sensitive to change over time. Situation-specific measures are preferable in this instance.

Perceived Control as an Independent Versus Dependent Variable

In most of the work done to date, perceived control beliefs are treated as independent variables or causal agents, having some effect on an outcome or criterion variable. Work also has been done on the determinants of perceived control beliefs. In those instances, perceived control is treated as a dependent variable. The more perceived control is viewed as a stable attribute of the person or situation, the more likely it would be treated as an independent variable. In experiments in which the investigator manipulates the level of perceived control, the construct is treated as an independent variable. However, in doing a check of the manipulation, perceived control is typically analyzed as a dependent variable. Investigators need to be clear about whether control is an independent or dependent variable (or both) in their analyses.

The following section presents a number of ways in which perceived control has been operationalized in health psychology research. Almost all of these involve some sort of paper-and-pencil measures of beliefs, utilizing either single-item scales or, more usually, multi-item summated belief scales.

OPERATIONALIZATIONS OF PERCEIVED CONTROL

Locus of Control

Historically, most of the work linking perceived control and health evolved from Rotter's (1966) construct of *locus of control*, a generalized expectancy within his version of social learning theory (Rotter, 1954; 1982; Rotter, Chance, & Phares, 1972). *Locus*, the Latin word for "place," was dichotomized by Rotter into *internal* and *external*. A person with an internal locus of control orientation was conceptualized as someone who believes that valued reinforcements (or outcomes) occur as a direct consequence of personal actions or, perhaps, as a result of who or what the person is. An internal locus of control orientation is generally equated with perceived personal control. In contrast, an external orientation

signifies a belief that reinforcements or outcomes are the result of other people's behaviors or, perhaps, random occurrences, not influenced by anything other than fate, luck, or chance. An external orientation typically is thought to signify a lack of perceived personal control.

Rotter (1966) developed the I-E scale as a means for assessing where along the internal-external continuum people's belief systems lay. The I-E scale is an example of assessment of perceived control at a general level. Generalized expectancies are developed through multiple experiences in varied situations (Rotter, 1954). By the time a person reaches adulthood and has experienced a wide range of situations, generalized expectancies have usually stabilized. Therefore, most investigators (e.g., Phares, 1976) have treated locus of control orientation as a personality trait. High I-E scores are reflective of externality and low I-E scores signify internality. I-E scale scores in late adolescents or adults are thought to be indicative of a relatively enduring characteristic of the individual, only changeable given profound new experiences or deliberate psychotherapy.

Health Locus of Control and Its Measurement

The I-E scale quickly became one of the most frequently used individual difference measures in psychology (cf. Rotter, 1975). Scores from Rotter's scale were applied to a wide variety of phenomena, including health. (See Strickland, 1978, and B. S. Wallston & K. A. Wallston, 1978, for reviews of early research linking I-E scores to health-related behaviors.) In 1973, the Wallstons became interested in applying the locus of control construct to health-related phenomena. Rotter (1975) stipulated that the predictability of behavior in a specific domain was more a function of expectancies related to that domain than generalized. Consequently, the Wallstons developed a midlevel, health domain-related locus of control scale, reasoning that such a measure would be general enough to cover a wide range of health-related behaviors and health-related circumstances while, at the same time, being specific enough to increase the predictability of health-related phenomena.

The first health locus of control (HLC) scale developed by B. S. Wallston, K. A. Wallston, Kaplan, and Maides (1976) was loosely modeled after Rotter's measure. Like the I-E scale, the original HLC scale was considered unidimensional, with high scores signifying increased externality. However, the HLC used a Likert response format rather than the forced-choice format employed by Rotter. The initial studies with the new scale (B. S. Wallston et al., 1976; K. A. Wallston, Maides, & B. S. Wallston, 1976) demonstrated its discriminant validity when compared to the I-E scale. The HLC scale predicted health outcomes and health-related information seeking better than the I-E scale, particularly among people for whom good health held high reinforcement value.

Multidimensionality of Locus of Control

A few investigators (e.g., Collins, 1974) used factor analysis to demonstrate that the I-E scale was multidimensional rather

than unidimensional. Levenson (1973, 1974) posited that internality and externality were different dimensions rather than opposite ends of the same dimension. Levenson also suggested that externality itself was multidimensional. She developed the I, P, and C scales (Levenson, 1973, 1974, 1981) in which "powerful others externality" (P) was assessed separately from "chance externality" (C), and both of these were separate from "internality" (I).

Multidimensional Health Locus of Control

The separateness of internality and externality was supported by further investigation by the Wallstons, who noted that the internal consistency reliability of the HLC scale was considerably lower in subsequent samples than it had been in the sample used to develop the instrument. The correlations between the five internally worded HLC items and the six externally worded items was essentially zero, confirming the multidimensional nature of the measure. They agreed with Levenson's decision to split externality into two distinct dimensions, while recognizing that the relatively high correlation between Levenson's P and C scales ($r \sim .60$) was not ideal.

The multidimensional health locus of control (MHLC) scales (K. A. Wallston, B. S. Wallston, & DeVellis, 1978) were developed to more fully capture the different dimensions of locus of control. Modeled explicitly after Levenson's generalized I, P, and C scales, the MHLC scales consist of two "equivalent" forms (A & B), each of which have three six-item subscales: *internal health locus of control* (IHLC), or the belief that personal behavior influences health status; *powerful others health locus of control* (PHLC), or the belief that health status is influenced by the actions of powerful others, such as family, friends, and health professionals; and *chance health locus of control* (CHLC), or the belief that health status is strictly a function of fate, luck, or chance. The two alternative forms were developed for researchers who wanted to administer a measure of health locus of control beliefs before and after an intervention designed to alter such beliefs.¹

The three subscales of the MHLC typically are orthogonal to (uncorrelated with) one another (K. A. Wallston et al., 1978; Wallston & Wallston, 1981). In most populations, IHLC and PHLC scores are uncorrelated. On occasion, however, a small positive association is found between IHLC and PHLC, particularly among older, less well-educated, or chronically ill samples. In most samples, IHLC and CHLC

¹If the pretest and posttest were to be done in relatively close temporal proximity to one another, then having equivalent forms would minimize the chance that subjects taking the posttest would answer exactly as they had on the pretest. However, Forms A and B of the MHLC are only somewhat equivalent; they are not identical and do not yield identical normative scores (see K. A. Wallston et al., 1978). Therefore, when these measures are used in this fashion, a random half of the sample should be pretested with Form A and the other half with Form B, and then the alternative form should be given as a posttest. Otherwise, it might spuriously be concluded that the intervention affected HLC beliefs when, in actuality, the change in mean scores might only be due to a change in the form of the measuring instrument.

are usually somewhat negatively correlated, although the correlation seldom exceeds $r = -.25$. The two external dimensions, PHLC and CHLC, often correlate as high as $r = .30$. Nevertheless, this means that less than 10% of the variance in one external dimension is explained by its association with the other. This is in contrast to Levenson's P and C scales, which shared over 35% common variance. Because the MHLC subscales are orthogonal to one another, it is inappropriate to combine the subscales to compute a total MHLC scale score.

Form A or Form B of the MHLC have been administered in over 1,000 studies in the United States and other countries. The scales have been used to examine every conceivable health-related phenomenon (see Wallston & Wallston, 1981; K. A. Wallston & B. S. Wallston, 1982, for reviews of some of the early work with the MHLC), but in no way do the results of these studies present a coherent pattern. Once the MHLC scales were developed, the Wallstons withdrew their support of the original HLC scale; the new measure did everything the old measure did—and then some.

Because the MHLC was modeled after Levenson's I, P, and C scales, no attempt was made to include "negatively" worded items. This was criticized by Lau and Ware (1981), who indicated that having all the items keyed in the same "positive" direction (i.e., agreement on each item contributes to a high subscale score) diminishes the validity of the scales for those respondents with a "yea-saying" or "nay-saying" response set (Campbell, Siegman, & Rees, 1967). Lau and Ware (1981) subsequently developed a multidimensional health locus of control scale in which negatively worded items were included. Three of the four dimensions in the Lau and Ware instrument mimicked the three MHLC dimensions. Lau and Ware's fourth dimension, labeled "general health threat," assesses motivation to control health, a distinctly different construct from locus of control beliefs.²

Condition-Specific Control: A New Approach

In the years since the MHLC was published, several other researchers developed disease-specific or health-related-domain specific versions of the measure (see K. A. Wallston, Stein, & C. A. Smith, 1994, for references). Each time someone developed a version of the instrument, however, they chose a different set of items from the MHLC. As a result, scores from one scale were not equivalent to scores from another, thus making it impossible to compare scale scores across studies.

Part of the rationale for developing these more specific instruments paralleled the original reason for constructing the HLC scale: to increase predictability within a specific domain. Another reason was that some patients with an existing

²Subsequently, there have been a couple of studies (e.g., Marshall, Collins, & Crooks, 1990) that have used statistical modeling techniques to pit the Lau and Ware scales against the MHLC scales. These studies have generally supported the three dimensions used in the MHLC rather than the four dimensions in the Lau and Ware (1981) measure.

medical diagnosis had difficulties responding to certain items such as, "I can pretty much stay healthy by taking good care of myself." It is difficult to respond to this item when you do not think of yourself as "healthy." The solution to the proliferation of nonequivalent disease-specific measures was to develop a generic version of the MHLC, labeled Form C (K. A. Wallston et al., 1994). Form C contains four, rather than three, dimensions. Factor analyses (K. A. Wallston et al., 1994) demonstrated that the "powerful others" items in Form C break down into two orthogonal dimensions, "control by doctors" (what Lau & Ware, 1981, called "provider control") and "control by others" (e.g., family or friends). Form C can be made specific to any medical condition by changing one word ("condition") in each item.

Form C appeals to many researchers investigating perceived control in persons with chronic diseases or other medical conditions. However, it must be remembered that Form C assesses beliefs in control over a particular condition (e.g., cancer or arthritis), not health locus of control, *per se*. These two types of beliefs (i.e., domain-specific and situation-specific) seldom intercorrelate higher than .60 (cf. K. A. Wallston et al., 1994). Just because individuals perceive control over their diagnosed condition does not necessarily mean they perceive control over their health in general, and vice versa. Thus, researchers using Form C may also wish to use Form A or Form B, if adding 18 items does not substantially increase subjects' burden. The advantage of administering both Form A/B and Form C is that this provides both a midlevel and a condition-specific assessment of locus of control beliefs, increasing the likelihood of discovering important relations with other constructs.

Limitations of the Locus of Control Construct

A limitation of the construct *locus of control* is its relation to only one of the targets of control: outcomes (or, in social learning terms, reinforcements). This is a problem because locus of control is an *outcome expectancy*. For instance, high scores on the IHLC scale signify individuals believe there is a relation between their behavior and their health status. What is not known, however, is the person's *behavioral expectancies*: Does the person feel capable of producing the behavior when it is called for? An outcome expectancy without a concomitant behavioral expectancy may not indicate much about perceptions of control. For example, a woman might feel the food she eats influences her weight and she might also think that her weight influences her health, but unless she also believes she is capable of limiting her caloric intake, she will not perceive much control over her weight or her health. Feeling "responsible" for an outcome is not exactly the same thing as being in control of that outcome.

Another shortcoming of locus of control as a means of conceptualizing perceived control is that just because a person believes other people play a role in determining outcomes does not necessarily imply a lack of perceived control. This is especially true in the context of health outcomes, particularly

when the "powerful others" are highly skilled health professionals. Many patients truly believe that transferring control to a benevolent, competent health care provider is, in fact, a means of gaining control over health. Similarly, individuals who blame themselves for their poor health but do not feel responsible for their good health could score highly on a measure of internal health locus of control without feeling in control of their health.

Marshall (1991) used covariance structure modeling with a sample of medical outpatients to conduct a multidimensional analysis of health-related personal control perceptions. As Marshall hypothesized, the structure of personal health control included four dimensions: response-outcome expectancies about illness prevention; response-outcome expectancies about illness management; self-blame for negative health outcomes; and perceived self-mastery over health outcomes. Only the latter dimension, perceived self-mastery over health outcomes, was uniquely associated with physical well-being. The constructs and measures to be described—specifically, self-efficacy, mastery, and competence—relate directly to Marshall's finding.

Self-Efficacy. Bandura, whose version of social learning theory (now called social cognitive theory) has eclipsed Rotter's, led the way in distinguishing between outcome and behavioral expectancies (Bandura, 1977, 1982). The most salient behavioral expectancy, labeled by Bandura (1977) as *self-efficacy*, is the individuals' confidence in their ability to carry out a specific behavior in a specific situation. Measures of self-efficacy have proven to be much better predictors of health behavior than measures of health locus of control beliefs (Bandura, 1997; O'Leary, 1992; Schwarzer, 1992; Wallston, 1992).

Self-efficacy relates to control of a different target—behavior—than locus of control that targets outcomes or reinforcements (K. A. Wallston et al., 1987). Most current social psychological theories of health behavior incorporate self-efficacy beliefs as a major explanatory construct. For example, Ajzen's Theory of Planned Behavior (Ajzen, 1985) has a construct labeled "perceived behavioral control," which is closely akin to self-efficacy. Even the venerable Health Belief Model (Rosenstock, 1966) has been reformulated to include self-efficacy as a separate mediator of health behavior (Rosenstock, Strecher, & Becker, 1988).

The difficulty for health researchers wanting to measure self-efficacy is that Bandura initially conceived of these beliefs as being highly behavior and situation specific. Thus, each new health behavior or health-related situation calls for a new and different measure of self-efficacy. Fortunately, there are now enough examples of self-efficacy measures in the literature (e.g., Conditte & Lichtenstein, 1982; Schwarzer, 1993) that researchers can adapt to fit their own particular needs. This latter strategy is commonplace, although it is not without peril. Any new or adapted instrument should be thoroughly pilot tested before use, and a psychometric analysis should be done once the data have been collected to assess the reliability and validity of the new measure (DeVellis, 1991).

Generalized Self-Efficacy, Mastery, and Competence. Some psychologists take exception to Bandura's original notion of strict situational specificity. They believe self-efficacy can be generalized across behaviors and situations and thus can be assessed as a stable individual difference. For example, Schwarzer and colleagues developed measures of *generalized self-efficacy* and applied them successfully to health-related phenomena (Schwarzer, 1992, 1993). Sherer and Maddux (1985) also developed a generalized self-efficacy scale, and others used Pearlin and Schooler's (1978) Mastery scale to assess individual differences in personal control over the environment and the future (Hobfoll & Lerman, 1989; Hobfoll, Shoham, & Ritter, 1991).

Wallston and colleagues developed a similar generalized measure, the Perceived Competence (PC) scale, which has been applied to health-related situations. For example, C. A. Smith, Dobbins, and K. A. Wallston (1991) showed that perceived competence mediates depression and life satisfaction in persons with rheumatoid arthritis. Pender, Walker, Sechrist, and Frank-Stromborg (1990) used this same instrument (which they referred to as the Personal Competence Rating scale) in a study of health behavior in six employer-sponsored health promotion programs. In the Pender et al. study, the PC scale predicted more variance in the measurement of health-promoting lifestyle behavior than any other measure, including the MHLC. It also contributed significant variance after controlling for all other constructs in their model.

There now exists a midlevel instrument for health researchers who do not want or need to assess self-efficacy at highly specific levels, but who also do not want to operate at a general level. The Perceived Health Competence scale (PHCS; M. S. Smith, K. A. Wallston, & C. A. Smith, 1995) measures essentially the same construct as Marshall's (1991) perceived self-mastery over health outcomes, and can easily be made even more outcome specific (e.g., pain, weight loss). This eight-item, psychometrically sound measure of perceived control of health is unidimensional, and combines behavioral and outcome expectancies in a single measure.

Situation-Specific Perceived Control Scales. In addition to utilizing already established measures of perceived control of health (e.g., locus of control, self-efficacy, mastery, and competence), many health psychologists ask just one or two questions about perceptions of control, often making those questions relevant to the situation under investigation. For example, Affleck, Tennen, Pfeiffer, and Fifield (1987) assessed rheumatoid arthritis patients' beliefs about personal control over daily symptoms, course of disease, medical care, and treatment. For all patients, regardless of severity of condition, the belief in personal control over medical care and treatment was associated with positive psychological outcomes. For patients with mild symptoms, perceiving personal control over symptoms was unrelated to outcomes. For those with moderate or severe symptoms, however, the more they perceived control over their symptoms, the more positive was their mood. Perceiving personal control over the course of their arthritis was marginally associated with positive mood in patients with mild

disease, but was negatively associated with positive mood in patients with more severe disease.³

Taylor, Helgeson, Reed, and Skokan (1991) conducted a longitudinal study of control and adjustment among a group of patients with severe coronary heart disease. At three points in time, participants were asked to respond to two control-related questions using 7-point rating scales: (a) "Regarding your heart problem, how much in control do you feel?" and (b) "Regarding your heart problem, how helpless do you feel?" Because the questions were highly correlated at each point in time, the investigators chose to combine them into an index (after reversing the second item) rather than to treat them separately. This strategy enhances the reliability of the measure.

In a study of gay men with AIDS, Taylor and colleagues (Reed, Taylor, & Kemeny, 1993) used a different measurement approach. In interviews in the subjects' homes, ratings (on 5-point scales) of personal control were obtained through three questions: (a) "How much control do you feel you have over the amount of fatigue, pain, or other symptoms you may experience on a daily basis?"; (b) "How much control do you feel you have over maintaining or improving your health, for example by influencing your immune system or by preventing AIDS-related conditions from occurring, getting worse, or coming back?"; and (3) "How much control do you feel you have over the medical care and treatment of your illness?" Like the study by Affleck et al. (1987), this study illustrates ways to assess the multiple targets of control.

In the series of field experiments by Wallston and colleagues, referred to earlier, in which patients' perceptions of control were manipulated in specific health care settings by providing choices and/or enhanced information (see K. A. Wallston, 1989, for a synopsis of these studies), the PCON scale (for perceived control) was used to assess the key intervening variable. PCON assesses control over actual health care delivery situations, not control over outcomes or behaviors. Although the general form of the PCON scale remained the same from situation to situation (e.g., outpatients receiving a barium enema or cancer chemotherapy; hospitalized patients postsurgery), the wording of the instructions and items were altered to fit the specifics of the situation. This type of easily adaptable measure is useful for health services researchers interested in patients' perceptions or those wishing to assess the effectiveness of control-enhancing interventions.

Learned Helplessness

When individuals learn over repeated trials that the things that happen to them are not contingent on their own actions, they develop learned helplessness (cf. Seligman, 1975). Learned helplessness is the obverse of perceived control; the greater the learned helplessness, the less the perceived control. Because of this, health psychologists can assess perceived con-

³Not only does this study by Affleck et al. (1987) illustrate the value of assessing multiple targets of control, it also reinforces the importance of including disease severity as a moderator variable in one's analyses.

trol at a mid- or specific-level by measuring the extent to which patients hold beliefs consistent with learned helplessness and/or exhibit behavioral/motivational deficits indicative of helplessness. A good example of this is the helplessness subscale from the Arthritis Helplessness Index (AHI; DeVellis & Callahan, 1994; Stein, K. A. Wallston, & Nicassio, 1989).

MODERATORS OF PERCEIVED CONTROL: THE ACTION IS IN THE INTERACTION

The major outcome measure in Rotter's (1954) social learning theory is "behavior potential"—the likelihood of a particular behavior (or set of functionally related behaviors) occurring in a given situation. According to Rotter's theory, measures of expectancy (such as locus of control beliefs) are supposed to work in conjunction with measures of reinforcement value to predict behavior potential in specific situations (Rotter, 1954).⁴ In other words, reinforcement value moderates the relation between locus of control beliefs and behavior. For high levels of reinforcement value, internal locus of control beliefs should be predictive of behavior; for low levels, locus of control should be uncorrelated with behavior.

Within the health domain, the most relevant reinforcer of health behavior is good health. Consequently, researchers attempting to predict health behavior using measures of health locus of control beliefs (or any expectancy measure) should also assess the reinforcement value of health (K. A. Wallston, 1991; K. A. Wallston et al., 1976), especially among relatively healthy populations. Although considerably less attention has been paid to the assessment of health value, there are a number of techniques that have been developed to do so (M. S. Smith & K. A. Wallston, 1992). When studying populations whose health statuses are already compromised by illness or disease, or when health value cannot be assessed directly, an alternative approach is to use a measure of disease severity as a proxy. In general, when health is threatened, its value is higher than when it is not (M. S. Smith & K. A. Wallston, 1992).

Behavioral expectancies (such as self-efficacy beliefs—the individuals' confidence in their ability to carry out the behaviors) have been suggested as the primary predictors of health behavior. These specific expectancies, in turn, are moderated by locus of control orientation and health value (K. A. Wallston, 1992). In other words, health behavior can be predicted by self-efficacy expectations only among individuals who value their health and who have an internal orientation toward their health. This calls for examining the three-way interactions among behavioral expectancies, outcome expectancies, and outcome value when attempting to predict health behavior.

Health psychologists, however, are interested in more than predicting health behavior. For many researchers, health status is the outcome they are attempting to explain. Theoretically, at least, expectancies about control (e.g., health locus of control or self-efficacy beliefs) should be related only to health status when the control expectancy predicts health behavior and the health behavior predicts health status. Conceptually, the relation between perceived control and subsequent health status is mediated by health behavior. This relation (between perceived control and health status) is also subject to moderation by individual and situational variables.

A good example of how perceived control beliefs interact with personal and situational variables can be found in a study of end-stage renal disease patients (Christensen, Turner, T. W. Smith, Holman, & Gregory, 1991). In this study, depressive symptomatology was the outcome and whether or not the patient had previously experienced a failed liver transplant was the situational factor. Christensen et al. predicted that the negative psychological effects of a transplant failure would be greater for those who had strong beliefs in the controllability of their illness, whether through their own efforts or through those of their health care providers. It was also predicted that among those patients who had not experienced a transplant failure, those with stronger beliefs in control would have more favorable psychological outcomes. Christensen et al. also predicted that disease severity would moderate the interaction, such that the more severe the disease, the stronger the interaction.

The results of the study were as predicted. Within the group of patients with lower disease severity, the two-way interaction between perceived control and transplant outcome was not significant. The predicted interaction was seen for those with higher disease severity, however. In the failed transplant group, the greater the perception of control, the more depressed the patient. Among the patients who never experienced a failed transplant, the results were just the opposite (Christensen et al., 1991).

The study of rheumatoid arthritis patients by Affleck et al. (1987) provides another example of the importance of examining interactions of perceived control with disease severity when predicting health status outcomes. Another study by the same team of investigators (Tennen, Affleck, Urrows, Higgins, & Mendola, 1992) found an even more complicated, but clinically important, set of interactional effects. Those patients who believed at the outset of the study that they had more control over their pain experienced less daily pain. With increased levels of pain, however, greater control was associated with less positive mood.

Indicators of disease severity are not the only potential moderators of the relation between control beliefs and health outcomes. For example, Kaplan and associates (Strawbridge et al., 1993; Wallhagen et al., 1994) found that internal health locus of control strongly predicted 6-year change in physical functioning for elderly women. Elderly men, on the other hand, were affected only if they had lower functioning at baseline. In these analyses, both gender and level of baseline functioning were treated as moderator variables. Other potential moderators (of the relation between perceived control and

⁴The phrase "in conjunction with" is best interpreted as "in interaction with" rather than "in addition to." Thus, measures of locus of control need to be multiplied by or crossed with reinforcement value to predict behavior (cf. B. S. Wallston & K. A. Wallston, 1984; K. A. Wallston, 1991).

health outcomes) are age, social class, social support, and availability of medical treatments. The important message from these studies is that variance in health status is poorly explained by direct (main) effects of perceived control. The action is in the interaction, and the challenge is to find the right moderators for each situation.

FUTURE DIRECTIONS

Other than predicting that perceived control will remain a central and important construct in health psychology well into the 21st century, it is not easy to speculate about the way the construct will be operationalized and utilized in the future. One thing is for certain: New and improved methods of measurement will be developed. These will probably occur in two diametrically opposite directions: a focus on perceived control of health as a unitary dimension; and an attempt to discover other important dimensions or loci of control, such as the influence of the environment and/or a "higher power" on one's health status.⁵ As health psychologists become more aware of and comfortable with alternative ways of assessment—such as using computers or qualitative methods—less and less reliance will be placed on traditional paper-and-pencil measures. Method triangulation, such as combining quantitative and qualitative assessments, will become the norm rather than the exception.

K. A. Wallston (1992) pointed out that "the focus isn't strictly on locus," which did not stem the tide of research using the MHLC scale, but slowed it down some. The challenge for health psychologists is to select the most appropriate ways of measuring perceived control and to develop analytic strategies that examine interactions among these methods as well as with other constructs.

CONCLUSIONS

This chapter described the development of measures of perceived control of health as well as the ways in which the construct of perceived personal control has been conceptualized and operationalized by health psychologists. The complexity and the multidimensionality of the construct has been emphasized. Different levels of specificity in operationalizing the construct were presented, concentrating on the mid- and situationally specific levels. It was stressed that although measures of health locus of control may play a role in explaining variance in health behaviors and health status, these measures should optimally be used in conjunction with other indicators of perceived control of health (e.g., perceived health competence or other efficacy measures). Also stressed was the notion that the action is in the interaction. Perceptions of control moderate, or are moderated by, many other constructs, among them individual differences in demographic characteristics, background experiences, situational factors,

and value orientations. Without adopting an interactionist perspective, health psychologists and other investigators in behavioral medicine will fail to discover the full explanatory power of perceived control.

On Who Gets Sick and Why: The Role of Personality and Stress

Richard J. Contrada

Max Gyll

Rutgers, The State University of New Jersey

It has long been thought that personality and physical health are related. From ancient theories of temperament, through early clinical descriptions of physical disorders, prescientific thinking drew a close association between personality attributes and various somatic disorders. Several threads of systematic theory and research on the topic emerged following the birth of psychology and psychosomatic medicine. Since the middle of the 20th century, interest in personality and health has intensified considerably. It now represents a major focus of psychosocial research concerned with physical disease (Friedman, 1990).

Potential points of contact between the personality and physical health domains are numerous. Each, by itself, is a large and complex area of inquiry. The personality field has undergone considerable expansion and differentiation over the past 50 years. During the latter portion of that time period, there has been tension between two major pursuits: construction of a taxonomy of personality descriptors and development of an understanding of personality process (Cervone, 1991; Mischel & Shoda, 1994; Pervin, 1990). This debate reflects an important component of variation in assumptions and approaches within the personality field. However, there are also wide differences in the views of investigators within each camp, and many issues in personality research that have implications for understanding physical health do not map neatly onto the description/process dichotomy.

As this handbook will attest, the study of physical health and disease is a vast and diverse enterprise. Many physical

conditions contribute to morbidity, mortality, and poor quality of life, and any one condition poses several subproblems, including diagnosis, epidemiology, etiology, prevention, treatment, and rehabilitation. As a result, the study of physical health and disease is a multidisciplinary endeavor, potentially involving investigators from several health-related fields, including psychologists interested in personality (Schwartz & Weiss, 1977).

This chapter is concerned with one portion of the personality–health interface, namely, that involving personality attributes that are thought to have health-damaging consequences because they increase psychological stress or exacerbate its effects. Like personality, stress has long been suspected of contributing to physical health problems. Moreover, the personality and stress constructs complement one another in that each provides a means of explaining and elaborating the other's role in shaping human adaptation. The concept of stress points to social and environmental factors outside the person that influence psychological well-being and physical health, and to psychological and physiological processes that mediate those effects. The study of personality points to dispositions within the person that can account for individual differences in responses to a stressor, and to attributes and processes that explain temporal and cross-situational consistency in stress-related response patterns. Thus, research that draws from both the personality and stress domains is more likely to provide a comprehensive understanding of psychosocial influences

on physical health than does work in which one of these constructs is utilized to the exclusion of the other.

This chapter provides a discussion of conceptual issues, empirical findings, and methodological concerns that bear on the relations among personality, stress, and health. It examines personality as a psychosocial risk factor for disease and as a moderator of psychological stress. The review is selective in emphasizing research that supports associations between certain personality dispositions and both measures of physical disorder and markers of disease-related processes. The focus is primarily on the relation between personality and disease promoting processes that involve direct, psychophysiological effects of stress. However, some consideration is also given to behavioral factors that may mediate the health effects of stress-related personality attributes independently of, or in interaction with, psychophysiological mechanisms. Issues and problems that emerge from this discussion are highlighted in a final section that takes stock of available theory and empirical findings and points to some potentially fruitful directions for further study.

WHO GETS SICK? PERSONALITY AS A RISK FACTOR

“Who gets sick?” is an epidemiological question that can only be answered by programmatic, prospective, multivariate research in which putative risk factors are evaluated with respect to their ability to predict objectively verified disease endpoints independently of potential confounds (Adler & Matthews, 1994). Personality represents but one of several psychosocial domains in which risk factors for physical disease have been sought, with other salient examples including psychological stress, social relationships, and health-related behaviors. However, the conceptual and methodological principles that arise from a consideration of the health effects of personality are relevant to a wide range of possible psychosocial risk factors, and there is reason to believe that personality and other psychosocial factors related to health often interact with one another rather than operating independently.

This section begins by describing major conceptual features that distinguish personality from other psychological constructs, and by discussing the implications of these features for framing the question, “Who gets sick?” An overview is then provided of the numerous personality attributes that have been implicated as possibly influencing vulnerability to physical disease. This section concludes with a discussion of those personality attributes for which the epidemiological evidence makes the strongest case for risk factor status.

Conceptual Elements of Personality

The question of how best to define *personality* and related terms such as *personology* has received extensive consideration (for classic discussions see Allport, 1937, and Murray, 1938; for more recent treatments, see Mischel, 1968, and Pervin, 1990). These analyses are not reviewed here. Instead,

the discussion draws on previous work to provide a heuristic overview of some of the major conceptual elements of personality psychology. This discussion is necessarily cursory, however, and the reader is urged to consult the sources already cited for more comprehensive coverage of these issues.

Individual Differences

Individual differences refer to between-person variations in behavior. In this context, “behavior” may be construed narrowly in terms of a single domain of psychological activity, or it may be defined broadly to include cognition, affect, motivation, overt action, and neurobiological activity. Personality psychologists do not share a single view of the nature of individual differences per se, or of the importance of any one domain of individual differences in particular. Moreover, not all individual differences involve personality. Nonetheless, in a general sense, personality and the study of individual differences are intimately related.

The relevance of individual difference dimensions to the development and course of physical health problems depends on their association with mechanisms involved in the etiology and pathogenesis of disease, or with processes that affect the detection, control, and outcome of physical disorders. A rather wide range of individual difference constructs have been implicated as possible risk factors for physical illness. The field is narrowed, somewhat, when it is limited to those areas of individual differences that involve personality.

Patterning in Behavior

Much personality research may be distinguished from other areas of psychology by virtue of its focus on two specific forms of *patterning in behavior*, namely, temporal and cross-situational consistency. It is the observed or hypothesized stability of individual differences over time and in different contexts that provides a rationale for inferring drives, motives, traits, cognitive styles, and other dispositional constructs employed in personality psychology. Temporal and cross-situational consistency set personality attributes apart from other person factors, such as transient cognitive or emotional states, or highly situation-specific behavioral tendencies. Of course, psychological states and individual behaviors can be reflective of enduring personality attributes, and may have significant effects on physical health regardless of such an association. However, the nature of those effects and the mechanisms whereby they are mediated may at times differ from those involving personality (Cohen, Doyle, Skoner, Gwaltney, & Newsom, 1995; Scheier & Bridges, 1995).

Personality is not the sole source of temporal and cross-situational consistency in behavior. Enduring factors that exist outside individuals—such as occupation, economic conditions, and relations between ethnic groups—also may contribute to regularities in a person’s behavior. Moreover, as argued from the standpoint of transactional theoretical orientations, the explanation of temporal and cross-situational consistency in behavior may defy a simple, analysis of variance like partitioning of person, situation, and person-by-situation

interaction (Lazarus & Folkman, 1984). Instead, person and environment factors may reinforce and sustain one another in ways that make efforts to disentangle their independent contributions difficult or arbitrary. Notwithstanding these complexities, the involvement of personality attributes in behavioral patterning has major implications for specifying the role of personality as a risk factor for physical disease.

The two forms of behavioral patterning associated with personality factors provide a theoretical basis for linkages to health damaging processes. Temporal stability in a suspected personality risk factor may indicate a relationship to disease promoting mechanisms that develop gradually over time. For example, as an enduring disposition, hostility may be associated with repeated activation of physiologic activity that contributes to slowly progressing disorders such as atherosclerosis (T. W. Smith, 1992). Cross-situational consistency may operate in a similar manner. Consider conscientiousness, a trait that may be related to good health (Friedman et al., 1995). To the degree that conscientiousness involves a pattern of careful, prudent behavior that is displayed in a wide range of situations, the opportunity for the accumulation of risk reducing actions is increased. Thus, the two forms of behavioral patterning that define personality attributes as distinct from other psychological factors are also important for their implications regarding associations with disease promoting processes.

Recent studies involving naturalistic observations have provided evidence of a third form of behavioral patterning that may have interesting implications for the interface between personality and health. Mischel and colleagues (Mischel & Shoda, 1995; Shoda, Mischel, & Wright, 1994) demonstrated that individuals show consistent patterns of variability in their behavior across different situations. For example, children in a residential summer camp reliably displayed higher levels of particular behaviors (e.g., verbal aggression) in some situations (e.g., being teased by a peer, being approached by a peer) than in others (e.g., being warned by an adult, being punished by an adult). These situation behavior profiles consist of stable, meaningful variations in behavior, but are treated as random error in the more traditional focus in personality, where behavior often is aggregated across situations that may not always be psychologically equivalent. There may be similar consistencies in patterns of variation in behaviors that individuals display in situations that involve exposure to health risk.

Organization

The term *organization* is frequently used by personality psychologists, although with more than one meaning. In one usage, organization refers to the idea that personality is pervasive, involving the whole person as a unified, although highly complex, system. This notion is similar in certain respects to self-regulation perspectives employed in health psychology and behavioral medicine (e.g., Carver & Scheier, 1981; Schwartz, 1979). A systems view of the person is integral to the multilevel, bio-psycho-social model of health and disease (Engel, 1977), and also provides a framework within

which to conceptualize processes whereby cognitive, affective, and other psychological systems may influence disease promoting mechanisms, a topic discussed later in this chapter.

In another usage, personality organization refers to the structure of interrelationships of personality descriptors. Multivariate methods have generated evidence of hierarchical organization in which relatively specific tendencies (e.g., being talkative, enjoying parties) cluster together to form more general dispositions (e.g., sociability, sensation seeking), which in turn cluster together to form still more general dispositions (e.g., extraversion; Eysenck, 1967). There is growing consensus that at a certain level of abstraction personality organization may be described in terms of a taxonomy of five personality factors that have been labeled extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience (McCrae & Costa, 1985). This five-factor model provides a general framework for characterizing major dimensions of individual differences in personality.

Some of the traits that form the five-factor model, such as conscientiousness (Friedman et al., 1995) and neuroticism (Bolger & Zuckerman, 1995), have been investigated in relation to stress and health. However, many personality variables of interest to health psychologists—such as Type A behavior (Matthews, 1982), hostility (Barefoot, Dodge, Peterson, Dahlstrom, & R. Williams, 1989), optimism (Scheier & Carver, 1985), hardiness (Kobasa, 1979), and repressive coping (Weinberger, Schwartz, & Davidson, 1979)—involve facets of more than one of the five-factor traits, or are defined in terms of attributes whose location within the five-factor taxonomy has yet to be determined. Thus, the five-factor model remains to be more fully explored as a framework for organizing health-related personality attributes (T. W. Smith & P. G. Williams, 1992).

Personality Structure

Structure refers to neurobiological and/or psychological entities that are real and exist beneath the person's skin. Personality structures must be distinguished from the individual difference patterns from which they are typically inferred. A particular pattern of consistency in behavior across time and context may reflect an underlying personality structure, but the personality structure and the behavior pattern are conceptually distinct, with the former a putative cause of the latter. The concept of psychological structure is illustrated by the notion that hostile behavior reflects a set of underlying attitudes characterized by cynicism and distrust (T. W. Smith, 1992). An example of neurobiological structure may be found in Krantz and Durel's (1983) proposal that the overt display of Type A behavior is, in part, a reflection of activity of the sympathetic nervous system.

Consideration of the notion of personality structure suggests that, with respect to the role of personality, the question "Who gets sick?" is really asking "What personality structures lead to disease?" The interviews, questionnaires, and other assessment tools used to measure personality necessarily provide only an indirect indication of the presence, content, and form of the underlying psychological structure that

presumably gives rise to both the observable manifestations of the personality attribute and to the risk for physical disorders. Moreover, the disease promoting structure for which the assessment device provides a marker may operate through mechanisms that do not involve all observable manifestations of the personality attribute. For example, it may be that cynical, distrusting attitudes need not be expressed in hostile behavior in order to increase coronary risk; it may suffice for those attitudes to operate through more subtle behavioral expressions to undermine the person's ability to develop and to maintain a supportive social network (T. W. Smith, 1992). Similarly, an underlying tendency toward hyperactivity of the sympathetic nervous system may be toxic to the coronary arteries regardless of whether it promotes the overt display of Type A behavior (Contrada, Krantz, & Hill, 1988). Although this problem is but a specific instance of the usual, third variable alternative to causal hypotheses, it is often overlooked in research concerning personality and health.

Context

Context refers to factors outside the skin that may influence behavior. Context is a multilevel concept. Revenson (1990) referred to four broad contextual dimensions: situational (immediate stimulus configuration), interpersonal (social relationships, group affiliations), sociocultural (socioeconomic status, reference group), and temporal (life stage). Of particular relevance to health problems are situational factors whose interaction with personality gives rise to stress and influences the coping process (Lazarus, 1966). These interactions must be viewed within the framework of interpersonal relationships from which stressful situations may emanate and to which the individual may turn for coping assistance (Thoits, 1986). The situational and interpersonal context is, in turn, shaped by larger sociocultural systems in which the origins of both stressors and coping resources frequently may be found and whose norms and conventions define the meaning of stress, coping, personality, illness, and health care (Kleinman, 1986). In the life of an individual, the foregoing elements of context are moderated by the temporal dimension within which development and maturation occur and shape personality, stress, coping, and physiological functioning.

As noted earlier, the relationship between context and behavior is not a one-way affair. Much has been written about processes whereby person and environment shape one another (Bandura, 1978; D. M. Buss, 1987; Lazarus & Folkman, 1984; Plomin, Lichenstein, Pedersen, McClearn, & Nesselrode, 1990; Scarr & McCartney, 1983). Theory concerning bidirectional pathways of influence between person and environment has far outrun its application in the study of personality and health. Much of the epidemiologic literature on psychosocial risk factors for physical disorders involves studies in which either person or environmental factors, but not both, have been examined in relation to disease outcomes. Thus, for example, even the relatively simple and familiar notion that Type A individuals show pathogenic physiological responses when confronted by "appropriately challenging and/or stressful situations" has not been given rigorous test in

prospective epidemiological studies, which would require measurement of Type A behavior, environmental stressors, and coronary disease (Glass, 1977). It is not surprising, therefore, that there has been little empirical work addressing more difficult questions concerning the health consequences of personality that may involve bidirectional influences between person and context.

Process

The notions of individual differences, patterning, organization, and structure imply numerous psychological *processes*. Broad questions of general interest to the larger field of personality concern personality development, expression, and change. Of special relevance to the personality–stress interface are those processes whereby psychological structures become activated, influence construal of the social and physical environment, and regulate the individual's response to those construals (Mischel & Shoda, 1995). We will return to this in a later section of this chapter when the stress construct is discussed.

Possible Personality Risk factors

Many personality attributes have been implicated as possible contributors to physical disease. Table 4.1 describes a number of personality characteristics that have been investigated in research involving measures of health or markers for potentially health-related processes. The list is meant to be illustrative rather than exhaustive. For some of the entries, there is a suggestive empirical basis for a physical health linkage in the form of associations with measures of disease endpoints, but much of the work is cross-sectional. As a consequence, although this research may be useful in generating hypotheses regarding possible risk factors, it does not permit evaluation of those hypotheses (Matthews, 1988). Moreover, in many studies, whether cross-sectional or prospective, other methodological problems may be operating, such as selection biases (Suls, Wan, & Costa, 1995), or reliance on "soft" disease measures that are susceptible to confounding (Watson & Pennebaker, 1989), thereby undermining conclusions regarding personality–disease associations.

In many cases, the association between personality and disease is conceptual, rather than empirical, in that it is suggested by research or theory implying an association between the personality attribute and physiological responses to psychological stress. This sort of hypothetical relationship to disease is strongest where the stress response measure itself has been linked to disease-promoting processes. For example, Type A behaviors are reliably associated with physiological responses to stress that are related theoretically to atherogenic processes (Krantz & Manuck, 1984; Schneiderman, 1983), and have been associated empirically with coronary atherosclerosis in animals (Manuck, Kaplan, & Clarkson, 1983) and with recurrent myocardial infarction and stroke in humans (Manuck, Olsson, Hjerdal, & Rehnqvist, 1992). A case for health relevance is obviously weaker if based on an association between the suspected personality factor and stress mea-

TABLE 4.1
Illustrative Selection of Personality Variables That Have Been Linked to Disease Through Associations With Stress Responses, Health-Damaging Behaviors, and/or Reactions to Illness

Person variable	Definition	Stress	Health behavior	Reaction to illness
Alexithymia (Henry et al., 1992)	Inability to understand or describe one's emotional state	✓	✓	
Anger control (Czajkowski et al., 1990)	Resistance to becoming angry and/or controlling the experience of anger	✓		
Anger in (Czajkowski et al., 1990)	The experience of angry feelings without their expression	✓		
Anger out (Czajkowski et al., 1990)	Engaging in aggressive behaviors motivated by angry feelings	✓		
Antagonistic interpersonal style (Suarez & R. B. Williams, 1990)	Tendency to be disagreeable and to express anger towards others			
Attachment style (Feeney & Ryan, 1994)	Quality of the mental representation of the relationship of self to an attachment figure	✓		
Avoidance coping (Dunkel-Schetter et al., 1992)	Diversion of attention from the source and/or effects of stress	✓	✓	
Conflict, ambivalence of emotional expression (King & Emmons, 1990)	Discrepancy between one's style of emotional expression and emotional behavior encouraged by relevant social norms or goals	✓		
Conscientiousness, social dependability (Friedman et al., 1993)	Disposition characterized by prudence, forethought, conscientiousness, truthfulness, and freedom from vanity and egotism	✓	✓	
Defensive anger (S. B. Miller, 1993)	Conscious and/or unconscious disavowal of the experience and/or expression of anger	✓		
Defensive hostility (Helmers et al., 1995)	Hostility accompanied by a disinclination to report socially undesirable aspects of oneself	✓		
Defensiveness (Esterling et al., 1993)	Conscious and/or unconscious disinclination to report socially undesirable aspects of oneself	✓		
Denial (Esteve et al., 1992)	Conscious disavowal of reality	✓	✓	
Depression (Weisse, 1992)	Dysphoric mood characterized by intense sadness, helplessness, worthlessness, loneliness, and guilt	✓	✓	✓
Emotion focused coping (DeGenova et al., 1994)	Efforts to regulate emotional experience	✓	✓	✓
Emotional suppression (Gross & Levenson, 1993)	Conscious inhibition of emotional expressive behavior	✓		
Energy and activity (Keltikangas-Jarvinen & Raikkonen, 1993)	Tendency to engage in physical activity	✓	✓	✓
Extroversion (Siegler et al., 1995)	Syndrome characterized by sociability, emotional expressiveness, and novelty seeking	✓		
Femininity (vs. Masculinity) (Helgeson, 1991)	Exhibition of characteristics associated with the female (vs. male) gender role	✓	✓	✓
Goal representations, motivational correlates (Karoly & Lecci, 1993)	Mental representation of personally meaningful aspirations	✓	✓	✓

Person variable	Definition	Stress	Health behavior	Reaction to illness
Hardiness (Wiebe, 1991)	Syndrome Consisting of Challenge (vs. Threat), Internal (vs. External) Locus of Control, and Commitment (vs. Alienation)	✓		✓
Harm avoidance (Freedland et al., 1991)	Awareness and avoidance of aversive stimuli	✓	✓	
Helplessness (T. W. Smith et al., 1990)	Belief that one cannot alter the occurrence of expected, highly aversive outcomes	✓		✓
Hostility (T. W. Smith, 1992)	Cynical attitudes that increase proneness to anger	✓	✓	✓
Hysteria (MMPI) (Gatchel et al., 1995)	Syndrome characterized by naivety, self-centeredness, and a general malaise regarding medical conditions		✓	
John Henryism (James, 1994)	Persistent use of problem-focused coping and emotional stoicism despite environmental conditions of extreme and chronic stress	✓		
Locus of control (Schneider et al., 1991)	Generalized beliefs as to whether outcomes are internally or externally controlled	✓	✓	
Mania (MMPI) (Lipkus et al., 1994)	Syndrome characterized by impulsivity, sensation seeking, and sociability		✓	
Monitoring (vs. Blunting) (Schwartz et al., 1995)	Scanning for (vs. Avoiding) threat-relevant information	✓	✓	
Negative affectivity (Brief et al., 1993)	Tendency to experience unpleasant emotional states	✓		
Neuroticism (Siegler & Costa, 1994)	Tendency to experience emotional lability and anxiety		✓	
Novelty seeking (Freedland et al., 1991)	Responding with excitement to novel stimuli and reinforcement cues		✓	
Optimism (Carver et al., 1993)	Generalized expectation for positive outcomes	✓		
Other deception (Newton & Contrada, 1992)	Deliberate deception of others for purposes of impression management or goal achievement	✓		
Pessimistic explanatory style (Kamen-Siegel et al., 1991)	Belief that negative events are caused by internal, stable, and global factors, and that positive events are caused by external, unstable, and specific factors	✓	✓	✓
Positive emotionality (Depue et al., 1994)	Emotional experience that is activated by, and motivates one to approach rewarding stimuli	✓		
Problem focused coping (DeGenova et al., 1994)	Efforts to address the source of stress	✓	✓	✓
Psychopathic deviance (MMPI) (Lipkus et al., 1994)	Syndrome characterized by rebelliousness, impulsivity, and nonconformity			
Realistic acceptance (Reed et al., 1994)	Resignation to the prospect of death, associated with a tired, peaceful, but not necessarily pleasant affective state			✓
Repressed hostility (Helmets et al., 1995)	Unconscious denial of one's own hostility	✓		
Repression (Wallbott & Scherer, 1991)	Unconscious process serving to decrease awareness of distressing thoughts	✓		
Resiliency (vs. Vulnerability) (R. E. Smith et al., 1990)	Exhibition of well-being (vs. distress) following exposure to stressors	✓		✓
Reward dependence (Freedland et al., 1991)	Increased awareness of reward cues, and persistence in behaviors associated with reward		✓	

Person variable	Definition	Stress	Health behavior	Reaction to illness
Risk-taking, sensation-seeking (M. R. Levenson, 1990)	Purposive activity entailing novelty or danger sufficient to create anxiety in most people		✓	
Self-deception (Linden et al., 1993)	Unconscious process serving to protect self-esteem	✓		
Self-discrepancy (Strauman et al., 1991)	Perceived discrepancy between the actual self and a standard for self-evaluation	✓		
Self-efficacy (Wiedenfeld et al., 1990)	Perceived ability to cope successfully with a stressor	✓	✓	✓
Shyness (Bell et al., 1990)	Behavioral inhibition when with others in unfamiliar situations, subjectively experienced as unpleasant	✓		
Social introversion (MMPI) (Lipkus et al., 1994)	Syndrome characterized by the lack of a preference to engage in social interaction	✓		
Somatization (Miranda et al., 1991)	Tendency to attribute stress-produced bodily symptoms to physical causes and, consequently, to seek unneeded medical services		✓	
Trait anger (Suls et al., 1995)	Tendency to experience anger			
Trait anxiety (Kohn et al., 1991)	Tendency to experience unwarranted apprehension	✓	✓	
Trait humor (Rotton, 1992)	Coping mechanism moderating the relationship between stressful events and well-being	✓		
Type A Behavior Pattern (Dimsdale, 1993)	Competitive achievement-striving, hostility, time-urgency, and vigorous speech and motor mannerisms	✓	✓	✓
Unrealistic optimism (Taylor & Brown, 1994)	Unwarranted expectation of positive outcomes and/or exaggerated feelings of invulnerability		✓	

sure for which there is neither theory nor evidence to suggest a relationship to disease promoting processes.

A conceptual basis for a personality–disease linkage can also be inferred from research demonstrating an association between personality and certain behaviors. The latter may involve behavioral risk factors for disease, such as cigarette smoking or unsafe sex, or behavioral reactions to disease, such as treatment delay or noncompliance with medical regimens. As in the case of physiologic responses to stress, measures of health-related behaviors vary in the strength of their association with disease and, whatever the strength of that relationship, behaviors cannot be taken as proxies for the presence of physical disorders. At best, the existence of linkages to health damaging behaviors, like cross-sectional associations with disease, can only suggest hypotheses regarding the possible risk factor status of personality attributes.

Promising Personality Risk Factors

As noted earlier, epidemiological principles require that a set of relatively stringent criteria be satisfied before a variable may be elevated to risk factor status (Siegel, 1984). Among these are: (a) prospective research designs, which avoid many of the interpretive problems associated with cross-sectional

research; (b) objective disease indicators, which reduce the effects of reporting biases and other confounding factors; (c) evidence of a consistent association, that is, replication of the personality–disease relation across diverse study populations and measures; (d) evidence of a strong association, such that the magnitude of the relationship is of practical significance; (e) biological plausibility, or the existence of theory and evidence of pathogenic mechanisms that can explain the personality–disease association. Application of these criteria severely shortens the list of contending personality attributes.

The following sections discuss three sets of personality dispositions: anger/hostility, emotional suppression/repression, and disengagement. Although they are not considered well-established risk factors, each appears promising as a potential risk factor for physical disease (Contrada, H. Leventhal, & O'Leary, 1990; Scheier & Bridges, 1995). Anger-related characteristics have for quite some time been subject to attention as possible contributors to somatic disorders (for a review, see Siegman, 1994), as has the suppression or repression of anger and of other negative emotions (e.g., Alexander, 1930). The term *disengagement* was recently suggested by Scheier and Bridges (1995) to refer collectively to helplessness/hopelessness, pessimism, fatalism, and depression, each of which has been linked to negative health outcomes.

Anger/Hostility

Anger, hostility, and aggressiveness are salient features of personality attributes that show promise as possible risk factors for physical disease. These three terms can be used to refer, respectively, to affective, cognitive, and behavioral constructs, and each may be conceived as either a state or trait (Spielberger et al., 1985). Factor analyses of relevant trait measures have generated findings consistent with this tripartite approach. Several studies have identified anger experience and anger expression factors (also referred to as neurotic and antagonistic hostility), which to some extent correspond to affective and behavioral dimensions (Musante, MacDougall, Dembroski, & Costa, 1989; Suarez & R. B. Williams, 1990). A third factor, found in at least one study, was labeled suspicion-guilt (Musante et al., 1989), and appears to be a cognitive-attitudinal dimension.

However, data calling into question the psychometric structure of some of the more frequently used scales for measuring anger-related attributes (e.g., Contrada & Jussim, 1992; Spielberger et al., 1985) pose problems for the three-factor structure of total scale scores. Moreover, an item-level factor analysis conducted by A. H. Buss and Perry (1992) generated evidence of four distinguishable anger-related attributes, and a recent, population-based study yielded evidence of eight separate dimensions (T. Q. Miller, Jenkins, Kaplan, & Salonen, 1995). Given the need for further clarification of these issues, the terms *anger/hostility* or *anger-related* are used here to refer collectively to the full set of characteristics in this domain, recognizing that the number and nature of its distinct elements remain to be determined.

The idea that anger-related attributes may contribute to physical disease has a long prescientific history (Siegman, 1994). Scientific interest in this hypothesis accelerated rapidly following the emergence of evidence suggesting that anger and hostility may reflect the "toxic" elements of the Type A, coronary-prone behavior pattern (Matthews, Glass, Rosenman, & Bortner, 1977). Currently available evidence provides fairly consistent support for this notion, pointing to a possible prospective association between anger/hostility and coronary heart disease (CHD; e.g., Barefoot, Dahlstrom, & R. B. Williams, 1983; Barefoot, Dodge, Peterson, Dahlstrom, & R. Williams, 1989; see reviews by Helmers, Posluszny, & Krantz, 1994; Scheier & Bridges, 1995; T. W. Smith, 1992).

In addition to studies of coronary disease, there is research suggesting that anger-related personality traits may contribute to traditional coronary risk factors. For example, Siegler (1994) reviewed evidence indicating possible associations between trait hostility and cigarette smoking, serum lipid levels, and obesity. In addition, Suls et al. (1995) reported a meta-analysis that provides some support for a relationship between trait anger and essential hypertension. However, inconsistencies across studies, and methodological problems in studies reporting positive findings, argue against drawing firm conclusions at the present time regarding the association between anger/hostility and coronary risk factors. It would seem that, for the most part, relationships between hostility and coronary disease are mediated by mechanisms not re-

flected in measures of traditional risk factors, such as may be associated with physiologic responses to stress.

Support for an association between anger/hostility and health outcomes other than coronary disease is limited (Scheier & Bridges, 1995). However, there is evidence to suggest a significant relationship between hostility and non-CHD mortality (Almada et al., 1991; Shekelle, Gale, Ostfeld, & Paul, 1983). In addition, other prospective studies suggest an association between hostility and cancer mortality (Carmelli et al., 1991), general health (Adams, 1994; Cartwright, Wink, & Kmetz, 1995), and suicide, attempted suicide, and nontraffic accidents and deaths (Romanov et al., 1994). Cross-sectional studies have reported associations between hostility and such non-CHD health outcomes such as asthma severity (Silverglade, Tosi, Wise, & D'Costa, 1994) and disorders of endocrine function (Fava, 1994). Although these findings suggest that anger/hostility may contribute to several sources of morbidity and mortality, the data on coronary disease appear more consistent and robust than those for other outcomes (Scheier & Bridges, 1995).

Emotional Suppression/Repression

To an even greater degree than is the case for anger/hostility, "emotional suppression/repression" is a collection of seemingly conceptually related attributes whose number and nature have yet to be determined. Among the various distinctions that have been made within this domain are several that concern the emotion portion of the construct, for example, whether it is negative emotion in general, or anxiety or anger in particular, that is involved. Other distinctions concern that portion of the construct that has to do with the individual's coping response to or orientation toward negative emotion. For example, the term *repression* has sometimes been used in the technical, psychoanalytic sense to refer to an ego-defensive process whereby negative affect and associated thoughts are automatically removed from consciousness. By contrast, the term *suppression* has been used to refer to the deliberate, conscious, and effortful inhibition of negative affect and/or its expression. Other relevant constructs include denial (Lazarus, 1983), alexithymia (G. J. Taylor, 1984), conflict over emotional expression (King & Emmons, 1990), and inhibited power motivation (Jemmott, 1987). Although these attributes are in many cases conceptually distinct, and do not always show expected interrelationships (e.g., Newton & Contrada, 1994), the designation "emotional suppression/repression" is used as a general rubric in the discussion that follows except where greater specificity is required.

The notion that emotional suppression/repression may promote physical disease is contained in very early writings (see Siegman, 1994, for an overview). This idea overlaps with interest in anger/hostility in the form of the psychosomatic hypothesis linking anger suppression to essential hypertension (Alexander, 1930). A recent evaluation provided a degree of support for this hypothesis. In the Suls et al. (1995) meta-analysis cited earlier, the strongest evidence for an association between anger and resting blood pressure came from studies examining anger-related traits that involve not only a

tendency to experience anger, but also a reluctance to express such feelings. There is also evidence from the Framingham Heart study indicating that the tendency to suppress anger may operate as a CHD risk factor for women, though not for men (Haynes, Feinleib, Kannel, 1980).

In addition to work in the cardiovascular area, emotional suppression/repression has been examined in relation to cancer. Indeed, low emotional expressiveness is a key feature of a "Type C" behavior pattern that has been suggested as a possible cancer risk factor (Temoshok, 1987). Support for this notion has been obtained in quasi-prospective studies indicating less frequent expression of anger in breast biopsy patients later found to have malignancies (Greer & Morris, 1975; Jansen & Muenz, 1984). However, negative results also have been obtained in this area (e.g., Greer, Morris, & Pettingale, 1979), and there is some evidence linking increased expression of emotion to breast cancer (Greer & Morris, 1975). Other findings indicate a possible prospective association between emotional inexpressiveness and cancer incidence (e.g., Grossarth-Maticzek, Kanazir, Schmidt, & Vetter, 1982), but methodological considerations argue that this conclusion should be viewed guardedly, at best (Fox, 1978; Scheier & Bridges, 1995).

Disengagement

As noted earlier, Scheier and Bridges (1995) suggested that the term *disengagement* be used to refer collectively to a set of conceptually related attributes that include helplessness/hopelessness, pessimism, fatalism, and depression. Not all of these constructs are personality dispositions in the strict sense. Depending on how they are operationalized, they may show only modest levels of temporal stability, and often are measured in relation to specific situations. However, such context-specific person factors may reflect personality and, in any case, need to be taken into consideration to provide a more comprehensive theoretical account of psychosocial influences on physical disease.

One attribute that falls into this category is the pessimistic explanatory style, a tendency to attribute negative life events to internal, stable, and global causes. This construct was developed as a means of accounting for individual differences in the severity, generality, and duration of human responses to uncontrollable stressors (Peterson & Seligman, 1984). Pessimistic explanatory style has been linked to illness as reflected in self-report measures of health (Peterson, 1988), physician health ratings (Peterson, Seligman, & Vaillant, 1988), and shorter survival time in patients with coronary disease (Buchanan, 1995) and breast cancer (Levy, Morrow, Bagley, & Lippman, 1988).

Fatalism, like pessimism, involves negative expectations about future outcomes (Scheier & Bridges, 1995). These constructs bear a resemblance to helplessness/hopelessness, a passive orientation toward psychological stress that has been linked to poor cancer prognosis (Greer et al., 1979; Greer & Haybittle, 1990; Pettingale, Morris, & Greer, 1985). Scheier and Bridges (1995) suggested that "fatalism" may be a better label for a "realistic acceptance" construct that was impli-

cated as a factor producing shorter survival time among individuals with AIDS in a study reported by Reed, Kemeny, Taylor, Wang, and Visscher (1994). There is also evidence of an association between pessimism/fatalism and enhanced risk of complications from coronary artery bypass graft surgery (CABG; Scheier et al., 1989).

The term *depression* has been used to refer to depressive symptomatology, that is, self-reports of low self-satisfaction, psychological distress, vegetative symptoms, and somatic complaints, which should be distinguished from a formally diagnosed clinical disorder (Coyne, 1994). There is evidence linking depression to cardiovascular events such as myocardial infarction (MI), CABG, and stroke (Carney, Freedland, & Lustman, 1994; Wassertheil-Smoller et al., 1994), and depression may operate as an independent risk factor for death following an MI (Frasure-Smith, Lesperance, & Talajic, 1993; Ladwig, Kieser, & Konig, 1991). Research examining depression in relation to the progression of AIDS has yielded mixed findings, however, and studies attempting to demonstrate a relationship between depression and cancer have yielded predominantly negative results (Scheier & Bridges, 1995).

WHY DO CERTAIN INDIVIDUALS GET SICK?: PERSONALITY AND STRESS

Research reviewed in the previous section provides promising clues concerning the personality attributes of individuals who may be expected to become sick. Those attributes—tendencies toward anger/hostility, emotional suppression/repression, and disengagement—provide a tentative and partial answer to what is essentially an empirical question: "Who gets sick?" The question, "Why do individuals with certain personality attributes get sick?" addresses the issue of causal process. This chapter is concerned with health damaging processes associated with psychological stress.

Health-related processes most closely associated with stress involve pathogenic changes that are produced as a result of direct, *psychophysiological* responses to environmental events or conditions. Research conducted in the past few decades has shed considerable light on the psychophysiology of stress. Building on Cannon's (1925) seminal research on the sympathetic-adrenomedullary system, and that of Selye (1956) on the pituitary-adrenocortical system, there now exist fairly detailed models describing the effects of stress on neuroendocrine, cardiovascular, immunological, and other biological systems. There has also been substantial progress in the identification of pathways whereby these physiological effects may influence mechanisms involved in the etiology and pathogenesis of physical disorders (e.g., Herbert & Cohen, 1993; Krantz & Manuck, 1984). To the degree that personality influences the frequency, intensity, and/or duration of stress, the psychophysiological correlates of stress constitute a plausible mediator of the effects of personality on health.

It was noted earlier that, in addition to direct, psychophysiological influences on disease mechanisms, personality may promote disease through its effects on health behaviors,

and on reactions to illness. Health behaviors are those actions and inactions that affect the likelihood of injury or disease and include factors such as physical risk taking, diet, exercise, substance use, and the practice of unprotected sex. Reactions to illness are actions and inactions that occur in response to injury and sickness, and include factors such as the detection and interpretation of physical symptoms, the decision to seek medical treatment, adherence to medical regimens, responses to invasive medical procedures, recovery from acute illness, and adjustment to chronic disease. Whether psychological stress provides an explanation for observed associations between personality and either health behaviors or reactions to illness is often an open question in a given piece of research. However, health behaviors such as cigarette smoking and alcohol use have been conceptualized in terms of coping processes (e.g., Abrams & Niaura, 1987), as have the processes involved in monitoring the signs and symptoms of disease and managing illness (Contrada, E. Leventhal, & Anderson, 1994; Miller, Shoda, & Hurley, 1996). In addition, both health behaviors and reactions to illness often must be considered as alternative explanations for personality disease linkages that appear to involve the direct physiological effects of psychological stress (Watson & Pennebaker, 1989). Thus, for both theoretical and methodological reasons, findings that bear on the behavioral pathways to illness are highly germane to the present discussion.

This section begins by describing the major constructs involved in psychological stress theory. This sets the stage for an analysis of the pathways whereby personality may promote stress and its health damaging effects. The section concludes with a discussion of some of the evidence linking anger/hostility, emotional suppression/repression, and disengagement to measures that may reflect health damaging processes associated with psychological stress.

Conceptual Elements of Psychological Stress and Coping

As in the case of personality, conceptual issues surrounding the stress construct have been subject to considerable discussion and debate (Lazarus, 1966; Lazarus & Folkman, 1984; Mason, 1975; Selye, 1975). Concerns about the scientific status of the stress concept have led to suggestions that the term *stress* be abandoned or limited to a nontechnical usage to refer to a general topic or area of study. Nonetheless, scientific interest in stress has endured, and the concept obviously serves a useful purpose, albeit often at a rather general level of analysis. The following discussion focuses on major conceptual categories rather than attempting to present a detailed review of issues and controversies.

Stressors

Stressors are events or conditions that are demanding, challenging, or constraining in some way. Among types of stressors that have received intensive study are calamitous events such as natural and technological disasters (e.g., Baum, Co-

hen, & Hall, 1993); major life changes such as marriage, divorce, and bereavement (Holmes & Rahe, 1967); minor events such as the daily "hassles" of living (Kanner, Coyne, Schaefer, & Lazarus, 1981); and chronic conditions such as occupational stress (Karasek, Baker, Marxer, Ahlbom, & Theorell, 1981), crowding (Baum & Valins, 1977), and marital conflict (Kiecolt-Glaser et al., 1987). The designation of events and conditions as stressors is probabilistic in the sense that their occurrence may or may not precipitate a stress response. Whether or not this occurs is thought to reflect the operation of psychological processes discussed next.

Appraisal

The concept of *cognitive appraisal* has been discussed at length by Lazarus (1966; Lazarus & Folkman, 1984). It refers to an automatic, cognitive-evaluative process whereby events and conditions are judged with respect to their relevance to physical and psychological well-being. Primary appraisal involves an evaluation of harm or loss that has already been sustained or is threatened. Secondary appraisal involves an evaluation of available strategies and resources for managing the problem and its effects on the person. Stressful appraisals include harm/loss (damage has already been sustained), threat (damage appears likely), and challenge (threat accompanied by the possibility of growth or gain). They arise when individuals perceive that circumstances tax or exceed their adaptive resources (Lazarus & Folkman, 1984).

Problem Representation

Leventhal and associates (e.g., H. Leventhal, Meyer, & Nerenz, 1980) used the term *problem representation* to describe the initiating psychological event in the stress process. Closely related to the notion of cognitive appraisal, problem representation refers to the creation of a mental structure that characterizes the stressor in terms of specific attributes. For example, a physical symptom constitutes a health threat depending on how it is construed by the person. Relevant attributes include its label (e.g., cancer), causes (e.g., smoking), consequences (e.g., death), and time line (e.g., slowly worsening), and form part of a conceptual problem space that defines the health threat. Other features of the problem space include propositions representing specific actions that may cure the disorder or minimize potential damage, such as health care seeking or self-medication. This sort of feature analysis presumably accompanies and follows the appraisal process (Lazarus, 1966). Thus, the concept of problem representation may be used to refer broadly to the set of psychological processes whereby the individual encodes a stressor by developing a cognitive-affective structure. That structure includes features corresponding to attributes of the stressor and of possible coping strategies, and is associated with an appraisal of the significance of the stressor for physical and/or psychological well-being.

Details of appraisal and problem representation have at least two major consequences for subsequent phases of the

stress process: They influence the quality and intensity of the ensuing emotional response, and guide the selection of procedures for coping with the stressor (Lazarus, 1991). For example, depending on specific features of perceived threat, harm, or loss, the individual may experience anger, fright, or sadness. In addition, it is the stressor as perceived by the individual, and the emotional reaction that arises from that perception, that influence the subsequent selection of coping procedures aimed at managing the situation. Because emotional and behavioral responses to stressors are accompanied by potentially pathogenic physiological changes, can involve disease promoting behaviors, and may affect the interpretation and response to physical symptoms and illness, it follows that the processes of cognitive appraisal and problem representation that mediate those responses are critically involved in the putative health damaging effects of stress.

Response Generation: Coping and Automatic Self-Regulation

Coping refers to effortful cognitive and behavioral activity that is aimed at managing either the stressor or its effects on the person (Lazarus & Folkman, 1984). Numerous coping strategies have been identified in stress research, and a broad distinction has been drawn between two forms of coping that have come to be referred to as *problem focused* and *emotion focused* (Lazarus, 1966; Mechanic, 1962). Problem-focused coping involves strategies aimed at altering the situation that gave rise to the stress appraisal, such as planning, information-seeking, and efforts at mastery. Emotion-focused coping involves strategies aimed at managing subjective responses to stressors, such as suppression of negative affect, distraction, and minimization. Alternative coping classifications also have been suggested in which additional, major classes of coping activity are distinguished from problem- and emotion-focused coping, such as avoidance strategies (Dunkel-Schetter, Feinstein, Taylor, & Falke, 1992) and relationship-focused coping (Coyne & Downey, 1991).

Not all cognitive and behavioral responses to stressors reflect coping. Lazarus and Folkman (1984) used the term coping to refer to activity that is conscious, deliberate, and effortful. Exposure to stress may elicit other, more automatic responses that, like coping, may play a role in determining how the stressful encounter is resolved. Examples of such automatic responses include motor patterns involved in the expression of emotion through facial movements (Tomkins, 1962) or vocal tone (Scherer, 1986), processes involved in the inhibition of communication between brain centers involved in emotion and language (Davidson, 1984), and ego-defense mechanisms such as repression (Haan, 1977). Rather than a categorical distinction, the difference between coping, and what might be referred to as more *automatic self-regulation*, may be conceptualized in terms of a continuum involving differences in the degree to which the activity is mediated by verbal-propositional cognition as opposed to schematic cognitive processing, or, at a more rudimentary level, reflex circuits.

The Stress Response

Stress may be manifested in many ways. Coping and the more automatic self-regulatory responses already discussed represent one set of stress manifestations. However, the term *stress response* is usually used to refer to indicators that reflect the negative impact or adaptive cost of stressful transactions. These responses may be characterized as falling within several broad domains, namely, subjective experience, cognitive functioning, emotional expression, physiological activity, and instrumental behavior (Baum, Grunberg, & Singer, 1982).

The stress response also may be viewed at a social level of analysis. Psychological stress can cause strain and conflict in interpersonal relationships, undermine group cohesion, and disrupt the functioning of organizations and institutions. Transactional approaches to stress point to the potential importance of the interplay between individual and social level stress processes. An individual may employ coping strategies whose effects on the social and physical environment have implications for future stress. Coping activity may eliminate, moderate, create, maintain, or exacerbate social level stressors (T. W. Smith, 1989), or it may enhance or diminish the social resources available to support subsequent coping efforts (Hobfoll, 1989).

The Personality–Stress Interface

The diagram in Fig. 4.1 depicts a framework that integrates the key conceptual elements implied by the personality and stress constructs. This chapter is concerned with the four major pathways whereby personality structure may influence the stress process. The reader is referred elsewhere for discussion of other aspects of the model (Contrada, 1994; Contrada et al., 1990) and of self-regulation principles on which the model is based (e.g., Carver & Scheier, 1981).

Stressor Exposure

There are several processes whereby personality may influence exposure to stressors. Three general mechanisms through which individuals determine the amount of contact they have with particular types of environmental settings were referred to by D. M. Buss (1987) as selection, evocation, and manipulation. Selection involves choosing whether or not to enter particular environments. By contrast, evocation and manipulation refer to the person's impact on the environment once it has been entered. In the case of evocation, attributes of the person elicit or provoke responses from the physical or social environment unintentionally, whereas manipulation entails intentional efforts to alter, create, or otherwise modify the environment. A fourth way a person can influence exposure to stressors is to prolong or shorten the length of stay in demanding situations.

Several personality attributes may promote disease, at least in part, by increasing exposure to stressful situations. There is evidence, for example, that Type A individuals hold demanding achievement-related goals for themselves, which

may encourage them to take on difficult tasks (Matthews, 1982; Snow, 1978). Type As also prolong exposure to uncontrollable stressors they cannot master rather than relinquishing control to more competent others (S. M. Miller, Lack, & Asroff, 1985). Depressives elicit negative reactions from others (Coyne, 1976), and a similar process may work to increase the amount of interpersonal stress experienced by hostile individuals (T. W. Smith, 1989). There is also evidence that neuroticism increases exposure to life stressors (Bolger & Schilling, 1991; Bolger & Zuckerman, 1995). Beyond exerting an influence on the amount of stress a person experiences, the regulation of environmental exposures may reinforce and sustain the underlying personality structure, and reduce the availability of coping resources such as social support (T. W. Smith, 1989), thereby transforming both the person and the environment in a health damaging way.

Appraisal and Problem Representation

The notion that personality shapes the perception of potentially stressful situations is an important component of the theory surrounding most personality attributes suspected of influencing susceptibility to disease. Given exposure to a particular environmental demand or constraint, psychological structures associated with health protecting personality char-

acteristics presumably operate so as to decrease the probability of a stress appraisal and, under the same conditions, health damaging attributes would be expected to increase the probability of a stress appraisal. Effects on stressor appraisal may account for a significant portion of the influence of personality on individual differences in the stress response.

Certain health-related personality traits are explicitly conceptualized in terms that point to linkages to appraisal and problem representation. For example, one component of hardiness (Kobasa, 1979) is a tendency to perceive life change as a challenge rather than a threat. Another component, internal locus of control, involves the belief that factors influencing the outcomes an individual experiences reside within the person, and are therefore at least potentially controllable. Thus, these dispositions show close conceptual relations to the appraisal process. Similarly, it is reasonable to posit an association between the generalized expectation for positive outcomes that characterizes optimistic individuals and a tendency to form stress dampening appraisals of demanding situations (Scheier & Carver, 1985). With respect to health damaging attributes, the pessimistic attribution style is likely to promote negative appraisals of life events (Peterson, 1988), and the cynical beliefs of hostile individuals are plausibly associated with stress inducing appraisals in the interpersonal domain (T. W. Smith, 1992).

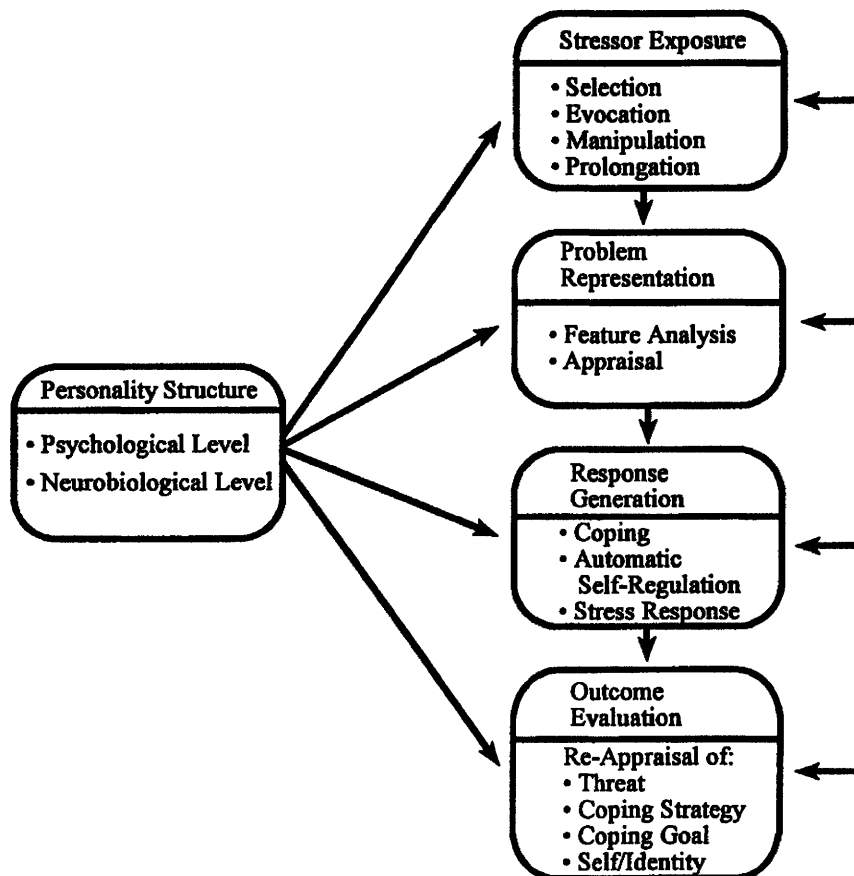

FIG. 4.1. Personality structures may influence each of four main elements of the stress process.

For other health-related attributes, associations with factors involved in the generation of emotional responses are less obvious. For example, the Type A behavior pattern was originally defined in terms of overt behavior, with little explicit reference to the appraisal process. However, subsequent analyses have suggested cognitive elements likely to influence the perception of stressors (e.g., Watkins, Fisher, Southard, Ward, & Schechtman, 1989). For certain emotion-related personality characteristics, such as the repressive coping style, it has been suggested that negative emotional reactions are themselves a source of threat in stressful circumstances (Newton & Contrada, 1992). In other words, after an environmental challenge or demand initiates a stress response, the repressive individual becomes anxious or upset, and this emotional reaction generates an additional threat appraisal because it conflicts with a desire to maintain emotional self-control.

Response Generation

Several health-related personality attributes have been explicitly conceptualized as coping styles, that is, characteristic tendencies to employ certain coping strategies in response to certain types of stressors. For example, according to Glass' (1977) uncontrollability model, the Type A, coronary-prone behavior pattern reflects vigorous efforts to master potentially uncontrollable stressors. Similarly, John Henryism, a possible risk factor for hypertension, has been defined as a tendency to cope actively with psychological stressors (James, 1994). At the level of definition, Type A behavior and John Henryism involve problem-focused coping styles, although both also appear to entail elements of stoicism that may influence emotion-focused coping. By contrast, other potentially health-related personality attributes are explicitly identified with emotion-focused coping, such as the cancer prone, Type C behavior pattern (Temoshok, 1987), anger-in (Spielberger et al., 1985), and repressive coping (Weinberger et al., 1979). Note that despite use of the term *coping* in the designations of several of these personality dispositions, it is in most cases an open question as to whether they involve coping in the sense of conscious, effortful, and deliberate activity, as opposed to more automatic responses to stressors.

Other health-related personality attributes are not defined as coping styles, but have been linked to coping styles. For example, as a belief structure, optimism cannot be equated with coping, but it has been shown to correlate with the use of particular coping strategies (e.g., Scheier et al., 1989). Similarly, trait hostility, which is also thought to involve a cognitive-affective structure, as distinct from being a coping style per se, has been associated with an antagonistic style of coping with interpersonal stressors (T. W. Smith, 1992).

Outcome Evaluation

Because outcome evaluation is a critical component of self-regulation (Carver & Scheier, 1981), it likely to be useful for understanding the effects of health-related personality characteristics. As the person responds to a stressor and engages in coping activity, information becomes available that

may provide a basis for modifying the problem representation. There may be changes in the perceived severity of the threat, the expected efficacy of the initial coping strategy, coping goals (e.g., managing the problem vs. managing subjective reactions), and self-perception. The relationship between personality and outcome evaluation has received less explicit attention than the exposure, appraisal, and coping pathways depicted in Fig. 4.1.

Outcome evaluation does play a role in several models of Type A behavior. For example, Matthews (1982) hypothesized that the excessive achievement striving of Type A individuals might reflect their efforts to satisfy very demanding and ambiguous evaluative standards. Scherwitz, Berton, and H. Leventhal (1978) also discussed the possibility that certain aspects of Type A behavior might reflect heightened attention to discrepancies between their accomplishments and achievement-related goals. In a somewhat different approach, Strube (1987) suggested that the behavior of Type A individuals may reflect not so much a desire to satisfy high evaluative standards, but a desire to generate diagnostic information that would clarify their performance levels vis-à-vis those standards.

Outcome evaluation has also been implicated in theoretical models involving personality attributes other than Type A behavior. Scheier and Carver (1985) discussed the role dispositional optimism may play in the feedback process whereby individuals evaluate their progress toward important goals, and have outlined the consequences of this process for the degree to which they remain actively engaged in the coping process. It is also possible that cynical attitudes associated with trait hostility increase stress by influencing the evaluation of coping outcomes in the interpersonal domain (Contrada, 1994; T. W. Smith, 1992). The hostile individual may cope with potential interpersonal conflict by scrutinizing the behavior of others in order to determine their intentions. The hostile person's cynical attitudes may subsequently bias the interpretation of those behaviors, leading to the false conclusion that vigilance has successfully uncovered hostile motives, when other, more benign motives may actually be operating. Cynical interpretations might also lead the hostile individual to express anger in the form of communication style or overt aggression, which may be reciprocated in kind, thereby providing further "confirmation" of initial inferences about hostile motives. Thus, positive evaluations of coping strategies that are premised on false assumptions regarding the motives of others may be an important element of processes whereby hostility increases interpersonal stress.

Promising Personality Risk Factors and Health Damaging Processes

Earlier it was noted that both epidemiologic and process-oriented research will be required to develop and strengthen the case for a causal connections between personality and health. This section discusses the three promising personality risk factors—namely, anger/hostility, emotional suppression/repression, and disengagement—in relation to markers for stress-related, disease promoting processes. In

each instance, the personality disposition is discussed first in relation to stress-related, potentially pathogenic psychophysiological activity, and then in relation to health- and illness-related behavior.

Anger/Hostility

Physiological Responses to Stressors. Cardiovascular and hormonal concomitants of anger and aggression have been the subject of study for quite some time (e.g., Ax, 1953; Funkenstein, 1956). Early research in this area was thought to have significance for understanding the development of essential hypertension and coronary disease, but the empirical observations that resulted were not highly consistent and the work was characterized by a number of conceptual and methodological problems (for a review and critique, see Diamond, 1982). More recently, this literature has come to exhibit some degree of coherence and methodological rigor, as well as a grounding in epidemiological findings, largely as a consequence of research on Type A behavior.

At the time that early psychophysiological studies of Type A were conducted, hostility was thought to be but one facet of a larger, coronary prone behavior pattern that also involved competitiveness, achievement striving, and time urgency. As a result, for many studies, it is not possible to determine whether anger-related or nonanger-related attributes were responsible for associations between global Type A assessments and physiologic responses to stressors. In other cases, it is unclear whether anger-instigation was the active ingredient in the stressors that were employed (for a detailed review of these studies, see Wright, Contrada, & Glass, 1985). More recent epidemiologic findings pointing to hostility as the most health damaging component of Type A behavior now make it clear that it would be of use to be able to distinguish the specific contribution of anger-related attributes and stressors in these earlier studies. Nonetheless, it is of interest to note that there does appear to be a reliable association between global Type A behavior and cardiovascular responses to laboratory stressors that may be related to processes involved in the etiology and pathogenesis of coronary disease (Lyness, 1993).

A more specific linkage between anger-related attributes and cardiovascular reactivity to stressors developed out of two research strategies employed in early Type A studies. One involved the use of experimental manipulations designed to isolate anger-instigation from other demands and challenges (Glass et al., 1980). The other involved the use of assessment tools, most notably component analysis of Type A structured interviews, which make it possible to differentiate psychophysiological correlates of anger-related and nonanger-related personality attributes (Dembroski, MacDougall, Shields, Petitto, & Lushene, 1978). There subsequently emerged a convergence between findings generated by epidemiological and psychophysiological research: Anger-related attributes that appeared to account for enhanced coronary risk among Type A individuals (e.g., Williams et al., 1980) also appeared most strongly associated with cardiovascular and other physiologic responses to

stressors, which could account for the epidemiologic findings (e.g., Houston, 1988).

Currently available findings continue to support the hypothesis that anger-related personality attributes are associated with heightened cardiovascular responses to laboratory stressors. Based on a meta-analysis, Suls and Wan (1993) concluded that an antagonistic interpersonal style appears related to enhanced systolic and diastolic blood pressure responses to stressors containing elements likely to provoke anger. There was also evidence, albeit less consistent, suggesting that cynical hostility is associated with heightened diastolic blood pressure responses to anger provocation. These findings accord with results of a programmatic series of studies involving an animal model of coronary disease. Cynomolgus monkeys that exhibit heightened cardiac responses to psychosocial stressors have been found to be more behaviorally aggressive than less reactive animals, and research involving pharmacological blockade suggests that cardiac activity may mediate the relationship between aggressiveness and coronary disease in these monkeys (Manuck, Marsland, Kaplan, & J. K. Williams, 1995).

Thus, a convergence of findings from epidemiological and psychophysiological research strongly suggests that anger-related attributes increase risk for coronary atherosclerosis through effects on stress-related physiological processes. There is also reason to suspect that anger-related personality attributes are related to stress-related reductions in immune competence, which may increase risk for noncardiovascular diseases. Kiecolt-Glaser et al. (1993) demonstrated that, relative to other married couples, married couples who were hostile or negative during a discussion of marital problems showed greater reductions on four measures of immune function. Other findings indicated that the same couples had diminished immunological control of the Epstein-Barr virus.

Behavioral Responses to Stressors. It was noted earlier that there are some suggestions of a linkage between trait hostility and CHD risk factors that either are behaviors or are partially behaviorally determined, such as cigarette smoking, serum lipid levels, and obesity (Siegler, 1994). Other health-related behaviors associated with trait hostility include low levels of physical activity, poor dental hygiene, poor sleep habits (Koskenvuo et al., 1988; Leiker & Hailey, 1988), and greater alcohol use (Houston & Vavak, 1991; Koskenvuo et al., 1988; Leiker & Hailey, 1988; Shekelle et al., 1983). As T. W. Smith (1992) pointed out, however, these findings are mainly descriptive in nature. Although they suggest that hostility may endanger health as a consequence of its behavioral correlates, they do not indicate whether these behaviors reflect coping efforts, are in some other way related to psychological stress, or come about entirely as a consequence of nonstress-related processes.

The situation is similar with respect to health-related behaviors that represent reactions to illness. Findings have been reported that suggest an association between trait hostility and noncompliance with chemotherapy among breast cancer patients (Ayres, Hoon, Franzoni, Matheny, & Contach, 1994), with use of medication among hypertensives (Lee et

al., 1992), and with an exercise rehabilitation program among cardiac patients (Digenio, Padayachee, & Groeneveld, 1992). Hostility also has been linked to slower recovery from physical trauma (K. E. Glancy et al., 1992) and a greater likelihood of experiencing cardiac symptoms among patients recovering from cardiac surgery (Jenkins, Stanton, & Jono, 1994). Further research is needed to determine whether these findings are best conceptualized as reflecting responses to stressors associated with being sick and undergoing treatment, involve stress not directly related to illness, or represent aspects of anger-related personality attributes that are unrelated to stress.

Emotional Suppression/Repression

Physiological Responses to Stressors. The psychophysiological literature on personality attributes involving suppression, repression, and other avoidant orientations toward emotion has not yielded a highly consistent pattern of findings. In part, this reflects the fact that research in this area is rather heterogeneous with respect to conceptual orientation and measurement approach. For example, in the cardiovascular area, suppression/repression typically has been studied in relation to anger. By contrast, in other applications, suppression/repression has been conceptualized in relation to anxiety, distress, or other negative emotions and impulses. In addition to this distinction, there are various other methodological factors that make it difficult to evaluate evidence concerning style of emotional expression and physiologic responsiveness to stress (Diamond, 1982; Engebretson, Matthews, & Scheier, 1989; Suls & Wan, 1993).

Despite conceptual and methodological difficulties, some tentative empirical generalizations in this area may be suggested. One is that nonexpression of anger and other negative emotions may be associated with heightened physiologic reactivity to stressors. Note that this evidence is not based on self-report measures such as the Anger-Expression scale (Spielberger et al., 1985), in which respondents are explicitly asked whether they tend to keep anger in (Houston, 1994; Siegman, 1994). Rather, research suggesting that failure to express anger may be associated with disease promoting physiologic responses has involved variations on an indirect measurement strategy introduced by Weinberger et al. (1979) as a means of assessing what they referred to as a repressive coping style. Repressive copers are identified as individuals with low scores on a measure of trait anxiety, such as the J. A. Taylor (1953) Manifest Anxiety Scale, and high scores on a disguised measure of defensiveness, the Marlowe-Crowne social desirability scale (Crowne & Marlowe, 1964; for a discussion of the rationale and construct validity of this assessment approach, see Weinberger, 1990). A series of studies employing this assessment approach has demonstrated that repressive copers show high levels of autonomic reactivity to various laboratory stressors (Asendorpf & Scherer, 1983; Kohlmann, Singer, & Krohne, 1989; Newton & Contrada, 1992; Weinberger et al., 1979).

Procedures for measuring repressive coping have been adapted by researchers interested in the cardiovascular effects of the suppression/repression of anger. Siegman, Ander-

son, and Boyle (1991) found that subjects with low trait anger scores and high Marlowe-Crowne scores exhibited greater heart rate responses to a serial subtraction task accompanied by harassment than "truly" low anger subjects with low scores on both measures. Using a somewhat different approach, Jamner, Shapiro, Goldstein, and Hug (1991) administered the Cook-Medley hostility scale (Cook & Medley, 1954) and Marlowe-Crowne social desirability scale to paramedics who underwent ambulatory blood pressure monitoring during the course of their workday. By contrast with the Siegman et al. (1991) study, Jamner et al. found that the combination of defensiveness (as reflected by high Marlowe-Crowne scores) and *high* levels of the anger-related trait, in this case, Cook-Medley hostility, was associated with cardiovascular responsiveness. The same conclusion is supported by results of a laboratory study reported by Helmers and Krantz (1994). High scores on both the Marlowe-Crowne and Cook-Medley scales, a pattern labeled "defensive hostility," identified men showing greater systolic and diastolic blood pressure responses to two laboratory stressors.

Recently, Helmers et al. (1995) utilized the defensive hostility construct in a study of individuals with coronary artery disease. It was found that patients characterized by this personality pattern showed more severe myocardial ischemia in response to an exercise test, more frequent ischemic episodes during daily life activities, and more severe ischemia in response to two laboratory stressors, by comparison with patients with other personality score combinations. Taken together with results reported by Jamner et al. (1991) and Helmers and Krantz (1994), the Helmers et al. (1995) findings suggest that cardiovascular responsiveness to stressors may exacerbate ischemic heart disease in coronary patients high in defensive hostility.

Other research suggests that the *expression* of anger is associated with heightened physiological reactivity. It was noted earlier that, in the meta-analysis conducted by Suls and Wan (1993), an antagonistic interpersonal style was found to be reliably associated with heightened blood pressure reactivity to anger provocation. Because antagonistic interpersonal style reflects the overt display of hostility during a structured interview (Dembroski et al., 1978), these results suggest that anger expression is associated with physiologic responses to interpersonal stressors that may promote cardiovascular disease. More recently, Siegman (1994) came to a similar conclusion, based both on correlational research involving trait measures of the expression of anger and experimental studies involving manipulations of paraverbal behaviors (e.g., loud and rapid speech) associated with the expression of anger.

Thus, both the suppression/repression and expression of anger/hostility have been implicated as correlates of stress-induced physiological responses that may promote cardiovascular disease. A detailed consideration of the conceptual and methodological factors that might reconcile these seemingly contradictory findings is beyond the purview of this chapter (for relevant discussions, see Houston, 1994, and Siegman, 1994). However, it is worth noting briefly the results of a study by Engebretson et al. (1989) in which some of these

issues were addressed. Support was obtained for a matching hypothesis according to which it is not the person's anger-expression style per se that determines the intensity of cardiovascular responsiveness, but the degree of match between the person's preferred mode of anger expression and the opportunity to employ that mode of expression in the anger provoking situation. Subjects who characteristically hold their anger in showed decreased cardiovascular reactivity when required to write a positive evaluation of an annoying confederate, but not when required to write a negative evaluation. Subjects who characteristically express their anger showed the opposite pattern of response. These findings suggest that, among other factors that may account for inconsistencies regarding the cardiovascular correlates of anger expression, the degree of fit between anger-expression style and situational demands and constraints warrants further study.

Before leaving the topic of physiological correlates of anger suppression/repression, some findings involving measures of immune function should be mentioned. There is evidence linking trait measures of repression or defensiveness to low monocyte counts (Jamner, Schwartz, & Leigh, 1988) and to low immunological control of latent Epstein-Barr virus (Esterling, Antoni, Kumar, & Schneiderman, 1990, 1993). There is also evidence to suggest that individuals who show low levels of emotional disclosure during the course of writing about traumatic life experiences also show lower levels of immune competence (Esterling et al., 1990; Pennebaker, Kiecolt-Glaser, & Glaser, 1988). These findings argue for further efforts to determine whether stress-induced immunosuppression may be a pathway linking suppressed/repressed emotion to negative health outcomes.

Behavioral Responses to Stressors. There is little research directly examining the possibility that emotional suppression/repression is associated with health damaging behavioral responses to stressors. It is possible that linkages between trait anger/hostility and health damaging behaviors reviewed earlier (e.g., Siegler, 1994) reflect or are qualified by the manner or degree of anger expression, but anger-related measures used in this research do not allow such a determination. It is also possible that the tendency to suppress or to repress anger and other negative affects is part of a more general, avoidant coping style in which threatening events and associated emotional responses are minimized. If so, emotional suppression/repression may promote disease through behavioral processes that involve failure to seek information about health threats, failure to cope with them by taking direct action, or both (S. M. Miller et al., 1996; Suls & Fletcher, 1985). However, here again, there is a need for measurement-oriented research to clarify the behavioral correlates of personality attributes involving the degree and manner of emotional expression.

Disengagement

Physiological Responses to Stressors. Attributes falling in the disengagement cluster have been linked to bio-

logical measures that may reflect responses to psychological stress. For example, there is evidence that clinical depression is associated with elevations in both pituitary-adrenocortical and sympathetic-adrenomedullary activity (Esler et al., 1982; Siever & Davis, 1985; Roy, Pickar, De Jong, Karoum, & Linnoila, 1988). In addition, parasympathetic (vagal) tone, which can modulate the cardiovascular effects of sympathetic activation, is lower in depressed individuals (Balogh, Fitzpatrick, Hendricks, & Paige, 1993; Carney et al., 1988). Thus, it is possible that depression exerts a health damaging effect, particularly with respect to heart disease, as a consequence of stress-related physiological mechanisms (Carney, Freedland, Rich, & Jaffe, 1995).

There is also reason to believe that disengagement can influence health through effects on the immune system. Kamen-Siegel, Rodin, Seligman, and Dwyer (1991) reported an association between the pessimistic attributional style and lower cell-mediated immunity. More recently, Herbert and Cohen (1993) conducted a meta-analysis that provides evidence of a strong and consistent relation between clinically significant depression and three parameters of immune competence, namely, lower proliferative response of lymphocytes to mitogens, lower natural killer cell activity, and alterations in numbers of several types of white blood cells. There was also evidence that depressed mood in nonclinical populations is associated with lower functional immunity. The meta-analysis did not address the mechanisms that account for the linkage between depression and immunity. One set of plausible mechanisms discussed by Herbert and Cohen (1993) involves the link between depression and neuroendocrine mechanisms mentioned earlier.

Behavioral Responses to Stressors. Attributes falling in the disengagement cluster may produce health damaging effects as a consequence of behavioral responses to psychological stress. For example, the pessimistic explanatory style has been associated with poor health habits, such as cigarette smoking, excessive alcohol use, and low exercise levels (Peterson, 1988), and with behaviors reflecting poor management of illness, such as failure to increase fluid intake and to get adequate bed rest (Peterson, Colvin, & Lin, 1992). Herbert and Cohen (1993) noted that altered immune function in depressives might reflect behavioral correlates of depression, such as inadequate sleep, low levels of exercise, poor diet, cigarette smoking, and alcohol and drug use. Depression also has been associated with low levels of compliance with various medical regimens (e.g., Blumenthal, R. S. Williams, Wallace, R. B. Williams, & Needles, 1982; Eisen, Hanpeter, Kreuger, & Gard, 1987; Guiry, Conroy, Hickey, & Mulcahy, 1987). As with anger/hostility and emotional suppression/repression, it is not clear whether these behaviors are best conceptualized as a reflection of stress-related processes.

CONCEPTUAL AND METHODOLOGICAL ISSUES

Research reviewed in this chapter suggests possible relationships between personality attributes falling in three domains

—anger/hostility, emotional suppression/repression, and disengagement—and both physiological and behavioral pathways to physical disease that may involve responses to psychological stress. However, support for this hypothesis is not entirely consistent. Even with the focus in this chapter on research reporting positive associations, methodological problems and the small numbers of available studies provide reason to view the findings with caution. Perhaps the most appropriate overall conclusion to draw at the present time is that the evidence supports the plausibility of the personality–stress–disease hypothesis.

Research on personality, stress, or health poses many conceptual and methodological difficulties. The additional challenges that emerge from efforts to establish linkages across these three domains can be daunting. This section discusses some of the more salient issues and attempts to identify theoretical perspectives and methodological strategies that may prove fruitful in this endeavor. These issues are grouped into two general categories, namely, those concerned with units of analysis in personality, and those concerned with establishing linkages with health-related processes.

Units of Analysis in Personality and Their Measurement

Research suggests a number of observations regarding personality units that appear to warrant further examination as possible risk factors for physical disease. The following are three of the more salient observations:

1. *Content*: The tendency to experience negative emotions is strongly implicated as a personality domain that is relevant to stress and health.
2. *Structure*: The breadth and complexity of the behavior patterns associated with promising personality attributes remain unresolved.
3. *Context relevance*: Relations between health-related personality attributes and relevant factors in the social and physical environment have yet to be adequately explored.

Content

Perhaps the clearest theme to emerge from this chapter is that all three promising personality risk factors involve negative emotion. Thus, as pointed out previously (e.g., Contrada et al., 1990), descriptions of health damaging personality attributes have changed little since the theory of temperaments was put forth by Hippocrates and Galen. This observation agrees with conclusions based on previous reviews (e.g., Friedman & Booth-Kewley, 1987), and it is, perhaps, unsurprising, given long-standing and well-documented linkages between negative emotions and biological responses to stressors that have been implicated in the production of disease (Cannon, 1925; Mason, 1975). Several implications may be drawn from this observation.

One implication of the central role of emotion in health-related personality attributes is that it underscores the need for

greater clarification of the statistical structure of affective trait measures. This issue, and the related issue of statistical structure of state affect measures, have received considerable attention, but a consensus has yet to emerge. The matter is often framed as a choice between two alternatives, one pointing to a set of five to seven qualitatively distinct affects (e.g., Ekman, 1992), and another to a two-factor space involving separable dimensions of positive and negative affect (e.g., Watson, Clark, & Tellegen, 1984). A structural model of affect also has been described that integrates these two perspectives (e.g., Diener & Fujita, 1995). Many of the studies reviewed here involved a single measure of a particular emotional trait; less frequently, a nonspecific measure (e.g., “neuroticism”) was used. Both approaches permit only limited inferences regarding the contribution of emotion-related personality to health outcomes. It would seem useful for future studies examining the relation between emotional traits and physical health to include measures representing both dimensional and discrete emotions perspectives.

Another suggestion that might be taken from the salience of emotion in health-related personality attributes, and one that appears to be promising, is the potential utility of working backward from experienced and overtly manifested emotion to the personality structures and processes that might constitute its determinants. As noted earlier, many theories of emotion (e.g., Lazarus, 1991) emphasize cognitive processes, such as appraisal and problem representation, in the production of emotional states. Of the personality attributes discussed in this chapter, the concept of pessimistic explanatory style is arguably most explicit in attending to cognitive process, given its focus on the attributions that individuals generate to account for negative experiences. Cognitive factors also have received extensive examination in accounts of depression (e.g., Coyne & Gotlib, 1983), and Scheier and Bridges (1995) discussed the potential for processes involved in setting and evaluating progress toward goals to account for behavioral and emotional responses in individuals characterized by depression, fatalism, and pessimism. Similar analyses of anger/hostility (Contrada et al., 1990) and emotional suppression (Newton & Contrada, 1992) also have been described. A better understanding of the cognitive structures and processes underlying emotion-related dispositions should lead to improvements in the measurement of those constructs and to more detailed models of the interface between personality and stress.

Whatever the structure of emotional traits and the cognitive determinants of personality-related emotional reactions, there is ample evidence to indicate that expressive behaviors play a major role in the subjective experience (Izard, 1990), physiologic concomitants (Siegman, 1994), and interpersonal consequences (Gottman & Levenson, 1986) of emotion. However, although the items on conventional trait measures of negative emotions tap into expressive and interpersonal aspects of emotion, they do not necessarily provide optimal assessments of those factors. Conceptual analyses and multivariate methods have only recently begun to identify coherent facets of emotional traits such as anger/hostility (Barefoot et al., 1989; A. H. Buss & Perry, 1992; Contrada &

Jussim, 1992; T. Q. Miller et al., 1995), a step that is prerequisite to efforts to establish the relative contributions of experiential versus expressive components. It remains to be seen whether paper-and-pencil measures will be adequate to the task, or whether it will be necessary to supplement these with direct observations of vocal, facial, and other behavioral responses to actual, emotion provoking situations (e.g., Dembroski et al., 1978; Seigman, 1994).

Still another implication of the central role of emotion in health-related personality characteristics is the potential for confounding that arises in research that involves subjective measures of physical health (Watson & Pennebaker, 1989). Negative affectivity, or neuroticism—a tendency to experience and to express distressing emotions and other negative states—may contribute both to scores on emotion-related personality attributes, and to responses on symptom checklists, use of health care, and medical diagnoses that reflect patient complaints. The result may be a correlation that is spurious in the sense that it does not reflect a direct, physiologically mediated association between personality and the etiology or progression of a disease process. On the other hand, such an association may be of considerable substantive interest as an instance in which personality contributes to illness or illness management through behaviorally mediated processes involving symptom detection and control. Thus, further examination of negative affectivity in producing associations between personality and health should be directed toward elucidating the mechanisms, both artifactual and substantive, that may bring about such linkages (T. W. Smith & P. G. Williams, 1992).

Structure

The study of personality and health has at different times and for different purposes focused on both broadly and narrowly defined personality attributes. This is well illustrated by the history of research in the Type A area. What began as a multifaceted but coherent pattern consisting of competitiveness, achievement striving, time urgency, hostility, and vigorous speech and motor mannerisms was dissected into its constituent elements (Dembroski et al., 1978). One of those elements—hostility—was then identified as the most promising predictor of coronary disease. Subsequently there have been efforts to resolve hostility into still more circumscribed facets. Several componential schemes of hostility have been proposed, including one distinguishing between antagonistic interpersonal style, hostile content, and anger-in (Suls & Wan, 1993), and one involving cynicism, hostile affect, and hostile attributional style (Barefoot et al., 1989). Conversely, attempts also have been made to weave these components together into broader dimensions, such as anger experience and anger expression (e.g., Musante et al., 1989). At the same time, meta-analysis has been used to infer a generic, “disease-prone” personality that is broad and nonspecific in assuming tendencies to experience other negative emotions in addition to anger (Friedman & Booth-Kewley, 1987).

Although factor analysis, component analysis, and meta-analysis of existing measures will likely continue to prove useful tools, efforts to determine the appropriate level

of generality for describing health-related attributes might also benefit from alternative approaches derived from social-cognitive approaches to personality (Cantor & Zirkel, 1990; Mischel & Shoda, 1995). Rather than seeking personality units solely within the structure of items and scales for measuring traits, various “middle-level” personality constructs have been defined in terms of their relevance to the individual’s identity, goals, and life concerns. Ewart and Kolodner (1991) followed such an approach in demonstrating the utility of a social competence interview for psychophysiological research. An interview protocol that required subjects to describe and to re-experience a recurring life goal or challenge provided a means of eliciting cardiovascular activity that may reflect disease promoting processes. Another example of an alternative to traditional structured personality tests is the assessment of self-discrepancies, or negative self-evaluations, the activation of which may provoke negative emotion states and associated reductions in immune competence (e.g., Strauman, Lemieux, & Coe, 1993). Personality structures reflected in life goals and standards for self-evaluation may lie closer to the personality–stress interface than more traditional, traitlike dispositions because their contents are defined by the individual, rather than by the investigator, and may have more explicit links to the social-environmental context from which stressors often emanate. At the same time, it should be possible to establish associations between these cognitive-motivational units and more traditional personality constructs, especially where the latter are well-established, major dimensions of personality, or are firmly tied to health or to health-related processes (T. W. Smith & P. G. Williams, 1992).

An issue related to the question of breadth concerns the structural complexity of health-related personality attributes. Type A, Type C, and hardiness are explicitly multifaceted but, at least in some formulations, the facets were thought to be highly interrelated, yielding single, albeit broad constructs. By contrast, the study of emotional suppression/repression suggests that it may be profitable to conceptualize health-related personality attributes as combinations of two or more relatively distinct dispositions. Both the repressive coping construct (Weinberger et al., 1979), and the concept of defensive hostility (Helmers et al., 1995; Jamner et al., 1991) are defined in terms of two, substantially independent personality factors, an emotional trait (anxiety or hostility) and a defensive or avoidant orientation toward negative emotion (as reflected in Marlowe–Crowne social desirability scores). Another example is the inhibited power motivation construct, which involves high power motivation, low affiliation motivation, and high activity inhibition (Jemmott, 1987). Beyond these few examples, very little is known about the health implications of particular combinations of distinctive personality attributes, and multicomponent models of personality dispositions raise conceptual and analytic issues that have yet to be resolved (Carver, 1989).

Context Relevance

Personality measures that have proved useful in identifying health damaging attributes differ in the way they represent

contextual factors. Instruments such as the Cook–Medley Hostility scale, the Marlowe–Crowne Social Desirability scale, and the Life Orientation Test (a measure of trait optimism) (Scheier & Carver, 1985) contain items that refer to or imply general types of situations, for example, occasions that might stimulate anger or aggression, situations that raise questions about the respondents' or others' pro-social motives, or possible future scenarios involving positive or negative outcomes. By contrast, the attributional style questionnaire (a measure of pessimistic explanatory style) (Peterson, 1988) presents the subject with specific but hypothetical situations involving various negative events. The Structured Interview (used to assess global Type A and various anger-related attributes) (Dembroski et al., 1978) also contains questions that refer to hypothetical situations, but differs from questionnaire approaches in that it primarily is used to create a real situation in which to observe directly the respondent's behavioral response to social challenge. To the degree that the display of personality dispositions is contingent on the presence of conceptually congruent situation factors (Mischel & Shoda, 1995), the measurement of health-related personality attributes might benefit from more systematic attention to situational parameters contained in assessment devices.

The issue of context extends beyond the content of questionnaires and interviews. Very little is known about the manifestations of many health-related personality dispositions in naturalistic settings, although technological developments may stimulate efforts to address this gap in knowledge (Stone & Shiffman, 1994). Naturalistic research efforts guided by Mischel and Shoda's (1995) notion of situation–behavior relations might reveal individual consistencies in the use of certain coping strategies to manage some types of types of stressors, but not others, or to engage in health damaging behaviors under certain psychological conditions, but not others. The generalizability of personality–health associations across social and cultural categories also warrants much more attention. Findings involving even the fairly well-studied anger/hostility constructs have raised questions about gender differences in the pathogenicity of attributes falling in this domain (Stoney & Engebretson, 1994). Much remains to be explored concerning the interplay between health-related personality attributes and gender, ethnicity, and socioeconomic status (Anderson & Armstead, 1995).

Personality and Health-Damaging Processes

Research reviewed above also suggests a number of observations regarding the causal analysis of personality–disease linkages. Two of these are discussed below: (1) *Psychophysiological advances*: Technological advances permit more penetrating examinations of mechanisms linking personality to stress-related physiological activity than are available in the published literature; (2) *Health-related behavior*: Although direct, psychophysiological pathways to illness may be thought of as more closely associated with the health effects of personality and stress, behavioral pathways may warrant greater consideration.

Psychophysiological Advances

The application of more sophisticated psychophysiological methods would advance knowledge concerning personality and health in a number of ways. Within the laboratory, the availability of techniques such as spectral analysis, which distinguishes between sympathetic and parasympathetic nervous system influences on cardiac activity, makes possible a more fine-grained analysis of the autonomic control of cardiac responses to stressors (e.g., Kamada, Miyake, Kumashiro, Monou, & Inoue, 1992). Similarly, impedance cardiography can be used to determine the relative contributions of myocardial and vascular processes to stress-related blood pressure elevations (Kamarck, Jennings, Pogue-Geile, & Manuck, 1994). Refinements in these and other psychophysiological methods permit the examination of neurogenic and hemodynamic mechanisms operating in healthy individuals. Still other techniques have become available to measure stress-induced physiological changes in coronary patients, such as myocardial ischemia and abnormalities in myocardial contraction (e.g., Helmers et al., 1995). Thus, in addition to focusing on psychophysiological processes thought to be involved in the development of cardiovascular disorders, it is now possible to examine personality and stress in relation to psychophysiological processes that may be responsible for the precipitation of clinical disease states at later stages of those disorders.

Outside the laboratory, the availability of instruments for the ambulatory monitoring of physiologic activity can generate evidence bearing on the relationship between personality and stress-related cardiovascular responses in the naturalistic setting (e.g., Jamner et al., 1991). As with laboratory methods, ambulatory methods also permit the assessment of clinically relevant events in patients with disease (Helmers et al., 1995). Evidence of this sort—involving associations linking personality, stress, and disease in naturalistic settings—is critical to arguments that psychophysiological correlates of personality dispositions are relevant to processes that culminate in physical disease (Krantz & Manuck, 1984).

In addition to the foregoing examples from cardiovascular psychophysiology, it is possible to point to increasing sophistication in methods for assessing a range of parameters that reflect biological responses to psychological stress, including various measures of immunity, neuroendocrine activity, neurotransmitter and peptide receptor function, and metabolism (e.g., Herbert & Cohen, 1993; Schneiderman, Weiss, & Kaufman, 1989). Future research examining personality in relation to physiologic aspects of the stress response must exploit these developments if it is to add detail to current models concerning the psychosocial causation of physical disease and generate data that increase confidence in the validity of those models. If so, it will be possible to hold the next generation of studies in this area to a criterion of persuasiveness, rather than mere biological plausibility.

Personality and Health-Related Behavior

Although the focus in this chapter has been on personality factors thought to influence health directly, through

psychophysiological pathways, there appears to be a sufficient basis for examining these attributes in relation to behavioral pathways as well. In some instances, evidence for associations between suspected personality risk factors and pathogenic behaviors was generated through efforts to introduce statistical controls for factors that might confound personality-disease relations deriving from physiological mechanisms. In other cases, the examination of associations between personality and health damaging behaviors appears to have been exploratory, or based on the general negative or maladaptive connotation of a personality descriptor. Research based on explicit theory linking personality attributes to health behavior or reactions to illness (e.g., S. M. Miller et al., 1996) might be expected to yield more consistent and robust findings.

In addition to the benefits of a more theoretical approach to work in this area, it may be useful to give greater consideration to the proper role of personality in this research. Some research appears to reflect a premature focus on one particular personality disposition, to the exclusion of others, and to rely too heavily on it alone in attempting to predict measures of health-related behavioral processes. Other research is based on a normative health behavior model in which personality is included in a list of relevant background variables in the absence of a systematic examination of potential points of connection between personality and the key elements of the behavioral model. If research guided by psychophysiological models has provided any lesson at all for more behavioral approaches, it is that personality is neither an overriding factor in physical illness nor an inconsequential one.

CONCLUSIONS

The major constructs and research approaches used in the study of personality, stress, and disease have evolved only to a modest degree in recent years. Current concerns about lack of theory, measurement problems, and other issues do not differ dramatically from those raised in reviews published decades ago. Nonetheless, although the robustness of beliefs in the importance of stress-related personality attributes is not always matched by effect sizes or theoretical sophistication, research in this area has progressed. Assertions that once were based on a single, prospective epidemiologic investigation, or on a handful of psychophysiological experiments, are now based on consistent patterns of findings from large numbers of studies. There is a greater tendency to select for study types of stressors that appear psychologically relevant to the particular personality attribute under investigation. Personality factors that were once vaguely conceptualized as capable of exacerbating stress responses are now embedded in detailed theoretical frameworks positing specific stress promoting processes. In short, it would seem that the study of personality, stress, and disease is alive and reasonably well.

ACKNOWLEDGMENTS

We thank Michael Diefenbach and Ann O'Leary for their helpful comments on an earlier draft of this chapter. Thanks also to Jennifer Betancourt for her help in preparing the manuscript.

Visceral Learning

Bernard T. Engel

Department of Psychiatry and Behavioral Sciences, Duke University Medical Center

This chapter includes three sections. The first part is an overview of the historical discoveries and evolution of concepts about the autonomic nervous system. The second part is a selective review of the experimental findings on operant conditioning of visceral function. The third part is a theoretical consideration of the significance of the findings that visceral responses can be brought under stimulus control. The chapter leans heavily on the writings of Sheehan (1936) for the review of the history of findings and concepts about the autonomic nervous system. It also examines the overviews by Kuntz (1953) and Pick (1970); however, it became clear that they also used Sheehan as a primary source. Thus, whereas specific citations to Sheehan are not included in the first part, his work is followed in detail and anyone who wishes to get closer to the original sources should read the original. The second part includes a review of a number of issues relevant to the topic of visceral learning. Therefore, the chapter considers not only studies of operant conditioning of autonomic responses, but also studies on visceral perception. Although it tries to address the salient issues, no effort is made to provide a complete survey of the literature. However, it does try to provide interested readers with enough guidelines to enable them to find that literature. The third part tries to give some conceptual meaning to the findings reported in the previous part, and attempts are made to fit those concepts into the concepts introduced in the history section.

1800 YEARS IN LESS THAN 10 PAGES

Throughout most of recorded history little or no differentiation was made between the physiological nature of the autonomic nervous system and the functional significance of its actions. Furthermore, much of the speculation about function

was part of the broader question of the way the nervous system worked, in general. Galen's hypothesis that "animal spirits" were generated by the brain and conveyed to the endorgans dominated thinking for more than one millennium. He proposed that the brain was the organ primarily responsible for regulating performance by communicating "sympathy" or "consent" among the different parts of the body. He also identified seven pairs of cranial nerves, among which the sixth had three main branches: the superior, recurrent laryngeal and costal. Thus, Galen included the vagus nerve and the sympathetic trunk as part of an anatomical and physiological unit. It is noteworthy that he felt that it was through these nerves that the viscera received "an 'exquisite' sensitivity from the brain, and a motor power from the spinal cord" (Sheehan, 1936, p. 1083). The "'exquisite' sensitivity" of the brain in the control of visceral function lies at the heart of the nature of visceral conditioning as that concept is understood today. It was not until the 17th century that Galen's model of the autonomic nervous system—a designation that did not appear until the late 19th century—began to be refined and eventually modified. Willis made several important anatomical and physiological observations and psychological speculations. He was the first to describe the spinal accessory nerve and the vagus nerve (which was referred to by him and others as the eighth nerve). He also was the first to note that stimulation of the vagal branch arising from the aortic arch (which is now called the depressor nerve) caused the heart to slow. He erred in perpetuating the view that the "intercostal" nerve originated in the brain. Willis was also among the first to introduce the concepts of voluntary and involuntary movement. According to Willis, the involuntary animal spirits flowed from the cerebellum to the body through the vagus and intercostal nerves: The voluntary spirits emanated from the brain

and spinal cord. The nature of these concepts, and the galenic concept of sensitivity of the brain can be seen in Willis' notion that although thoracic and abdominal sensations were typically unconscious, they could become conscious if they were strong enough. Likewise, the cerebrum could voluntarily act (through the cerebellum) on visceral structures; for example, the exercise of the will over breathing. Thus, Willis believed that the intercostal and wandering (vagus) nerves served two functions: the origination of voluntary movements and the communication of sympathy among the various parts of the body.

Whytt, who followed Willis by about 100 years, introduced a very fundamental concept to explain involuntary movements. He proposed that there were local stimuli that were responsible for eliciting involuntary movements. Thus, he anticipated the existence of reflex pathways long before any evidence for these existed, and he recognized the importance of local stimuli in understanding the nature of visceral sensation. I believe that even today, the significance of adequate (local) stimuli is not fully appreciated. Whytt also elaborated greatly on the concept of sympathy by pointing out that sympathy required afferent feedback. For example, it was well known in his day that vomiting and nausea were associated with headaches, that the pupil of one eye would contract when light was shone in the opposite eye, and that the sight or smell of food provoked the flow of saliva. He argued that such sympathies presuppose feeling, and there must be sensory nerves that caused these perceptions.

Du Petit's studies in the early 18th century showed conclusively that the intercostal nerve did not originate in the brain. This finding raised a number of questions about the way in which voluntary and involuntary movements might interact: These questions are still not fully answered. However, for 18th century anatomists and physiologists, the predominant question was structural: How does information get to and from the brain and viscera? Winslow proposed that the sympathetic ganglia were independent neural control centers. Johnstone, who followed Winslow, proposed that the ganglia intercepted and prevented determinations of the will from reaching certain parts of the body. However, both models were inadequate because they did not explain Willis' observation that "strong" sensations could become conscious, and Whytt's argument about the existence of adequate stimuli and their roles in mediating sympathies. Nevertheless, there is one important implication of Winslow's and Johnstone's models that does require further consideration; namely, that the existence of autonomous control centers (Winslow) or sensory filters (Johnstone) means that there can be specific visceral effects as well as sympathies: Specificity is a necessary condition for visceral learning.

Bichat, who flourished in the early 19th century, introduced the concepts of organic and animal life (*la vie organique* and *la vie animale*). These concepts exist today in the notions of visceral and somatic functions, respectively. Bichat took this formulation further, ascribing the regulation of the continuous processes of organic life to the various nerve clusters that comprise the sympathetic ganglia; and, the intermittent, interactive (behavioral?) functions of animal life

to the brain. He also argued that there was no such thing as a sympathetic nerve. Rather, there were multiple communications among the disseminated ganglia, which function independently and in concert with one another. Nevertheless, he left some room for Willis' strong sensations by suggesting that the sympathetic rami somehow enabled the animal life with its center in the brain to communicate with the organic life with its centers in the ganglia: how, and under what conditions was unclear. Reil, a contemporary of Bichat, accepted the notion that the ganglia were independent control centers; however, he also elaborated on the role of the white rami, suggesting that these were filters that normally prevented visceral sensations from reaching the brain except in certain diseases when visceral sensations could become conscious. Thus, a recurrent theme that still persists: Visceral sensations are involuntary and unconscious, except when they are not!

Throughout the first half of the 19th century there was a great deal of work directed at understanding how animal spirits and organic spirits interacted. Much of this took the form of anatomic and physiologic studies of the function of the sympathetic rami. One view was that they were the origin of the sympathetic nerves; a second view was that they were pathways for sympathetic nerves that arose in the ganglia; and the third was that they were regions where animal and organic fibers interacted. The latter view, which was championed by Remak and Müller, prevailed. What is especially noteworthy about this model is that it reflected an effort on the part of anatomists and physiologists to correlate structure and function, an effort that still goes on (e.g., Precht & Powley, 1990). There was a prevailing belief that it is possible to reliably differentiate between the animal and organic fibers on the basis of their structures. Students of the history of physiological psychology will recognize the similarity between this effort to correlate structure with function, and the position of the advocates of localization of brain function *vis-à-vis* the mass action theorists. Experimental psychologists also should recognize the similarity between Bichat's dichotomy between animal and organic spirits and the point of view still held by some that the distinction between operantly and classically conditionable responses has an anatomic basis; for example, according to Roberts (1986): "The [somato-]motor system (including perceptual processing) is the system by which organisms interact with an environment whose demands and particular features are unique to each member of the species" (p. 301).

Technological developments that occurred throughout the 19th century (and which are beyond the scope of this overview) led to great advances in neurophysiology and neuroanatomy. Bernard set out to understand how the nervous system mediated thermoregulation. In the process, he discovered the vasomotor nerves. Within a few years, he and others not only demonstrated the existence of vasoconstrictor and vasodilator fibers but also showed that vasomotor effects were mediated, at least in part, from brain stem structures. Also in the 19th century, Hall defined the basic principles of the reflex arc, and Cyon and Ludwig described the main features of the baroreflex. Thus, it was well-known and widely accepted that the sympathetic system included afferent as

well as motor fibers. Because autonomic afferent activity was generally not perceived, these afferent, sympathetic fibers were regarded as elements in reflex arcs. Nevertheless, the possibility that these ordinarily insensible events could become sensible under poorly defined conditions was still troublesome and required special consideration.

By the end of the 19th and beginning of the 20th century, anatomical, physiological, and behavioral analyses of the autonomic nervous system began to diverge. Following a series of elegant anatomical studies, Gaskell defined the "involuntary nervous system" and its three major central, neural outflow pathways: the bulbar, thoracolumbar, and sacral divisions. He emphasized that these outflow pathways mediated two, antagonistic sets of nerves, which controlled the involuntary muscles and glands, one excitatory and the other inhibitory, and that they subserved catabolic and anabolic organic functions. Langley, his younger contemporary, greatly extended the analysis of the nature and structure of the two nervous systems through the use of pharmacologic tracing agents (e.g., nicotine, epinephrine, and pilocarpine). Langley also introduced the terms, autonomic nervous system and parasympathetic nervous system, to the literature. Conceptually, Langley had a major impact on 20th century thinking because he excluded visceral afferents from the autonomic nervous system: "the autonomic nervous system consists of the nerve cells and nerve fibres, by means of which efferent impulses pass to tissues other than the multinuclear striated muscle" (1921, p. 1).

Langley's exclusion of afferent fibers from the autonomic nervous system (ANS) has been very troublesome for physiologists. Pick (1970) characterized it as a "limited concept [that] subsequently gave rise to the widespread but erroneous notion concerning the lack of visceral afferent fibers" (p. 23). Contemporary physiologists largely ignore Langley's definition although anatomists still take it seriously (e.g., Precht & Powley, 1990). In addition to the "deafferentation" of the ANS, there was another related problem that evolved in the first 60 years or so of this century: It is the notion that the sympathetic nervous system responds en masse. Even though Whytt pointed out more than 200 years ago that there must be specificity in autonomic responding, the exclusion of afferent fibers, coupled with the clinical observation that visceral organs are relatively insensitive unless they are distended, has encouraged the view that the sympathetic nervous system is monolithic in its response because without feedback there is no mechanism for specificity. Several examples should illustrate the kinds of problems that result from this attribution. Bernard's emphasis on the relative constancy of the *milieu interior* and Cannon's concept of homeostasis are especially obvious because it is impossible to conceptualize the degree of regulation they intended in the absence of afferent feedback and specificity of action. Cardiovascular physiologists who have given their attention to blood pressure regulation (baroreflexes, chemoreflexes and renal control of blood pressure) also have found it necessary to include afferent feedback and specificity as factors in the regulation of the cardiovascular system. Exercise physiologists have built their models of cardiopulmonary regulation, and the interac-

tion between cardiovascular and sudomotor regulation during exercise around the existence of highly specific, afferent, feedback mechanisms. Finally, physiologists who study thermoregulation have emphasized that the interaction between heat conservation (vasomotor regulation) and heat production (a- and b-adrenergic regulation of heat production in brown adipose tissues, and muscle activity, including shivering), depend greatly on feedback from peripheral, and feedforward from central neural receptors. The impact of Langley's definitions can be seen as recently as 1977, when Wurster found it necessary to write that "the monolithic view of mass sympathetic discharge has fallen" (p. 239).

Wurster (1977) also added that "much of the past and present sympathetic neurophysiology has been studied under anesthetized and paralyzed conditions. Almost all concepts of sympathetic control require testing in the unanesthetized, instrumented animal" (p. 239). Obviously, behavioral studies of autonomic function have always been carried out in unanesthetized animals. Classical conditioning methodology has been used extensively to demonstrate the integrative function of central, neural control of visceral efferent action, and even more importantly, the extent to which visceral afferent activity can serve as a conditional signal for efferent responses (the works of Bykov, 1957, Chernigovsky, 1967, and Adam, 1967, 1998 are especially noteworthy). Another important area of investigation has been the study of the autonomic concomitants of emotional behaviors (Cannon, 1929; Turpin, 1983). Also of special interest here is the research in exercise physiology. Despite the fact that Johansson (1895), and Krogh and Lindhard (1913) showed that some aspects of the cardio-pulmonary adjustments to exercise are emitted behaviors, namely, "central commands," exercise physiologists have generally attempted to explain all of the cardiopulmonary adjustments to exercise in terms of peripherally mediated reflexes (e.g., Rowell, 1980).

CONDITIONING OF VISCERAL RESPONSES

In 1938, Skinner wrote:

Any given skeletal respondent may be duplicated with operants and hence may also be conditioned according to Type R. Whether this is also true of the autonomic part is questionable. There is little reason to expect conditioning of Type R in an autonomic response, since it does not as a rule naturally act upon the environment in a way that will produce a reinforcement. (p. 112)

Although he went on to cite anecdotal evidence for an autonomic operant that does "act naturally upon the environment"—the well-known disposition of young children to emit tears to obtain reinforcement—it was the negative statement cited earlier, coupled with the general eschewal of physiology among most experimental psychologists of the time, that became the dominant view in Western psychology over the next 30 years. Thus, behavioral scientists, who were the persons

most likely to address the role of learning in autonomic regulation in conscious animals, were simply not interested.

The renaissance of the experimental analysis of operant autonomic conditioning began in the 1950s with studies of electrodermal conditioning by Kimmel and Hill (1960). Later Shearn (1961) wrote a review with a provocative question as its title: "Does the Heart Learn?" However, his answer was equivocal. Within a few years a few positive papers appeared: for example, Engel and Hansen (1966), Miller and Carmona (1967), followed by an extraordinarily large number of reports and reviews—mostly positive, many negative, many critical, and many excessive. Consider the spectrum of articles reprinted in Barber et al., (1971), and the large number of claims for clinical efficacy that provoked a largely critical rebuke from Orne (1979). The interested readers can examine these articles for themselves, so they are not reiterated here. Rather, the remainder of this section, addresses three, specific questions: Are the viscera sensitive? Are there any studies that have demonstrated autonomic conditioning under conditions in which somatomotor effects have been excluded? And, irrespective of the mechanism of action of visceral conditioning, does visceral conditioning have clinical significance?

Visceral Afferents

The existence of visceral afferents clearly is a necessary condition for the occurrence of operant visceral conditioning. If Langley's definition of the autonomic nervous system is valid, then it would be impossible to understand how contingent reinforcement could modulate visceral responses directly. Thus, the demonstration of visceral afferents, and the presence of central neural feedback from these afferents is a first step in addressing the existence of visceral learning. Several techniques have been exploited to evaluate the extent and importance of visceral afferents. Most of the traditional, Western physiological studies have focused on intrinsic effects, that is, direct recording of reflex reactions to adequate stimuli. Eastern European physiologists have made extensive use of classical conditioning methodology—so called, interoceptive conditioning—to demonstrate the existence of visceral sensation. American psychologists (mostly) have used traditional psychometric methods to demonstrate sensitivity. Rather than review all of these studies, each is illustrated and then a few salient articles are cited from which the interested reader can educe further information.

Evidence for the Existence of Visceral Afferents.

Langley (1921), of course, knew about the existence of afferent nerves; however, his justification for classifying all autonomic nerves as motor was that "the afferent nerves accompanying [the efferent, autonomic nerves] were not as a whole distinguishable from the other afferent nerves" (p. 9). Although it is not clear what Langley meant by "as a whole distinguishable," it is clear that there is evidence for the existence of visceral afferents in all vertebrates (Nilsson, 1983), and that these afferents perform in a way that makes them integral to the overall function of the visceral organs they serve in that they are sensitive to the kinds of stimuli that these or-

gans are likely to experience. Thus, separating the afferent from the efferent function of the autonomic nervous system makes little sense. For example, there are both mechanoreceptors and chemoreceptors in the heart, lung, and blood vessels (Armour, 1977) that provide important mechanisms for integrating cardiac function with systemic and pulmonary vascular function. There is also an extensive literature on the input from these receptors to brain stem foci (e.g., Langhorst, Schulz & Lambertz, 1983), which integrate cardiovascular function systemically. Similar principles apply to the regulation of other visceral organs such as the gut system and the urinary bladder.

Visceral Perception. It should be apparent that there has been an enduring interest in the nature of visceral perception. Abdominal sensations are often the earliest indicators of inflammation or obstruction (viz. Willis' "strong" sensations). The James theory of emotion—usually inappropriately called the James-Lange theory—appears in almost every introductory psychology text. According to the James (1890) theory, the perception of bodily changes is emotion. One of the earliest studies of visceral perception was the report by Cannon and Washburn (1912) in which they correlated hunger pangs with gastric contractions. It has also been reported that many patients can detect the occurrence of premature ventricular contractions (Kline & Bidder, 1946). This finding is especially interesting because it is one of the few examples of a sensible visceral response that does not involve either significant stretch in a viscus or the introduction of a chemical agent such as CO₂. The recognition that it is possible to operantly condition visceral responses has enhanced the interest in studies of visceral perception. Brener (1974) proposed that afferent feedback from a visceral response enables a subject to "calibrate" their performance relative to a response image that they have previously acquired and that is elicited by an external stimulus; and that "activation of the [response image] leads to a state of nervous system imbalance resulting in the response specified by the image" (p. 368). In 1977, Whitehead, Drescher, and Heyman (1977) described a psychometric method for measuring heart rate perception, and reported that there was no relation between the ability of subjects to learn to control their heart rates, and their ability to perceive their heart beats. There are several interpretations to this finding. The most obvious, of course, is that the finding shows that it is not possible to sense heart beats directly; however, that interpretation requires the elimination of alternative possibilities. One such possibility is that perception measured psychometrically is an inaccurate index of afferent neural activity from the heart; that is, the signal to which the subjects responded in the Whitehead et al. (1977) study is not mediated by receptors in the heart. For example, the signal to which the subjects responded in the Whitehead et al. (1977) study could have originated from stretch receptors in the ventricle or aorta responding to ventricular contraction and/or aortic stretch following the rise in blood pressure. It is common experience that people often report feeling their hearts "pounding" and that these sensations are the result of the pressure generated by the heart beat. As previously noted there is

evidence that some patients can detect the occurrence of premature ventricular beats (Kline & Bidder, 1946). This study also showed that the patients detected the premature beat itself—which is relatively weak because the ventricle has not filled normally, and not the beat following the premature beat, which is relatively strong because the ventricle is especially distended. Another possibility for the Whitehead et al. (1977) finding is that the relation between detection and performance is not appropriately assessed using linear correlation methodology; for example, direction of change but not magnitude of response may be perceived. Since the report by Whitehead et al. (1977), there have been recurrent reports of the ability of human subjects to sense their heart beats, mostly appearing in PSYCHOPHYSIOLOGY. The reports have been largely preoccupied with methodological issues; however, most have in common the finding that people can detect their heart beats.

Interoceptive Conditioning. Probably most readers of this chapter will have a greater interest in conditioning studies than they will in perceptual or psychometric experiments. The classic works of Bykov (1957), Chernigovsky (1967) and Adam (1967) have already been cited. A study from Adam's laboratory illustrates the kinds of findings these experiments have yielded. Bardos (1989) studied the effect of intestinal distension on taste aversion in rats. He found that pairing a novel tasting solution with aversive, intestinal distension resulted in suppression of consumption of the novel solution on a subsequent test, during which there was no distention. He also tested the effect of the distending stimulus on a variety of behaviors: he compared distension with a fluid-filled balloon and an isovolumic, air-filled balloon. Because the fluid-filled balloon was nondistensible, and the air-filled balloon could be compressed, the fluid-filled balloon caused greater stretch in the gut wall. He found that consumption of a neutral, saccharine solution was similar in the two conditions, but the greater degree of stretch caused by the fluid-filled balloon suppressed other behaviors such as grooming and rearing. Thus, these studies showed evidence for interoceptive conditioning, and showed further that the gut manifested stimulus specificity (NB, Whytt's, adequate stimulus). In addition to the laboratory studies cited here, there also is evidence that taste aversion classical conditioning can mediate clinically significant effects. Bovbjerg et al. (1992) reported a controlled study of conditioned nausea in women receiving chemotherapy for breast cancer. Patients receiving a fruit-flavored drink, paired with infusion of a chemotherapeutic agent, reported significantly more nausea to the fruit drink in postchemotherapy trials than did control subjects in whom the fruit drink was not paired with infusion.

Operant Conditioning of Visceral Responses.

Skinner (1938) raised the two major conceptual problems that need to be addressed in studies of operant conditioning of visceral responses: One is to demonstrate that visceral responses can "act upon the environment in any way that will produce a reinforcement," and the second is that, "the respondent may be chained to an operant." The majority of studies with people have tried to deal with the first issue by showing that the autonomic

response in question can be modified so as to increase the probability of positive or negative reinforcement. However, studies with human subjects have not addressed the chaining question well; probably, because most experimental attempts to deal with this question call for surgical or pharmacological interventions that are difficult or impossible to implement in people. This section reviews a number of studies—mostly in animals—that seem to address Skinner's concerns. The reader who wishes to pore through the extensive literature published during the 1970s will find useful the collections of reprints useful published by Aldine under the title "Biofeedback and Self-Control" (Barber et al., 1971; Stoyva et al., 1972; Miller et al., 1974; Shapiro et al., 1973; DiCara et al., 1975; Barber et al., 1976; Kamiya et al., 1977; Stoyva et al., 1979) and "Biofeedback and Behavioral Medicine" (Shapiro et al., 1981). Those who want to avail themselves of bibliographic searches to review the literature after 1980, may find that the term *biofeedback* is more useful than the terms, *visceral conditioning* or *operant conditioning of visceral responses*.

The evidence that visceral responses can "act upon the environment in a way that will produce a reinforcement" is extensive. There are a multitude of studies that have shown that contingent reinforcement will change the rate of emission of visceral responses. The number of successful studies, mostly with people, included in the reviews cited here are very great. In addition, the studies with patients that are summarized later also are convincing. Animal studies are far fewer; however, these also show that visceral responses (in particular, cardiovascular responses) can be operantly conditioned (Engel, 1986). The reader should be warned that in evaluating the validity of such studies, it is important to separate habituation from conditioning. Multiple session experiments are the best way to control for habituation. The studies by Plumlee (1969), Harris, Gilliam, Findley, and Brady (1973), and Bardos, Talan, and Engel (1989), who taught monkeys to modify their blood pressures, and Engel and Gottlieb (1970), who successfully conditioned the same monkeys to increase and decrease their heart rates, showed that these autonomic responses could be operantly conditioned and that habituation was not a likely mechanism for the observed changes. In addition, the studies by Bardos et al. (1989) and Engel and Gottlieb (1970) are based on differential conditioning of a response within the same subject, a procedure that is a more robust test of visceral learning than is unidirectional conditioning. There are also anecdotal examples from common experience that indicate it is possible to emit a visceral response in order to obtain reinforcement. One example is the one that Skinner cited: "the ability of young children to cry 'real tears' to produce a reinforcing stimulus" (1938, pp. 112-113). A second example is the common experience (especially noteworthy in dogs) of salivation at the sight of food. And a third example is the ability that most people acquire to inhibit urinary bladder contractions—except under appropriate conditions. Also noteworthy is the capacity that many mammals (e.g., dogs, rodents) have to urinate repeatedly in order to mark their territories. The evidence that autonomically mediated responses can interact with the environment to obtain contingent reinforcement is unequivocal. However, to

properly evaluate this interaction, the nature of the reinforcing stimulus must be considered. In Whytt's terms, the interaction will occur when the stimulus is adequate.

Skinner's second argument "that the respondent may be chained to an operant" is much more difficult to refute. There are two problems: First, the fact that a correlation can be demonstrated between a somatomotor response and an autonomically mediated response does not necessarily mean that the "respondent is chained to the operant." The converse could also be true; for example, B. R. Dworkin, Filewich, Miller, Craigmyle, and Pickering (1979) showed that an acute rise in blood pressure will reduce the distance rats will run on a treadmill to escape a noxious stimulus. Second, even if one or another somatomotor response was experimentally ruled out, this does not necessarily mean that all somatomotor responses are ruled out. With regard to the last point, it is also important to recognize that even if the somatomotor system was paralyzed, the existence of chaining would not have unequivocally been excluded because paralysis prevents only the expression of the response but not its central neural mediation. As a matter of fact, the dichotomy between operants and respondents is physiologically naive because somatomotor and autonomic responses are necessarily integrated; for example, it is impossible to sustain striate muscle action without adequate blood flow. In any case, there have been several attempts to exclude somatomotor mediation as a factor in operant autonomic conditioning. One is by selecting responses that are not somatically mediated; for example, contraction of the urinary bladder (Lapides, Sweet, & Lewis, 1957). A second is to use pharmacological blockade to elucidate autonomic control mechanisms. Black (1967) carried out a series of studies of cardiac conditioning in dogs using curarization to block somatomotor responses. His general conclusion was that "heart rate can be changed by operant conditioning procedures. Secondly, these changes in heart rate are associated with skeletal movement. They are not necessarily associated with overt skeletal movement, but at least with central processes involved in the initiation and maintenance of movement." (p. 20). Nevertheless, he also took pains to point out that his studies were "far from conclusive" (p. 20). The studies of Miller and his colleagues using curare to control movement in cardiac conditioning studies of rodents should be well-known and should not need detailed review. What is important, however, is the recognition reported by Miller and B. R. Dworkin (1974) that curarization is a complex technical procedure, and that the earlier reports using this methodology were faulted and not definitive. Nevertheless, after many years of effort, B. R. Dworkin and S. I. Dworkin addressed and overcame these problems (1990). Hopefully, in the near future, they will be able to clarify the role of somatomotor activity in cardiac conditioning in this model.

Several autonomic responses have been studied that are emitted independent of any somatomotor control: Many of these studies have been done with patients. This section considers only the behavioral and physiological aspects rather than the clinical implications. Weiss and Engel (1971) studied a series of patients who were trained to increase and decrease the prevalence of premature ventricular contractions of the heart.

There is no evidence that these intracardiac effects have somatomotor correlates. Most of the patients were able to perform reliably. One patient was especially interesting because she reported a great deal of anxiety and distress when the frequency of her premature beats diminished. An interview revealed that she had found the presence of these aberrant beats reinforcing, and when they began to disappear, she feared that her heart had stopped beating! Clearly, this is further evidence for the reinforcing property of visceral sensation. Bleecker and Engel (1973b) studied a group of patients with atrial fibrillation. In these patients, the normal cardiac rate control mechanism—modulation of the depolarization of the atrial pacemaker—is absent. Thus, the ability of these patients to regulate their heart rates must have occurred either at the level of the arterio-ventricular node or at the ventricle, itself. Neither of these mechanisms has ever been shown to be affected by somatomotor activity. Burgio, Whitehead, and Engel (1985), and Burgio, Stutzman, and Engel (1989) trained patients with so-called, uninhibited urinary bladder contractions to inhibit these contractions (see, Burgio, Whitehead, & Engel, 1985; Fig. 3). Because the urinary bladder has only autonomic innervation, the ability to emit these responses could only occur through direct autonomic action.

The "chaining" issue has been addressed in other ways. First, the interaction between an operantly conditioned autonomic response (heart rate) under conditions where heart rate and blood pressure responses were elicited by another stimulus has been studied. In particular, two conditions have been studied: classical conditioning and exercise. In the first study, monkeys were alternately trained in a classical conditioning paradigm and in operant, heart rate slowing or speeding, training schedules (Ainslie & Engel, 1974). In all cases, the classical, unconditional stimulus (tail shock) was identical to the operant punisher. After operant training, the heart rate responses to the classical, conditional stimulus was modified in the direction of the operant heart rate response suggesting that the classical, unconditional stimulus may actually be an operant reinforcer. One other interesting aspect of this study was that although the classically conditioned heart rate response was altered as a result of the operant heart rate training, the blood pressure responses that were never under stimulus control did not change. This latter finding is a further demonstration of the degree of specificity to which autonomically mediated responses can be emitted.

Second, attempts were made to show that the cardiac response to exercise can be emitted independently of any reflexes. Bolme and Novotny (1969) demonstrated that if dogs are classically conditioned to exercise by walking on a treadmill, an increase in leg blood flow can be observed which occurs in response to the conditional stimulus, (i.e., prior to the onset of the exercise itself). Furthermore, if the animals are trained to discriminate between two conditional signals, one indicating a higher level of exercise than the other, then the animal will emit a greater blood flow response during the fore-period of the higher level cue. This study showed that the anticipatory responses to exercise (both somatomotor and cardiovascular) can be conditioned. However, it did not address the question of the role of conditioning in the regulation

of the cardiovascular responses during exercise. Talan and Engel (1986) and Engel and Talan (1991b) built on this model. First, they operantly conditioned monkeys to exercise (lift weights) to avoid a tail shock. Then, they operantly conditioned them to slow their heart rates to avoid the identical shock. The two behavioral contingencies were signaled by different sets of cues. When the animals were performing the two behaviors reliably—training took place over months—they then taught them to perform both tasks at the same time. Thus, the animals had to lift weights to avoid tail shock, and they had to attenuate the tachycardia of exercise to avoid tail shock. In a typical experimental day, an animal performed in four experimental sessions: two that were exercise only and two that were combined heart rate slowing and exercise. In both studies, all animals learned the contingencies and performed highly reliably. In fact, some animals were able to attenuate the tachycardia of exercise in the combined sessions even while lifting the weights more often than in the exercise only sessions. These experiments showed that the heart rate response during exercise could become an operant; however, there was still the possibility that some undefined somatomotor reflex could have mediated the cardiac response, although it is unclear how such a reflex could result in a slower heart rate during greater exercise. In order to address this last question, Engel and Talan (1991a) repeated these studies with three of the same animals at times when the animals were receiving any of three autonomically active drugs: (a) *atenolol*, which is a cardiac-specific β -blocker; (b) *atenolol* and *prazosin*, the latter being an α -adrenergic blocker; or (c) *methyl-atropine*, which is a vagal blocker that does not cross the blood-brain barrier. Thus, these drugs completely blocked one or another efferent component of the autonomic nervous system. If the heart rate response, during the combined session, was the result of a reflex response, then this intervention should have eliminated the animals' abilities to perform reliably because the drugs blocked one or another arm of the putative reflex, and it should have extinguished the reflex. In fact, none of the drugs interfered with performance. No matter which drug the animals received, they were able to consistently and reliably attenuate the tachycardia of exercise. In a later experiment from this laboratory (Chefer, Talan, & Engel, 1997) the investigators identified several brain areas that played a role in mediating conditioned attenuation of the tachycardia of exercise. This series of experiments would seem to answer Skinner's questions: animals can learn to attenuate the tachycardia of exercise to avoid shock, and an operantly conditioned heart rate response is not necessarily the result of a somatomotor mediated reflex.

CLINICAL FINDINGS

There are a great many studies of the clinical application of operant conditioning technology to the regulation of aberrant physiological responses, such as EEG activity in children with attention deficit disorders (Lubar, 1991), or anal (Engel, Nikoomanesh & Shuster, 1974) or urinary (Burgio, Robinson & Engel, 1986) sphincter training in incontinent patients. However, the responses brought under stimulus control in

these studies were not autonomically mediated and are not considered here. Relatively wide-ranging reviews of many such clinical applications can be found in Hatch, Fisher and Rugh (1987), and Basmajian (1989).

The previous section, reviewed some of the evidence to support the hypothesis that autonomically, mediated responses can "act upon the environment in [a] way that will produce a reinforcement" and that "the [autonomic response need not] be chained to an operant." It should be clear that whereas these theoretical questions are important, they are secondary to the question of the clinical applicability of visceral conditioning. If visceral learning can occur, then it may be useful no matter what the underlying behavioral and physiological mechanisms are. This section reviews a number of studies that have shown that visceral responses can be operantly trained, and this training will result in clinically beneficial outcomes. It should be emphasized that not every study with patients is necessarily designed with a clinical endpoint in mind. For example, some studies already cited with patients were designed to enable a better understanding of the mediating mechanisms rather than to reveal a therapeutic benefit. In addition, readers should recognize that just because an outcome is clinically beneficial, it does not necessarily follow that it is optimal because that is determined by a variety of factors such as cost, ease of application, likelihood of patient compliance, and practitioner competence.

Operant training of autonomic responses has been applied clinically in two ways: (a) to train subjects to emit an operant, autonomic response; for example, skin vasodilatation, in the expectation that this behavior will result in a generalized reduction in sympathetic nervous activity and thus will facilitate relaxation; and (b) to train subjects to emit an operant autonomic response because the response itself is aberrant. There is very little physiological evidence to support the notion of generalized activation or reduction in sympathetic nervous activity. Given the extensive evidence for specificity within the autonomic nervous system already cited, there is very little reason to believe that any particular, sympathetically mediated response will represent all sympathetically mediated responses. Furthermore, in the case of skin vasodilatation, which is always implemented by teaching subjects to warm their hands or feet, there is strong evidence that the vasodilatation is not under direct, sympathetic, nervous control (Freedman et al., 1988). Therefore, this section will limit its review to a few studies that have provided evidence that an aberrant, autonomic response can be altered to a degree sufficient to produce a clinically significant effect.

There have been a number of reports of successful outcomes using operant conditioning methodology to train patients with abnormal, autonomically mediated responses to gain or regain control of their aberrant responses. Two reports have been published that describe successful clinical outcomes in patients with cardiac arrhythmias: Weiss and Engel (1971) showed that some patients could learn to diminish the prevalence of ectopic ventricular beats; and Bleecker and Engel (1973a) showed that it was possible to teach a patient with Wolf-Parkinson-White syndrome to modulate her aberrantly conducted heart beats. Several studies have shown

that it is possible to teach hypertensive patients to lower their blood pressures reliably in the laboratory (Benson, Shapiro, Tursky, & Schwartz, 1971; Kristt & Engel, 1975), and at home (Glasgow, Gaarder, & Engel, 1982; Glasgow, Engel, & D'Lugoff 1989; Pearce, Engel, & Burton, 1989). Finally, Burgio et al. (1985), and Burgio et al. (1989), have reported highly successful results in treating urinary incontinence in patients with uninhibited bladder dysfunction and Burgio et al. (1998) have shown that behavioral treatments, including operant conditioning of bladder control, were significantly more effective than drugs in reducing urge urinary incontinence. Freedman, Ianni, and Wenig (1983) reported success in reducing the prevalence and severity of vasospastic responses in patients with Raynaud's disease by teaching them to warm their hands; however, as noted earlier, it is likely that the effect of such training is not mediated by the sympathetic fibers innervating the blood vessels in the skin.

CONCLUSIONS

My assessment of the history of research and conceptualization about the autonomic nervous system suggests that it is characterized by discovery and denial. The main point of the discoveries is that the nervous system is integrative and regulatory. Galen's basic notion that the brain communicates a sympathy among the parts of the body is true, and the rest is detail, however profound and complex. The denial comes largely from philosophical traditions that impute special properties to human function, even in the face of contradictory evidence. The imputation is that behavior can be conveniently dichotomized into voluntary and involuntary, conscious or unconscious. The hallmark of such dichotomies rests heavily on the apparent inability of human subjects to characterize their visceral sensations verbally. When evidence arises, which does not neatly fit into these dichotomies, it is dealt with as a special case (e.g., Willis' "strong" sensations), it is defined out of existence (e.g., Winslow's notion of the sympathetic ganglia as autonomous nerve centers; Johnstone's notion that the ganglia serve as filters to prevent visceral information from becoming conscious; Langley's extraordinary definition excluding afferent fibers from the autonomic nervous system; and Skinner's concern that autonomically mediated responses do not "naturally" act on the environment), or the data are simply ignored (e.g., the well-known ability of mammals to inhibit or induce bladder contractions and the experimental evidence of visceral sensation). There is a modern counterpart to this cartesian disposition to dichotomize. Within psychiatry the concept of psychosomatic medicine evolved as a dualistic model that separated putative, physical from mental, conscious from unconscious and voluntary from involuntary events (e.g., Alexander & French, 1948; Dunbar, 1954). Behavioral medicine evolved, in part, as a reaction to this dualism. However, as argued elsewhere (Engel, 1994), it failed to meet the challenge. Instead, it maintained the differentiation between physical and mental illness. The failure of behavioral medicine to deal with dualism in its manifold forms is clearly evident in the

contemporary neologism, *biobehavioral*. Biobehavioral is simply a euphemism for psychosomatic.

In order to understand why the term, *biobehavioral*, needed to be invented, it is first necessary to understand how psychologists define behavior. *The Dictionary of Behavioral Science* defines behavior as the interaction of an organism with its physical and social environments (Wolman, 1989). The term, *organism*, is interpreted, literally, to mean the whole animal or person, and the term, *environment*, refers to the external environment. Thus, an autonomically, mediated response (or for that matter, a somatomotorically, mediated response!) and an interoceptive stimulus are excluded from the domain of behavior. Because behavior is limited to organisms rather than effectors, and because contemporary research has shown that motor responses, however mediated, are capable of interacting with the environment, it is necessary either to redefine behavior or to deny, once again, the implications of the data reviewed here. Obviously, contemporary proponents of behavioral medicine have chosen the latter course. It is clear that the definition of behavior is inadequate, and the host of dichotomies that infest the literature are inhibiting progress. Accordingly, behavior should be redefined to mean the interaction of an effector system with the environment. The effector system could be an organism, muscle contraction, glandular secretion, or immune response: The environment could be external or internal. When a response interacts with the environment, the process is behavior. The essence of the current definition, and of the definition proposed here, is that behavior is an *interaction* between a response and a stimulus; however, the definition proposed permits the investigator to define both the relevant stimuli and the appropriate unit of response. Within the framework of the proposed definition it will no longer be necessary to invoke dualistic notions. Anyone who wants to invoke dualistic processes, such as conscious/unconscious, voluntary/involuntary, or mental/physical should be expected to define the process and then empirically justify its autonomous existence. The bias is that if this level of rigor is implemented, none of these dualistic concepts will survive empirical test.

There is another feature to the proposed redefinition of behavior that is especially salient to students of visceral conditioning, namely, the interrelation between behavior and physiology. *Physiology* is defined as the science that treats of living organisms or their parts (Hoerr & Osol, 1956). *Behavior*, as defined here, is the interaction of an organism's effectors with the environmental contingencies (and the organism's learning history). Thus, physiology, as a science, focuses on organ function, whereas behavioral science is concerned with how that function serves the nearterm survival (coping) of the organism. Clearly, a comprehensive biological science (viz. the science of life) needs both. Integrative physiologists who are especially concerned with the ways in which organs interrelate, and behavioral scientists should recognize that their interests overlap greatly. An understanding of the ways organs work is fundamental to an understanding of the capacities for visceral learning: A knowledge of the extent to which visceral adaptations to envi-

ronmental contingencies occur is fundamental to an understanding of the ways organs function.

Biofeedback and Self-Regulation of Physiological Activity: A Major Adjunctive Treatment Modality in Health Psychology

Robert J. Gatchel

University of Texas Southwestern Medical Center at Dallas

Before Harry Houdini performed one of his famous escapes, a skeptical committee would search his clothes and body. When the members of the committee were satisfied that the Great Houdini was concealing no keys, they would put chains, padlocks and handcuffs on him. . . . Of course, not even Houdini could open a padlock without a key, and when he was safely behind a curtain, he would cough one up. He could hold a key suspended in his throat and regurgitate it when he was unobserved. . . . The trick behind many of Houdini's escapes was in some ways just as amazing as the escape in itself. Ordinarily, when an object is stuck in a person's throat he will start to gag. He can't help it—it's an unlearned automatic reflex. But Houdini had learned to control his gag reflex by practicing hours with a small piece of potato tied to a string. (Lang, 1970, p. 2)

Through the years, there have been other unusual instances of the exercise of voluntary control over physiological functions noted in the scientific literature. Such was the case of a middle-aged male who had the ability to control the eruption of hairs over the entire surface of his body (Lindsley & Sassaman, 1938), or the case of an individual who could willfully produce complete cardiac arrest for periods of several seconds at a time (McClure, 1959). Numerous instances of voluntary acceleration of pulse rate were reported by Ogden and Shock (1939). Luria (1958) described a mnemonist who had obtained remarkable control of his heart rate and skin temperature. This individual could abruptly alter his heart rate by 40 beats per minute. He could also raise the skin temperature of one hand while simultaneously lowering the temperature of the other hand.

The modification of physiological activities such as those described has been the subject of practice and investigation by mystics and scientists for a considerable period of time. The goal of such control of physiological functions has been pursued for at least three reasons:

1. To achieve spiritual enlightenment. Yogis and other mystics of the Eastern tradition have shown that through certain physical exercises or by sheer act of will they are capable of producing tremendous physiochemical changes in their bodies resulting in perceived pleasant states of consciousness (Bagchi, 1959; Bagchi & Wenger, 1957).
2. To test theories of learning. Within psychology, learning theorists have long debated the issue of whether autonomic responses could be operantly conditioned.

3. As a clinical treatment procedure for modifying psychological and medical disorders.

This chapter focuses on this third category of how volitional control of physiological activity has been used as a clinical treatment modality for medically related disorders. This area has contributed significantly to the growing field of behavioral medicine and health psychology.

THE DEVELOPMENT OF BIOFEEDBACK TECHNIQUES

The previously reviewed acts of unusual physiological bodily control were traditionally viewed as rare feats that only certain extraordinarily gifted individuals could accomplish. However, starting in the 1960s, behavioral scientists began to develop techniques and empirically demonstrate that the "average person on the street" could learn a significant degree of control over physiological responding. The primary training method developed and utilized in this learning process has been labeled *biofeedback*. This initial research activity began to stimulate more interest, among both the scientific community and the general public, in the area of biofeedback because of its many potentially important clinical and medical applications. For example, it would be therapeutically valuable if it was possible to teach patients with hypertension how to lower their blood pressure, or to teach patients with headaches how to control the vasodilation process involved in the pain phenomenon. Indeed, Birk (1973) was the individual who coined the term *behavioral medicine* to describe the application of a behavioral treatment technique (biofeedback) that could be applied to medicine or medical problems (e.g., headache pain).

The biofeedback technique itself is based on the fundamental learning principle that people learn to perform a particular response when they receive feedback or information about the consequences of that response, and then make the appropriate compensatory behavior adjustments. This is how individuals have learned to perform the wide variety of skills and behaviors utilized in everyday life. For instance, people learn how to drive a car by receiving continuous feedback concerning how much to turn the steering wheel in order to turn the car a certain distance, and how much pressure must be applied to the accelerator in order to make the car move at a certain speed. If this feedback is denied, for example by being blindfolded, individuals would never receive information about the consequences of their driving responses. They would therefore never be able to learn the proper adjustments needed in order to perform a successful driving maneuver. Accurate information feedback is thus fundamental to the learning of visual-motor skills. Indeed, Annett (1969) initially reviewed numerous experimental studies demonstrating the importance of feedback in the learning and performance of a wide variety of motor skills.

The availability of feedback is also of utmost importance in learning how to control internal physiological responses. However, much biological behavior is concerned with maintaining a constant internal "homeostasis" and is not readily

accessible to conscious awareness. Indeed, people do not consciously experience some interoceptive awareness of internal biological activity, such as muscle tension or their pulse, because there is normally adaptive advantage to not having to consciously attend or control these activities on a continuous basis. Moreover, interoceptors do not normally have the extensive afferent representation at the cortical level that is needed for a high degree of perceptual acuity or the fine discriminability characteristics of audition or vision.

People do not normally receive feedback of these internal events in day-to-day situations, so they cannot be expected to control them. However, if individuals are provided biofeedback of, say, blood pressure via a visual display monitor, they can become more aware of the consequences of blood pressure changes and the ways adjustments can be made to modify and eventually control it. Receiving feedback serves to remove the "blindfold," enabling individuals to voluntarily control a response. The development of sensitive physiological recording devices and digital-logic technology has made it possible to detect small changes in visceral events and provide subjects with immediate feedback of these biological responses.

Today, biofeedback is broadly, and loosely, defined as a procedure for transforming some aspects of physiological behavior into electrical signals that are made accessible to exteroception or awareness (usually vision or audition). Sometimes, the feedback signal is combined with a tangible reward such as money or the opportunity to view attractive pictures in an attempt to motivate the individual and strengthen the effect of the targeted physiological response. In other instances, the clinician provides verbal praise for success in addition to feedback. These latter practices are also forms of biofeedback, because they too convey information to learners about their biological performance. In most instances, however, response-contingent lights or tones alone can be shown to augment voluntary control of physiological activity.

Borrowing heavily from operant conditioning techniques, the early biofeedback investigators during the 1960s and 1970s demonstrated some degree of operant or voluntary control in a wide variety of visceral, central nervous system, and somatomotor functions. Gatchel and Price (1979) provided an early review of this research that demonstrated learned control by human subjects of a wide variety of "involuntary responses": cardiac ventricular rate, systolic and diastolic blood pressure, peripheral vascular responses, electrodermal activity, gastric motility, skin temperature, penile tumescence, and various brain wave rhythms.

Encouraged by these early successes demonstrating voluntary control of normal physiological activity, medical and psychological clinicians soon began to question whether pathophysiological activity could also be controlled with the goal of restoring health or preventing illness. This stimulated a rapid growth of the scientific literature evaluating the clinical effectiveness of biofeedback. This research has been reviewed in a number of different sources (e.g., Hatch, Fisher, & Rugh, 1987). There is also a journal (*Biofeedback and Self Regulation*), and a professional society specializing in bio-

feedback and self-regulation (Association for Applied Psychophysiology and Biofeedback) that celebrated its 25th anniversary year in 1994. There are also a number of useful practitioner guides that have been published (e.g., Basmajian, 1989; Schwartz, 1987).

To date, the research literature has amply demonstrated that some degree of self-control is possible over behaviors long assumed to be completely involuntary. It has also been shown that, with biofeedback, it is possible to extend voluntary control to pathophysiological responding in order to modify the maladaptive behavior in the direction of health. Table 6.1 summarizes the various disorders for which biofeedback has been applied.

As can be seen in Table 6.1, many of the results produced are highly significant achievements. However, as reviewed elsewhere (Gatchel, 1997), many important questions still remain concerning the extent to which biofeedback and other physiological self-control techniques will be medically effective. Unfortunately, research evaluating therapeutic effectiveness of these procedures has been plagued by a number of problems. For example, to date, there are very few well-controlled clinical outcome studies that have been conducted using large numbers of patients having well-confirmed medical diagnoses. Moreover, the few comparative outcome studies that have been performed compare the relative effectiveness of biofeedback to various other behavioral techniques (e.g., simple relaxation training that is discussed later in this chapter). It would be extremely helpful to also compare biofeedback techniques with more traditional medical treatments, some of which have fairly well-established success rates. Combinations of medical and behavioral techniques should also be explored and evaluated.

It should also be noted that, unfortunately, there have been claims for the therapeutic efficacy of biofeedback that had been grossly exaggerated and even wrong. Overall, it is justified to conclude that relevant and encouraging data do exist, but at the present time the value of clinical training and biofeedback still has to be questioned in some areas. Moreover, terms such as *biofeedback therapists* and *biofeedback clinic*, which are now regularly encountered in many medical centers, are difficult to justify. They imply that a form of treatment exists that is more or less generally applicable to a variety of ills. Worse yet, they imply, at least in the minds of some, that biofeedback is a new alternative treatment modality. Currently, in the majority of areas in which it is applied, biofeedback should be viewed merely as an *adjunctive* treatment modality.

OTHER SELF-REGULATION METHODS FOR PRODUCING VOLITIONAL CONTROL OF PHYSIOLOGICAL ACTIVITY

Controlled Breathing

Many forms of yoga and meditation have traditionally viewed breathing as fundamentally linked to relaxation and good health. Indeed, one type of yoga—*Pranayama Yoga* (or the Science of Breath)—is totally devoted to the study of the effects of breathing exercises on mental and physical health.

The relaxation methods discussed in the next section begin with a focus on correct breathing. Deep, relaxed breathing involves allowing the air to flow easily to the bottom of the lungs with each inhalation (expanding the diaphragm and moving the stomach gently out) and slowly exhaling as the stomach moves gently in. The shoulders and chest remain still and relaxed during this process. Such deep, relaxed breathing serves as an effective distressor. In contrast, strained, shallow breathing and stress go hand in hand. Often, individuals who have breathed incorrectly for years (shallow breathing with their chests) are unaware of these effects until they experience correct, controlled breathing.

Muscle Relaxation Training

Systematic desensitization is a technique originally developed by Wolpe (1958) as a means of alleviating fear and anxiety. Wolpe based this procedure on the principle of *counter-conditioning*, in which an attempt is made to substitute relaxation (an adaptive behavior), through learning, for anxiety (the deviant or maladaptive behavior) in response to a particular fear-producing object or situation. The procedure typically involves the pairing of deep muscle relaxation, which is taught by a progressive muscle relaxation technique originally developed by Jacobson (1938), with imagined scenes depicting situations or objects associated with fear or anxiety. Wolpe had his patients imagine the anxiety-related objects or situations because many of the fears treated were abstract in nature (e.g., fear of rejection by a loved one) and, therefore, could not be presented *in vivo* (in real life). However, even when the objects and situations can be presented in real life (e.g., fear of a specific object such as a bug), *in vitro* systematic desensitization is often employed. The effectiveness of systematic desensitization has been well documented (Gatchel, Baum, & Krantz, 1989).

Progressive muscle relaxation, which is an important component of the systematic desensitization treatment method, often can serve as a powerful therapeutic technique in its own right. Clinicians now frequently use it by itself to treat a wide variety of disorders, including generalized anxiety, insomnia, headache, and mild forms of agitated depression. Moreover, unlike the extensive training initially advocated by Jacobson, which took many months, many abbreviated forms taking only a few sessions have been developed. Overall, the technique is based on the premise that muscle tension is closely related to stress and anxiety, and that an individual will feel a significant reduction in experienced anxiety when tensed muscles can be made to relax.

Autogenic Training

At the time that Jacobson was developing the technique of progressive relaxation in the United States, Schultz was developing a relaxation technique called *autogenic training* in Europe. This work was subsequently published in this country (Schultz & Luthe, 1959). The technique was based on the clinical observation that hypnotized subjects often report sensations such as heaviness and warmth. These sensations, in

TABLE 6.1
Summary of Disorder/Problem Behavior for Which Physiological Self-Regulation Techniques Have Been Applied

Disorder	Summary of Findings
Anxiety	Studies have found that heart rate biofeedback may be useful for inhibiting cardiac acceleration and self-reported anxiety during acute stress. There is no conclusive evidence that biofeedback of other physiological responses such as electromyogram (EMG) is any more effective than simple muscle relaxation training. Research has also demonstrated the important role that placebo factors play in producing and maintaining fear reduction in a biofeedback treatment program.
Asthma	Although clinical studies have suggested the effectiveness of EMG biofeedback for asthma reduction, there have been a number of methodological problems associated with such studies. Nonspecific placebo factors may play an important role in asthma reduction.
Cancer Chemotherapy Side-Effects	Relaxation techniques have been effectively used in reducing the side effects (e.g., nausea and anticipation anxiety) often associated with cancer chemotherapy.
Cardiac Arrhythmias	The few cases available indicate that heart rate biofeedback seems to be effective in the treatment of cardiac arrhythmias such as sinus tachycardia, atrial fibrillation, and premature ventricular contractions. However, judgment must be withheld with regard to therapeutic value of biofeedback for such disorders generally until more research is conducted.
Depression	There are a number of studies indicating that mild forms of agitated depression can be treated with biofeedback and relaxation techniques. However, methodological problems with such studies, such as nonstandard methods employed in evaluating depression, make it difficult to interpret results across studies.
Dermatological Disorders	Although there have been some case studies suggesting the therapeutic effectiveness of biofeedback-assisted behavioral treatment techniques, there have been no well-controlled studies conducted to date. Moreover, there are various forms of dermatological disorders that may be differentially responsive to such treatment.
Dyskinesias	Biofeedback techniques have been used to treat a number of different dyskinesias, including spasmodic torticollis, Parkinson's disease, tardive dyskinesia, and Huntington's disease. Individual and multiple case reports suggest a possible use of EMG in the treatment of these disorders. However, the role of biofeedback is unclear because controls were not used.
Epileptic Seizures	At this time, the amount of control group research concerning possible therapeutic effects of EEG biofeedback for the treatment of epileptic seizures is limited, and all but the most speculative conclusions are premature. Positive results have been reported that are encouraging and it would seem to justify additional research.
Essential Hypertension	Research has shown some degree of success in reducing the symptoms of essential hypertension with biofeedback. Blood pressure can be effectively reduced using biofeedback. However, biofeedback is still an experimental form of treatment for hypertension, with little known about the exact physiological mechanisms involved in the process. Thus, it cannot be considered an alternative to pharmacological treatment at this time. Biofeedback is often used as one component in a more comprehensive behavioral intervention.
Gastrointestinal Disorders	Research results of the biofeedback-assisted modification of gastrointestinal behaviors are encouraging. Biofeedback by means of rectal or anal devices is currently the treatment of choice for many types of fecal incontinence. Moreover, it is likely to become a preferred treatment method for patients with constipation related to the inability to relax the striated pelvic floor muscles during defecation. In addition, thermal-biofeedback, as part of a comprehensive behavioral treatment program, is a promising approach to the treatment of irritable bowel syndrome.
Insomnia	There is a great deal of evidence indicating that biofeedback and relaxation techniques, as components of a more comprehensive behavioral treatment program, are effective in the treatment of insomnia.
Lower Motor Neuron Dysfunctions	The case studies reporting the successful application of biofeedback in the treatment of lower motor neuron dysfunction (EEG, peripheral nerve injury, Bell's Palsy) must currently be interpreted with some caution, given the lack of control procedures.
Migraine Headache	Research suggests that temperature biofeedback, combined with autogenic training, is more effective than no treatment and possibly superior to placebo treatments. Thus, such an approach is warranted for the treatment of migraine.
Muscle Contraction Headaches	The effects of EMG biofeedback exceed those for medication placebo, biofeedback placebo, and psychotherapy procedures. In addition, although research suggests that biofeedback and relaxation produce similar levels of improvement, biofeedback may offer greater benefits to a subset of patients.

Muscular Pain	Although tentative results are promising with regard to the biofeedback treatment of pain, the role of placebo factors is probably a potent one. As they are in many other pain syndromes, such factors need to be more carefully evaluated. It should also be recognized that the etiology of many muscular pain disorders, such as low back pain and myofascial pain, remains a mystery, and therefore, it is difficult to determine what specific physiological response to assess and modify.
Postural Hypotension	There is no effective treatment for this disorder, and severely affected patients must remain in the supine position. Although control group studies are not yet available, several good case studies have demonstrated that systolic blood pressure biofeedback training has enabled some patients to sit upright or to stand with crutches, which prior to training produced fainting.
Premenstrual Syndromes	There have been some studies suggesting the effectiveness of relaxation training for premenstrual symptoms, especially for severe symptoms. However, because of the current limited understanding of the syndrome (or syndromes), as well as the high rates of placebo responding, more research is needed.
Raynaud's Disease	Recent controlled research studies involving over 160 patients have shown that behavioral treatment, with biofeedback as a key modality, can be very effective, equalling the best clinical effects of many medical and surgical interventions. In light of the limitations of current medical and surgical treatments for Raynaud's disease, behavioral interventions appear to have much to offer for these patients.
Sexual Dysfunctions	Although genital responses have been shown to be responsive to both instructional control and biofeedback, there is no evidence that the direct conditioning of genital responses through biofeedback has therapeutic value. However, biofeedback may have a role to play in guiding the development of erotic and nonerotic fantasy, which can, in turn, have significant therapeutic value.
Temporomandibular Disorders (TMD)	A considerable number of studies indicate that EMG biofeedback training, often accompanied by relaxation training or general stress management training, is an effective treatment modality for TMD. However, the mechanism by which such treatment works is not clearly understood.
Tinnitus	There have been a few case studies indicating the effectiveness of biofeedback and relaxation methods in reducing the severity of tinnitus symptoms.
Upper Motor Neuron Dysfunctions	A number of well-designed individual and multiple case studies has suggested the therapeutic effectiveness of biofeedback in the treatment of upper motor neuron disorders such as paresis, cerebral palsy, and incomplete spinal cord lesion. However, an appropriate number of control group experiments is still lacking except in the biofeedback treatment of paresis, where results are negative or ambiguous.

turn, appear to correspond to a state of deep relaxation. Schultz demonstrated that these sensations of relaxation can be created voluntarily, without hypnosis, when an individual passively repeats verbal statements focusing on these sensations (e.g., "my hands are heavy and warm"). The training is called *autogenic*, because patients repeat the verbal "formula" to themselves.

Autogenic training was referred to by Schultz and Luthe as *psychophysiological psychotherapy* because of their perspective that mental and bodily processes occur simultaneously and interactively. This, of course, is similar to the current perspective of many therapies that emphasize the integrated training of mind and body. Although the early training program involved several months of training, therapists today have developed abbreviated training exercises that can be taught in one or two sessions.

The Relaxation Response

Transcendental meditation was initially developed by Maharishi Mahesh Yogi in India as a streamlined form of meditation to produce increased tranquility and spiritual growth. Maharishi believed that through the practice of his simple meditation methods, individuals could experience inner quietness and increased consciousness that would have positive health

consequences. The meditation was called *transcendental* because it was believed that the mind would "transcend" ordinary thinking because the mind has a natural tendency to expand its boundaries under appropriate circumstances.

In 1968, Benson was asked by practitioners of transcendental meditation to evaluate its effects on physiological processes. At this time, during the 1960s, transcendental meditation was becoming very popular in the United States as a relatively simple method for experiencing increased awareness and inner tranquility. Indeed, during the 1960s and 1970s, many alternative forms of self-awareness (some involving drugs) were being experimented with by the lay public.

Benson and colleagues conducted a series of studies demonstrating that transcendental meditation did produce significant physiological changes, such as reduced oxygen consumption, metabolic rate, and cardiovascular responses, leading to a highly relaxed state associated with decreased sympathetic nervous system activity. Moreover, similar to the therapists in this country who shortened progressive relaxation and autogenic training methods, Benson embarked on creating a shortened, more Westernized version of the basic elements of transcendental meditation. He called his technique the *relaxation response* because it produces physiological effects eliciting a relaxation response. In evaluating transcendental meditation and other meditation tech-

niques, Benson delineated four basic elements in these techniques: a quiet environment in which to practice; a word or object of meditation on which to focus (e.g., the "mantra"); a positive attitude of just letting go or just "let it happen;" and a comfortable sitting position that does not lead to sleep. Benson originally recommended practicing the relaxation response technique daily for about 20 minutes. His research (Benson, 1975) found that the relaxation response will produce significant physiological changes, especially decreases in sympathetic nervous system activity.

The Quieting Reflex

The Quieting Reflex is another type of relaxation method initially developed by Stroebel. Stroebel, after suffering with headaches for a long period of time, decided that stress and accompanying muscle tension were the primary cause of the excruciating headaches. In an attempt to reduce tension, he tried different techniques such as transcendental meditation and biofeedback. After receiving relief from the headaches using these techniques, he became convinced that the major method of reducing stress is learning to have a quiet body and an active mind. Moreover, he thought it was important to develop a technique that did not demand too much time from the hectic schedule that might prompt nonadherence. He sought a technique that had simplicity and would not take too much time so that a person could consistently practice it enough to make it a learned response or habit. He therefore developed the Quieting Reflex (Stroebel, 1983), with training directed at mastering a technique that eventually can be produced reflexibly. This technique is often taught for several sessions in conjunction with biofeedback training, which helps to increase experiences of heaviness and warmth through relaxation. Again, the goal is to produce a reduced state of physiological activation.

STRESS, HEALTH AND VOLITIONAL CONTROL

During the 1960s and 1970s, various self-management or self-control techniques were being developed for people to use in making healthy lifestyle changes such as diet control, exercise, smoking cessation, and so on. Physiological self-regulation methods were a natural extension of the trend. Moreover, volitional control techniques such as biofeedback and muscle relaxation became even more popular during the 1970s when results from the burgeoning field of stress research started to appear in the scientific literature. This research began to clearly document a close link between stress and health/illness. Stress has been shown to be a major behavioral/psychological link to illness (Gatchel et al., 1989). Chronic stressors can cause neural and endocrine change that alters the normal functioning of the organism (e.g., change in cardiovascular activity or immune system functioning). This physiological response to stress is also accompanied by behavioral responses as well. Stress and the subsequent behavioral response to it can affect health and facilitate, if not cause, some illnesses.

Stress has direct physiological effects on the body, and the cumulative wear and tear on the system caused by recurring stress can eventually cause damage to the system. Indeed, there is abundant evidence that stress can cause a number of physiological and biochemical changes. There is also a growing literature indicating that some of these changes can be linked directly to illness (Gatchel, 1994; Gatchel et al., 1988). Moreover, there are data to suggest that self-regulation methods to reduce stress (such as relaxation) may have beneficial health effects. For example, in a study of elderly nursing home residents who received a series of relaxation training sessions, it was found that there was an enhancement of natural killer cell activity (an indice of immune system functioning) at the end of training relative to pre-training levels (Kiecolt-Glaser et al., 1985).

With the realization of the relation between stress and maladaptive physiological activity, there has been an increased interest in attempts to develop *stress management techniques* in order to help individuals directly deal with stress and avoid negative psychophysiological consequences. Biofeedback and other volitional self-control techniques are integral parts of such stress management programs. Moreover, during the past decade, health psychologists have paid great attention to developing techniques of stress management that can be taught to large groups of people. This is because stress-related disorders appear to account for as much as \$17 billion per year in lost productivity, with some estimates placing the annual cost of stress-related illnesses at \$60 billion (Adams, 1978). This has caused increased motivation on the part of businesses and organizations to help their workers identify and cope more effectively with a variety of stressful events experienced on the job.

It is beyond the scope of this chapter to review the major components and types of stress management programs. There is a rapidly growing literature on this topic (Gatchel, 1994; Gatchel, Baum & Krantz, 1989). It should be noted, however, that these stress management programs have been developed and utilized extensively with populations that already suffer from a stress-related illness or are at high risk for a stress-related illness. Thus, individuals with psychophysiological disorders—such as essential hypertension, headache, and gastrointestinal problems—have been treated with such techniques (Gatchel & Blanchard, 1993; Gatchel et al., 1989). Moreover, stress management techniques have also been developed as a means of modifying Type A behavior associated with increased risk of coronary disease (e.g., Roskies et al., 1986). These programs have been documented to be helpful, and results demonstrating a decrease in physiological symptomatology again point to the close link between stress, behavior, and illness/health.

PERCEIVED VOLITIONAL CONTROL

The direct control of physiological responding can have significant implications for the modification of many psychological and physical disorders. Besides the direct effects on physiological functioning that these different methods of volitional control and stress management techniques, in general, produce, there has also been an interest in delineating impor-

tant concomitant psychological factors that contribute to therapeutic efficacy. One such factor shown to be important is *perceived control*. Evidence has been reviewed elsewhere (Gatchel, 1980), indicating that individuals react differently to emotionally stressful events they perceive to be personally controllable relative to those perceived to be not in their control. This dimension of perceived controllability/uncontrollability of an emotional stressor has been shown to significantly affect self-report, behavioral, and physiological components of emotional stress.

There have also been studies demonstrating that many stress-reducing effects can be produced merely by creating the belief in subjects that they can control the amount of stress, even though they actually cannot do so. The first widely cited study that experimentally manipulated the perception of control over a stressor, where there actually was none, was conducted by Geer, Davison, and Gatchel (1970). There were two separate parts of this study. In the first part, all subjects were instructed to press a microswitch at the onset of a 6-second, painful electric shock so that their reaction time could be measured. Following 10 such trials, half of the subjects (perceived-control group) were told that by decreasing their reaction times during the second part of the experiment, which would also consist of 10 trials, they could reduce shock duration by half. These subjects were thus led to believe that they could actually exert control during the next 10 stressful trials. The other group of subjects were not led to believe that they could do anything to control the shock (perceived no-control group). All subjects, however, regardless of group assignment or reaction time speed, received 3-second shocks on all 10 pain trials during the second part of the experiment. Thus, the actual amount of aversive stimulation was held constant across the two groups. A major finding of this study was that the perceived no-control group subjects had a significantly greater frequency of spontaneous skin conductance fluctuations (an indication of heightened emotional stress) during the second half of the study relative to the perceived-control group subjects. These results therefore demonstrated that the perception of effective control, even if not veridical, can significantly decrease the electrodermal component of autonomic arousal produced by an aversive situation. Thus, there is little doubt that the perception of control, whether or not veridical, can significantly reduce the impact of emotionally stressful events. There are other studies documenting the stress-reducing effects of perceived control (Gatchel, 1980).

There is also research demonstrating the importance of the perception of the control in the context of studies in which subjects are taught self-control of physiological responses. For example, in an experiment by Gatchel, Hatch, Watson, Smith, and Gaas (1977), the relative effectiveness of heart rate biofeedback, false heart rate biofeedback, muscle relaxation, and combined heart rate biofeedback/muscle relaxation training in reducing anxiety in speech anxious subjects was evaluated. Subjects in the false biofeedback placebo group were led to believe that they were successfully learning to decrease heart rate voluntarily (even though they were actually not), which would later serve as an effective means of

alleviating anxiety. Results of this study indicated that all four experimental groups showed a decrease in a self-report component of public speaking anxiety as a result of the treatment they received. There were no significant differences among the four groups. The fact that the false biofeedback placebo group demonstrated as much improvement as the active treatment group indicates the powerful impact of a false biofeedback false placebo condition. The perception by the group that they had active control over an anxiety competing response (heart rate deceleration), even when they in fact had none, significantly influenced their self-report of anxiety.

Although there were no significant differences found among groups on the self-report measure of anxiety, an evaluation of physiological indices yielded some interestingly different findings. Results indicated that the three active physiological self-control treatment groups showed significantly smaller heart rate and skin conductance level increases during a posttreatment assessment of anxiety, in comparison to the false biofeedback group. Thus, direct control over physiological activity translated into significant reduction in the overall psychophysiological indices of stress and anxiety.

The Placebo Effect

Research clearly demonstrates the important impact that the placebo effect has in biofeedback and other physiological self-control techniques directed at eliminating emotional stress. The placebo effect itself was originally shown to be an important factor in medical research when it was found that inert chemical drugs, which had no direct effect on physical events underlying various medical disorders, were often found to produce symptom reduction. An extensive literature on the placebo effect in medicine undeniably demonstrates that a patient's belief that a prescribed medication is active, even if it is in fact chemically inert, often leads to significant symptom reduction (e.g., Honigfeld, 1964; Shapiro, 1971). Indeed, Shapiro (1959) noted that "the history of medical treatment until relatively recently is the history of the placebo effect" (p. 303). Even response to a chemically active drug to some degree depends on a belief in the drug's actions and the faith in the doctor prescribing it.

The placebo effect has also been found to be an active ingredient in psychotherapy (e.g., Wilkens, 1973), especially when anxiety is being treated. Although the placebo effect is a "multidetermined phenomenon" that is not yet completely understood, one important psychological factor contributing to the placebo effect that has been shown to affect the outcome of psychotherapy is generalized expectancy of improvement (Wilkens, 1973). This can be produced merely by creating the belief in patients that they can control some degree of emotional stress.

The Placebo Effect and Perceived Control

How does perceived control relate to the placebo effect? Merely the expectancy or belief that a treatment is going to be therapeutic and effective, and that it is going to provide a means of coping with a stressful symptom or array of symptoms, will

often lead to that very state of affair of symptom reduction. People suffering from a significant amount of stress and tension often feel at the mercy of this aversive emotional state, with no effective means of alleviating or personally controlling it. One of the chief attractions of tranquilizers, besides the reduction of the physiological components of stress, is that they allow individuals the comforting perception that they have a means of actively controlling the ingestion of a drug.

Indeed, this same perception of control factor can be seen in nonpharmacological treatments. For example, Goldfried and Trier (1974) demonstrated the effectiveness of muscle relaxation training in reducing anxiety when presented as an active self-control coping skill. This self-control concept has been reviewed as an important component of behavioral treatment techniques (e.g., Goldfried & Merbaum, 1973). Goldfried and Trier found that subjects who were given relaxation training presented as an active coping skill over which they exerted personal control demonstrated a significantly greater reduction in anxiety than subjects who were given identical muscle relaxation training, but that was presented as an "automatic" procedure for passively reducing anxiety.

Of course, the concept of personal or perceived control is not the entire reason why techniques such as muscle relaxation and biofeedback work. The techniques are still effective when relaxation is passively induced. There is little doubt, however, that the psychological or cognitive factor of perceived controllability plays a significant role in the stress reduction process. Indeed, the concept of *self-efficacy* in the treatment of maladaptive or emotional behavior has been emphasized (e.g., Bandura, 1986). A sense of self-efficacy greatly contributes to the reduction of emotional distress. Thus, direct volitional control of physiology may not only impact on the physiological component of stress, but may also simultaneously affect the other more psychological concomitants of this complex psychophysiological process.

CONCLUSIONS

Physiological self-regulation techniques such as biofeedback have an important place in the rapidly growing field of health psychology. To date, there is a great deal of research demonstrating the efficacy of these techniques in helping to manage a wide array of medically related disorders. It should again be emphasized, however, that more controlled research is needed to unequivocally document effectiveness for many of the disorders. Moreover, these techniques should be viewed merely as important *adjunctive* treatment modalities to be used as part of a more comprehensive treatment program. Many disorders are far too complex psychophysiological, and will not be totally responsive to a single treatment modality. Finally, the therapeutic effects of these techniques are not only due to the direct link to physiological activity, but also the psychological process of perceived control. The further investigation of the complex psychophysiological mechanisms underlying the therapeutic efficacy of self-regulation techniques should lead to a

greater refinement of training methods and a resultant more effective overall treatment strategy.

ACKNOWLEDGMENT

Some research reported in this chapter was supported by grants from the National Institutes of Health (MH46452, MH01107, and DE10713).

Behavioral Conditioning of the Immune System

Alexander W. Kusnecov
Rutgers, The State University of New Jersey

The past two decades have witnessed the growth of a multidisciplinary research area centered around the notion that the brain, through the neuroendocrine system, modulates the immune system, while the immune system in turn modulates the brain. The various converging lines of evidence supporting this concept have been summarized elsewhere (Ader, Felten, & Cohen, 1991). However, serving as the basis for the present chapter is one of the most compelling demonstrations of brain-immune system interactions: behaviorally conditioned immunomodulation. This phenomenon is based on the observation that alterations of immune function can be linked in a learned manner to a conditioning stimulus (CS), such that the CS attains the power to reenlist the immunological change with which it had previously been associated. In the terminology of the conditioning literature, the inducer (e.g., immunosuppressive drug) of the immunological alteration may be viewed as the unconditioned stimulus (UCS), whereas the reenlisted immunological alteration after reexposure to the CS is a conditioned response (CR). Thus, not unlike the traditional Pavlovian conditioning of the salivary response in hungry dogs, the activity of the immune system can also be manipulated by conditioning.

Not surprisingly, the concept of conditioning the immune system first emerged from the former Soviet Union during the first half of the 20th century. Conducting research in laboratory animals, and examining the modulation or elicitation of specific and nonspecific host defenses within classical Pavlovian conditioning paradigms, results were obtained that suggested the immune system could be classically conditioned. Unfortunately, many of the studies were poorly re-

ported and badly controlled (for a detailed review of these studies see Ader, 1981). More recently, Ader and Cohen (1975) demonstrated a conditioned immunopharmacologic effect on the antibody response in rats, and initiated the modern era of research on conditioning of the immune system. In doing so, they suggested in almost heretical fashion a possibly “learned” functional alteration in a biological system—the immune system—that presumably had been thought to function independently of the central nervous system (CNS). This implication was received with considerable skepticism, but spurred by a rapid accumulation of knowledge in the brain, behavioral, and immunological disciplines, it has gained general acceptance (Ader et al., 1991; Kusnecov & Rabin, 1994).

Much of the literature on behavioral conditioning of the immune system has been reviewed in detail elsewhere, with considerable emphasis on such issues as the generality of conditioning paradigms, conditioned and unconditioned stimuli, and immunological measures (Ader & Cohen, 1991; Kusnecov, Husband, & King, 1988). Therefore, this chapter tries to avoid detailed descriptions of studies already reviewed, and focuses more on recent and clinically applicable observations. A brief overview of the immune system is provided in the next section for those readers unfamiliar with immunology.

OVERVIEW OF THE IMMUNE SYSTEM

The immune system is a diffuse collection of specialized cells that function to protect the body (the *host*) from infection

caused by foreign (or nonself) microorganisms, such as bacteria and viruses. Although it consists of well-circumscribed anatomic regions, the immune system is constantly in motion, its cells circulating throughout the body to maintain surveillance against potential pathogens breaching the skin and mucosal surfaces (e.g., upper respiratory, gastrointestinal, and urogenital tracts). Protection from infection is accomplished through two interdependent processes referred to as *natural* (i.e., *innate*) and *acquired* (i.e., *learned* or *adaptive*) immunity. Innate immunity is achieved by established non-specific mechanisms that do not discriminate between the different types of infectious agents. The major cells of the innate immune response are the phagocytic cells, chief among which is the macrophage. Macrophages can be found in almost every tissue of the body (for this reason, they are also referred to as *tissue macrophages*).

Acquired immunity involves stimulation of a unique population of cells called lymphocytes, which are committed to respond against specific microorganisms. This type of immunity is a learning (or cognitive) process that is retained (memorized) by the immune system, and will recur again only to the same foreign substance. In contrast, the performance of innate defenses does not improve with repeated exposure to the same infectious microorganism.

The foreign substance against which an acquired immune response occurs is called an *antigen*. In a more restricted sense, an antigen is a specific molecular configuration against which only a small subset of lymphocytes will respond. There are potentially many antigens on a single bacterial cell or virus, such that within the subgroup of lymphocytes that react against a particular bacterial cell, different lymphocytes will react against different parts of the bacterial cell.

In contrast to innate immunity, then, the acquired immune response is distinguished by a number of hallmark characteristics:

1. *Specificity*: Each distinct antigen elicits only one immune response; that is, multiple immune responses may take place to several antigens present at the same time (e.g., different antigens present on the same bacterial cell).
2. *Diversity*: Each antigen is recognized by only one set of precommitted lymphocytes (i.e., different lymphocytes will recognize different antigens).
3. *Memory*: Each lymphocyte that responds to a specific antigen will do so again at a later time with greater speed and intensity; the first response is called a primary response, and subsequent responses on reexposure to the same antigen are called secondary, tertiary, and so on.
4. *Self-Limitation*: Responding lymphocytes can be downregulated so that the immune response need not persist after the antigen is removed from the body.
5. *Self/Nonself Discrimination*: Lymphocytes possess the ability to discriminate between molecules derived from the host (self) and those that appear from outside the organism (nonself); this is immunological tolerance, and it is a particularly critical function that prevents lymphocytes from attacking host tissue and causing autoimmune disease.

When a lymphocyte responds to an antigen it progresses through three distinct phases. Initial binding and recognition of antigen is the *inductive* phase, which initiates intracellular processes that progress to the *activation* phase, in which lymphocytes divide and multiply (or proliferate) and then differentiate (i.e., change form and function). Differentiation leads to the final *effector* phase. In this phase, lymphocytes are now effector cells, secreting various soluble products, such as cytokines and antibody, which promote the recruitment and expansion of more lymphocytes (and other types of cells) and the neutralization and elimination of antigen either through cytotoxic or antibody-mediated functions.

Although lymphocytes are not stationary and circulate throughout the body, they do localize in well-defined and widely distributed organs called lymph nodes. In addition, there are the *peyer's patches*, which are small lymphoid nodules that traverse the small intestine. And finally, there is the spleen (located beneath the liver), a heavily vascularized and the most commonly used lymphoid organ in experimental animal studies.

The cells of the immune system are hematopoietic (i.e., blood borne), and therefore, their formation is part of a continuing blood cell generating process known as *hematopoiesis*. This takes place in the bone marrow. Although in the bone marrow and another organ, the thymus, lymphocytes, macrophages, and other cells of the immune system are said to be immature, and cannot emigrate until they have differentiated into the "mature" state necessary to perform their specific functions. To emphasize this distinction, the bone marrow and thymus are referred to as *primary lymphoid organs*, whereas the spleen, lymph nodes, and gut-associated lymphoid tissue are called the *secondary lymphoid organs*.

Because they mediate the antigen-specific acquired immune response, lymphocytes are the preeminent cells of the immune system. All other cells (e.g., monocytes/macrophages, dendritic cells, granulocytes) that interact with lymphocytes serve either to present antigen to lymphocytes or to eliminate antigen in a nonspecific, innate manner. There are two major types of lymphocytes: **T** and **B** lymphocytes (interchangeable with the terms "T"-cells and "B"-cells).

In mammals, the B lymphocyte (so-called because of its discovery in the bursa of chickens, although there is no bursal equivalent in mammals) is derived from a common progenitor hematopoietic stem cell, and matures during fetal life in the liver and then in the adult bone marrow. The major function of B lymphocytes is the production of immunoglobulin molecules (abbreviated Ig). Structurally, there are five major classes or isotypes of immunoglobulin molecules: IgA, IgD, IgE, IgM, and IgG. When an immunoglobulin molecule is produced to specifically bind an antigen it is called an antibody. The production of antibodies against an antigen is called the humoral immune response.

B-cell induction occurs via binding of antigenic determinants to the B-cell receptor, which is commonly an IgM or IgG molecule. The receptor mediated recognition of antigen results in the B-cell undergoing clonal expansion. This type of activation can either be T lymphocyte dependent (i.e., helped by T-cells) or independent (i.e., direct interaction of antigen with

B-cells results in activation and antibody production without any co-stimulatory signals from T-cells). Ultimately, B-cell activation leads to differentiation into a bigger plasma cell, which produces and secretes antibodies. A plasma cell is more commonly referred to as an antibody forming cell (AFC), which in certain types of B-cell assays, is synonymous with a plaque forming cell (PFC).

Although most classes of antibody molecule are produced during the primary response, IgM production predominates. Once memory B-cells have formed during the effector stage of the primary response, their reactivation in a secondary immune response to the antigen that they are specific for results in predominantly IgG production systemically (e.g., in blood and spleen) and IgA mucosally (e.g., in the small intestines or upper respiratory tract).

T lymphocytes (or T-cells) are so-called because of their maturation in the thymus gland. Within the thymus, T-cells mature into cells that express various distinct molecules (e.g., CD4, CD8, and a T-cell receptor, TCR) that mediate important T-cell functions. Maturation in the thymus is essentially a selection process based on whether T-cells possess close affinity for molecules expressed by the major histocompatibility complex (MHC; see later), and the absence of reactivity to molecules (other than the MHC encoded molecules) expressed on self tissue. This latter criterion is the basis of self-tolerance, or absence of autoaggressive responses. A mature T-cell, therefore, will not react against non-MHC self antigens, but will strongly recognize MHC encoded molecules. This capability optimizes T-cell recognition of foreign antigens, which are presented to the T-cell in association with MHC encoded molecules. This is the molecular basis of antigen presentation to T-cells by macrophages, B-cells, and dendritic cells.

All T-cells emigrating from the thymus express a TCR, the purpose of which is to recognize specific antigenic peptides and initiate intracellular signals that will result in cell division (mitosis) and differentiation. However, T lymphocytes also differentially express molecules (CD4 and CD8), which is the basis of their segregation into two major functional subtypes. Hence, mature T-cells are designated as either CD4⁺ or CD8⁺. The CD4 T-cell helps or promotes antigen-specific B-cell responses, and is called a T-helper cell; CD8 T-cells mediate cytotoxic responses against foreign cells or host cells infected with viruses, and are therefore called cytotoxic T-cells.

Induction of a CD4 or CD8 T-cell response requires a recognition step in which antigen specifically binds to the TCR. The recognition step between antigen and TCR involves a physical interaction between the T-cell and another (non-T) host cell that presents the antigen in the molecular "clutches," as it were, of one of the proteins encoded by the MHC. This latter non-T-cell is called an antigen presenting cell (APC). For example, after performing their innate function of indiscriminately ingesting a large foreign substance by phagocytosis or endocytosis, macrophages will digest this substance into peptide fragments that are then loaded onto the MHC Class II molecule (see later) and transported to the cell surface. Induction of an immune response will then take place

through the recognition of the MHC-bound foreign peptide by the appropriate T-cell that expresses a TCR "fitting" in a complementary manner the molecular configuration of the peptide antigen.

To understand this more fully it is necessary to consider the nature and function of the MHC more closely. The MHC is a set (*complex*) of genes found in all vertebrate mammals and located on distinct chromosomes (e.g., chromosome 6 in humans; chromosome 17 in the mouse). These genes code for protein molecules that are expressed on the cell membrane and, as described earlier, play a critical role in the presentation of antigen to T-cells. The main protein molecules encoded by the MHC are the Class I and Class II molecules. Class I MHC molecules are expressed on most cells in the body (i.e., cells of the immune system and cells not of the immune system). Expression of Class II MHC molecules is more restricted, occurring on B-cells, macrophages, dendritic cells, epidermal langerhans cells (found in skin), and thymic epithelial cells. These latter cells are said to be professional APC.

The major function of MHC encoded Class I and II molecules is the binding and presentation of antigenic peptides to T-cells whose receptors are capable of recognizing the peptide + MHC protein complex. In general, CD4⁺ T-cells recognize antigen when it is bound by a MHC Class II molecule; CD8⁺ T-cells recognize antigen when it is presented by a MHC Class I molecule. Thus, because of their dependence on MHC Class I and II expression, immune responses mediated by CD4 and CD8 T-cells are said to be MHC restricted.

It should be noted that there is another class of cytotoxic lymphocyte, known as a large granular lymphocyte, which does not appear to respond in a MHC-restricted and antigen-specific manner. These cells spontaneously lyse bacterial, viral, and tumor cells, and are known as natural killer (NK) cells. These lymphocytes, therefore, may be viewed as part of the innate, nonspecific immune response.

Much of the effector function of the acquired immune response involves the production of soluble substances (i.e., nonparticulate molecular products) that promote the elimination of antigen. Antibody molecules produced by B-cells represent one class of soluble effector mediators. However, another important class of molecules, and the most intensively studied, are the cytokines. Cytokines are protein molecules synthesized and secreted by cells (hence the cyto-) to serve as autocrine/paracrine signaling and growth and differentiation factors. Fibroblasts and endothelial cells secrete cytokines, but so do cells of the immune system. T lymphocytes, monocytes, and macrophages all secrete cytokines. There are some reports that B lymphocytes can also secrete cytokines.

The term *cytokines* is a generic term. Cytokines produced by T-cells are called lymphokines. Cytokines produced by monocytes and macrophages are called monokines. However, for convenience, and the fact that some monokines are also lymphokines, these products are referred to generically as cytokines, whether derived from T-cells or monocytes/macrophages. (To add to the confusion, many cytokines are called interleukins, i.e., to reflect the observation that they act "between leukocytes," and are abbreviated, IL. Many interleukins are produced by T lymphocytes.)

The major characteristics of cytokines are as follows: (a) They are generally not constitutively expressed and need to be induced. (b) Their actions are mediated through a specific receptor synthesized by the target cell. (c) Many cytokines have overlapping functions (i.e., they are pleiotropic, affecting more than one cell type), which allows for some redundancy. The latter characteristic is extremely germane to the present chapter, because cytokines both affect and are produced in the CNS.

In closing this section, it should be stated that the distinction between two major types of immunity—innate and acquired immunity—is largely a matter of convenience, because neither process functions independently of the other during immune defence. That is, the immune response against an infectious agent involves both the cells of the innate immune system (e.g., monocytes, macrophages, and neutrophils) and the lymphocytes of the acquired immune response. To provide a simple scenario, invasion of the host by bacterial cells results in their immediate ingestion by tissue macrophages. The ingested bacteria are fragmented by degradative enzymes into various peptide fragments and bacterial elimination is then further facilitated by a sensitization process in which the peptide fragments are presented by MHC Class II molecules to B and T lymphocytes. The specific lymphocytes recognizing the presented antigen are then activated and expanded into a population of effector cells that secrete antibodies and cytokines. The antibodies bind to any noningested bacterial cells and facilitate their destruction by other phagocytic cells. Cytokine production promotes this process by influencing B-cell antibody production, various T-cell functions (e.g., proliferation, cytotoxic activity, and cytokine production), and the bacterial killing functions of macrophages. Hence, innate and acquired immune responses are ongoing simultaneously through a sophisticated network of cellular and cytokine interactions.

For readers wanting to know more about the immune system, the introductory textbooks by Abbas, Lichtman, and Poher (1994) and Roitt, Brostoff, and Male (1989) are a particularly good place to start.

BEHAVIORAL CONDITIONING OF THE IMMUNE SYSTEM

There is now no question that immune function is under significant neuroendocrine and autonomic nervous system (ANS) control. Because the activities of the ANS and neuroendocrine system fluctuate in relation to behavior (e.g., stress), optimal protection from infectious disease may be determined by specific modes of behavior. The relation of psychosocial factors to immune function is reviewed elsewhere in this handbook, and represents one significant example of how behavior can modulate immune function. This section considers additional evidence demonstrating that the immune system may actually influence behavior in a learned manner. Because of space limitations, it is assumed that the reader is familiar with the general notions and terminology of learning theory.

As stated in the introduction, the first formal and exquisitely controlled demonstration of behaviorally conditioned

modulation of an immune response was provided by Ader and Cohen (1975). This study is described in considerable detail because it is the prototype of the many studies that were conducted subsequently in other laboratories. Based on some serendipitous observations, Ader and Cohen (1975) hypothesized that an immunologic alteration could be reestablished in a learned or conditioned manner by an environmental stimulus or stimuli previously associated with an immunomodulatory event. To test this, they utilized the conditioned taste aversion (CTA) paradigm in which a novel tasting solution (CS) is paired with an illness inducing drug (UCS), the result being that subsequent CS reexposure elicits enhanced neophobia or aversion. Behaviorally this is measured as reduced ingestion of the CS. Thus, in Ader and Cohen's experiment, the UCS was cyclophosphamide, a cytotoxic drug commonly used to destroy tumor cells in cancer patients, but that also has noxious and immunosuppressive side effects. The immune measure that was used in this experiment was the primary antibody response to sheep red blood cells (SRBC).

Thus, rats received a learning trial consisting of a paired presentation of the CS (saccharin solution) and an injection of cyclophosphamide. Three and/or 6 days later, these now conditioned animals were either reexposed to the CS, not given the CS (received water), or were injected again with the UCS. Thirty minutes after these treatments on Day 3, all groups were immunized with SRBC. Additional control groups were included to eliminate any placebo effects. Although a nonconditioned group was included (received water and UCS on the conditioning day), this was not a noncontingent control group. Later studies from Ader and Cohen's laboratory (and that of others) included this necessary control group without any change in the interpretation of the results. Measurement of the antibody response 6 days after immunization revealed the following pattern of results. As expected, animals that did not receive the immunosuppressive UCS had the highest antibody response, whereas those that received the UCS on the learning day and on the test day, just prior to immunization, had the lowest response. Between these two extremes, the remaining groups showed the pattern of results that had been predicted. The critical control group consisted of animals that were conditioned, but received the SRBC in the absence of the CS. As predicted, the antibody response of this group was significantly higher than the conditioned group that had been reexposed to the CS 30 minutes prior to immunization.

These results were interpreted as demonstrating a behaviorally conditioned immunosuppression. Subsequent confirmation of these results, using essentially the same paradigm and antigen (Rogers, Reich, Strom, & Carpenter, 1976; Wayner, Flannery, & Singer, 1978), served to establish the reliability of this phenomenon. In the ensuing years, numerous laboratories have extended these observations, seeking to characterize the parameters, behavioral and immunological, which allow for the expression or manifestation of this phenomenon. The phenomenon is not species specific, having been demonstrated in rats, mice, guinea pigs, and (as is discussed here) in humans. Further, it is not restricted to the taste aversion paradigm: novel odors, discrete sounds, environmental contexts, as well as tactile stimulation, have all proven

to be effective conditioning stimuli for demonstrating BCI (for reviews see Ader & Cohen, 1991, and Kusnecov, Husband, & King, 1988). Although cyclophosphamide has been the most commonly used UCS, other compounds with immunosuppressive properties have been tested. For example, behaviorally conditioned immunosuppression has been demonstrated using methotrexate (Ader & Cohen, 1981), cyclosporine A (Grochowicz et al., 1991; Klosterhalfen & Klosterhalfen, 1990), antilymphocyte serum (Kusnecov et al., 1983), and morphine (Coussons-Read, Dykstra, & Lysle, 1994). Moreover, the phenomenon is not confined to demonstrations of conditioned immunosuppression, with numerous studies showing a conditioned enhancement of antigen-specific and nonspecific immune responses (Bovbjerg, Cohen, & Ader, 1987; Husband, King, & Brown, 1986–1987; Russell et al., 1984; Solvason, Ghanta, & Hiramoto, 1988).

The range of immune parameters amenable to conditioning is quite impressive. The antibody response to SRBC has been the most popular antigen-specific measure tested (Ader & Cohen, 1991; Gorczynski, 1991), although conditioned suppression of immunoglobulin responses to protein antigens, as well as to nonspecific mitogens, such as pokeweed mitogen (Kusnecov et al., 1988) have been successfully used. In addition to humoral immune responses, *in vitro* T-cell proliferative responses (Kusnecov et al., 1988) and T-cell mediated responses such as the graft-versus-host response (Bovbjerg, Ader, & Cohen, 1984), delayed-type hypersensitivity (Roudebush & Bryant, 1991), and tissue transplant rejection have been shown to be conditioned (Gorczynski, 1990; Grochowicz et al., 1991). Indeed, the latter demonstrates the potential clinical applicability of conditioned immunosuppression. Patients that have received organ transplants are maintained on immunosuppressive drug treatment to prevent rejection of transplanted tissue by mature T-cells intolerant of specific antigens expressed by the new organ. In two separate studies in mice, it was shown that rejection of foreign skin or cardiac tissue could be delayed by a CS that had been paired with either cyclophosphamide or cyclosporine, a potent T-cell immunosuppressant (Gorczynski, 1990; Grochowicz et al., 1991). In a clinical situation, therefore, it may be possible to enhance the immunosuppressive effects of drugs, such as cyclosporine, without increasing dosage, which carries the risk of deleterious side effects.

This applies to most clinical situations where drug therapy is provided for the specific purpose of suppressing the immune system. Autoimmune disease is a condition in which there has been a failure of self-tolerance by the immune system, resulting in T and B lymphocytes attacking either specific organs or any tissue expressing the self antigen that is being responded against. Patients with autoimmune disease receive a wide range of immunosuppressive treatments, including cyclosporine and cyclophosphamide. It has been demonstrated in animal models of autoimmune disease that the therapeutic use of either of these drugs can be enhanced by introducing a conditioning component into the regimen of drug treatment (Ader & Cohen, 1982; Klosterhalfen &

Klosterhalfen, 1990; Klosterhalfen & Klosterhalfen, 1983). For example, Ader and Cohen used mice that spontaneously develop systemic lupus erythematosus and eventually die. Prior to onset of mortality, there is increased proteinuria, which can be delayed by treating mice with intermittent doses of cyclophosphamide. Ader and Cohen showed that if drug treatment was specifically paired with a novel saccharine solution, which served as a CS, proteinuria and mortality were significantly delayed in comparison to a control group of animals that had received saccharin on alternate days to that of drug treatment. Klosterhalfen & Klosterhalfen (1990) obtained similar results in rats with an experimentally induced autoimmune arthritis. They found that rats receiving paired presentations of cyclosporine and a novel chocolate milk solution developed less arthritic paw swelling, than nonconditioned animals receiving the same drug regimen. Thus, introducing a conditioning component into an ongoing therapeutic drug regimen may enhance the therapeutic efficacy of drug treatment.

Human Studies of Conditioning

Animal studies can suggest the plausibility of applying behaviorally conditioning paradigms in clinical settings requiring immunotherapy, but additional information is required to show that immune responses can be conditioned in humans. Demonstrations of conditioned immunomodulation in human subjects have been reported, although these are few in number. Gauci, Husband, Saxarra, and King (1994) investigated whether conditioning could modulate the allergic response in humans with perennial allergic rhinitis. Subjects received a single paired presentation of a novel drinking solution with exposure to a house dust mite allergen. Subsequent reexposure to the drinking solution alone revealed that mast cells from conditioned subjects contained increased levels of tryptase. This indicated increased mast cell degranulation, which constitutes part of the allergic response. Hence, consistent with previously held notions about the conditionability of allergic reactions, this finding provided experimental support that allergic responses may in part be influenced by conditioning stimuli.

Additional evidence for conditioning of a specific cellular immune response to antigen was provided by G. R. Smith and McDaniels (1983). In a study where subjects served as their own controls, it was shown that when an antigen (the purified protein derivative of tuberculin) was administered from a colored vial that consistently had been associated with saline (i.e., subjects received intradermal injections of saline, which not unexpectedly failed to elicit the classical swelling and redness associated with an immediate hypersensitivity response), the expected hypersensitivity reaction was significantly diminished. Although this study has not been repeated, it offers a reverse spin on the placebo literature in that expectations of a null response may actually drive a natural immune response in a similar direction.

In a more recent study, Buske-Kirschbaum, Kirschbaum, Stierle, Lehnert, and Hellhammer (1992)

demonstrated a classical enhancement of the natural killer cell response in humans. Natural killer cells have long been considered an important surveillance mechanism against tumor cells. Consequently, upregulation of their function is of considerable clinical importance. Prior to this study, it had already been shown that NK cell activity can be both suppressed and enhanced by conditioning in rats and mice (O'Reilly & Exon, 1986; Solvason et al., 1988). In Buske-Kirschbaum et al.'s (1992) study, college students received paired presentations of a novel taste (a sherbet sweet) and an intravenous injection of epinephrine. The unconditioned response (the natural effect of exogenous epinephrine) was increased NK cell activity in the peripheral blood. Similarly, when conditioned subjects were reexposed to the CS some days later, the same effect was observed relative to conditioned subjects not reexposed to the CS. Hence, in human subjects it is possible to reenlist the NK cell enhancing effects of epinephrine using a taste CS. An additional follow-up study by the same group (Buske-Kirschbaum, Kirschbaum, Stierle, Jabaj, & Hellhammer, 1994) replicated these initial findings using a discriminative conditioning paradigm. This involved the presentation of a compound stimulus (CS⁺: consisting of a novel sherbet sweet taste combined with white noise) together with epinephrine, whereas a second, different compound stimulus (CS⁻: also taste + noise) was not associated with epinephrine. On subsequent testing, presentation of the CS⁺ elicited a conditioned increase in NK cell activity, whereas the CS⁻ had no effect. These findings suggest that it may be possible to enhance the activity of NK cells using a conditioning approach. The advantage of increasing NK cell activity is most relevant in the treatment of cancer. However, additional studies using clinical populations are needed to test whether this is possible.

Conditioned Chemotherapeutic Effects. It is known that cancer patients receiving radiotherapy and chemotherapy experience conditioned anticipatory nausea. Not unlike the conditioned taste aversion paradigm, which itself reflects a biological predisposition to avoid toxic foods, a high percentage of cancer patients associate the nausea and illness induced by their therapy with aspects of the clinical setting, such as the staff, building, rooms, and so on. Bovbjerg et al. (1990) tested whether such a conditioned psychological reaction translates into immunological changes. The subject population for their study consisted of people with ovarian cancer, and who were receiving a schedule of chemotherapeutic treatment that was given every 4 weeks. Testing for a conditioned immunomodulation was conducted after at least three visits to the clinic, with patients arriving the evening prior to their next dose of chemotherapy. A baseline blood sample was obtained at home 3 to 8 days prior to the hospital visit, and a second blood sample was obtained just prior to drug infusion. Comparison of baseline and hospital blood samples did not reveal any differences in NK cell activity or percentages of lymphocyte subsets (Bovbjerg et al., 1990). However, the proliferative function

of lymphocytes assayed with various T-cell mitogens was significantly reduced in the hospital. Behavioral assessments revealed that patients reported experiencing greater anxiety and nausea in the hospital.

In contrast to this latter study, Frederikson, Furst, Lekander, Rotstein, and Blomgren (1993) failed to observe any changes in mitogenic function of peripheral blood lymphocytes from breast cancer patients that had previously received several regimens of chemotherapeutic treatment and were tested prior to an additional drug treatment. Measures of anxiety and nausea were obtained, but were not related to immune changes. However, it should be noted that several methodological differences exist between this and Bovbjerg et al.'s (1990) study. Patients in the latter study received a more severe chemotherapeutic treatment, and, perhaps more importantly, 80% of patients requested sedative treatment during their hospital stay. In addition to differences in the cancerous condition (ovarian vs. breast cancer) of the two subject populations, it is unlikely that the two studies can be adequately compared.

An inherent problem in assessing conditioning effects in cancer patients is the sensitivity of the circumstances. The level of anxiety and concern about physical well-being naturally serves as a deterrent against establishing experimental designs of the type observed in animal studies, or the human studies cited earlier (e.g., Buske-Kirschbaum et al., 1992, 1994). A critical control in such studies is always a previously conditioned group that does not receive CS reexposure. This group represents a measure of residual immunomodulation during the learning trial(s). However, such a group appears to be difficult to obtain among cancer patients undergoing chemotherapy. To obtain such a group, it would be necessary to include a group that would have to skip a scheduled visit to the hospital, but still receive a blood draw at home. The experimental group would be patients who go in for their scheduled visit and are sampled in the hospital. Clearly, such a situation is unrealistic.

Alternatively, it is possible to establish designs in which a specific stimulus (e.g., taste) is paired with drug treatment. This stimulus can then be introduced in a neutral setting and should serve as a CS that elicits memories of the hospital experience. Baseline blood draws and CS reexposures could all be performed away from the hospital, and different groups can be included in which some are given the CS whereas others are either given no CS or a different CS not associated with the hospital and drug treatment. Indeed, Bovbjerg et al. (1992) demonstrated in breast cancer patients that the pairing of a distinctive beverage with drug treatment produced a conditioned nausea reaction to the beverage, compared to patients that had not received the beverage with chemotherapy. Thus, in light of this experimental demonstration of conditioned nausea, it may be possible to establish designs that may more adequately assess whether there are conditioned immunomodulatory changes in cancer patients. The importance of this information is more than academic, because conditioned suppression of important immune parameters may alter the effectiveness of immune surveillance against immunogenic tumors.

Is Conditioned Immunomodulation a Stress Artifact?

Despite abundant evidence for behaviorally conditioned immunomodulation, a persisting question is whether the CS is reenlisting the immunological effects of the UCS in a learned manner, or whether the CS is reenlisting the stressor component of an aversive UCS. Because many of the agents used to modify the immune system—in particular, cyclophosphamide—have aversive properties independent of their direct immunological effects (e.g., illness), it is possible that these additional indirect effects are linked to the CS, resulting in a conditioned stress response. Indeed, Lysle and colleagues used a conditioned fear paradigm to show that when rats are reexposed to a context associated with prior delivery of electric footshock (viz. the shock chamber), there is an immediate suppression of lymphocyte proliferative activity in the spleen and in blood (Lysle, Cunnick, Fowler, & Rabin, 1988). This is also the same effect that the UCS itself exerts. Others have reported similar data for the antibody response of mice to SRBC (Zalcman, Richter, & Anisman, 1989).

Unconditioned stressors activate a variety of hormonal and neurotransmitter systems, many of which have been shown to modulate immune function (Kusnecov & Rabin, 1994), so it is reasonable to argue that conditioning paradigms using a UCS that in and of itself has a stressor component, are conditioning the stress reaction and not the actual immunobiological changes it engenders. On the other hand, because the immunobiological alteration itself is a component of the cascade of responses to a specific stressor, it is possible that the immunologic change is linked to the CNS in a learned manner. Lysle, Cunnick, and Maslonek (1991) assessed this by blocking, during the learning trial, the immunological effects of a shock UCS with the beta adrenergic receptor blocker propranolol. When animals were subsequently reexposed to the CS, the immunosuppressive effects were still evident. Clearly, the animals learned to fear the context CS independent of whether there was blockade of the immunological alteration during learning. This can be interpreted as showing that what the animal learns is fear of the context CS. Therefore, the results are consistent with the abundant evidence for stress effects on immune function (Kusnecov & Rabin, 1994), and pose serious problems for the interpretation of conditioned immunomodulatory effects in conditioning paradigms involving the use of an inherently aversive UCS.

On the other hand, there are examples of a disparity between the presence of a conditioned behavioral response and immunological alteration due to CS reexposure. For instance, a robust conditioned taste aversion can exist up to 10 days after conditioning with cyclophosphamide, although evidence for a conditioned suppressive effect on spleen cell mitogenic activity and IgM production was observed only when the CS was represented 2 days after the conditioning trial (Kusnecov et al., 1988). Because rat spleen cell mitogenic function is an immune measure shown to be very sensitive to stressor-induced modulation (Lysle et al., 1988), the inability of a robust conditioned taste aversion response to alter mitogenic func-

tion at later times following conditioning with cyclophosphamide is inconsistent with a stress-mediated interpretation of conditioning data. Other examples of where conditioned immune alterations take place in the absence of conditioned taste aversion responses are provided elsewhere (Ader & Cohen, 1991).

If there is a learned interaction between the CNS and the immune system, it may require direct immunological perturbation through mechanisms that bypass initial CNS processing. For instance, in the case of CNS-initiated immune alteration, the necessity for a cognitive interaction between the brain and the immune system may be minimal, because the immune system already is likely to be sensitized to fluctuations in the concentration of various circulating stress-related hormones (e.g., catecholamines and glucocorticoids). Hence, any perturbation of the immune system due to a hormonal fluctuation that results from CNS arousal may not require a specific learned association between neural detection of an external stressor stimulus and the altered component of the immune system. On the other hand, learned associations more likely may take place if the immune system is altered independently of the CNS. Under these circumstances, the changes within the immune system serve as an interoceptive stimulus to the CNS. The processing of this information by the CNS may then be linked to parallel processing of any other exteroceptive information that could then be linked in a meaningful way to the immunologic perturbation. This type of analysis makes more biological sense if, as has been suggested (see Blalock, 1984), the immune system is viewed as a sensory organ that detects stimuli existing below the threshold of detection by conventional sensory modalities mediated by the CNS (e.g., touch, sight, etc.).

The use of immunopharmacologic agents that possess indirect aversive properties is unequivocally a confounding element in the interpretation of conditioning results. It has even led to some argument in relation to a theory proposed by Eikelboom and Stewart (1982) concerning the direction conditioned biologic responses should take relative to whether the UCS is acting on the afferent or efferent side of the CNS. If, for example, the UCS perturbs the immune system (the perturbation being the unconditioned response) without first acting through the CNS, then the CNS will attempt to restore homeostasis by correcting the perturbation; and it is this process of restoration that is conditioned. Therefore, in the case of immunosuppression due to a direct action on the immune system by a pharmacologic agent, efferent signals from the CNS function to overcome this suppression by enhancing immune function. Consequently, any CS linked with direct immunosuppression should actually be associated with the CNS processes that are compensating for this suppression, and therefore, the effect of CS reexposure should be a conditioned immunoenhancement. However, the predictions of this theory for conditioned immunomodulatory effects are generally outweighed by evidence to the contrary. Of course, there are cases where data can and have been interpreted in terms of this theory (Krank & MacQueen, 1988), but by and large, most conditioned immunomodulation studies, and in

particular those using cyclophosphamide as the UCS, do not seem to conform to this theoretical perspective.

Activation of the Immune System as a UCS

The most profitable approach to elucidating whether the immune system and the CNS interact in a learned manner is likely to be through studies that utilize activation of the immune system as a UCS. This is predicated on an overwhelming body of evidence showing that activation of the immune system induces functional changes in the CNS (Besedovsky & Del Rey, 1992). Thus, it has been reported that immune activation alters sleep and feeding behaviors, increases the production of pituitary hormones, increases the synthesis and release of catecholamines peripherally and centrally, and increases neuronal firing in the hypothalamus (Besedovsky & Del Rey, 1992). Although these effects can be evoked by injection of antigens, they are also observed following treatment with cytokines, in particular, the proinflammatory cytokines IL-1, IL-6, and TNF (Schobitz, De Kloet, & Holsboer, 1994). The study of CNS activation by inflammatory cytokines is dominated by two experimental approaches: exogenous administration of recombinant cytokines, and challenge with the lipopolysaccharide (LPS) endotoxin of gram negative bacteria such as *E. Coli* (Tilders et al., 1994). Many of these studies are concerned with the characterization of behavioral and/or neuroendocrine changes, as well as the mode of cytokine action and specific target regions within the CNS.

Given the impact of cytokines and infection on illness-related behaviors, it is fitting that contemporary studies of conditioned immunomodulation began with the use of the conditioned taste aversion paradigm. Obviously, the ability to learn the physiological consequences of ingestion is fundamental to survival, and a functional link between this and the immune system should not be surprising. Indeed, conditioned taste aversion has been demonstrated using IL-1 and endotoxin administration as UCSs, indicating that these agents will signal illness centers in the brain (Tazi, Dantzer, Crestani, & Le Moal, 1988). Indeed, several reports now implicate the subdiaphragmatic vagus nerve as mediating the behavioral and physiological effects of endotoxin and IL-1 (which is induced by endotoxin; Bret-Dibat, Bluthe, Kent, Kelley, & Dantzer, 1995; Fleshner et al., 1995; Gaykema, Dijkstra, & Tilders, 1995). Because the subdiaphragmatic vagus is involved in regulating feeding behavior (G. P. Smith, Jerone, & Norgren, 1985), and because the gastrointestinal tract is the main portal of entry for potential pathogens, it should not be surprising that the mucosal immune system serves not only to eliminate pathogens, but also to initiate adaptive behaviors. Hence, it is well recognized that injection of animals with endotoxin, IL-1 and TNF will reduce food intake and physical activity, and prolong sleep (for review see Schobitz et al., 1994). The same behaviors are observed during infection. This evidence suggests that the immune system communicates local information to the CNS for the purpose of initiating appropriate behaviors that either promote recovery or maintain health.

The conditioned taste aversion paradigm demonstrates that organisms will retain information about gustatory stimuli associated with illness, especially that due to infection. In fact, recent studies have demonstrated that the behavioral and metabolic effects associated with endotoxin administration can be conditioned. Fever is a centrally regulated reaction to infectious illness, and is believed to optimize the immune response against bacterial infection. In a single trial conditioned taste aversion paradigm in which rats received a pairing of saccharin solution and an injection of endotoxin, it was shown that the initial (first few hours) hypothermic and subsequent hyperthermic effects of endotoxin could be reenlisted 7 days after the learning trial by reexposure to the CS alone (Bull, Brown, King, & Husband, 1991; Exton, Bull, King, & Husband, 1995). Other studies have similarly demonstrated conditioning of temperature alterations using nonantigenic stimuli, such as polyinosinic:poly-cytidylic acid (Poly I:C), which is a synthetic double-stranded RNA polynucleotide used to mimic double-stranded RNA viral infection (Dyck & Greenberg, 1991).

In addition to temperature, the endotoxin-induced increase in slow wave sleep has also been shown to be conditioned, implying that environmental cues may potentially influence the behavioral effects of infection (Exton, Bull, King, & Husband, 1995). Endotoxin is most notably recognized as a strong inducer of proinflammatory cytokines (eg., IL-1, TNF) produced by macrophages (Tilders et al., 1994), thus it is conceivable that these conditioned effects reflect an association between conditioning cues and cytokine effects on the CNS. For example, administration of IL-1 elicits many of the same thermogenic, anorectic, and sleep inducing effects of endotoxin (Schobitz et al., 1994). Indeed, conditioned taste aversion can take place using IL-1 as the UCS (Tazi et al., 1988), and this can result in the conditioned reenlistment of the thermogenic and adrenocortical activities of IL-1 (Dyck & Greenberg, 1991).

Endotoxin is not strictly speaking an antigen, and it activates primarily innate immune processes, so these studies demonstrate conditioning of the physiological effects of indiscriminate immune activation. Hence, there remains the question of whether antigenic stimulation can serve as a UCS. Unlike substances like endotoxin, injection with foreign proteins rarely results in a rapid and significant build up of circulating proinflammatory cytokines. The response to antigen is more selective, recruits less immune cells, and is usually anatomically confined to lymph nodes that drain the site where antigen entered the body. This relatively "low key" handling of antigen is due to the small fraction (1:50,000–1:100,000) of lymphocytes that is committed to any particular antigenic configuration potentially present in the world and that mammals are likely to encounter. It has been shown that recruitment of cytotoxic T-cells can be conditioned if engraftment of foreign skin tissue serves as a UCS in mice (Gorczyński, Macrae, & Kennedy, 1982). Foreign tissue contains a large number of antigens, and therefore the UCS in this case was immunological activation by an assembly of different antigens. More recently, two studies have been conducted that have used a single protein antigen as a UCS. In the first, re-

peated injections of egg albumin were administered to rats in association with audiovisual contextual cues (MacQueen, Marshall, Perdue, Siegel, & Bienenstock, 1989). Reexposure to the CS alone resulted in increased production of an enzyme (protease II) produced by rat mast cells that colonize the gastrointestinal tract. It remains to be determined whether this enzyme release was due to actions mediated by antigen-sensitized lymphocytes activated by the CS.

In the second study, Ader, Kelly, Moynihan, Grotta, and Cohen (1993) exposed mice to repeated injections of a low, "physiologic" dose of the protein antigen keyhole limpet hemocyanin (KLH). These repeated injections were always paired with a novel gustatory CS, chocolate milk. Measures of serum IgG antibody produced specifically against KLH revealed enhanced production of antibody when these animals were reexposed, on the test day, to the CS and a low suboptimal dose of antigen. This low dose of antigen only marginally elevated residual levels of KLH-specific IgG in conditioned animals that did not receive the CS; but in the presence of CS reexposure, it resulted in a marked stimulation of KLH-specific antibody production. Presentation of the CS in the absence of a low "booster" dose of KLH did not increase antigen-specific IgG, indicating that the CS alone does not have the capacity to induce B cells to produce antibody in the absence of actual antigen.

These latter results by Ader et al. (1993) demonstrate a conditioned enhancement of the antibody response of memory B lymphocytes to a specific antigen. The mechanisms underlying this effect have yet to be dissected but, as alluded to earlier, may include the various cytokines produced in response to immunogenic stimulation. In the case of antigen-stimulated cytokine production, it is possible that locally produced cytokines within regionally distinct lymph nodes may activate the CNS via afferent neuronal pathways, thereby forming the link between immune activation and perception of unique environmental cues.

CONCLUSIONS

This chapter has reviewed evidence showing that the inherent link between the immune system and the brain can be exploited through conditioning techniques. As discussed earlier, conditioning studies using immunosuppressive drugs suggest clinical applicability in situations where autoimmune diseases or clinical suppression of transplanted tissue is the desired goal. This is especially pertinent in light of the aversive properties of immunosuppressive therapy. Given what it is understood about the impact of stress on immune function (see Glaser & Kiecolt-Glaser, 1994), it is important to minimize the physical side effects of drug treatment. This will undoubtedly also reduce the psychological reaction to such side effects, and any further harm this may have on disease outcome.

The few studies demonstrating direct conditioning of the immune response using immunological stimulation as the UCS suggest possibilities for the optimization of the immunological effects of vaccines that are routinely given to ward

off infectious illnesses (e.g., polio, tetanus, etc.). This can be done through the alignment of vaccination regimens with behavioral conditioning procedures. Alternatively, if further studies are carried out to understand the physiological mechanisms underlying direct conditioning of the immune response to antigen, it may be possible to manipulate these systems to optimize the development of immunological memory against various vaccines.

Finally, given that cytokines have been shown to modulate CNS function, it is important to learn how they may be involved in the development of conditioned antigen-specific immune responses. Moreover, the use of cytokines has been tested clinically on cancer patients, with some serious side effects, including neuroendocrine and neuropsychological alterations (Denicoff et al., 1989). Given that cytokines represent a potentially powerful tool for the treatment of cancer, it may be important to introduce behavioral strategies that can optimize the immunobiological effects of cytokine therapy while minimizing the physical and psychological side effects. However, further research is required to confirm its utility as an adjunct to traditional medical therapy.

Physiological and Psychological Bases of Pain

Dennis C. Turk
University of Washington

Pain has existed since time in memoriam. Perhaps the first documented mention of pain was in the Ebers papyrus dating back to the fourth century B.C. that indicated the use of opium for the treatment of headaches. Since that time, pain has been the focus of philosophical speculation and scientific attention, yet it continues to remain a challenging problem for the sufferer, health care providers, and society.

Pain has been classified in a number of different ways, including the use of a single temporal dimension ranging from acute (momentary pain or pain extending from several hours, days, and weeks) to chronic (persisting over periods of months) to single categorical systems, such as presumed etiology (e.g., neuropathic, somatic, psychogenic), to more multiaxial diagnoses in which multiple factors are included in the classification (e.g., location, system involved, temporal characteristics and pattern of occurrence, intensity, and etiology; Merskey, 1986). For simplicity, this chapter uses a categorical approach referring to four categories of pain: *acute*, *acute recurrent* (e.g., migraine headache), *chronic noncancer pain* (e.g., low back pain), and *pain associated with a malignant disease process* (i.e., cancer).

Pain is essential for survival because of its alarm function. In acute pain states, nociception (activation of sensory transduction in nerve fibers that convey information about tissue damage) has a definite purpose, it acts as a warning signal that requires immediate attention, reflexive withdrawal, and other actions in order to prevent further damage and to facilitate the healing process. In chronic pain states, this adaptive function plays a significantly smaller role and can often no longer be discerned. In the case of recurrent acute pain diagnoses, such as migraine headaches, the role of pain is even less clear because there is no protective action that can be taken or any tissue damage that can be prevented. Pain associ-

ated with neoplastic disease has some features in common with acute pain in that it may be a warning signal; whereas in others it is more like chronic pain because the pain may serve no purpose.

Pain is a common symptom in people who seek medical assistance accounting for over 70 million office visits to physicians each year (National Center for Health Statistics, 1986). Each of the four pain categories are extremely prevalent. Consider a sample of some available statistics. Over 23 million surgical procedures were performed in the United States in 1989 (Peebles & Schneidman, 1991) and most of these involved acute pain. Acute recurrent and chronic pain affect over 70 million Americans, with over 10% reporting the presence of pain over 100 days/year (Osterweis, Kleinman, & Mechanic, 1987). Estimates suggest that over 11 million Americans suffer from recurring episodes of migraine headaches (Stewart, Lipton, Celentano, & Reed, 1991), over 30 million experience chronic or recurrent back pain (Holbrook, Grazier, Kelsey, & Stauffer, 1984), and 37 million have pain associated with arthritis (Lawrence et al., 1989). Approximately 3.5 million people in the United States have cancer (Raj, 1990). Bonica (1979) estimated that moderate to severe pain is reported by from 40% to 45% of patients initially following the diagnosis, from 35% to 45% at the intermediate states of the disease, and from 60% to 85% in advanced states of the cancer.

Given the lengthy history of pain and the statistics on its prevalence, it might be assumed that pain is well understood and readily treated. Despite advances in the understanding of anatomy and physiological processes and innovative and technically sophisticated pharmacological, medical, and surgical treatments, pain continues to be a perplexing puzzle for health care providers and a source of significant distress for

individual pain sufferers. Moreover, pain is an extremely costly problem for society in health care expenditures, indemnity costs, and lost productivity. It has been estimated that chronic pain alone costs the American people approximately \$65 billion a year (Bonica, 1986).

With such astronomical figures, it is all too easy to lose sight of the incalculable human suffering accompanying pain for both individuals and their family. Chronic pain, recurrent acute pain, as well as pain associated with cancer extend over long periods of time. The average duration of pain noted for patients treated at pain clinics exceeds 7 years with durations of from 20 to 30 years not uncommon (Flor, Fydrich, & Turk, 1992).

The emotional distress that is prevalent in a majority of pain patients may be attributed to a variety of factors, including fear, inadequate or maladaptive support systems and other coping resources, iatrogenic complications, overuse of tranquilizers and narcotic medication, inability to work, financial difficulties, prolonged litigation, disruption of usual activities, and sleep disturbance. Moreover, the experience of "medical limbo"—the presence of a painful condition that eludes diagnosis and that carry the implication of either psychiatric causation, malingering, on the one hand, or an undiagnosed life threatening disease—is itself a source of stress and can initiate psychological distress or aggravate a premonitory psychiatric condition. In the case of cancer, the stress of pain is superimposed on the general fear of living and possibly dying from a potentially lethal disease.

People with persistent pain complaints become enmeshed in the medical community as they go from doctor to doctor and test to test in a continuing search to have pain diagnosed and treated. For many, the pain becomes the central focus of their lives. As pain sufferers withdraw from society, they lose their jobs, alienate family and friends, and become isolated. In this ongoing and often elusive quest for relief, it is hardly surprising that they experience feelings of demoralization, helplessness, hopelessness, and outright depression.

In sum, the different forms of persistent pain create a demoralizing situation that confronts the individual not only with the stress created by pain but with a cascade of ongoing stressors that compromise all aspects of their lives. Living with persistent pain conditions requires considerable emotional resilience and tends to deplete people's emotional reserve, and taxes not only the individual but also the capacity of family, friends, coworkers, and employers to provide support.

It is reasonable to ask questions concerning how a problem as prevalent and costly as pain can be so poorly understood and managed. The primary intention of this chapter is to address the factors that contribute to the current unsatisfactory state of affairs regarding the treatment of pain. This survey begins with a review of the most common conceptualizations of pain and then examines the role of psychological factors in the etiology and exacerbation of pain and disability. This is followed by a description of several attempts to integrate physiological and psychological variables in comprehensive conceptual models. Finally, the current understanding of the physical, anatomical, and chemical bases of pain is reviewed, illustrating the physiological bases of both sensory and psychological components of pain.

CONCEPTUALIZATIONS OF PAIN

The concept of pain has undergone multiple transformations. In the past quarter century there has been a significant paradigm shift in thinking about pain that was ushered in by the gate control theory (Melzack & Wall, 1965). The gate control theory is examined later. First, it is helpful to examine the traditional unidimensional conceptualization that has been dominant since it was formally proposed by Descartes in the 15th century (although it dates back to the ancient Greeks; Melzack & Wall, 1982).

Unidimensional Sensory Model

Historically, pain has been understood from the perspective of Cartesian mind-body dualism in which pain was viewed as a sensory experience dependent on the degrees of noxious sensory stimuli impinging on the individual. From this perspective, there are two ends of a pain pathway just as there are two ends of a direct communication line where sensory stimulation at one end (at the periphery) has a direct stimulatory effect at the other end (the brain). From this view, stimulation at the periphery inevitably results in stimulation at the other, as if pulling one end of a string pulls a bell located somewhere in the brain.

Unidimensional models of pain adhere to a specificity concept postulating that pain is a specific sensation and that pain intensity is directly proportional to the amount of peripheral nociceptive input related to tissue damage (Melzack & Wall, 1982). From this model, the production of pain is traced to peripheral pain receptors at the site of the injury. It is assumed that some form of tissue damage will excite receptors that are specific, responding exclusively to nociceptive stimuli, initiating pain-specific nerve impulses that were transmitted along specific afferent pain pathways to specific pain centers localized in the brain where the experience of pain will motivate actions to avoid further harm.

The core of sensory-physiological models is that the amount of pain is a direct result of the amount, degree, or nature of sensory input or physical damage and is explained in terms of specific physiological mechanisms. Clinically, it is expected that the report of pain will be directly proportional to physical pathology.

This sensory model has prevailed largely unchanged despite its inability to account for a number of observations. For example, patients with objectively determined, equivalent degrees and types of tissue pathology vary widely in their reports of pain severity. The surgical procedures designed to inhibit pain transmission by severing neurological pathways that are believed to be subserving the reported pain may fail to alleviate it, and patients with equivalent degrees of tissue pathology treated with identical treatments respond in widely different ways (Turk & Nash, 1996).

Psychogenic Perspectives

As is frequently the case in medicine, when physical explanations prove inadequate to explain symptoms, psychological

alternatives are invoked. If the pain reported is disproportionate to objectively determined physical pathology, or if the complaint is recalcitrant to "appropriate" treatment, then it is assumed that psychological factors must be involved, even if not causal.

Several variants of psychogenic etiologic models have been proposed. For example, a model of a "pain-prone" personality that predisposes individuals to experience persistent pain was originally described by Engel (1959) and extended by Blumer and Heilbronn (1981, 1982). According to Blumer and Heilbronn, the pain-prone disorder is characterized by denial of emotional and interpersonal problems, inactivity, anhedonia, depressed mood, guilt, inability to deal with anger and hostility, insomnia, craving for affection and dependency, lack of initiative, and a family history of depression, alcoholism, and chronic pain. People who can be characterized in this way are considered by Blumer and Heilbronn to be a homogeneous diagnostically unique group that can be considered part of the "depressive spectrum." Engel proposed that once the psychic organization necessary for pain has evolved, the experience of pain no longer requires peripheral stimulation.

Turk and Salovey (1984) critically examined both the hypothesis of a pain-prone personality and the empirical support for it marshaled by Blumer and Heilbronn (1982). Turk and Salovey found the hypothesized pain-prone disorder to be flawed conceptually, circular in reasoning with the definition itself tautological, and the explanatory model lacking in parsimony. In addition, the purported empirical support was criticized as being retrospective and based on small sample sizes. Moreover, the data used to support the existence of a pain-prone personality was judged to be analyzed by inappropriate statistical methods and the results subject to alternative and simpler explanations.

Beutler, Engle, Oro'-Beutler, Daldrup, and Meredith (1986) proposed a model that was conceptually similarly to Blumer and Heilbronn (1982). They suggested that difficulty expressing anger and controlling intense emotions in general are the predisposing factors linking chronic pain and the experience of negative affect. They viewed the experience of chronic pain and depression as similar disturbances or failures to process intensively emotional information (e.g., prolonged blocking or inhibition of intense interpersonal anger).

Recently, the American Psychiatric Association (1994) created two psychiatric diagnoses, pain associated with psychological factors either with or without a diagnosed medical condition. The specific diagnosis of "Pain Disorder Associated with Psychological Factors and a General Medical Condition" (307.89) is characterized by the fact that psychological and a general medical condition both have important roles in the onset, severity, exacerbation, and maintenance of pain. This set of diagnoses is so broadly defined, however, that virtually all patients who have persistent pain are likely to be viewed as suffering from a psychiatric problem.

The somatogenic-psychogenic dichotomy forms the basis for the distinction underlying attempts to identify "functional" versus "organic" groups, as well as references to a "functional overlay" (Leavitt & Garron, 1979; McCreary, Turner, & Dawson, 1977). It is also found in a residual man-

ner in other current concepts linking "nonorganic" findings with psychological manifestations of pain and related "abnormal illness behavior" (Pilowsky, 1970; Pilowsky & Spence, 1975; Waddell, Main, Morris, DiPaola, & Gray, 1984; Waddell, McCulloch, Kummel, & Venner, 1980).

These psychogenic views are posed as alternatives to purely physiological models. Put simply, dichotomous reasoning is invoked. If the report of pain occurs in the absence of or is "disproportionate" to objective physical pathology, ipso facto, the pain has a psychological component.

Motivational View

A variation of the dichotomous somatic-psychogenic views is a conceptualization that is ascribed to by many third-party payers. They suggest that if there is insufficient physical pathology to justify the report of pain, the complaint is invalid, the result of symptom exaggeration or outright malingering. The assumption is that reports of pain without adequate biomedical evidence are motivated primarily by financial gain. This belief has resulted in a number of attempts to "catch" malingerers using surreptitious observation methods and the use of sophisticated biomechanical machines geared toward identifying inconsistencies in functional performance. There are, however, no studies that have demonstrated dramatic improvement in pain reports subsequent to receiving disability awards. Yet, Koplow (1990) suggested that it is fear of malingering that drives the entire Social Security Disability System.

Although there appears to be little question that psychological factors play an important role in pain perception and response, the aforementioned models view physical and psychological factors as largely independent. Before examining models that attempt to integrate psychological factors with somatic factors, it is useful to examine the nature of the psychological factors involved in detail.

PSYCHOLOGICAL CONTRIBUTORS TO PAIN

Psychologists have made important contributions to understanding pain by demonstrating the importance of psychosocial and behavioral factors in the etiology, severity, exacerbation, and maintenance of pain. Several effective treatments have been developed based on these factors.

Operant Learning Mechanisms

As long ago as the early part of the 20th century, Collie (1913) discussed the effects of environmental factors in shaping the experience of people suffering with pain. A new era in thinking about pain began with Fordyce's (1976) description of the role of operant factors in chronic pain. The operant approach stands in marked contrast to the biomedical model of pain described earlier.

In the operant formulation, behavioral manifestations of pain rather than pain per se are central. It is suggested that when a person is exposed to a stimulus that causes tissue dam-

age, their immediate response is withdrawal and attempts to escape from noxious sensations. This may be accomplished by avoidance of activity believed to cause or exacerbate pain, help seeking to reduce symptoms, and so forth. These behaviors are observable and, consequently, subject to the principles of operant conditioning.

The operant view proposes that acute "pain behaviors" (e.g., limping to protect a wounded limb from producing additional nociceptive input) may come under the control of external contingencies of reinforcement and thus develop into a chronic pain problem. Pain behaviors may be positively reinforced directly, for example, by attention from a spouse or health care providers. Pain behaviors may also be maintained by the escape from noxious stimulation by the use of drugs or rest, or the avoidance of undesirable activities such as work. In addition, "well behaviors" (e.g., activity, working) may not be sufficiently reinforcing, and therefore pain behaviors may be maintained because they are more rewarding. The pain behavior originally elicited by organic factors may come to occur, totally or in part, in response to reinforcing environmental events. Because of the consequences of specific behavioral responses, it is proposed that pain behaviors may persist long after the initial cause of the pain is resolved or greatly reduced.

The operant conditioning model does not concern itself with the initial cause of pain. Rather, it considers pain an internal subjective experience that may be maintained even after an initial physical basis of pain has resolved. The operant conditioning model focuses on overt manifestations of pain and suffering expressed as pain behaviors such as limping, moaning, and avoiding activity. Emphasis is placed on the communicative function of these behaviors. Thus, in one sense, the operant conditioning model can be viewed as analogous to the psychogenic models already described. That is, psychological factors are treated as secondary reactions to sensory stimulation, rather than directly involved in the perception of pain per se.

Several studies have provided evidence that supports the underlying assumptions of operant conditioning. For example, Cairns and Pasino (1977) and Doleys, Crocker, and Patton (1982) showed that pain behaviors (specifically, inactivity) can be decreased and well behaviors (i.e., activity) can be increased by verbal reinforcement with or without feedback and the setting of exercise quotas. Block, Kremer, and Gaylor (1980) demonstrated that pain patients reported differential levels of pain in an experimental situation depending on whether they knew they were being observed by their spouses or ward clerks. Pain patients with nonsollicitous spouses reported more pain when a neutral observer was present than when the spouse was present. When sollicitous spouses were present, pain patients reported more pain than in the neutral observer condition. Two additional studies (Flor, Kerns, & Turk, 1987; Turk, Kerns, & Rosenberg, 1992) found that chronic pain patients reported more intense pain and less activity when they indicated their spouses were sollicitous. These later studies suggest that spouses can serve as discriminative stimuli for the display of pain behaviors by chronic pain patients, including their reports of pain severity.

The operant view has also generated what has proven to be an effective treatment for select samples of chronic pain patients (see Keefe, Dunsmore, & Burnett, 1992; Keefe & Williams, 1989). Treatment focuses on extinction of pain behaviors and positive reinforcement of well behaviors.

Although operant factors undoubtedly play a role in the maintenance of disability, exclusive reliance on the operant conditioning model to explain the experience of pain has, however, been criticized for its exclusive focus on motor pain behaviors, failure to consider the emotional and cognitive aspects of pain (A. Schmidt, 1985a, 1985b; A. Schmidt, Gierlings, & Peters, 1989; Turk & Flor, 1987), and failure to treat the subjective experience of pain (Kotarba, 1983). The applicability of this model is problematic for pain associated with cancer because stoic behaviors and the inhibition of such pain behaviors as talking about pain and requesting medication are encouraged and even essential to inform health care providers regarding disease progress (Wilkie, Keefe, Dodd, & Copp, 1992).

A fundamental problem with the operant approach in practice is the emphasis on pain behavior rather than pain per se because behaviors that are observed are then used as the basis to infer something about the internal state of the individual—that the behaviors are communications of pain (Turk & Matyas, 1992). This is an indirect method and there is no way of determining from the behavior whether it results from pain or from a structural abnormality. Limping, for example, from the operant perspective is viewed as a pain behavior; however, this is an inference. It is quite possible that limping may result from physical pathology and has no direct association with pain, distress, or suffering. In the latter case, attempts to extinguish the putative pain behaviors will be fruitless and inappropriate.

To underscore the distinction between pain behavior as a communication and as a result of physical perturbation, two studies reported by Keefe et al. (1990a, 1990b) can be examined. These investigators failed to find a reduction of pain behavior in osteoarthritic knee pain patients following a coping skills program; however, the program did produce a reduction in pain and disability. Alteration of specific behaviors that result from structural pathology are not likely to result from coping skills training. Thus, calling these behaviors "pain behaviors" is open to question (Turk & Matyas, 1992).

A related concern about the pain behavior construct is captured by the emphasis on the communicative role of these behaviors. Several attempts to operationalize the pain behavior construct have broadened to the point that any behavior can be subsumed under the rubric of pain behaviors. For example, Vlaeyen, Van Eck, Groenman, and Schuerman (1987) asked nurses to observe pain patients and to enumerate behaviors that they felt communicated pain. Some of the behaviors identified included the failure of the patient to take initiative, insomnia, falling asleep during the day, querulousness, and boredom. Philips and Jahanshahi (1986) created a "pain behavior checklist" that included "self-help" strategies and "distraction."

Boredom, querulousness, fatigue, distraction, or other self-help strategies can readily be imagined to have causes

and effects other than communication of pain. Boredom can result from an unstimulating environment, querulousness may be a premorbid characteristic of the individual, fatigue may be a consequence of vigorous exercise, and lying down during the day might indicate compliance with recommendations to practice relaxation exercises or to practice appropriate pacing behaviors. Importantly, distraction and other self-help strategies can clearly have adaptive functions above and beyond any communicative function.

Respondent Learning Mechanisms

Factors contributing to chronicity that have previously been conceptualized in terms of operant learning may also be initiated and maintained by respondent conditioning (Gentry & Bernal, 1977). Fordyce, Shelton, and Dundore (1982) hypothesized that avoidance behavior does not necessarily require intermittent sensory stimulation from the site of bodily damage, environmental reinforcement, or successful avoidance of aversive social activity to account for the maintenance of protective movements. Avoidance of activities has been shown to be related more to anxiety about pain than to actual reinforcement (Linton, 1985).

Lentherm, Slade, Troup, and Bentley (1983) and Linton, Melin, and Götestam (1985) suggested that once an acute pain problem exists, fear of motor activities that the patient expects to result in pain may develop and motivate avoidance of activity. Nonoccurrence of pain is a powerful reinforcer for reduction of activity and thus the original respondent conditioning may be followed by an operant learning process whereby the nociceptive stimuli and the associated responses need no longer be present for the avoidance behavior to occur. In acute pain states it may be useful to reduce movement, and consequently avoiding pain, to accelerate the healing process. Over time, however, anticipatory anxiety related to activity may develop and act as a conditioned stimulus (CS) for sympathetic activation (conditioned response, CR) that may be maintained after the original unconditioned stimulus (US, e.g., injury) and unconditioned response (UR, pain and sympathetic activation) have subsided (Lentherm et al., 1983; Linton et al., 1985; Philips, 1987a).

Pain related to sustained muscle contractions might, however, also be conceptualized as a US in the case where no acute injury was present and sympathetic activation and tension increases might be viewed as UR that may elicit more pain, and conditioning might proceed in the same fashion as already outlined. Thus, although the original association between pain and pain-related stimuli results in anxiety regarding these stimuli, with time the expectation of pain related to activity may lead to avoidance of adaptive behaviors even if the nociceptive stimuli and the related sympathetic activation are no longer present. (See Seligman & Johnson, 1973, on the role of expectation in learning processes.)

In acute pain, many activities that are neutral or pleasurable may elicit or exacerbate pain and are thus experienced as aversive and avoided. Over time, more and more activities may be seen as eliciting or exacerbating pain and will be avoided (stimulus generalization). Fear of pain may become condi-

tioned to an expanding number of situations. Avoided activities may involve simple motor behaviors, but also work, leisure, and sexual activity (Philips, 1987a). In addition to the avoidance learning, pain may be exacerbated and maintained in these encounters with potentially pain increasing situations due to the anxiety-related sympathetic activation and muscle tension increases that may occur in anticipation of pain and also as a consequence of pain (Flor, Birbaumer, & Turk, 1990). Thus, psychological factors may directly affect nociceptive stimulation and need not be viewed as only reactions to pain.

The persistence of avoidance of specific activities reduces disconfirmations that are followed by corrected predictions (Rachman & Arntz, 1991). The prediction of pain promotes pain avoidance behavior and overpredictions of pain promote excessive avoidance behavior as demonstrated in the A. Schmidt (1985a, 1985b) studies. Insofar as pain avoidance succeeds in preserving the overpredictions from repeated disconfirmation, they will continue unchanged (Rachman & Lopatka, 1988). By contrast, repeatedly engaging in behavior that produces significantly less pain than was predicted is followed by adjustments in subsequent predictions, which also become more accurate. These increasingly accurate predictions are followed by increasingly appropriate avoidance behavior, even to elimination of all avoidance if that is appropriate. These observations add support to the importance of physical therapy, with patients progressively increasing their activity levels despite fear of injury and discomfort associated with renewed use of deconditioned muscles.

Thus, from a conditioning perspective, the patient may have learned to associate increases in pain with all kinds of stimuli that were originally associated with nociceptive stimulation (stimulus generalization). Sitting, walking, engaging in cognitively demanding work or social interaction, sexual activity, or even thoughts about these activities may increase anticipatory anxiety and concomitant physiological and biochemical changes (Philips, 1987a). Subsequently, patients may display maladaptive responses to many stimuli and reduce the frequency of performance of many activities other than those that initially induced pain. The physical abnormalities often observed in chronic pain patients (such as distorted gait, decreased range of motion, muscular fatigue) may thus actually be secondary to changes initiated in behavior through learning. As the pain symptoms persist, more and more situations may elicit anxiety and anticipatory pain and depression because of the low rate of reinforcement obtained, when behavior is much reduced (cf., Lentherm et al., 1983). With chronic pain, the anticipation of suffering or prevention of suffering may be sufficient for the long-term maintenance of avoidance behaviors.

Social Learning Mechanisms

Social learning has received some attention in the development and maintenance of chronic pain states. From this perspective, the acquisition of pain behaviors may occur by means of observational learning and modeling processes. That is, individuals can acquire responses that were not previously in their behavioral repertoire by the observation of

others performing these activities. Bandura (1969) described and documented the important role of observational learning in many areas of human functioning. Children acquire attitudes about health and health care, the perception and interpretation of symptoms and physiological processes from their parents and social environment, as well as appropriate responses to injury and disease and thus may be more or less likely to ignore or overrespond to symptoms they experience (Pennebaker, 1982). The culturally acquired perception and interpretations of symptoms determines how people deal with illness (Nerenz & Leventhal, 1983). The observation of others in pain is an event that captivates attention. This attention may have survival value, may help to avoid experiencing more pain, and may help to learn what to do about acute pain. There is ample experimental evidence of the role of social learning from controlled, laboratory pain studies (Craig, 1986, 1988) and some evidence based on observations of patients behaviors in naturalistic and clinical settings (Christensen & Mortensen, 1975; Fagerhaugh, 1975). For example, Vaughan and Lanzetta (1980, 1981) demonstrated that physiological responses to pain stimuli may be vicariously conditioned during observation of others in pain. Richard (1988) found that children of chronic pain patients chose more pain-related responses to scenarios presented to them and were more external in their health locus of control responses than were children with healthy or diabetic parents. Moreover, teachers rated the pain patients' children as displaying more illness behaviors (e.g., complaining, whining, days absent, visit to school nurse) than children of healthy controls.

Expectancies and actual behavioral responses to nociceptive stimulation are based, at least partially, on prior leaning history. This may contribute to the marked variability in response to objectively similar degrees of physical pathology noted by health care providers.

Role of Cognitive Factors in Pain

A great deal of research has been directed toward identifying cognitive factors that contribute to pain and disability (Jensen, Turner, Romano, & Karoly, 1991; Turk & Rudy, 1986, 1992). These studies have consistently demonstrated that patients' attitudes, beliefs, expectancies about their plight, themselves, their coping resources, and the health care system affect the reports of pain, activity, disability, and response to treatment (Flor & Turk, 1988; Jensen, Turner, & Romano, 1994; Tota-Faucette, Gil, Williams, & Goli, 1993).

Beliefs About Pain. Clinicians working with chronic pain patients are aware that patients having similar pain histories and reports of pain may differ greatly in their beliefs about their pain. The cognitive-behavioral perspective (Turk, Meichenbaum, & Genest, 1983) suggests that behavior and emotions are influenced by interpretations of events, rather than solely by objective characteristics of the event itself. Thus, pain, when interpreted as signifying ongoing tissue damage, is likely to produce considerably more suffering and

behavioral dysfunction than if it is viewed as being the result of a stable problem that may improve, although the amount of nociceptive input in the two cases may be equivalent (Spiegel & Bloom, 1983).

Certain beliefs may lead to maladaptive coping, increased suffering, and greater disability. Patients who believe their pain is likely to persist may be quite passive in their coping efforts and fail to make use of cognitive strategies or behavioral strategies to cope with pain. Patients who consider their pain to be an unexplainable mystery may negatively evaluate their own abilities to control or decrease pain, and are less likely to rate their coping strategies as effective in controlling and decreasing pain (Williams & Keefe, 1991; Williams & Thorn, 1989). People's cognitions (beliefs, appraisals, expectancies) regarding the consequences of an event and their ability are hypothesized to impact functioning in two ways. They may have a direct influence on mood and an indirect one through their impact on coping efforts.

A. Schmidt (1985a, 1985b) found evidence demonstrating that low back pain patients showed poor behavioral persistence in various exercise tasks and although their performance on these tasks was independent of physical exertion or actual self-reports of pain, it was related to previous pain reports. These patients appear to have a negative view of their abilities and expected increased pain if they performed physical exercises. Thus, the rationale for their avoidance of exercise was not the presence of pain but their learned expectation of heightened pain and the accompanying physical arousal that might exacerbate pain and reinforce their beliefs regarding the pervasiveness of their disability. These results are consistent with the respondent learning factors described earlier. A. Schmidt postulated that these negative perceptions of their capabilities for physical performance form a vicious circle, with the failure to perform activities reinforcing the perception of helplessness and incapacity.

A cognitive schema that views disability as a necessary aspect of pain, that activity despite pain is dangerous, and that pain is an acceptable excuse for neglecting responsibilities is likely to increase disability (Smith, Follick, Ahern, & Adams, 1986). Jensen, Turner, Romano, and Lawler (1994) demonstrated that patients' beliefs that emotions affect pain, that others should be solicitous when the patient experiences pain, and that one is disabled by pain were positively associated with psychosocial dysfunction. Patients who believed they were disabled by pain and that activity should be avoided because pain signified damage were more likely to reveal physical disability compared to patients who did not hold these beliefs. Similarly, Slater, Hall, Atkinson, and Garfin (1991) reported that patients' beliefs about their pain and disability were significantly related to actual measures of disability but not to physicians' ratings of disease severity.

The presence of pain may change the way people process pain-related and other information. For example, the presence of chronic pain may focus attention on all types of bodily signals. Chronic pain patients have been shown to complain about a multitude of bodily symptoms in addition to pain (A. Schmidt et al., 1989). Patients may interpret pain symptoms as indicative of an underlying disease and they may do every-

thing to avoid pain exacerbations, most often by resorting to inactivity. For example, in acute pain states bed rest is often prescribed to relieve pressure on the spine. Patients ascribe to a belief that any movement of the back may worsen their condition and may still maintain this belief in the chronic state when their inaction is unnecessary as well as harmful.

Pennebaker, Gonder-Frederick, Cox, and Hoover (1985) showed that once cognitive structures (based on memories and meaning) about a disease are formed, they become stable and are very difficult to modify. People tend to avoid experiences that could invalidate their beliefs and they guide their behavior in accordance with these beliefs even in situations where the belief is no longer valid. Consequently, as noted, when the role of respondent conditioning was described, they do not receive corrective feedback.

In addition to beliefs about capabilities to function despite pain, beliefs about pain per se appear to be of importance in understanding response to treatment, compliance, and disability. For example, Schwartz, DeGood, and Shutty (1985) presented patients with information about the role of cognitive, affective, and behavioral factors and their own role in the rehabilitation process. They found that patients who rated the information as applicable to their pain condition had much better treatment outcomes. Those who disagreed with the concepts presented were found at follow-up to have higher levels of pain, lower levels of activity, and a high degree of dissatisfaction.

The results of several studies suggest that when successful rehabilitation occurs there appears to be an important cognitive shift from beliefs about helplessness and passivity to resourcefulness and ability to function regardless of pain. Consistent with the central role of a cognitive shift in rehabilitation, Herman and Baptiste (1981) noted that successes and failures in their treatment program could be distinguished most prominently on the basis of changes versus unchanged thought patterns relative to the prospect of living useful lives despite pain. Williams and Thorn (1989) found that chronic pain patients who believed that their pain was an "unexplained mystery" reported high levels of psychological distress and pain and also showed poorer treatment compliance than patients who believed they understood their pain.

In an innovative process study designed to evaluate the direct association between patients' beliefs and pain symptoms, Newton and Barbaree (1987) used a modified thought-sampling procedure to evaluate the nature of patients' thoughts during and immediately following headache both prior to and following treatment. Results indicated significant changes in certain aspects of headache-related thinking in the treated groups compared to the control group. Reduction in negative appraisal and increase in positive appraisal (e.g., "It's getting worse," "There is nothing I can do") revealed a significant shift in the thoughts of treated subjects in comparison with untreated subjects, indicating that treated subjects were evaluating headaches in a more positive fashion. Treated patients reported experiencing significantly fewer headache days per week and lower intensity of pain than untreated controls. Correlational analyses suggested that complaints of more intense pain were associated with more negative appraisals of

headache episodes. Similar results were reported by Flor and Turk (1988) in which back pain and RA patients' negative thoughts predicted pain, disability, and physician visits. Newton and Barbaree noted that patients who reported the largest positive shift in appraisal also reported the greatest reduction in headache intensity.

The results of the Newton and Barbaree (1987) study support the argument that changes in cognitive reactions to headache might underlie headache improvement (see also, Blanchard, 1987; Holroyd & Andrasik, 1982). There appears to be strong evidence pointing toward a reduction in negative appraisal as representing the potential change mechanism in many pain treatment outcome studies. In considering the efficacy of biofeedback for back pain patients, Nouwen and Solinger (1979) concluded that "simultaneous accomplishment of muscle tension reduction and lowering reported pain convinced patients that muscle tension, and subsequently pain, could be controlled. ... As self-control could not be demonstrated in most patients, it seems plausible that the feeling of self-control, rather than actual control of physiological functions or events is crucial for further reductions" (p. 110). In other words, it appears that the extent to which voluntary control over muscles has been achieved dictate the outcome, which is not necessarily accompanied by lasting reductions in muscular reactivity.

Similar to Nouwen and Solinger (1979) interpretation, Blanchard (1987) speculated that, for headache patients, the maintenance of treatment effects endures in spite of almost universal cessation of regular home practice of biofeedback because the self-perpetuating cycle of chronic headache has been broken. The experience of headache serves as a stressor to cause, in part, a future headache. It may also serve to maintain improper analgesic medication consumption, the cessation of which can also lead to "rebound headache." By the end of treatment when the patient has experienced noticeable headache relief, it is as if patients redefine themselves as someone able to cope with headaches. As a consequence, one source of stress is removed and the person copes with recurrences more adaptively. The experience of headache serves as a stressor to cause, in part, a future headache.

Clearly, it appears essential for patients with chronic and recurrent acute pain to develop adaptive beliefs about the relation among impairment, pain, suffering and disability, and to deemphasize the role of experienced pain in their regulation of functioning. In fact, results from numerous treatment outcome studies have shown that changes in pain level do not parallel changes in other variables of interest, including activity level, medication use, return to work, rated ability to cope with pain, and pursuit of further treatment (see the meta-analysis reported by Flor et al., 1992).

Arntz and A. Schmidt (1989) suggested that the processing of internal information may become disturbed in chronic pain patients. It is possible that pain patients become preoccupied with and overemphasize physical symptoms and interpret them as painful stimulation, although they may be less able than healthy controls to differentiate threshold levels. Studies with diverse populations (e.g., irritable bowel syndrome: Whitehead, 1980; fibromyalgia: Tunks, Crook, Norman, &

Kalaher, 1988; angina pectoris: Droste & Roskamm, 1983; headaches: Borgeat, Hade, Elie, & Larouche, 1984) of pain patients have supported the presence of what appears to be a hypersensitivity characterized by a lowered threshold for labeling stimuli as noxious.

Even in nonmuscular pain states, the interpretation of painful stimulation may be important. For example, Spiegel and Bloom (1983) reported that the pain severity ratings of cancer patients could be predicted by the use of analgesics, the patients' affective state, but also the *interpretations of pain*. Patients who attribute their pain to a worsening of their underlying disease experienced more pain despite the same level of disease progression as compared to patients with more benign interpretations.

Beliefs About Controllability. There is evidence that the explicit expectation of uncontrollable pain stimulation may make the following nociceptive input be perceived as more intense (Leventhal & Everhart, 1979). Thus, people who have associated activity with pain may expect heightened levels of pain when they attempt to get involved in activity and then actually perceive higher levels of pain or avoid activity altogether. There are many laboratory studies demonstrating that controllability of aversive stimulation reduces its impact (cf. Averill, 1973; Thompson, 1981).

In chronic pain patients, lack of personal control is typically perceived and likely relates to the ongoing but unsuccessful efforts to control their pain. A large proportion of chronic pain patients tend to believe that they have limited ability to exert control over their pain (Turk & Rudy, 1988). Such negative, maladaptive appraisals about the situation and personal efficacy may reinforce the experience of demoralization, inactivity, and overreaction to nociceptive stimulation commonly observed in chronic pain patients (Biederman, McGhie, Monga, & Shanks, 1987). Furthermore, uncontrollability has been shown to augment the perception of pain intensity in laboratory studies (Miller, 1981).

The relation between perceived controllability and pain has been demonstrated in a variety of chronic pain syndromes. Mizener, Thomas, and Billings (1988) demonstrated that successfully treated migraine headache patients reported correlations between reduction in headache activity and increases in perceived control over physiological activity and their health in general. Flor and Turk (1988) examined the relation between general and situation-specific pain-related thoughts, conceptions of personal control, pain severity, and disability levels in chronic low back pain patients and rheumatoid arthritics. The general and situation-specific convictions of uncontrollability and helplessness were more highly related to pain and disability than disease-related variables for both samples. The combination of both situation-specific and general cognitive variables explained 32% and 60% of the variance in pain and disability, respectively. The addition of disease-related variables improved the predictions only marginally. Jensen and Karoly (1991) showed an association between patients' beliefs about the extent to which they can control their pain and outcome variables, including medication use, activity levels, and psychological functioning.

Self-Efficacy. Closely related to the sense of control over aversive stimulation is the concept of self-efficacy. A self-efficacy expectation is defined as a personal conviction that one can successfully execute a course of action (perform required behaviors) to produce a desired outcome in a given situation. This construct has been demonstrated as a major mediator of therapeutic change.

Bandura (1977) suggested that given sufficient motivation to engage in a behavior, it is a person's self-efficacy beliefs that determine the choice of activities that the person will initiate, the amount of effort that will be expended, and how long the person will persist in the face of obstacles and aversive experiences. Efficacy judgments are based on the following four sources of information regarding peoples' capabilities, in descending order of impact: (a) their own past performance at the task or similar tasks; (b) the performance accomplishments of others who are perceived to be similar to themselves; (c) verbal persuasion by others that they are capable; and (d) perception of their own state of physiological arousal, which is in turn partly determined by prior efficacy estimation. Performance mastery experience can be created by encouraging patients to undertake subtasks that are increasingly difficult or close to the desired behavioral repertoire. From this perspective, the occurrence of coping behaviors is conceptualized as being mediated by the person's beliefs that situation demands do not exceed their coping resources.

Dolce, Crocker, Moletteire, and Doleys (1986) and Litt (1988) reported that low self-efficacy ratings regarding pain control are related to low pain tolerance, and they are better predictors of tolerance than pain levels. Several studies also obtained self-efficacy ratings from pain patients and related them to patients' ability to control pain. For example, Manning and Wright (1983) obtained self-efficacy ratings from primipara concerning their ability to have a medication-free childbirth. These ratings were good predictors of medication use and time in labor without medication. Similarly, Council, Ahern, Follick, and Kline (1988) had patients rate their self-efficacy as well as expectancy of pain related to the performance of movement tasks. Patients' performance levels were highly related to their self-efficacy expectations, which in turn appeared to be determined by patients' expectancies of pain levels.

Converging lines of evidence from investigations of both laboratory and clinical pain indicate that perceived self-efficacy operates as an important cognitive factors in the control of pain (e.g., Bandura, O'Leary, Taylor, Gauthier, & Gossard, 1987; Lorig, Chastain, Ung, Shoor, & Holman, 1989), adaptive psychological functioning (e.g., Lorig et al., 1989; Rosensteil & Keefe, 1983; Spinhoven, Ter Kuile, Linssen, & Gazendam, 1989), disability (e.g., Dolce, Crocker, & Doleys, 1986; Lorig et al., 1989), impairment (e.g., Lorig et al., 1989), and treatment outcome (e.g., O'Leary, Shoor, Lorig, & Holman, 1988; Philips, 1987b). What are the mechanisms that account for the observed association between self-efficacy and behavioral outcome? Cioffi (1991) suggested at least four psychological processes could be responsible: (a) As perceived self-efficacy decreases anxiety and its concomitant physiological arousal, the patient may approach the task

with less potentially distressing physical information to begin with; (b) the efficacious person is able to willfully distract attention from potentially threatening physiological sensations; (c) the efficacious person perceives and is distressed by physical sensations but simply persists in the face of them (stoicism); and (d) physical sensations are neither ignored nor necessarily distressing but rather are relatively free to take on a broad distributions of meanings (change interpretations).

Bandura (1977) suggested that those techniques that enhance mastery experiences the most will be the most powerful tools for bringing about behavior change. He proposed that cognitive variables are the primary determinants of behavior, but that these variables are most effectively influenced by performance accomplishments. The studies on headache, back pain, and rheumatoid arthritis cited above appear to support Bandura's prediction.

Cognitive Errors. In addition to specific efficacy beliefs, a number of investigators have suggested that a common set of cognitive errors will effect perceptions of pain and disability. A cognitive error may be defined as a negatively distorted belief about oneself or one's situation.

Lefebvre (1981) developed a Cognitive Errors Questionnaire (CEQ) to assess cognitive distortion in back pain patients. He found that chronic low back pain patients were particularly prone to cognitive errors such as "catastrophizing" (self-statements, thoughts, and images anticipating negative outcomes or aversive aspects of an experience or misinterpreting the outcome of an event to be extremely negative; characterized by lack of confidence and control and an expectation of negative outcome), "overgeneralization" (assuming that the outcome of one event necessarily applied to the outcome of future or similar events), "personalization" (interpreting negative events as reflecting personal meaning or responsibility), and "selective abstraction" (selectively attending to negative aspects of experience). Dufton (1989) reported that persons experiencing chronic pain had a tendency to make cognitive errors related to the emotional difficulties associated with living with pain, rather than the pain intensity alone, and those who made such errors were more depressed.

As was the case with self-efficacy, specific cognitive errors and distortions have been linked consistently to depression (e.g., Gil, Williams, Keefe, & Beckham, 1990; Lefebvre, 1981; Slater et al., 1991), self-reported pain severity (e.g., Gil et al., 1990; Keefe & Williams, 1989), and disability (e.g., Flor & Turk, 1988; Smith, Follick, et al., 1986b) in chronic pain patients. Such negative thoughts predict long-term adjustment to chronic pain, may mediate a portion of the relation between disease severity and adjustment, and make a unique contribution (over and above other cognitive factors) to the prediction of adjustment (Smith, Peck, & Ward, 1990).

Catastrophizing. Catastrophizing appears to be a particularly potent way of thinking that greatly influences pain and disability. Several lines of research (including experimental laboratory studies) of acute pain with normal volunteers and field studies with clinical patients suffering clinical pain have indicated that "catastrophizing"—extremely nega-

tive thoughts about one's plight—and adaptive coping strategies are important in determining people's reaction to pain. Two findings from laboratory studies are particularly important. Individuals who spontaneously utilize less catastrophizing self-statements and/or more adaptive coping strategies rated experimentally induced pain as lower and tolerated painful stimuli longer than those who indicate they engaged in more catastrophizing thoughts (Heyneman, Fremouw, Gano, Kirkland, & Heiden, 1990; Spanos, Horton, & Chaves, 1975).

People who spontaneously utilize less catastrophizing self-statements reported more pain in several acute and chronic pain studies (Butler, Damarin, Beaulieu, Schwebel, & Thorn, 1989; Martin, Nathan, Milech, & Van Keppel, 1989; Turner & Clancy, 1986). Moreover, Rosensteil and Keefe (1983) found that cognitive coping and suppression (adaptive strategies) and catastrophizing were predictive of adjustment.

Butler et al. (1989) demonstrated that in the case of post-surgical pain, cognitive coping strategies and catastrophizing thoughts correlated significantly with medication, pain reports, and nurses' judgments of patients' pain tolerance. Turner and Clancy (1986) showed that during cognitive-behavioral treatment reductions in catastrophizing were significantly related to reductions in pain tolerance and physical and psychosocial impairment. They showed that reducing in catastrophizing following cognitive-behavioral treatment related to reduction in pain intensity and physical impairment. Flor and Turk (1988) found that in low back pain sufferers and arthritis patients between 32% and 60% of the variance in pain and disability, respectively, was accounted for by cognitive factors that they labeled catastrophizing, helplessness, coping, and resourcefulness. In both the low back pain and the arthritis groups, the cognitive variables of catastrophizing and adaptive coping had substantially more explanatory power than did disease variables impairment. Finally, Keefe, Brown, Wallston, and Caldwell (1989) found that rheumatoid arthritis patients who reported high levels of pain, physical disability, and depression indicated excessive catastrophizing ideation reported on questionnaires administered 6 months earlier.

Some concerns with viewing catastrophizing as an independent cognitive variable have recently been raised. Sullivan and D'Eon (1990) reported significant association between catastrophizing and depression, suggesting that catastrophizing indexes the cognitive and affective components of dysphoria rather than measuring distinct aspects of pain-related cognition. In other words, catastrophizing is conceptually and operationally confounded with depression. They suggested that depression might entirely explain the relation between the use of coping strategies and disability. Additional research is needed to directly address the links between catastrophizing and depression.

Coping. Self-regulation of pain and its impact depends on the person's specific ways of dealing with pain, adjusting to pain, and reducing or minimizing pain and distress caused by pain—that is, their coping strategies. Coping is assumed to

be manifested by spontaneously employed purposeful and intentional acts, and it can be assessed in terms of overt and covert behaviors. *Overt* behavioral coping strategies include rest, medication, and use of relaxation. *Covert* coping strategies include various means of distracting oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving. These need not always be adaptive or maladaptive. Coping strategies are thought to act to alter both the perception of intensity of pain and a person's ability to manage or tolerate pain and to continue everyday activities (Turk et al., 1983).

Studies have found active coping strategies (efforts to function in spite of pain or to distract oneself from pain such as activity, ignoring pain) to be associated with adaptive functioning, and passive coping strategies (depending on others for help in pain control and restricted activities) to be related to greater pain and depression (Brown & Nicassio, 1987; Brown, Nicassio, & Wallston, 1989; Lawson, Reesor, Keefe, & Turner, 1990; Tota-Faucette et al., 1993). However, beyond this, there is no evidence supporting the greater effectiveness of one active coping strategy compared to any other (Fernandez & Turk, 1989). It seems more likely that different strategies will be more effective than others for some individuals at some times but not necessarily for all individuals all of the time.

A number of studies has demonstrated that if instructed in the use of adaptive coping strategies, the rating of intensity of pain decreases and tolerance of pain increases (for a review see Fernandez & Turk, 1989). The most important factor in poor coping appears to be the presence of catastrophizing rather than differences in the nature of specific adaptive coping strategies (e.g., Heyneman et al., 1990; Martin et al., 1989). Turk et al. (1983) concluded that "what appears to distinguish low from high pain tolerant individuals in their cognitive processing, catastrophizing thoughts and feelings that precede, accompany, and follow aversive stimulation" (p. 197).

EFFECTS OF PSYCHOLOGICAL FACTORS ON PHYSIOLOGICAL PARAMETERS ASSOCIATED WITH PAIN

Psychological factors may act indirectly on pain and disability by reducing physical activity, and consequently reducing muscle flexibility, strength, tone, and endurance. Fear of reinjury, fear of loss of disability compensation, and job dissatisfaction can also influence return to work. Several studies have suggested that cognitive factors may actually have a direct effect of physiological parameters associated more directly with the production or exacerbation of nociception. Cognitive interpretations and affective arousal may have a direct effect on physiology by increasing autonomic sympathetic nervous system arousal (Bandura, Taylor, Williams, Meffort, & Barchas, 1985), endogenous opioid (endorphins) production (Bandura et al., 1987), and elevated levels of muscle tension (Flor et al., 1985; Flor, Birbaumer, Schugens, & Lutzenberger, 1992a).

Effects of Thoughts on Sympathetic Arousal

Circumstances that are appraised as potentially threatening to safety or comfort are likely to generate strong physiological reactions. For example, Rimm and Litvak (1969) demonstrated that subjects exhibit physiological arousal when they only think about or imagine a painful stimuli. Barber and Hahn (1962) showed that subjects' self-reported discomfort and physiological responses (frontalis electromyographic activity, EMG; heart rate; skin conductance) were similar when they imagined taking part in a cold pressor test as compared to actually participating in it. In patients suffering from recurrent migraine headaches, Jamner and Tursky (1987) observed increase in skin conductance related to the processing of words describing migraine headaches.

Chronic increases in sympathetic nervous system activation, known as increased skeletal muscle tone, may set the stage for hyperactive muscle contraction and possibly for the persistence of a contraction following conscious muscle activation. Excessive sympathetic arousal and maladaptive behaviors are viewed as the immediate precursors of muscle hypertonicity, hyperactivity, and persistence. These in turn are the proximate causes of chronic muscle spasm and pain. It is not usual for someone in pain to exaggerate or amplify the significance of their problem and needlessly "turn on" their sympathetic nervous system (Ciccone & Grzesiak, 1984). In this way, cognitive processes may influence sympathetic arousal and thereby predispose the individual to further injury or otherwise complicate the process of recovery.

Several studies support the direct effect of cognitive factors on muscle tension. For example, Flor et al. (1985) demonstrated that discussing stressful events and pain produced elevated levels of EMG activity localized to the site of back patients' pain. The extent of abnormal muscular reactivity was best predicted by depression and cognitive coping style rather than pain demographic variables (e.g., number of surgeries or duration of pain). Flor et al. (1992a) replicated these results and extended them to patients with temporomandibular disorders. For this group, imagery reconstruction of episodes and pain produced elevated muscle tension in the facial muscles.

Although "causal," pain eliciting psychophysiological mechanisms (e.g., elevated EMG) may exist, only one longitudinal study has been reported that directly tested the causal relation and it found no consistent muscle hyperactivity during headache attacks compared to pain-free baseline, no differences in EMG activity between tension-type headache patients and controls, and EMG did not covary with stress, negative affect, or pain (Hatch et al., 1991). Moreover, the natural evolution and course of many chronic pain syndromes is unknown. At the present time, it is probably more appropriate to refer to abnormal psychophysiological patterns as antecedents of chronic pain states or to view them as consequences of chronic pain that subsequently maintain or exacerbate the symptoms rather than to assign them any direct etiological significance.

Effects of Thinking on Biochemistry

Bandura and his colleagues (1987) directly examined the role of central opioid activity in cognitive control of pain. They provided training in psychological control of pain where subjects received instructions and practice in using different coping strategies for alleviating pain, including attention diversion from pain sensations to other matters, vivification of engrossing imagery, dissociation of the limb in pain from the rest of the body, transformation of pain as nonpain sensations, and self-encouragement of coping efforts. They demonstrated that self-efficacy increased with cognitive training, self-efficacy predicted pain tolerance, and naloxone (an opioid antagonist) blocked the effects of cognitive control. The latter result directly implicates the direct effects of thoughts on the endogenous opioids. Bandura et al. (1987) concluded that the physical mechanism by which self-efficacy influences pain perception may at least be partially mediated by the endogenous opioid system. This conclusion fits well with the data from Maier, Dugan, Grau, and Hyson (1984), who showed that the uncontrollability of the stressor elicits opioid-mediated hypoalgesia. Opioid release is closely related to psychological factors, specifically subject's sense of control.

O'Leary et al. (1988) provided cognitive-behavioral stress management treatment to rheumatoid arthritis (RA) patients. RA is an autoimmune disease that may result from impaired functioning of the suppressor T-cell system. Degree of self-efficacy (expectations about the ability to control pain and disability) enhancement was correlated with treatment effectiveness. Those with higher self-efficacy and greater self-efficacy enhancement displayed greater numbers of suppressor T-cells (a direct effect of self-efficacy on physiology). Significant effects were also obtained for self-efficacy, pain, and joint impairment. Increased self-efficacy for functioning was associated with decreased disability and joint impairment.

Much more research is required before there can be confidence in the direct role of thoughts on physical mechanisms inducing nociception. However, the large body of research in psychoneuroimmunology attests to the direct role of psychological factors on the body's immune system. Based on the results of a handful of studies, it would seem that greater research efforts examining the direct effects of thoughts on the physiology known to be associated with pain—namely, sympathetic nervous system activity and the endorphins—would be a fruitful endeavor.

INTEGRATIVE MODELS

An integrative model of pain and chronic pain and acute recurrent pain, in particular, needs to incorporate the mutual interrelations among physical, psychosocial, and behavior factors and the changes that occur among these relations over time (Flor et al., 1990; Turk & Rudy, 1991). A model focusing on only one of these three core sets of factors will inevitably be incomplete.

Several sets of investigators have proposed integrative models of pain. Each with somewhat different emphasis but each of them attempts to integrate physiological and psychological variables in the etiology, severity, exacerbation, and maintenance of pain. The physiological model proposed by Melzack and Wall (1965) can be contrasted with the more psychological model of Turk et al. (1983) and the diathesis-stress model of Flor et al. (1989). Melzack and Wall focused primarily on the basic anatomy and physiology of pain, whereas Turk et al. and Flor et al. emphasized the influence of psychological processes on physical factors subserving the experience of pain.

Gate Control Theory

The first attempt to develop an integrative model designed to address the problems created by unidimensional models and to integrate physiological and psychological factors was the gate control theory proposed by Melzack and his colleagues (Melzack & Casey, 1968; Melzack & Wall, 1965). Perhaps the most important contribution of the gate control theory is the way it changed thinking about pain perception. Melzack and Casey (1968) differentiated three systems related to the processing of nociceptive stimulation—sensory-discriminative, motivational-affective, and cognitive-evaluative—which are all thought to contribute to the subjective experience of pain. Thus, the gate control theory specifically includes psychological factors as an integral aspect of the pain experience. It emphasized the central nervous system (CNS) mechanisms and provides a physiological basis for the role of psychological factors in chronic pain.

The gate control theory proposes that a mechanism in the dorsal horn substantia gelatinosa of the spinal cord acts as a spinal gating mechanism that inhibits or facilitates transmission of nerve impulses from the body to the brain on the basis of the diameters of the active peripheral fibers as well as the dynamic action of brain processes. It was postulated that the spinal gating mechanism was influenced by the relative amount of excitatory activity in afferent, large diameter (myelinated) and small diameter (unmyelinated nociceptors) fibers converging in the dorsal horns. It was further proposed that activity in A-beta (large diameter) fibers tend to inhibit transmission of nociceptive signals (closes the gate), whereas A-delta and c (small diameter fibers) primary afferent activity tends to facilitate transmission (open the gate). The hypothetical gate is proposed to be located in the dorsal horn and it is at this point that sensory input is modulated by the balance of activity of small diameter (A-delta and c) and large diameter (A-beta) fibers.

Melzack and Wall (1965) postulated further that spinal gating mechanism is influenced not only by peripheral afferent activity but also by efferent neural impulses that descend from the brain. They proposed that a specialized system of large diameter, rapidly conducting fibers (the central control trigger) activate selective cognitive processes that then influence, by way of descending fibers, the modulating properties

of the spinal gating mechanism. They suggested that the brain stem reticular formation functions as a central biasing mechanism inhibiting the transmission of pain signals at multiple synaptic levels of the somatosensory system.

The gate control theory maintains that the large diameter fibers play an important role in pain by inhibiting synaptic transmission in dorsal horn cells. When large fiber input is decreased, mild stimuli, which are not typically painful, trigger severe pain. Loss of sensory input to this complex neural system—such as occurs in neuropathies, causalgia, and phantom limb pain—tend to weaken inhibition and lead to persistent pain. Herniated disc material, tumors, and other factors that exert pressure on these neural structures may operate through this mechanism. Emotional stress and medication that affect the reticular formation may also alter the biasing mechanisms and thus intensity of pain.

From the gate control perspective, the experience of pain is an ongoing sequence of activities, largely reflexive in nature at the outset, but modifiable even in the earliest stages by a variety of excitatory and inhibitory influences, as well as the integration of ascending and descending nervous system activity. The process results in overt expressions communicating pain and strategies by the person to terminate the pain. In addition, considerable potential for shaping of the pain experience is implied, because the gate control theory invokes continuous interaction of multiple systems (sensory-physiological, affect, cognition, and ultimately, behavior).

The gate control model describes the integration of peripheral stimuli with cortical variables, such as mood and anxiety, in the perception of pain. This model contradicts the notion that pain is either somatic or psychogenic and instead postulates that both factors have either potentiating or moderating effects on pain perception. In this model, for example, pain is not understood to be the result of depression or vice versa, but rather the two are seen as evolving simultaneously. Any significant change in mood or pain will necessarily alter the others.

The theory's emphasis on the modulation of inputs in the dorsal horns and the dynamic role of the brain in pain processes and perception resulted in psychological variables such as past experience, attention, and other cognitive activities being integrated into current research and therapy on pain. Prior to this formulation, psychological processes were largely dismissed as reactions to pain. This new model suggested that cutting nerves and pathways was inadequate as a host of other factors modulated the input. Perhaps the major contribution of the gate control theory was that it highlighted the central nervous system as an essential component in pain processes and perception.

The physiological details of the gate control model have been challenged and it has been suggested that the model is incomplete (Nathan, 1976; Price, 1987; R. F. Schmidt, 1972). As additional knowledge has been gathered since the original formulation in 1965, specific points of posited mechanisms have been disputed and have required revision and reformulation (Nathan, 1976; Wall, 1989). Overall, however, the gate control theory has proved remarkably resilient and flexible in the face of accumulating scientific data and challenges to it, and still provides a "powerful summary of the phenomena ob-

served in the spinal cord and brain, and has the capacity to explain many of the most mysterious and puzzling problems encountered in the clinic" (Melzack & Wall, 1982, p. 261). This theory has had enormous heuristic value in stimulating further research in the basic science of pain mechanisms as well as in spurring new clinical treatments (Abram, 1993).

The gate control theory can be credited as a source of inspiration for diverse clinical applications to control or manage pain, including neurophysiologically based procedures (e.g., neural stimulation techniques, from peripheral nerves and collateral processes in the dorsal columns of the spinal cord, North, 1989), pharmacological advances (Abram, 1993), behavioral treatments (Fordyce, Roberts, & Sternbach, 1985), and those interventions targeting modification of attentional and perceptual processes involved in the pain experience (Turk et al., 1983). After the gate control theory was proposed in 1965, no one could try to explain pain exclusively in terms of peripheral factors.

Although the gate control theory provided a physical basis for the role of psychological factors in pain, it does not address the nature of the psychological factors in depth. That is, it does not incorporate many of the specific psychological variables reviewed here. The two models to be described, the diathesis-stress and cognitive-behavioral models, offer more conceptual models of the role of operant, respondent, social learning, and cognitive factors already described. These models, however, emphasize psychological factors adding little to the physiological factors postulated in the gate control theory.

Diathesis-Stress Model

Although everyone experiences acute pain, only a small percentage of people develop chronic pain syndromes. Flor et al. (1990) suggested that neither somatogenic nor psychogenic factors by themselves were sufficient to explain the development of chronic pain. They proposed that preconditions for chronic pain, including predisposing factors, precipitating stimuli, precipitating responses, and maintaining processes, were all required to explain the processes involved. The existence of a physiological predisposition or diathesis involving a specific body system is the first component of this model. This predisposition consists of a reduced threshold for nociceptive activation that may be related to genetic variables, previous trauma, or social learning experiences and results in a physiological response stereotypy of the specific body system. The existence of persistent aversive external and internal stimuli (pain-related or other stressors) with negative meaning activate the sympathetic nervous system and/or muscular processes (e.g., various aversive emotional stimuli such as familial conflicts or pressures related to employment) as unconditioned and conditioned stimuli and motivate avoidance responses. Aversive stimuli may be characterized by "excessive" intensity, duration, or frequency of an external or internal stimulus. "Inadequate" or "maladaptive" behavioral, cognitive, or physiological repertoire of the individual reduce the impact of these aversive environmental or internal stimuli.

Flor et al. (1990) suggested that an important role is played by the cognitive processing of external or internal stimuli re-

lated to the experience of stress and pain: for example, increased perception, preoccupation, and overinterpretation of physical symptoms or inadequate perception of internal stimuli such as muscle tension levels. Moreover, this suggests that the nature of the coping response (active avoidance, passive tolerance, or depressive withdrawal) may determine the type of problem that develops as well as the course of the illness. The diathesis-stress model proposes further that subsequent maladaptive physiological responding such as increased and persistent sympathetic arousal and increased and persistent muscular reactivity may induce or exacerbate pain episodes. The authors suggested that learning processes in the form of respondent conditioning of fear of activity (including social, motor, and cognitive activities) and operant learning of pain behaviors—but also operant conditioning of pain-related covert and physiological responses as described earlier—make a contribution to chronicity.

In short, the diathesis-stress model places greatest emphasis on the role of learning factors in the onset, exacerbation, and maintenance of pain for those people with persistent pain problems. Flor et al. (1990) suggested that a range of factors predispose individuals to develop chronic or recurrent acute pain; however, the predisposition is necessary but not sufficient. Conditioning and individual differences are central to this model.

Cognitive-Behavioral Model

The diathesis-stress model previously described tends to give priority to conditioning. The cognitive-behavioral model incorporates many of the same constructs as the diathesis-stress model (viz. anticipation, avoidance, and contingencies of reinforcement), but suggests that cognitive factors, and in particular expectations rather than conditioning factors, are of central importance (cf. Brewer, 1974). It suggests that so-called conditioned reactions are largely self-activated on the basis of learned expectations rather than automatically evoked. The critical factor for the cognitive-behavioral model, therefore, is not that events occur together in time, but that people learn to “predict them and to summon appropriate reactions” (Turk et al., 1983). It is the individual patient’s processing of information that results in anticipatory anxiety and avoidance behaviors.

From the cognitive-behavioral model, people with pain are viewed as having negative expectations about their own ability to control certain motor skills without pain. Moreover, pain patients tend to believe they have limited ability to exert any control over their pain. Such negative, maladaptive appraisals about the situation and personal efficacy may reinforce the experience of demoralization, inactivity, and overreaction to nociceptive stimulation (Biederman et al., 1987; Brown & Nicassio, 1987). These cognitive appraisals and expectations are postulated as having an effect on behavior leading to reduced efforts and activity that may contribute to increased psychological distress (helplessness) and subsequently physical limitations.

If it is accepted that pain is a complex, subjective phenomenon that is uniquely experienced by each person, then

knowledge about idiosyncratic beliefs, appraisals, and coping repertoires become critical for optimal treatment planning and for accurately evaluating treatment outcome. This view is nicely demonstrated in Reesor and Craig (1988). They showed that the primary difference between chronic low back pain patients who were referred because of the presence of many “medically incongruent” signs and those who did not display these signs was *maladaptive thoughts*. Interestingly there were no significant differences between these groups on the number of surgeries, compensation, litigation status, or employment status. These maladaptive cognitive processes may amplify or distort patients’ experiences of pain and suffering. Thus, the cognitive activity of chronic pain patients may contribute to the exacerbation, attenuation, or maintenance of pain, pain behavior, affective distress, and dysfunctional adjustment to chronic pain (Turk & Rudy, 1986, 1992).

Biomedical factors that may have initiated the original report of pain play less and less of a role in disability over time, although secondary problems associated with deconditioning may exacerbate and serve to maintain the problem. Inactivity leads to increased focus on and preoccupation with the body and pain and these cognitive-attentional changes increase the likelihood of misinterpreting symptoms, overemphasis on symptoms, and the perception of oneself as being disabled. Reduction of activity, fear of reinjury, pain, loss of compensation, and an environment that perhaps unwittingly supports the “pain patient role” can impede alleviation of pain, successful rehabilitation, reduction of disability, and improvement in adjustment. As has been noted, cognitive factors may not only affect patients’ behavior and indirectly their pain, but may actually have a direct effect of physiological factors believed to be associated with the experience of pain.

People respond to medical conditions in part based on their subjective representations of illness and symptoms (schema). When confronted with new stimuli, people engage in a “meaning analysis” that is guided by the schema that best match the attributes of the stimulus (Cioffi, 1991). It is on the basis of the person’s idiosyncratic schema that incoming stimuli are interpreted, labeled, and acted on.

People build fairly elaborate representations of their physical state, and these representations provide the basis for action plans and coping (Nerenz & Leventhal, 1983; Turk, Rudy, & Salovey, 1986). Beliefs about the meaning of pain and people’s ability to function despite discomfort are important aspects of the cognitive schema about pain (Slater et al., 1991). These representations are used to construct causal, covariational, and consequential information from their symptoms. For example, a cognitive schema that a person has a serious debilitating condition, that disability is a necessary aspect of pain, that activity is dangerous, and that pain is an acceptable excuse for neglecting responsibilities will likely result in maladaptive responses (Jensen et al., 1994; Schwartz et al., 1985; Williams & Thorn, 1989). Similarly, if people believe they have a serious condition that is quite fragile and a high risk for reinjury, they may fear engaging in physical activities (Philips, 1987a). Through a process of stimulus generalization, patients may avoid more and more activities, become more physically deconditioned, and consequently more disabled.

Patients' beliefs, appraisals, and expectations about their pain, their ability to cope, their social supports, their disorder, the medicolegal system, the health care system, and their employers are all important as they may facilitate or disrupt the patient's sense of control and ability to manage pain. These factors also influence peoples' investment in treatment, acceptance of responsibility, perceptions of disability, adherence to treatment recommendations, support from significant others, expectancies for treatment, and acceptance of treatment rationale (Slater et al., 1991; Turk & Rudy, 1991).

Cognitive interpretations also will affect how patients present symptoms to significant others, including health care providers and employers. Overt communication of pain, suffering, and distress will enlist responses that may reinforce the pain behaviors (overt communications of pain such as limping, moaning, ambulating in a guarded or distorted fashion) and impressions about the seriousness, severity, and uncontrollability of the pain. That is, complaints of pain may lead physicians to prescribe more potent medications, order additional diagnostic tests, and in some cases perform surgery. Family members may express sympathy, excuse the patient from usual responsibilities, and encourage passivity thereby fostering further physical deconditioning. It should be obvious that the cognitive-behavioral perspective integrates the operant conditioning emphasis on external reinforcement and respondent view of learned avoidance within the framework of information processing.

From the cognitive-behavioral perspective, people with chronic pain, as is true for all people, are viewed as active processors of information. They have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, they often view themselves as helpless. Such negative, maladaptive appraisals about their condition, situation, and their personal efficacy in controlling their pain and problems associated with pain serve to reinforce the experience of demoralization, inactivity, and the overreaction to nociceptive stimulation. These cognitive appraisals are posed as having an effect on behavior, leading to reduced effort, reduced perseverance in the face of difficulty, and activity and increased psychological distress.

The specific thoughts and feelings that people experienced prior to exacerbations of pain, during an exacerbation or intense episode of pain, as well as following a pain episode, can greatly influence the experience of pain and subsequent pain episodes (Newton & Barbaree, 1987). Moreover, the methods people use to control their emotional arousal and symptoms have been shown to be important predictors of both cognitive and behavioral responses (Flor & Turk, 1988; Reesor & Craig, 1988). As described previously, interrelated sets of cognitive variables include thoughts about the controllability of pain, attributions about the person's own ability to use specific pain coping responses, expectations concerning the possible outcomes of various coping efforts, and common erroneous beliefs about pain and disability.

The primary focus of the cognitive-behavioral model, similar to the diathesis-stress model, is on the person, rather than symptoms and pathophysiology. Unlike the diathesis-stress model, however, the cognitive-behavioral model places em-

phasis on the person's thoughts and feelings because these will influence behavior. Conversely, the cognitive-behavioral model acknowledges that environmental factors can also influence behavior and behavior can affect patients' thoughts and feelings. Bandura (1978) referred to this as a process of reciprocal determinism. From this perspective, assessment of and consequently treatment of the person with persistent pain requires a broader strategy than those based on the previous dichotomous models described, which examined and addressed the entire range of psychosocial, behavioral, and biomedical factors (Turk & Rudy, 1989, 1991).

Because of the emphasis placed on cognitive factors, cognitive-behavioral theorists sometimes read as if cognition is the most salient constituent of the pain experience; however, there is generally an attempt to temper this impression by emphasizing the continuously interactive nature of the pain experience, thereby rendering it pointless to attempt to identify any one constituent of the experience as more important than any others (Turk & Rudy, 1986, 1992).

The cognitive-behavioral perspective on pain management focuses on providing patients with techniques to gain a sense of control over the effects of pain on their life, as well as actually modifying the affective, behavioral, cognitive, and sensory facets of the experience. Behavioral experiences help to show people that they are capable of more than they assumed, increasing their sense of personal competence. Cognitive techniques help to place affective, behavioral, cognitive, and sensory responses under the patient's control. The assumption is that long-term maintenance of behavioral changes will occur only if patients have learned to attribute success to their own efforts. There are suggestions that these treatments can result in changes of beliefs about pain, coping style, and reported pain severity, as well as direct behavior changes (Dolce et al., 1986; Turner & Clancy, 1986, 1988). Further, treatment that results in increases in perceived control over pain and decreased catastrophizing also are associated with decreases in pain severity ratings and functional disability (Jensen et al., 1991; Turner, 1991).

The chapter now turns from these integrative conceptual models to specific anatomy, physiology, and chemical bases of pain. The models that have been described need to incorporate current understanding of the physical mechanisms of pain.

ANATOMICAL, PHYSIOLOGICAL, AND CHEMICAL BASES OF PAIN

Between the stimulus of tissue injury and the subjective experience of pain is a series of complex electrical and chemical events. In considering pain it is important to have a conceptual understanding of the physiological processes involved as well as the anatomical structures that are believed to be important. It is equally important to be aware that the understanding of pain is far from complete and thus what is described in this section must be viewed as a puzzle with many pieces missing and some in the wrong place.

Four distinct physiological processes have been identified in pain: transduction, transmission, modulation, and percep-

tion (Fields, 1987). Consideration of these processes will guide the review of anatomical, physiological, and chemical bases subserving the experience of pain.

Transduction

Embedded in the various tissues are nerve endings that respond best to noxious stimuli. Transduction or receptor activation is the process where one form of energy (chemical, mechanical, or thermal) is converted into another, in this case, the electrochemical nerve impulse in the primary afferents. By this process, information about a stimulus is converted to a form that is accessible to the brain. Information is coded by the frequency of impulses in the primary afferents activated by the stimulus. Noxious stimuli lead to electrical activity in the appropriate sensory nerve endings.

Transmission

Transmission refers to the process by which coded information is relayed to those structures of the central nervous system (CNS) whose activity produces the sensation of pain. The first stage of transmission is the conduction of impulses in primary afferents to the spinal cord. At the spinal cord, activity in the primary afferents activates spinal neurons that relay the pain message to the brain. This message elicits a variety of responses ranging from withdrawal reflexes to the subjective perceptual events ("It hurts!"). Once the noxious stimulus has been coded by the impulses in the peripheral nerve, the sensations that result are determined by the neurons of the pain transmission system.

There are three major neural components of the pain transmission system: the peripheral sensory nerves, which transmit impulses from the site of transduction to their terminals in the spinal cord; a network of relay neurons that ascend the spinal cord to brainstem and thalamus; and reciprocal connections between the thalamus and cortex. CNS neurons receive convergent input from numerous primary afferents, often of different types, including both nociceptive and non-nociceptive neurons that have spatially extensive receptive fields, which in some cases include the entire body surface. In addition, the responses of CNS neurons to noxious stimuli are variable because they are subject to inhibitory influences elicited by peripheral stimulation or originating within the brain itself.

The neurons activated by noxious stimuli and their pattern of activity is thus a complex function of the primary afferent barrage that arrives at the spinal cord and the inhibitory influences that are active at the time. The primary afferent nociceptors terminate in the dorsal horn of the spinal cord. The axons of spinal neurons activated by these afferent nociceptors cross to the anterolateral quadrant on the side opposite to the activated nociceptors. The message then ascends to the brainstem and via the thalamus to the cortex.

Melzack and Casey (1968) proposed that the paramedian pathway, with its diffuse projection to the limbic system and to the frontal lobe, primarily subserves the affective-motivational aspects of pain. Consistent with this idea is the well-established role of the brainstem reticular formation in

behavioral arousal and in cortical arousal produced by a variety of sensory stimuli. In addition to producing arousal, the paramedian reticular formation plays an important role in escape behavior.

Noxious stimuli activate peripheral ending of the primary afferent nociceptor by the process of transduction. The message is then transmitted over the peripheral nerve to the spinal cord where it synapses with cells of origin of the two major ascending pain pathways, the spinothalamic and spinoreticulothalamic. The message is relayed in the thalamus to both the frontal and the somatosensory cortex, tracing the pain message along neural pathways from peripheral receptors to the cortex. It would appear that the relations among stimulus intensity, activity in pain transmission cells, and the perceived intensity of pain are simple and reproducible. This has an appealing simplicity, however, clinical observations indicate that the correlation between stimulus intensity and reported pain is actually unusual. In fact, the severity of reported pain may range from minimal to unbearable in different individuals with apparently similar injuries, and it is obvious that the subjectively experienced intensity of pain not only depends on the stimulus intensity but to a very large extent on psychological factors as described previously.

Modulation

Modulation refers to the neural activity leading to control of the pain transmission pathway. Input from the frontal cortex and hypothalamus activate cells in the midbrain, which control spinal pain transmission cells by means of cells in the medulla. The activity of this modulatory system is one reason why people with apparently severe injuries may deny significant levels of pain (Beecher, 1959; Wall, 1979).

Although we are far from understanding all the complexities of the human mind, we know that there are specific pathways in the CNS that control pain transmission, and there is evidence that these pathways can be activated by the psychological factors described earlier. The midbrain, periaqueductal gray matter, and adjacent reticular formation that project to the spinal cord via the rostroventral medulla, are all involved in the modulation of nociceptive signals (Fields, 1987). This pathway inhibits spinal neurons that respond to noxious stimuli. There is also a pain modulating pathway from the dorsolateral pons to the cord. The pathway from the rostral medulla to the cord is partly serotonergic, whereas that from the dorsolateral pons is at least noradrenergic.

In addition to the biogenic amine containing neurons, endogenous opioid peptides are present in all the regions implicated in pain modulation. The opioid-mediated analgesia system can be activated by electrical stimulation or by opiate drugs such as morphine. It can also be activated by pain, stress, and suggestion. Opioids produce analgesia by direct action on the CNS and activate the nociceptive modulating system. Opioid receptors have two distinct functions: chemical recognition and biological action. Researchers reasoned that the brain itself ought to synthesize molecules that would act at these highly specific receptor sites. Endogenous opioid peptides, namely, leucine-enkephalin, methionine-

enkephalin, beta-endorphin, dynorphin, alpha-neoendorphin pharmacologically similar to morphine reversed by opioid antagonists (e.g., naloxone) have all been identified.

Perception

The final physiological process involved with pain is perception. Somehow, the neural activity of the pain transmission neurons produces a subjective experience. How this comes about is obscure, and it is not even clear in which brain structures the activity occurs that produces the perceptual event. The question remains, "How do objectively observable neural events produce subjective experience?" Because pain is fundamentally a subjective experience, there are inherent limitations to understanding it.

Pain responses cannot be predicted with certainty because there is great subjective variability. In some people, innocuous stimuli produce excruciating pain. In other situations, patients with severe injuries deny any significant pain. This variability presents a conundrum to health care providers and patients alike.

To understand the variability in individual experiences, it is useful to distinguish between pain detection threshold and pain tolerance. Pain threshold is a property of the sensory system that depends on the stimulus. It is highly reproducible in different people and in the same person at different times. In contrast to this reproducibility, pain tolerance is highly variable. No two people react to pain in quite the same way. This distinction helps to understand the variability of pain. Pain tolerance is a manifestation of a person's reaction to pain and is highly dependent on psychological variables, described earlier. Not only does it vary between different people in the same situation, but the same individual may react differently in different situations.

There are several reasons for the variability: There may be an injury to the pain transmission system activity of the modulatory system that lowers pain intensity. There may be abnormal neural activity that may produce hypersensitivity that can result from self-sustaining processes set in motion by an injury but that may persist beyond the time it takes for the original injury to heal. This self-sustaining process may even create a situation where pain is present without the noxious stimulus produced by an active tissue damaging process (neuropathic pain, causalgia). Finally, the psychological processes and factors previously described may affect normal pain intensity creating unpredictable responses.

If pain were simply a sensation, these neural pain mechanisms would probably be sufficient to explain most of the clinically observed variability. However, pain is more than a sensation. The close association of the pain sensory system with the function of protection of the body from damage is unique among sensory systems. It is essential for understanding pain patients that the desire to escape from or terminate the sensation be considered. If it is not unpleasant, then it is not pain.

As noted in the discussions of the diathesis-stress and cognitive-behavioral models earlier, the meaning of pain is one important factor in determining pain tolerance. Different peo-

ple have learned different ways of coping with pain; some minimize it and some overreact. Thus, for many people it may be as important to know what they think their pain means as it is to know its cause. Because of the importance of the person's interpretation, it is imperative, especially for persistent or recurrent pain, to make some inquiry about this issue for treatment.

Physical Factors Subservient Pain

Next some of the specific physical factors involved in pain are examined. When a stimulus of sufficient intensity to be tissue damaging (i.e., noxious) is applied to a sensitive part of the body such as the skin, somatic (musculoskeletal), and visceral structures, a chain of events is set in motion that eventually results in a sensation identifiable as painful. The capacity of tissues to elicit pain when noxious stimuli are applied to them depends on their innervation of nociceptors. Nociceptors are primary afferent nerves with peripheral terminals that can respond specifically and differentially to noxious stimuli. The peripheral terminals of the nociceptive afferents (pain receptors or nociceptors) are directly sensitive to brief intense thermal, mechanical, and chemical stimuli. Some of the chemicals that excite the nociceptors include kinins, histamine, and K^+ and H^+ ions that usually result from inflammation.

By the complex cascade of events described earlier, nociceptor activity produces several results. On the peripheral side there is prolongation of pain long after the termination of the stimulus and the development of hyperalgesia (stimuli above normal pain threshold perceived as more intense than in uninjured areas). In the peripheral tissues, the activity in nociceptors acts synergistically with the other processes initiated by tissue damage to produce increased blood flow and edema.

In addition to transient responses to these brief stimuli, nociceptors show relatively long-lasting increases in sensitivity when noxious stimuli are repeatedly applied. Long-lasting enhancement of nociceptor activity can be produced by a variety of diffusible substances that activate (potassium, serotonin, bradykinin, histamine) or sensitize the primary afferent (prostaglandins, leukotrienes, substance P) synthesized.

Of the afferent sensory fibers, A-delta and C-fibers, readily found in skin, muscle, and fascia, are slow conducting small diameter fibers that carry nociception, whereas A-beta fibers are activated by touch and pressure. The nociceptive fibers, which utilize substance P as a neurotransmitter, synapse at the dorsal horn, cross to the other side, and ascent via the spinothalamic tract. This tract transmits connecting fibers to the reticular formation of the brain stem and thalamic nuclei before ending in the somatosensory cortex. Although the cortex does not play an essential role in pain perception, it integrates the cognitive and behavioral aspects of pain.

The important endogenous pain inhibitory system involves descending analgesic pathways from the periaqueductal grey areas of midbrain to spinal dorsal horn via raphe magnus nucleus of the pons; local enkephalinergic interneurons in the spinal cord; and peripheral A-beta sensory fibers that presynaptically inhibit A-delta and C-fibers at the

dorsal horn. The inhibitory system utilizes several neurotransmitters including serotonin, enkephalin, norepinephrine gamma aminobutyric acid (GABA), and somatostatin. The periaqueductal grey receives neuronal fibers from cortex, hypothalamus, and the limbic system, probably explaining the interaction of cognitive and emotional elements with pain perception and inhibition. Given the same noxious stimuli, the pain perception between two people may vary according to the phenomenon of attention or inhibition, both of which are probably modulated by various descending neurons. Emotion, attention, and motivation may all influence pain perception, probably through a complex network of reticular, limbic, and cortical fibers.

CONCLUSIONS

From the patient's point of view, the pain complaint connotes distress and is a plea for assistance. The subjective experience includes an urge to escape from the cause or, if that is not possible, to obtain relief. It is the overwhelming desire to terminate it that gives pain its power. Pain can produce fear, and if it persists, depression, and ultimately it can take away the will to live.

It has become abundantly clear that no isomorphic relation exists between tissue damage and pain report. The more recent conceptualizations discussed view pain as a perceptual process resulting from the nociceptive input and modulation on a number of different levels in the CNS and not as directly proportional to nociceptive input.

Pain is a subjective, perceptual experience, and one characteristic differentiating it from pure sensation is its affective quality. Thus, pain appears to have two defining properties: bodily sensation and an aversive affect (Fernandez & Turk, 1992; Melzack & Casey, 1968). Quintessentially, pain is experienced at a physical levels and an affective level. As underscored by the International Association for the Study of Pain (Merskey, 1986), "it [pain] is unquestionably a sensation in a part or parts of the body but it is also always unpleasant and therefore also an emotional experience" (p. S217).

In this chapter, conceptual models were presented to explain the subjective experience of pain. Current state of knowledge suggests that pain must be viewed as a complex phenomenon that incorporates physical, psychosocial, and behavioral factors. Failure to incorporate each of these factors will lead to an incomplete understanding. The range of psychological variables that have been identified as being of central importance in pain along with current understanding of the physiological basis of pain were reviewed. Several integrative models were described that try to incorporate the available research and clinical information. Pain has become a vigorous research area and the virtual explosion of information will surely lead to refinements in understanding of pain and advances in clinical management.

Personality Traits as Risk Factors for Physical Illness

Timothy W. Smith

Linda C. Gallo
University of Utah

The belief that stable patterns of thought, emotion, and behavior contribute to the development of physical illness has been present throughout the history of medicine (McMahon, 1976). Hippocrates, for example, argued that four basic temperaments or personality types reflected excesses of specific humors and caused corresponding medical disorders. Many centuries later, Sir William Osler (1892) suggested that coronary heart disease befell “not the neurotic, delicate person ... but the robust, the vigorous in mind and body, the keen and ambitious man, the indicator of whose engine is always at full speed ahead” (p. 839). The descriptions of personality, disease, and the nature of their relation have varied widely, but the essence of this psychosomatic hypothesis has remained unchanged.

Earlier in this century, the hypothesis was refined by the psychoanalytic school in psychosomatic medicine (Alexander, 1950; Dunbar, 1943). These models assigned a pathophysiological role to unconscious personality dynamics, and suggested a correspondence between specific emotional conflicts and medical conditions. Unlike previous psychoanalytic formulations of hysteria or hypochondriasis (Freud, 1933), these models identified causes for actual disease, rather than unfounded physical symptoms. For example, an unconscious conflict between aggressive impulses and anxiety concerning the consequences of their expression was described as a cause of essential hypertension. Although a weak scientific foundation limited the impact of this approach on the mainstream of either medicine or psychology (Surwit, R.

B. Williams, & Shapiro, 1982), it set the stage for current research on personality and illness.

During the same period, developments in the physiology of stress provided an essential, scientifically credible set of mechanisms connecting personality and disease (Ax, 1953; Cannon, 1939; Seyle, 1936, 1952; Wolff, 1950). Not surprisingly, the psychophysiology of stress and emotion remains an integral component of this research area (Contrada, Leventhal, & O’Leary, 1990). The immediate predecessor of the current interest in the issue is undoubtedly the seminal work of M. Friedman and Rosenman (1959) on the Type A coronary prone behavior pattern. Although M. Friedman and Rosenman actively avoided describing their work in the language of personality traits, their work is now recognized as involving personality characteristics (Suls & Rittenhouse, 1987). Friedman and Rosenman’s version of the centuries-old psychosomatic hypothesis was a major force in the early development of the larger fields of behavioral medicine and health psychology (G. C. Stone, F. Cohen, & Adler, 1979; Weiss, Herd, & Fox, 1981).

An often overlooked forerunner to current research on personality traits as risk factors for illness are early studies that used psychometrically sound measures of personality in large, prospective designs (e.g., Ostfeld, Lebovits, Shekelle, & Paul, 1964). Effects of personality variables on subsequent disease were examined while attempting to control statistically the possible confounding medical or demographic variables. Studies of this type provided important evidence of the merit of

the hypothesis and the outlines of a methodology for constructing a credible epidemiological foundation for the field.

The current state of research on the hypothesis that personality traits can influence physical health comprises notable achievements and clear limitations. On the one hand, several literatures have matured to the point that the evidence is compelling; specific personality characteristics are indeed associated with increased risk of serious illness and premature death (e.g., T. Q. Miller, T. W. Smith, Turner, Guijarro, & Hallet, 1996). Further, plausible mechanisms accounting for this association have been articulated and evaluated, at least in a preliminary manner (S. Cohen & Herbert, 1996; Manuck, 1994). On the other hand, a steady climate of skepticism persists in much of the medical community (e.g., Angel, 1985), and the empirical support for the health relevance of some personality traits discussed in this literature is quite limited. Further, the implications of this work for the treatment and prevention of illness are largely unknown. Fortunately, conceptual, methodological, and analytic tools in personality psychology and behavioral medicine have evolved to the point where future studies will address these limitations in an increasingly compelling manner.

This chapter provides an overview and critique of the literature concerning personality traits as risk factors for physical disease. It begins by addressing some basic issues regarding the nature of personality, disease, and their potential association. After reviewing models of this association, it turns to theory and research on the major personality attributes in the field. Finally, it concludes with a critical evaluation of the state of the literature and issues to be addressed in its future.

BASIC ISSUES

What Is Personality?

Allport (1937) succinctly argued that “personality *is* something and personality *does* something” (p. 48, emphasis added). Personality traits are stable patterns of thought, emotion, and behavior that characterize an individual across time and situations. Traits are presumed to be based in psychological and/or biological structures within the individual, and they form a dimensional basis for comparing individuals. For example, some people are generally friendly and warm, whereas others are cold and disagreeable, presumably because of differences in their biologic and/or psychologic “make-up.” Thus, from this perspective, personality *traits* are things that people “have” (Cantor, 1990).

In Allport’s other, more active meaning, personality refers to the *processes* through which an individual’s thoughts, emotions, and behavior cohere into meaningful patterns over time and across situations. These processes include the ways in which individuals select and interpret the contexts and situations of their lives, the goals they pursue, the strategies and tactics they employ in doing so, and the ways in which they evaluate and react to the outcome of these activities. These more circumscribed and dynamic psychological processes are closely associated with the stable patterns of thought, emotion, and behavior that are indicators of traits. Yet, this

other sense of personality is obviously much more concerned with how traits operate, rather than their description. Thus, the study of personality as “doing” rather than having (Cantor, 1990) focuses on describing both the psychological mechanisms underpinning more broadly defined, static personality traits and the ways in which these “middle units” of personality are dynamically interrelated and expressed.

Current personality psychology reflects both of Allport’s meanings, and recent developments of both types have the potential to make enormously valuable contributions to the study of personality and health (T. W. Smith & P. G. Williams, 1992). In the classic trait perspective, a far-reaching development is the emergence of the five-factor model of personality as an adequate taxonomy of basic personality characteristics (Digman, 1990; John, 1990; McCrae & John, 1992). Although descriptions vary across versions of this model, and despite several notable critics (e.g., Block, 1995), there is general consensus regarding the traits listed in Table 9.1—Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness to Experience. These traits have been recovered in factor analyses of self- and other- ratings, and several reliable and valid measures of these broad dimensions and their subcomponents have been developed (Digman, 1990; John, 1990).

The validity and potential impact of this taxonomy are evident in the fact that these traits are clearly not simple mental abstractions or linguistic conveniences used by raters (e.g., Funder & Colvin, 1991; Moskowitz, 1990). Rather, they reflect verifiable, general dimensions of individual functioning. Further, these broadly defined traits are stable (McCrae & Costa, 1990), show patterns of variability consistent with genetic influences (Bouchard, Lykken, McGue, Segal, & Tellegen, 1990), and predict behavior in many circumstances (Kendrick & Funder, 1988).

The elements of this taxonomy can provide a useful guide for organizing the growing array of otherwise conceptually isolated traits suggested as risk factors for physical illness (Costa & McCrae, 1987b; Marshall, Wortman, Vickers, Kusulas, & Hervig, 1994; T. W. Smith & P. G. Williams, 1992). Traits studied as risk factors are often described and studied individually, without attention to their overlap or even redundancy with other traits. One important application of the five-factor taxonomy is the conceptual and empirical description of traits suggested as potential risk factors. This use of the five-factor taxonomy might reveal similarities and differences among otherwise isolated traits. In addition, the five traits themselves might be viable candidates as risk factors (e.g., Costa, McCrae, & Dembroski, 1989). In either of these applications of the model, the well-validated assessment devices are likely to be useful to health researchers.

One important variation on the five-factor model substitutes the dimensions of Friendliness versus Hostility and Dominance versus Submissiveness for Agreeableness and Extraversion, respectively (Trapnell & Wiggins, 1990). This permits the integration of the five-factor approach with the interpersonal approach to personality (Carson, 1969; Kiesler, 1983; Leary, 1957; Wiggins, 1979). As depicted in Fig. 9.1, the dimensions of dominance and friendliness define a

TABLE 9.1
Elements of the Five-Factor Model of Personality

Trait	Opposite Pole	Facets or Components
Neuroticism	Emotional Stability	Anxiety, depression, angry hostility, self-consciousness, vulnerability, impulsiveness
Agreeableness	Antagonism	Trust, altruism, modesty, straight forwardness, compliance, tender mindedness
Extraversion	Introversion	Warmth, gregariousness, assertiveness, activity, excitement seeking, positive emotions
Conscientiousness	Unreliability	Competence, order, self-discipline, dutifulness, achievement striving, deliberation
Openness to Experience	Closed Mindedness	Fantasy, aesthetics, introspection, curiosity, novelty seeking, low dogmatism

Note. Adapted from Costa & McCrae, 1990.

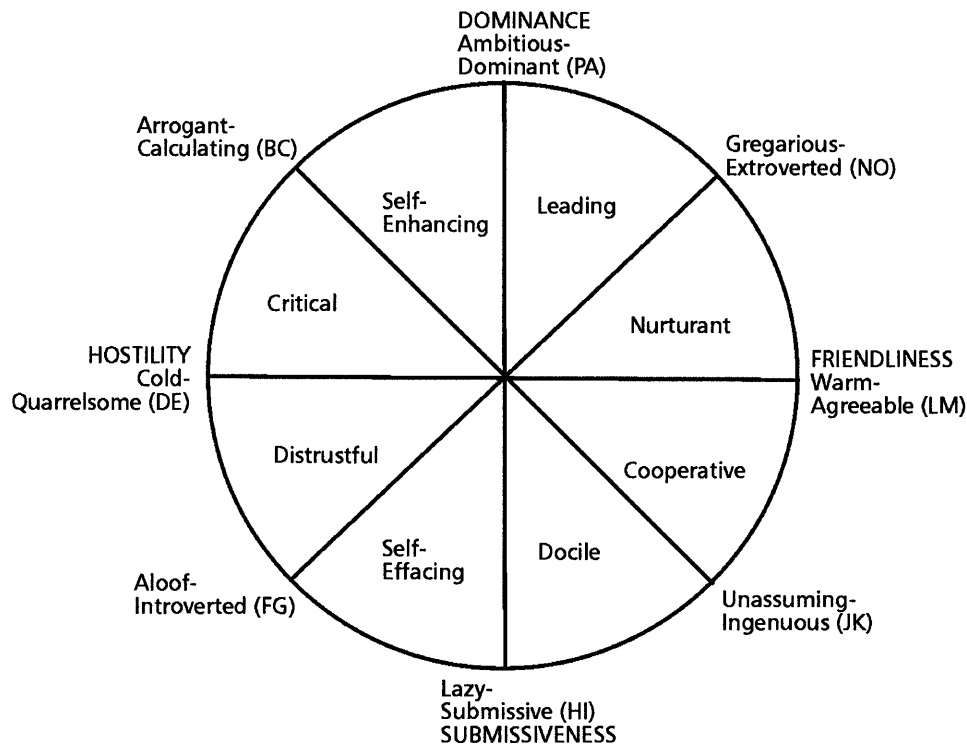

FIG. 9.1 The interpersonal circumplex.

two-dimensional space, or circumplex. The circumplex model has been used, conceptually and empirically, to describe a variety of personality characteristics, interactional behaviors, and social stimuli (Kiesler, 1991; Wiggins, 1991; Wiggins & Broughton, 1991). As a result, it has considerable potential for facilitating the integration of personality and social risk factors for disease (Gallo & Smith, 1998; T. W. Smith, Gallo, Goble, Ngu, & Stark, 1998; T. W. Smith, Limon, Gallo, & Ngu, 1996). That is, personality traits and aspects of the social environment can be described and even assessed through a common framework.

Although the five-factor model and its variants are potentially invaluable in identifying and organizing traits in the study of personality and health, they have less to say about the mechanisms through which traits influence behavior, emo-

tion, and ultimately health. It is here that the second major emphasis in personality psychology is of use. Unfortunately, less agreement exists regarding an adequate taxonomy of the "middle units" of personality processes (Cantor, 1990). However, several overlapping sets have been articulated, and clear themes have emerged in the related research. These approaches follow from the cognitive social learning tradition in personality psychology (Kelly, 1955; Mischel, 1973; Rotter, 1954), and they share many conceptual similarities to interpersonal approaches in personality and clinical psychology (Kiesler, 1996; Westen, 1991). Examples of the constructs described in this literature are mental representations (i.e., schemas) of the self, others, relationships, and social interaction sequences (i.e., scripts); life tasks, motives, and goals; appraisals, values, and beliefs; strategies, tactics,

and competencies in goal-directed behavior; and coping styles and behaviors (Cantor, 1990; McAdams, 1995; Mischel & Shoda, 1995, 1998; Oglevie & Rose, 1995; Westen, 1995).

An underlying premise in this tradition is that characteristics of the person are reciprocally related to the social environment. Intentionally or not, people choose to enter some situations and not others, and their actions and overt expressions of emotion elicit responses from their interaction partners in ways that reflect their personality traits (Asendorpf & Wilpers, 1998). These selected, evoked, and intentionally manipulated features of the individual's social environment in turn influence the individual (Bandura, 1977; Buss, 1987; Ickes, Snyder, & Garcia, 1997). Thus, an individual's thoughts, emotions, and behavior are seen as highly responsive to characteristics of the specific situation, and many situations are modified by the individual's actions. Through these recurring, reciprocal patterns, individuals foster social environments that maintain central features of their personalities over time (Caspi et al., 1989; Kiesler, 1996; Wachtel, 1994; Wagner, Kiesler, & Schmidt, 1995). A further implication of this view is that personality processes are best understood in the *contexts* that comprise and surround these reciprocal interactions between people and social environments (Revenson, 1990), such as characteristics of the physical environment, subculture, and socioeconomic factors. Personality descriptions are likely to be more accurate and informative to the extent that they consider individuals, their recurring social circumstances, and the context in which they are embedded.

Current versions of the cognitive-social approach to personality offer the potential for a comprehensive description of broad traitlike characteristics and recurring patterns of situationally specific responding (e.g., Mischel & Shoda, 1995, 1998). That is, the approach has the potential to describe the mechanisms through which traits, such as those in the five-factor taxonomy, influence thought, emotion, and behavior in interaction with social situations. Another important advantage of the cognitive-social perspective is its overlap with current stress and coping theory, given their mutual emphasis on cognitive appraisal processes, self-regulation of emotional responses, and strategies for managing situational threats and demands (Contrada, 1994). The general stress and coping model (e.g., Lazarus & Folkman, 1984; Lazarus, 1991) has become a cornerstone of health psychology and behavioral medicine, and it provides an important conceptual and empirical connection to the psychophysiological responses hypothesized to link personality traits and subsequent disease.

Another benefit of the cognitive-social approach is its relevance for interventions. Although the general trait approach is useful in identifying the personality characteristics that might be useful foci in interventions intended to prevent or manage illness, it has less to say about specific targets for change. With its increased attention to specific psychological mechanisms and dynamic patterns, the cognitive-social approach is likely to aid in the articulation and refinement of intervention techniques. For example, whereas the five-factor taxonomy might identify neuroticism and (low) agreeableness as useful targets

for change, the cognitive-social perspective could suggest specific patterns of appraisals, beliefs, interaction tactics, and coping behaviors to be included in such interventions.

What Are the Appropriate Indications of Illness?

A revolutionary difference between psychoanalytic writing on hysteria and hypochondriasis as opposed to the later work of Alexander, Dunbar, and their colleagues lies in the nature of the health endpoint under consideration—abnormal illness behavior versus actual illness. This distinction was clearly drawn more recently in conceptual discussions of the potential effects of personality on health (e.g., F. Cohen, 1979). Outcomes such as symptom reports, utilization of health care resources (e.g., physician visits), taking medication, or receiving other treatments typically reflect the presence of illness, but are fallible indicators. In evaluating the role of personality in physical illness, care must be taken to avoid mistaking an association between personality traits and illness behavior for an association with actual illness. The former may or may not reflect the latter.

Despite the early and clear articulation of this issue, many influential empirical reports on the association between personality and physical illness relied heavily on these less definitive indices (e.g., Haynes, Feinleib, & Kannel, 1980; Kobasa, 1979; Scheier & Carver, 1985). Similarly, several important reviews of this literature (e.g., H. S. Friedman & Booth-Kewley, 1987) have been criticized for the potential misinterpretation of associations between personality traits and illness behaviors—especially somatic complaints—as reflecting the effects of personality on actual physical health (e.g., Matthews, 1988; Stone & Costa, 1990; T. W. Smith & Rhodewalt, 1991).

In the most notable example of this issue, several investigators have demonstrated that neuroticism is consistently related to somatic complaints, even in the absence of actual illness (Costa & McCrae, 1985a, 1987; Watson & Pennebaker, 1989). If the personality characteristic under consideration is associated with neuroticism and if the disease endpoint studied wholly or even partly reflects illness behavior rather than objectively documented disease, then this interpretive ambiguity arises; the association observed might involve personality traits and actual illness, or personality and illness behavior. Given this concern and its potential negative impact on the identification of robust causal influences on actual illness, symptom reports and other illness behaviors are no longer considered an acceptable operational definition of illness. Although illness behaviors are important topics for research, cumulative progress in the study of personality traits as risk factors requires less ambiguous methodologies.

A second major development in this literature is the recognition that the pathophysiology of the major diseases studied varies considerably across their progression. For example, the beginning stage of coronary heart disease (CHD) is characterized by microscopic injuries to the endothelial lining of the coronary arteries. The potential psychophysiological influences on this process might differ from those of the next stage—the slow progressive buildup of fatty deposits at the

injury sites. Further, the factors that precipitate the emergence of overt symptoms of CHD (i.e., angina, myocardial infarction, sudden cardiac death) may differ still from those that hasten the progression of previously asymptomatic coronary artery disease (CAD; S. Cohen, J. R. Kaplan, & Manuck, 1994; Kamarck & Jennings, 1991). The natural histories of many forms of cancer and the course of HIV infection and AIDS include similar possibilities for heterogeneous psychophysiological influences over time. This poses two challenges for researchers in the area. First, biologically plausible mechanisms linking personality and disease must be articulated, and second, mechanisms must be tied to identifiable points in the etiology of the illness.

How Do We Evaluate the Personality–Disease Hypothesis?

In order to reach valid conclusions about the presence or absence of a hypothesized relation between a personality trait and illness, several common methodological issues must be addressed. These can be grouped into the classic, four categories of validity in research design specified by Cook and Campbell (1979)—statistical conclusion validity, internal validity, construct validity, and external validity (or generalizability).

Statistical associations between personality traits and illness are generally small, at least by the standards typical in behavioral research (J. Cohen, 1990). These effects are often at least as large as those involving more conventional risk factors for disease. Given the prevalence and cost of the diseases studied, even small effects can have important public health implications. However, small effects, multifactorial etiologies, and changing influences across the course of disease can make it difficult to detect significant covariation between personality characteristics and disease. As a result, large epidemiological studies and quantitative combination of independent results (i.e., meta-analysis) are essential in the development and evaluation of this literature. The results of individual studies must be considered with caution, especially if they employ small, select samples. T. Q. Miller and his colleagues (1991) demonstrated that the use of high risk samples and the associated restriction of range in disease prevalence and severity (i.e., disease-based spectrum bias) can mask the statistical association of personality traits and other risk factors with disease.

Given that personality characteristics are rarely manipulated experimentally, the issue of internal validity is central in this literature. A common strategy in early stages of investigation of a risk factor is the concurrent case control design, in which individuals with the disease (or more severe disease) are compared with controls on the trait of interest. However, given the many possible consequences of serious illness, the alternative interpretation that cognitive, emotional, and behavioral correlates of a disease might reflect consequences rather than causes of the condition often seems equally plausible (S. Cohen & Rodriguez, 1995). Prospective designs eliminate this ambiguity to a large extent, but because of their cost are often underrepresented in the literature on specific traits.

Further, the possibility of unmeasured third variables accounting for statistical associations between personality and disease remains as a threat to internal validity even in prospective designs. Biologic, psychologic, and sociodemographic variables could exert simultaneous effects on personality and health, thereby producing a noncausal association.

As previously noted, many studies have relied on symptom reports or diagnoses in which somatic complaints are primary criteria (e.g., angina to operationalize CHD). This poses the threat to construct validity described earlier; the statistical associations might involve illness behavior rather than illness itself. The field has shown an increasing recognition of this concern over time.

However, the construct validity of the personality variables studied as predictors of illness is still often underemphasized. Scales are sometimes specifically developed to assess an individual trait described in a newly proposed model of personality and health. Sometimes such scales are employed prior to thorough construct validation. As a result, it is often uncertain if the statistical associations examined actually involve the personality trait(s) under study, as opposed to some other characteristic(s) assessed unintentionally. Similarly, the distinct versus overlapping nature of the growing array of traits in the field is largely neglected (H. S. Friedman et al., 1995). Thus, it is often unknown whether or not scales intended to assess similar characteristics actually do so (i.e., convergent validity), and whether or not scales with dissimilar names and conceptual descriptions actually assess distinct traits (i.e., discriminant or divergent validity). Careful attention to the issue, possibly using the five-factor model as an integrative tool and source of validated indicators (Gallo & Smith, 1998; Marshall et al., 1994; T. W. Smith & P. G. Williams, 1992), could improve the quality of this literature considerably.

Finally, as with much medical research, the literature on personality traits as risk factors can be rightfully criticized as employing samples that are disproportionately White, middle-class, and male (N. B. Anderson, 1989; N. B. Anderson & Armstead, 1995; Stanton, 1995). Thus, the generalizability of effects across sexes, races, and socioeconomic status is often unknown. Once apparently robust relationships are identified, their generalizability to more diverse groups should be examined. Given that many of these personality traits vary systematically as a function of age, race, sex, and socioeconomic status (e.g., Siegler, 1994), and that these demographic characteristics are themselves risk factors, the issue is likely to be important in the future of the research area.

MODELS OF THE ASSOCIATION BETWEEN PERSONALITY AND DISEASE

Even if reliable and valid associations between personality traits and subsequent illness can be established, the processes or mechanisms that underlie these effects have yet to be determined. Several models have been proposed to describe the association of personality characteristics and subsequent health (F. Cohen, 1979; S. Cohen & Rodriguez, 1995; Krantz & Glass, 1984; Suls & Sanders, 1989). The interactional and

transactional *stress moderation models* suggest that physiological reactivity is the critical link underlying this statistical association. Likewise, the *constitutional vulnerability* model posits a physiological influence on disease, but identifies personality as a noncausal correlate or epiphenomenon of this responsiveness. The *health behavior model* suggests that personality influences health by affecting health practices. Finally, the *illness behavior model* indicates that personality impacts the subjective experience of illness and the behavioral responses to perceived symptoms. The subsequent section elaborates on each of these models. It is important to note that they are not necessarily mutually exclusive, and that for any given personality characteristic, several models may explain health effects in a complementary manner.

Stress Moderation Models

Stress moderation models are based on the premise that stress is a fundamental component of the relation between personality and disease (e.g., F. Cohen, 1979; S. Cohen & Rodriguez, 1995; Contrada, Leventhal, & O'Leary, 1990; Houston, 1989; Suls & Rittenhouse, 1987). To explain the historically modest association of stress and illness (Rabkin & Struening, 1976), the interactional stress moderation model goes beyond a direct or main effect model by suggesting that individuals will differ in their degree of vulnerability to the detrimental effects of stress, as a consequence (in part) of their personality characteristics. Thus, personality traits are seen as moderators (Baron & Kenney, 1986) of the stress—illness relation, in that illness is more accurately predicted by the statistical interaction of environmental stress and personality traits. Further, the interactive effect of stress and personality on illness is, in turn, seen as mediated by differential psychophysiological responses to stressors as a function of an individual's standing on the personality dimension(s).

Given its central role in this model, it is important to describe the current status of the hypothesis that the psychophysiology of stress can influence disease. The prevailing theory suggests that psychological stress elicits increases in activity in the sympathetic adrenomedullary and hypothalamic, pituitary adrenocortical axes. Over time, pronounced, repetitive, or prolonged physiological responses are thought to contribute to the etiology of illness. Cardiovascular illnesses (e.g., CHD, hypertension, stroke) are believed to be fostered by activation of neuroendocrine (e.g., catecholamines, cortisol) and cardiovascular (e.g., blood pressure) responses (Barnett, Spence, Manuck, & Jennings, 1997; Kamarck & Jennings, 1991; Manuck, 1994; Markovitz, Raczynski, Wallace, Chettur, & Chesney, 1998). Infectious illnesses and cancer are presumed to be influenced by the effects of stress on the immune system (Herbert & S. Cohen, 1993; Kiecolt-Glaser & Glaser, 1995). Although definitive evidence is lacking, these pathways are biologically plausible and the research to date provides considerable, albeit preliminary, support for their role in pathophysiology.

Personality may serve to attenuate or exacerbate (i.e., moderate) the connection between stress and pathophysiology at several places in the stress and coping sequence (see

Fig. 9.2). First, the degree to which a given event will be experienced as stressful depends on an individual's subjective appraisal of harm or loss, as well as the resources believed to be available for managing the situation (Lazarus & Folkman, 1984). Certain personality characteristics are thought to influence this subjective appraisal. For example, Type A individuals frequently appraise situations as involving more threat or demand than do Type B persons—a tendency thought to link TABP to cardiovascular disease (Houston, 1989). In contrast, hardy individuals are believed to perceive life events to be challenging, rather than threatening, which may decrease their vulnerability to disease (e.g., Kobasa, 1979). Through these appraisals, personality influences the emotional and motivational responses to events (Houston, 1992), and emotions and aroused motives influence psychophysiological response (Wright, 1996). Second, personality may influence the coping mechanisms that the individual applies in managing the stressor. Specific coping mechanisms probably cannot be categorically regarded as adaptive or maladaptive (e.g., Lazarus, 1990). However, personality may influence the likelihood that the individual will employ strategies that are adaptive in a given circumstance (Bolger & Zuckerman, 1995).

Although the succinctness of the interactional stress moderation approach is appealing, the model is somewhat limited. Fundamentally, it is a model of individual differences in responses to potentially stressful circumstances. These responses are viewed as the result of the static or statistical interaction of personality traits and aspects of the situation. Several researchers have advocated a more process-oriented approach (e.g., Bolger, 1990; Contrada et al., 1990; Houston, 1989; Lazarus, 1990; Revenson, 1990) that emphasizes the ongoing interplay between personality, coping, and contextual factors. Such models move beyond the static or statistical interactional approach by acknowledging the type of reciprocal transactions between persons and their environments typical of the cognitive-social learning and interpersonal models of personality already described. Thus, transactional views of the stress moderation process emphasize the ways in which people influence the objective features of their environments by actively choosing situations and subsequently responding to them in characteristic ways (Bandura, 1977; Buss, 1987; Cantor, 1990; Mischel, 1973). For example, because of their antagonistic interactional style, hostile persons are likely to evoke frequent interpersonal strain. Such conflicts probably confirm hostile expectations and increase the likelihood of future antagonistic behavior (Wagner et al., 1995).

The transactional approach submits that personality influences the stress/illness relation at three points in the stress and coping cycle (see Fig. 9.3). As in the interactional stress moderation approach, personality is thought to alter the appraisal of events and to influence the choice of coping responses. In addition, personality is thought to affect exposure to stressful events, through the individual's selection, evocation, and intentional provocation of characteristics of the situations they encounter (Buss, 1987). Personality characteristics that expose the individual to increased stress through these processes will also elicit the increased psychophysiological

reactivity and subsequent potential for disease discussed earlier. Thus, from this perspective, psychosomatic processes are not simple consequences of specific personality characteristics, but reflect a dynamic process emerging from the recurring transactions between people and the social contexts they inhabit (Revenson, 1990; T. W. Smith, 1995).

Health Behavior Model

The stress moderation and transactional models rest on the assumption that the physiological components of stress mediate the association between personality and disease. In contrast, the health behavior model posits that the effects of personality traits on health are indirect, mediated by the intervening effects of health practices (see Contrada et al., 1990; F. Cohen, 1979). (See Fig. 9.4). This model is derived from research suggesting that certain behaviors (e.g., smoking, leading a sedentary lifestyle, and practicing poor nutrition habits) are reliably associated with disease risk (e.g., Blair et al., 1989; Holroyd & Coyne, 1987; Paffenbarger & Hale, 1975). Fur-

ther, the model draws on research suggesting that personality traits, including hardiness (Wiebe & McCallum, 1986), neuroticism (Costa & McCrae, 1987a; McCrae, Costa, & Bosse, 1978), and hostility (Leiker & Hailey, 1988; Siegler, 1994) affect the likelihood that one will practice negative health habits.

Personality might influence the choice of health practices in several ways. First, psychological factors presumed to guide lifestyle choices may be components or correlates of personality constructs. Examples include variables such as locus of control, health beliefs and values, and self-efficacy (Bandura, 1989; Lau, 1988; Strickland, 1978). Alternatively, negative health practices may reflect ineffectual coping practices. That is, personality characteristics, such as hostility, may not only increase the likelihood that subjective stress will be experienced, but also that maladaptive behaviors, such as smoking or substance use, will be utilized as emotion-focused coping strategies. Research suggesting that individuals often adopt more negative health habits when exposed to stress is consistent with this hypothesis (Horowitz et al., 1979;

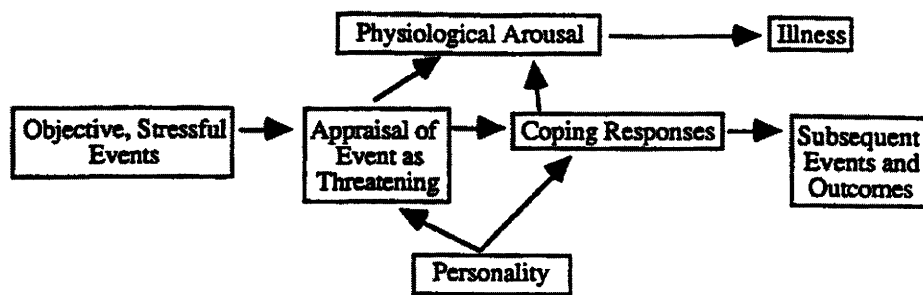

FIG. 9.2 The interactional stress moderation model.

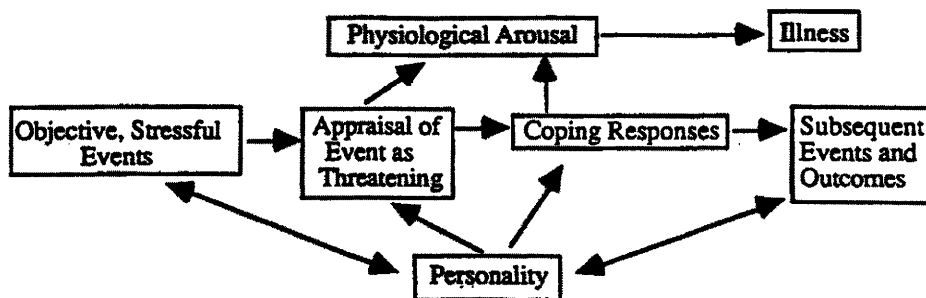

FIG. 9.3 The transactional stress moderation model.

FIG. 9.4 The health behavior model.

Langlie, 1977; Shachter, Silverstein, Kozlowski, Herman, & Liebling, 1977).

As noted earlier, the health behavior model does not suggest that a direct physiological pathway connects personality to health. However, there may be physiological correlates of health behaviors that operate through the set of psychophysiological responses described in the stress moderation models. As portrayed in the lower panel of Fig. 9.4, many health practices produce physiological changes similar to those generated by stress. For example, stress-related alterations in nutrition or sleep habits appear to attenuate immune functioning (Hall et al., 1998; O'Leary, 1990). Furthermore, certain health practices, such as smoking, leading a sedentary lifestyle, and consuming caffeine, appear to intensify laboratory-induced stress responses (e.g., Blumenthal et al., 1990; MacDougall, Musante, Castillo, & Acevedo, 1988; M. D. Davis & Matthews, 1990). Thus, it is possible that the effects of stress on health behaviors produce pathophysiological responses similar to those described in the stress moderation models.

The health behavior model suggests that the common practice of controlling traditional risk factors (e.g., smoking, exercise, etc.) in epidemiological research might lead to an underestimate of the effects of personality on illness, as some of the impact of personality traits on health may occur through unhealthy lifestyles. Contrada et al. (1990) described several other methodological concerns with evaluations of this model. In particular, they emphasized the problems associated with utilizing self-report indices to assess health practices. Methodological artifacts such as social desirability may be particularly problematic in these studies, given the widespread publicity about the detrimental effects of health practices like smoking. In addition, Contrada and colleagues noted that the health behaviors commonly assessed in this research often exhibit only modest intercorrelations (e.g., Leventhal, Prochaska, & Hirshman, 1985; Norris, 1997), and that health behaviors appear to be inconsistent over time (Mechanic, 1979). Failure to recognize the limitations of most measures of health behavior could lead to an underestimate of their role as a mediator of the association between personality traits and subsequent illness.

Constitutional Predisposition Model

Regardless of whether or not the connection is direct, via psychophysiological responses, or indirect, via intervening

effects on health behavior, the stress moderation and health behavior models share the common assumption that the statistical association between personality and health reflects a causal relation. Several researchers have suggested that it may not be causal, but instead may reflect the existence of a third variable (Krantz & Durel, 1983; Suls & Sanders, 1989; R. B. Williams, 1994). As depicted in Fig. 9.5, this model proposes that an underlying constitutional vulnerability causes a predisposition for autonomic lability, which subsequently influences both personality processes (e.g., emotional responses, etc.) and health problems. Thus, this model considers statistical associations between personality and subsequent health to be artifacts resulting from the existence of a biologic third variable.

Given the growing body of evidence suggesting that certain personality factors and physiological stress responses may be at least partially determined by genetic factors (Bouchard et al., 1990; Smith et al., 1987; Turner & Hewitt, 1992), this model may be particularly important. This approach has been applied to the relation of Type A behavior and coronary heart disease (Krantz & Durel, 1983), and more recently, to the association of hostility and disease (R. B. Williams, 1994). Future research is necessary to clarify possible genetic influences on other personality–disease relations.

Illness Behavior Model

In contrast to the previous models, the illness behavior approach suggests that personality does not actually affect illness, but that it influences behaviors related to the subjective perception of physical health. This model is derived from evidence indicating that objective health versus illness does not fully explain illness behaviors such as health care utilization, symptom reporting, work absenteeism, and self-medication (e.g., G. A. Kaplan & Camacho, 1983; Kaplan & Kotler, 1985; Maddox & Douglas, 1973). On the contrary, psychological variables strongly affect the likelihood that individuals will attend to physiological sensations and perceive that they are indicative of illness (Cioffi, 1991; F. Cohen, 1979; Pennebaker, 1982; Watson & Pennebaker, 1989).

Figure 9.6 depicts the potential effects of psychological variables on various manifestations of illness behavior. Symptom reports, which are reliably but weakly predictive of objective health outcomes (Idler, Kasl, & Lemke, 1990), provide the clearest example of the less than perfect relation between illness behaviors and disease. Self-reports of physical

FIG. 9.5 The constitutional vulnerability model.

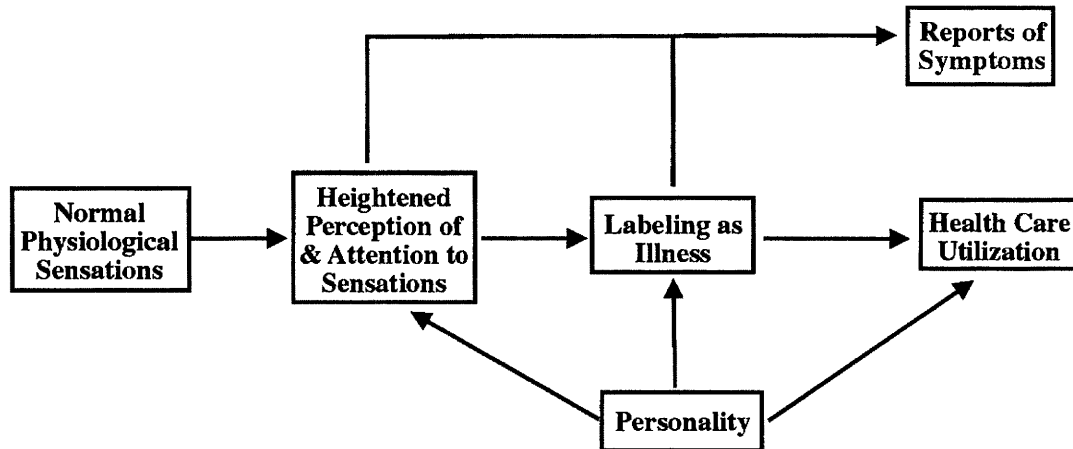

FIG. 9.6 The illness behavior model.

symptoms are influenced by various psychological factors, including health beliefs and differences in focus of attention (Pennebaker, 1982). For example, individuals higher in neuroticism are more likely to be concerned with somatic sensations, and subsequently, to report symptoms (Costa & McCrae, 1985a, 1987; Watson & Pennebaker, 1989). Furthermore, behavioral health indices such as health care visits may be influenced by somatic perceptions and other psychological processes. This phenomenon may be particularly relevant to studies comparing samples selected through medical clinics to control groups solicited from the community. These samples may be biased by psychological characteristics that relate to self-selection into health care settings. Any observed association between a targeted personality trait and illness may be confounded by the relation of the trait to health care utilization behaviors.

The preceding discussion illustrates the distinction between actual illness and illness behavior, and suggests the necessity of carefully evaluating the methodology utilized in studying personality and disease. As discussed previously in the section on validity threats, before the mechanism(s) by which personality contributes to disease can be clarified, the research must demonstrate that illness—and not simply illness behavior—is influenced by personality.

TRAITS LINKED TO HEALTH

The following sections review literature regarding several specific personality traits studied as risk factors. The list is not exhaustive; some traits discussed in this literature are not included. The criteria for including traits are that research published in refereed outlets shows considerable evidence of a prospective association of the trait with objective indicators of serious illness, or that despite the lack of such evidence, the trait is widely studied in the field. For each trait, a description of its usual measurement, the findings linking it to illness outcomes, and theory and research regarding the processes underlying this association are presented.

Type A Behavior

As noted earlier, the Type A behavior pattern (TABP) occupies a central place not only in the modern literature on personality and health, but also in the evolution of the larger fields of behavioral medicine and health psychology. The recent history of research on the topic illustrates most of the central conceptual and methodological issues in this area of research.

Assessment. Following M. Friedman and Rosenman's (1959) description of an "action-emotion complex" consisting of achievement striving, competitiveness, excessive job involvement, time urgency, and easily provoked hostility, two assessment procedures quickly achieved widespread use. The Structured Interview (SI; Rosenman, 1978) is a semistandardized interview intended to elicit a behavioral sample of the behaviors comprising the TABP, or their relative absence (i.e., the Type B pattern). With sufficient training in administration and scoring, reliable ratings can be achieved. A variety of studies indicate that valid ratings can be made with the procedure, with the caveat that the style of administration can affect the quality of ratings (Scherwitz, 1988). The second principal measure is the Jenkins Activity Survey (JAS; Jenkins, Rosenman, & Zyzanski, 1974). This self-report measure primarily assesses achievement striving, competitiveness, job involvement, and hard-driving behavior. Unlike the SI, it does not adequately sample individual differences in hostility. However, many years of research with various versions of the JAS have indicated that it is a reliable and valid measure of the other aspects of the TABP (Rhodewalt & T. W. Smith, 1991).

Because of its availability in a large, prospective study of coronary risk, the Framingham Type A scale (Haynes et al., 1980) is also recognized as a potentially important measure. However, it is poorly correlated with the SI and is more closely associated with both neuroticism and symptom reporting than either the SI or JAS (T. W. Smith, O'Keeffe, &

Allred, 1989; Suls & Marco, 1990). Thus, some of the association between the FTAS and illness endpoints involving symptom reports (e.g., angina vs. myocardial infarction or cardiac death) might involve the association between neuroticism and symptom reports already described.

Notably, the convergence among the three principal measures is more modest than would be expected if they are to be interpreted as reflecting a single construct. Thus, a basic measurement concern—poor convergent validity—limits much of the literature on the TABP (Rhodewalt & T. W. Smith, 1991).

Association With Disease. After nearly 20 years of cross-sectional and prospective research, a panel of experts convened by the American Heart Association concluded that the TABP was a robust risk factor for CHD (Cooper, Detre, & Weiss, 1981), with Type As having about a twofold greater risk than Type Bs. Several notable failures to replicate this relation appeared soon after the expert panel's conclusion. These included not only several prospective, multicenter studies (Shekelle, Gale, & Norusis, 1985; Shekelle, Hulley, et al., 1985), but a long-term follow-up from the original prospective study of the TABP (Ragland & Brand, 1988).

These and other negative findings (e.g., Barefoot, Peterson, et al., 1989) called into question the status of the TABP as a risk factor, and prompted a more fine-grained analysis of the broadly defined pattern. The negative reports also prompted skepticism in both the medical and popular health literature. However, skepticism about the TABP may have been both premature and too general. In a carefully rendered quantitative review of this literature, T. Q. Miller and his colleagues (1991) demonstrated that when it is assessed via the SI as opposed to self-report methods, the TABP is indeed a reliable risk factor for the subsequent development of CHD, even when the illness is defined in terms of objectively verified events (i.e., MI and SCD). This conclusion echoed the results of a previous quantitative review by Matthews (1988).

Additional analyses by T. Q. Miller et al. (1991) indicated that the historical trend toward more frequent negative findings was probably related to a shift over time in the types of populations studied. Whereas early studies included large proportions of initially healthy, low risk subjects, the later studies included a greater proportion of high risk subjects. The resulting overrepresentation of Type As in the samples and the restriction of range in the disease endpoint (i.e., disease-based spectrum bias) is likely to have reduced the statistical power for finding the association between the TABP and CHD.

The potential clinical importance of the TABP was suggested by the results of the Recurrent Coronary Prevention Project (RCPP; M. Friedmann et al., 1984). In this clinical trial, group therapy not only reduced Type A behavior in CHD patients, but also successfully reduced the rate of recurrent coronary events by nearly 50% (M. Friedman et al., 1984). Among patients with a mild previous infarction, treatment reduced the occurrence of cardiac death (Powell & Thoresen, 1988). Thus, in one of a very few attempts to experimentally alter a personality risk factor for serious illness, the results were quite encouraging.

Models of Association. Each model of the mechanisms linking the TABP to CHD has been based on a specific description of the psychological underpinnings of the pattern. For example, Glass (1977) suggested that these overt behaviors reflect a heightened motivation to exert control over environmental events, a low threshold for perceiving potential threats to this control, and an aggressive style in reasserting it. Powell (1992) elaborated this view, arguing that Type As see external events and other people as the primary cause of their difficulties and distress. When combined with the Type As' exaggerated belief in their ability to control others and the view that exerting control is the only coping strategy available to them, this external attribution leads Type As to engage in vigorous attempts to exert control and manage the events of their lives.

Price (1982) argued that a set of core beliefs is the foundation of the overt behavior pattern. For example, Type As are seen as believing that individuals must constantly prove themselves worthy through continual achievement, resources and opportunities for such achievements are limited, and no universal moral principles exist to ensure that people will be fair. As a result, Type As are engaged in an ongoing struggle to bolster their tentative sense of self-worth through what they perceive as a competition with potentially ruthless adversaries.

In all three models, appraisals of environmental threat and engagement in effortful coping are seen as activating psychophysiological reactivity—the final common pathway between the TABP and CHD. In the dozens of studies examining differences between Type As and Bs in their cardiovascular and neuroendocrine responses to threat and challenge, the majority have supported the basic prediction that Type As are more reactive (Harbin, 1989; Houston, 1988). These effects are most reliable when the SI is used to assess the TABP, and when the situation is at least mildly provoking or challenging. Thus, the results are generally consistent with the interactional stress moderation model discussed earlier.

A transaction model of the association between the TABP and CHD has also been outlined (T. W. Smith & N. B. Anderson, 1986; T. W. Smith & Rhodewalt, 1986). From this perspective, Type As are seen not only as overresponding to environmental stressors, but also as creating more frequent, severe, and enduring stressors. Thus, the increased psychophysiological responsiveness believed to link the pattern to disease comes from two sources: the stressors that most individuals experience, and the additional stressors Type As create for themselves through their stress engendering behavior. Examples of Type A stress engendering behaviors include selection of more demanding tasks, appraisal of tasks as requiring a greater level of achievement, eliciting or provoking competitive and disagreeable behavior from others, and evaluating their own performances harshly. Such cognitive and overt behaviors would increase the cumulative amount of exposure to threat and demand, increase psychophysiological responses, and perpetuate the Type A style itself (T. W. Smith & N. B. Anderson, 1986; T. W. Smith & Rhodewalt, 1986).

Another important view of the association between the TABP and illness takes the form of a constitutional predispo-

sition model. From this perspective, overt Type A behaviors are seen as the consequence—rather than cause—of heightened sympathetic nervous system responsivity (Krantz & Durel, 1893). Likewise, this underlying biologic responsivity is thought eventually to cause disease. Thus, the statistical association between the TABP and CHD is a noncausal one, as both are influenced by a third variable. Some evidence suggests that there may be genetic influences on the TABP (Matthews, Rosenman, Dembroski, Harris, & MacDougall, 1984), as well as basic physiologic differences between Type As and Bs (R. B. Williams, Suarez, Kuhn, Schanberg, & Zimmermann, 1991). However, even if an underlying biologic substrate does account for the phenotypic behavioral differences between As and Bs, these overt behaviors are likely to remain important in the development of disease. For example, as described in the transactional view, biologically vulnerable Type As would be prone to exposing themselves to additional stressors. Such increased exposure to threats and demands would exert a negative effect on health, especially among individuals who are constitutionally hyperreactive.

Hostility as the Toxic Component of Type A

Concern about the inconsistent findings regarding the health effects of the TABP has had one invaluable effect on subsequent work in the field; it prompted the examination of the individual elements or components within the pattern. Beginning with a seminal paper by Matthews, Glass, Rosenman, and Bortner (1977), efforts to isolate a “toxic” component of the TABP quickly converged on hostility (Dembroski, MacDougall, Costa, & Grandits, 1989; Hecker, Chesney, Black, & Frautchi, 1988). This development sparked a resurgence of interest in the centuries-old hypothesis that chronic anger and hostility contribute to the development of CHD (Dembroski et al., 1989; Siegman, 1994).

Assessment. Although this area of research is usually identified by the label of hostility, that term is more accurately reserved for one of three closely related constructs (T. W. Smith, 1994). Anger refers to an unpleasant emotion, varying in intensity from mild irritation to rage. It can be construed as either a transitory state or a more enduring disposition (i.e., trait). Closely related emotions include contempt and resentment. In contrast, hostility refers to a cognitive phenomenon. In part, it refers to a negative attitude about others, consisting of enmity, denigration, and ill will. Cynicism—the belief that others are motivated by selfish concerns—and mistrust are closely related cognitive processes. Aggression refers to verbal behavior and physical actions that are destructive or hurtful. Although these three broad constructs are clearly related and often co-occur, they are distinct.

As with the TABP, two assessment procedures have become central indices of this trait (Barefoot & Lipkus, 1994; T. W. Smith, 1992). Several different behavioral rating systems have been developed, primarily in the context of systems for scoring individual components of the TABP (Dembroski et al., 1989; Hecker et al., 1988). The most thoroughly developed and validated of these is the Interpersonal Hostility As-

essment Technique (IHAT; Barefoot & Lipkus, 1994; Haney et al., 1996). This rating system scores four specific aspects or manifestations of hostility in the Structured Interview—direct challenges or confrontations with the interviewer, hostile or uncooperative evasions of questions, indirect challenges, and expression of irritation. These ratings can be made reliably, and have been found to correlate with angiographically documented coronary artery disease (Barefoot et al., 1994; Haney et al., 1996).

The second widely used measure is the Cook and Medley Hostility (Ho) Scale (W. Cook & Medley, 1954). It consists of 50 true–false items, selected from the Minnesota Multiphasic Personality Inventory (MMPI) based on their ability to discriminate between teachers with good versus poor rapport with students (W. Cook & Medley, 1954). Subsequent research with the scale has shown that it correlates highly with other self-report measures of hostility, and correlates significantly, but less closely, with measures of other negative affects (e.g., Pope, T. W. Smith, & Rhodewalt, 1990; T. W. Smith & Frohm, 1985). The scale has also been found to be reliably associated with other affective, cognitive, and behavioral indicators of hostility (Allred & T. W. Smith, 1991; Pope et al., 1990; Rosenberg et al., 1998; T. W. Smith, Sanders, & Alexander, 1990).

One troublesome psychometric characteristic of the scale is its poorly defined internal structure (Contrada & Jussim, 1992). This has led some investigators to explore various approaches to identifying more homogeneous subsets of items (e.g., Barefoot, Dodge, et al., 1989; Costa, Zonderman, McCrae, & R. B. Williams, 1986). The scale’s poor internal structure and its correlation with characteristics other than anger and hostility are clear limitations of the scale. However, the availability of large MMPI data sets in which previously established cohorts can be reevaluated regarding health status has permitted the rapid development of an epidemiological database on the health consequences of hostility, albeit with a somewhat flawed measure of the construct.

As in the case of the TABP, the primary behavioral and self-report measures of the construct are only modestly intercorrelated (Dembroski, MacDougall, R. B. Williams, Haney, & Blumenthal, 1985). Thus, the questionable convergence of these measures raises a concern about the nature of the construct(s) under study. There are a variety of other self-report and rating scale measures of anger, hostility, and aggressive behavior used in this literature (for a review, see Barefoot & Lipkus, 1994; T. W. Smith, 1992), but only a few of these have been used in large, follow-up studies of objective health outcomes (e.g., Barefoot et al., 1987).

Association With Disease. The initial studies of the prospective association between behavioral ratings of hostility and subsequent CHD all suggested that hostility was indeed an important risk factor (Dembroski et al., 1989; Hecker et al., 1988; Matthews et al., 1977). Similarly, several early studies suggested that self-reported hostility as measured by the Ho scale also predicted CHD and premature mortality (e.g., Barefoot, Dahlstrom, & R. B. Williams, 1983; Shekelle, Gale, Ostfeld, & Paul, 1983). However, several failures to

replicate the latter effect soon appeared in the literature (Hearn, Murray, & Leupker, 1989; Leon, Finn, Murray, & Bailey, 1988), again raising concerns about the consistency and importance of the risk associated with this trait.

A recent meta-analysis of the literature on hostility and health supports the basic conclusion that this characteristic is associated with increased risk of serious illness and early death (T. Q. Miller et al., 1996). For example, behavioral measures of hostility were significantly associated with objectively defined CHD (i.e., MI, coronary death), as was the Ho scale. Interestingly, the association between the Ho scale and subsequent CHD was small, suggesting that negative findings in some studies may be due to limitations in sample size and the resulting low statistical power. The Ho scale and other measures of cognitive aspects of hostility were also reliable—and stronger—predictors of all-cause mortality. This suggests that there may be pathways between hostile attitudes and beliefs and serious illness that are outside the pathophysiology of CHD.

Mechanisms of Association. Several models of the association between hostility and health have been presented in the literature (T. W. Smith, 1992, 1994). Similar to the process described in the interactional stress moderation model and in the description of psychophysiological correlates of the TABP, R. B. Williams, Barefoot, and Shekelle (1985) suggested that hostile persons are likely to respond to everyday stressors with exaggerated cardiovascular and neuroendocrine responses. Further, heightened reactivity could facilitate the development of CVD. Some initial studies of the psychophysiological correlates of hostility suggested that this trait was not associated with greater reactivity to standard laboratory stressors, such as mental arithmetic (e.g., Sallis, Johnson, Trevorrow, Kaplan, & Hovell, 1987; M. A. Smith & Houston, 1987). However, subsequent studies have indicated that interpersonal stressors (e.g., harassment, conflict, self-disclosure) elicit reliably larger psychophysiological responses from hostile than nonhostile persons (Christensen & T. W. Smith, 1993; Hardy & T. W. Smith, 1988; S. B. Miller et al., 1998; Powch & Houston, 1996; T. W. Smith & Gallo, 1999; Suarez & R. B. Williams, 1989; Suarez, Kuhn, Schanberg, R. B. Williams, & Zimmermann, 1998). This literature generally supports the conclusion that hostility is associated with psychophysiological reactivity to interpersonal, but not nonsocial, stressors (Houston, 1994; Suls & Wan, 1993). In an interesting extension of this pattern, Lepore (1995) found that the provision of social support attenuated cardiovascular reactivity in nonhostile persons. Hostile subjects did not benefit from the availability of support. Thus, hostility may be associated with both heightened reactivity to social stressors and decreased psychophysiological benefit from social resources.

Hostility has also been linked to physiological stress responses in the natural environment. For example, Pope and T. W. Smith (1991) demonstrated that hostility is associated with larger daily excretion of cortisol, and Jamner, Shapiro, Goldstein, and Hug (1991) found that hostility is associated with larger ambulatory blood pressure responses to interpersonally stressful situations. Several ambulatory studies have

indicated that hostility is associated with higher levels of blood pressure and/or heart rate during daily activities (Benetsch, Christensen, & McKelvey, 1997; Linden, Chambers, Maurice, & Lenz, 1993; Guyll & Contrada, 1998). Recent research has also shown that hostility is associated with stress-induced changes in immune responses, perhaps suggesting a mechanism through which this trait might influence noncardiovascular illnesses (Christensen, Edwards, Wiebe, Benetsch, & McKelvey, 1996).

Anger and hostility, considered either as individual difference variables or as transient, situationally evoked responses, have also been linked to the precipitation of myocardial ischemia among patients with significant coronary artery disease. The arousal of anger, irritation and frustration can precipitate ischemic changes during laboratory tasks (Ironson et al., 1992) and during routine daily activity, as assessed with ambulatory monitoring (Gabbay et al., 1996; Gullette, Blumenthal, & Babyak, 1997). Episodes of anger have also been found to precipitate acute myocardial infarctions (Mittleman et al., 1995). Further, ischemic changes have been found to be more pronounced among hostile patients, both in response to laboratory stressors (Burg, Jain, Soufer, Kerns, & Zaret, 1993), and during the course of daily activities (Helmets et al., 1993). One study suggested that the combination of high hostility and defensiveness as measured by the Marlowe-Crown Social Desirability Scale, was associated with greater ischemia among heart patients both in response to laboratory stressors and during ambulatory monitoring (Helmets et al., 1995). Thus, regardless of whether or not hostility can initiate and hasten the development of CAD, it is likely to contribute to CHD through the precipitation of ischemic events. Behavioral ratings of hostility have also been found to predict more rapid restenosis following coronary angioplasty (Goodman, Quigley, Moran, Meilman, & Sherman, 1996).

In addition to these direct psychophysiological connections between hostility and disease, research has addressed behavioral links. For example, hostility has been found to be consistently associated with increased experience of stressful life circumstances and decreased levels of social support, a pattern described as *psychosocial vulnerability* (T. W. Smith & Frohm, 1985; T. W. Smith, Pope, Sanders, Allred, & O'Keeffe, 1988). Compared with their more agreeable counterparts, hostile persons report more major life stressors and minor events (i.e., daily hassles), and fewer and less satisfactory social supports (Barefoot et al., 1983; Houston & Kelly, 1989; Scherwitz, Perkins, Chesney, & Hughes, 1991; T. W. Smith et al., 1988; Suls, Martin, & David, 1998). Hostility is also associated with self-reports and behavioral displays of marital conflict (Houston & Kelly, 1989; T. W. Smith, Sanders, & Alexander, 1990). This pattern of high conflict and low support also appears in hostile persons' descriptions of their work environments (T. W. Smith et al., 1988) and families of origin (Houston & Vavak, 1991; McGonigle, T. W. Smith, Benjamin, & Turner, 1993; T. W. Smith et al., 1988).

Although most of this research on psychosocial vulnerability has relied on cross-sectional or even retrospective methodologies, recent studies found evidence of a prospec-

tive association between hostility and subsequent increases in marital conflict (T. Q. Miller, Marksides, Chiriboga, & Ray, 1995; Newton & Kiecolt-Glaser, 1995). So, in addition to the heightened reactivity to interpersonal stressors described in the psychophysiological reactivity model, the psychosocial vulnerability model suggests that the risk associated with hostility might also reflect a greater degree of exposure to such situations and a concurrent lack of resources or buffers in facing them.

The transactional approach has also been applied to hostility (T. W. Smith, 1995; T. W. Smith & Pope, 1990). From this perspective, the heightened interpersonal conflict and reduced support experienced by hostile persons reflects a reciprocal relation between their actions and the responses of others. Through their expectations of mistreatment and outwardly disagreeable behavior, hostile persons are likely to create conflict, undermine cooperation and support, and foster opposition from others (T. W. Smith, 1995; T. W. Smith & Pope, 1990). Once created, such an environment would likely be interpreted as confirming the accuracy of the hostile person's interpersonal "world view," as well as the apparent necessity of an antagonistic behavioral style in dealing with others. Such dynamic patterns are likely to be seen in momentary interactions lasting a few minutes, in more enduring relations, and in repeating patterns over many years (Caspi et al., 1989; Henry, 1996; Kiesler, 1991; Wachtel, 1994).

Another psychological connection between hostility and health is consistent with the health behavior model. Several studies have indicated that hostile persons engage in unhealthy practices, such as smoking and excessive alcohol use (Siegler, 1994). Epidemiological studies attempting to control statistically the possible role of such health practices have suggested that the health behavior model does not account for the health consequences of this trait (T. Q. Miller et al., 1996). However, as noted earlier, compelling tests of such mediational models are extremely difficult to conduct (Conrada et al., 1990), and some studies do support the health behavior model of the effects of hostility on health (Evenson et al., 1997).

Constitutional models of the health consequences of hostility have also been presented. For example, R. B. Williams (1994) argued that low brain levels of serotonin could underlie the affective and behavioral features of hostility (cf. Coccaro, Kavoussi, Cooper, & Hauger, 1997), the autonomic lability identified as a psychophysiological mechanism linking hostility and health, and unhealthy behaviors associated with this trait (e.g., smoking, alcohol consumption, excessive calorie and fat intake). Thus, a single central deficit—reduced brain levels of a specific neurotransmitter—is seen as responsible for this cluster of biobehavioral characteristics and the statistical association between hostility and health. J. R. Kaplan, Botchin, and Manuck (1994) similarly suggested that reduced central serotonergic drive might be the basis of the associations between aggressive behavior and related affect, physiological responsivity, and CHD in animal models.

Unlike the early literature on the global TABP, descriptions of these mechanisms linking hostility and health have not included detailed discussion of the psychological underpinnings of hostility. Certainly, hostile behavior can be seen

as a strategy for exercising interpersonal control (Averill, 1982) or attempting to secure desired outcomes during competitive struggles (Bandura, 1973). Further, hostility is associated with endorsement of the beliefs related to the TABP (P. L. Watkins, Ward, Southard, & Fisher, 1992). Thus, the psychological perspectives on coronary prone behavior proposed by Glass (1977), Powell (1992), and Price (1982) described earlier are also relevant to hostility. However, other perspectives from outside traditional health psychology and behavioral medicine are relevant as well. For example, developmental models (Crick & Dodge, 1994; Lemerise & Dodge, 1993) suggest that chronic anger and aggressiveness arise in children from the tendency to attribute harmful intent to the actions of others, to overestimate the perceived appropriateness and effectiveness of aggression as a problem-solving strategy, and a lack of alternative prosocial strategies. Related work in developmental psychology suggests that reduced empathy contributes to aggressive behavior (P. A. Miller & Eisenberg, 1988).

Many of these developmental models of anger, hostility, and aggressive behavior suggest that social learning experiences in the family context during childhood are contributing factors (e.g., Lyons-Ruth, 1996). Central themes in these models are that hostility arises from a pattern of low positive involvement with parents, hostile and coercive parental behavior, and observations of dysfunctional marital interactions (Davies & Cummings, 1994; Patterson, 1985). Consistent with this view, hostile persons describe their early family environment as including low levels of affection and high levels of hostility and coercion (Houston & Vavak, 1991; McGonigle et al., 1993; T. W. Smith et al., 1988, 1996; Woodall & Matthews, 1989). Further, Matthews, Woodall, Kenyon, and Jacob (1996) reported that behaviorally rated family conflict predicted increases in hostility among adolescent males. Thus, the negative expectations, mistrust, and antagonistic social strategies of hostile adults seem likely to have been forged in a similar family context. Interestingly, young adults' perceptions of their parents as uncaring have been found to predict poor health in midlife (Russek & Schwartz, 1997).

This view of the effects of early experience on adult hostility reflects the psychological processes of identification and internalization (Henry, 1994). Identification (i.e., modeling) refers to the process through which individuals enact behavior they previously observed in significant others, such as observations of maladaptive interactions between parents (Davies & Cummings, 1994). Internalization refers to the development of abstract representations of others and relationships (i.e., schemas and scripts), which in turn form the basis for more generalized interpersonal expectancies (Westen, 1991). In this process, individuals come to view others and themselves in a manner consistent with recurring family patterns during childhood. That is, hostile persons would have acquired generalized expectations that others are neglectful, coercive, and blaming, similar to the treatment received from parents.

A third social learning process—introjection—provides additional insight into the likely psychological underpinnings of hostility. Introjection refers to the process through which

individuals learn to respond to themselves in a manner similar to the treatment received from parents or other significant caregivers during development (Benjamin, 1994; Henry, 1996). Thus, hostile neglect and coercion from parents should result in low self-esteem and pointed self-criticism. Interestingly, despite the obvious external focus of anger and hostility, research suggests that these traits indeed have a self-directed component as well. Several investigators have found that individual differences in anger and hostility are correlated with vulnerable self-esteem, harsh self-evaluation, and the tendency to experience shame (Kernis, Grannemann, & Barclay, 1989; T. W. Smith, McGonigle, & Benjamin, 1998; Tangney, Wagner, Hill-Barlow, Marschall, & Gramzow, 1996). This pattern may lead hostile persons to be emotionally and behaviorally overresponsive to perceived mistreatment and criticism from others. Thus, the psychological underpinnings of hostility may include several central elements within current cognitive-social views of personality, such as negative working models of self, others, and relationships, goals of defending against others' attempts to take advantage of or dominate the individual, and a reliance on antagonistic social problem-solving strategies.

Are There Other Coronary Prone Characteristics?

Research on the health consequences of hostility was largely motivated by the hypothesis that it was the "toxic" element within the TABP. However, some evidence suggests that at least one other characteristic might be worth pursuing in future research. In an important reanalysis of the original prospective study linking the TABP to subsequent CHD (i.e., the Western Collaborative Group Study), Houston, Chesney, Black, Cates, and Hecker (1992) identified several distinct groups of subjects through cluster analyses of individual behavioral characteristics (e.g., hostility, speech rate and volume, etc.). Not surprisingly, they found one cluster of subjects, defined by high levels of hostility, to be at significantly greater risk of subsequent CHD. Importantly, they identified a second group at increased risk: This one is identified by loud, rapid speech and the tendency to "talk over" the interviewer. The investigators suggested that this pattern reflected socially dominant or controlling behavior during the interview, raising the possibility that both hostility and social dominance are coronary prone behaviors. In additional analyses of this data, social dominance was significantly associated with all-cause mortality (Houston, Babyak, Chesney, Black, & Ragland, 1997), and a similar prospective association between self-reported dominance (i.e., low submissiveness) and incidence of myocardial infarction has been demonstrated in a large sample of men and women (Whiteman, Deary, Lee, & Fowkes, 1997).

Some previous research has suggested that the TABP is associated with interpersonal dominance (Yarnold & Grimm, 1986). Interestingly, individual differences in social dominance are a well-established risk factor for CAD in a nonhuman primate model of psychosocial risk (J. R. Kaplan et al., 1994; J. R. Kaplan & Manuck, 1998). Further, consistent with the psychophysiological reactivity perspective, the act of influencing or controlling others elicits heightened cardiovas-

cular reactivity (T. W. Smith, Allred, Morrison, & Carlson, 1989; T. W. Smith, Baldwin, & Christensen, 1990; T. W. Smith et al., 1996). Thus, before accepting the conclusion that hostility is the lone risk factor within the TABP, researchers should consider the second primary axis of the interpersonal circumplex (see Fig. 9.1).

Neuroticism and Negative Affectivity

Negative emotions such as fear and sadness figured prominently in the early psychoanalytic formulations regarding the effects of personality processes on health (Alexander, 1950; Dunbar, 1943), as they did in early and continuing research on the psychophysiology of stress and emotion (Ax, 1953). Current interest in this general trait involves two distinct issues—the role of dispositional emotional distress or instability in the development of actual disease and the contribution of this trait to artifactual associations between personality and illness.

Although conceptualizations and definitions of this construct vary to some extent, it can be generally seen as "individual differences in the tendency to experience distress, and in the cognitive and behavioral styles that follow from this tendency" (McCrae & John, 1992, p. 195). High levels of neuroticism, emotional instability, or negative affectivity (Watson & Clark, 1984) are associated with chronic negative affect (including anxiety, tension, sadness, guilt, frustration, and irritability), as well as related characteristics (such as low self-esteem, impulsiveness, and self-consciousness). Individuals with low levels of this trait are characterized as calm, relaxed, and stable.

It is important to distinguish between elevations on this dimension that are within the range of normal variation and clinically significant conditions involving one or more negative affects (i.e., mood or anxiety disorders). Individuals with such disorders certainly are characterized by high levels of neuroticism or negative affectivity (Clark, Watson, & Mineka, 1994), and high levels of this trait pose an increased risk of developing a related clinical disorder (e.g., Hirschfeld et al., 1989; Zonderman, Herbst, Schmidt, Costa, & McCrae, 1993). Given this overlap, associations between the related clinical conditions and subsequent illness might actually reflect the health consequences of neuroticism. Therefore, the following section reviews research with both types of predictors: normal trait variation and presence of a diagnosable emotional disorder. However, because of the many potential differences between normal personality variation and pathological extremes, the parallels between these two types of research must be interpreted with caution (S. Cohen & Rodriguez, 1995; Coyne, 1994; T. W. Smith & Rhodewalt, 1991; Watson, Clark, & Harkness, 1994).

Assessment. Neuroticism and its components or facets are assessed by a great variety of self-report and observer rating scales (Gotlib & Cane, 1989; McCrae & John, 1992; Watson et al., 1994). These scales assess either the broad dimension, or one or more of its components. Similarly, the symptoms comprising diagnosable anxiety and mood disor-

ders can be assessed by a variety of inventories and structured interviews (Clark, 1989). A review of the available measures is beyond the scope of this chapter. However, it is important to note two measurement issues. First, as discussed earlier, the overlapping yet distinct quality of neuroticism and diagnosable emotional disorders poses a difficult interpretive challenge. Findings obtained with measures of either type might reflect—wholly or in part—the effects of the other. Second, scales purporting to measure a single component of this broader dimension (e.g., anxiety, depression, low self-esteem) are likely to correlate closely with the higher order dimension and other components. Thus, scale names often imply more specificity and discriminant validity than is actually present. Yet, the individual components within this broad trait are conceptually and empirically distinguishable, and it is quite possible that they are differentially related to illness (Carver, 1989).

Neuroticism and Somatization. A large body of literature demonstrates that neuroticism is reliably associated with self-reports of illness (Costa & McCrae, 1985a, 1987; Watson & Pennebaker, 1989). As previously noted, the correlation between self-reports of physical symptoms and actual illness is significant but small. This raises the question as to whether the association between neuroticism and self-reported illness involves the component of variance in self-reports that overlaps with actual health or the component that is independent (i.e., illness behavior in the absence of illness).

Most of the literature on the association between neuroticism and self-reported illness does not include the independent measures of objective health that would answer this question. However, some evidence suggests neuroticism or negative affectivity accounts for discrepancies between objective indicators of disease and symptom reports. The correlation between neuroticism and the extent of CAD among patients undergoing diagnostic coronary angiography provides one such example. Despite the invasiveness of the procedure and the fact that it is usually reserved for cases in which there are at least some clear indications of the presence of CAD, a significant minority of coronary angiography patients is found to have normal arteries (T. W. Smith & Leon, 1992). These patients have much better prognoses than patients with documented disease, essentially equivalent to normal individuals. Yet, they continue to complain of anginalike chest pain (Bass & Wade, 1984; Lantinga et al., 1988; Ockene, Shay, Alpert, Weiner, & Dalen, 1980; Wielgosz & Earp, 1986).

Importantly, angiography patients without clinically significant CAD have been found to report higher levels of neuroticism or negative affectivity than do patients with CAD (Bass & Wade, 1984; Elias, Robbins, Blow, Rice, & Edgcomb, 1982; Lantinga, Spafkin, McCroskery, 1988; Wielgosz & Earp, 1986). This has prompted the interpretation that physically healthy but high N/NA individuals complain about noncardiac chest pain with sufficient intensity to undergo angiography in the absence of the usual medical indications for the procedure (Costa & McCrae, 1987a). Consistent with this interpretation, the tendency to complain about phys-

ical symptoms, as measured by the MMPI Hypochondriasis scale, is positively associated with longevity among angiography patients (Shekelle, Vernon, & Ostfeld, 1991). That is, the physically healthy somatizing patients live longer than do the emotionally stable patients with significant coronary occlusions.

When such findings are combined with the results of prospective studies in which measures of N/NA do not predict premature death or the development of objectively verified illness (e.g., Almada, Zonderman, & Shekelle, 1991; Costa & McCrae, 1987a; G. A. Kaplan & Reynolds, 1988), it is quite possible that N/NA is a robust predictor of somatic complaints but not actual illness (Costa & McCrae, 1987a; Watson & Pennebaker, 1989). Some investigators have suggested that the association between N/NA and somatic complaints is so robust that somatic distress should be considered a component rather than correlate of the broader dimension (Watson & Pennebaker, 1989). Given the pervasive association of N/NA with a variety of measures of personality traits, virtually any correlation between a personality characteristic and an illness outcome influenced by illness behavior might be open to this alternative interpretation; rather than reflecting a link between psychological traits and actual illness, such correlations could reflect an association between neuroticism and illness behavior.

Neuroticism and Actual Illness. Several recent studies have challenged the broad conclusion that N/NA is related to illness behavior but not actual illness. In prospective designs with statistical controls for potential confounding factors, neuroticism and/or its components have been found to predict objectively verified physical morbidity or premature death. Similarly, diagnosable anxiety and mood disorders have been found to predict such objective health outcomes.

For example, individual differences in self-reported fear, anxiety, and depression have been found to predict increases in resting blood pressure levels and the incidence of essential hypertension (Jonas, Franks, & Ingram, 1997; Markovitz, Matthews, & Kannel, 1993; Markovitz, Matthews, Wing, Kuller, & Meilahn, 1991; Spiro, Aldwin, Ward, & Mroczek, 1995). Among individuals with essential hypertension, symptoms of depression are associated with increased risk of stroke and CVD-related death (Simonsick, Wallace, Blazer, & Gerkman, 1995). Similarly, self-reports of anxiety, tension, depression, and stress have been found to predict the development of CHD in initially healthy samples (Anda et al., 1993; Barefoot & Schroll, 1996; Eaker, Pinsky, & Castelli, 1992; Ford et al., 1998; Haines, Imeson, & Meade, 1987; Kawachi, Colditz, et al., 1994; Kawachi, Sparrow, Vokonas, & Weiss, 1994; Kubzansky et al., 1997; Rosengren, Tibblin, & Wilhelmsen, 1991). Emotional distress and maladjustment have also been prospectively linked to premature mortality (Herrmann et al., 1998; Martin et al., 1995; Somervell et al., 1989). Among patients with CHD, symptoms of anxiety and depression, as well as depressive disorders, have been found to predict length of survival and recurrent morbid events (Ahern et al., 1990; Barefoot et al., 1996; Carney, Rich, & Freedland, 1988; Denollet, Sys, &

Brutsaert, 1995; Follick et al., 1988; Frasure-Smith, Lesperance, & Taljic, 1993, 1995a, 1995b; Moser & Dracup, 1996). Finally, depressive and other symptoms of emotional distress have been found to predict more rapid immunological deterioration in HIV+ patients (Burack, Barrett, & Stall, 1993; Vedhara et al., 1997), although similar studies have failed to replicate this effect (Lyketsos, Hoover, & Guccione, 1993; Perry, Fishman, & Jacobsberg, 1992). Thus, contrary to earlier views, N/NA, its components, and related clinical conditions might indeed confer risk for the onset of serious illness and a poor prognosis.

It is important to note that the literature cited is selective; well-controlled studies employing large samples exist in which N/NA or its components do not predict the development or course of serious illness (e.g., G. A. Kaplan & Reynolds, 1988; Shekelle et al., 1991; Zonderman, Costa, & McCrae, 1989). Nonetheless, the effects of this trait on health clearly go beyond the well-documented association with illness behavior. Previous reviews of the evidence regarding the health effects of N/NA concluded that chronic emotional distress constituted a disease prone personality style (H. S. Friedman & Booth-Kewley, 1987), but were appropriately criticized for basing this conclusion, at least in part, on studies actually demonstrating an association between emotional distress and somatic complaints (Stone & Costa, 1990). The research reviewed here suggests that emotionally distressed persons may indeed be disease prone, but the two types of associations must be carefully distinguished.

Several approaches to resolving this ambiguity have appeared in recent years, each of which suggests that large, multifaceted personality constructs pose difficult challenges for research (Briggs, 1992; Carver, 1989). For example, Barefoot, Beckham, Peterson, Haney, and R. B. Williams (1992) found that among angiography patients, only the somaticizing component of N/NA was inversely related to CAD severity. Despite their significant correlations with somaticizing, measures of anxiety or global neuroticism were not independently correlated with objectively verified CAD. Thus, perhaps it is a specific facet of N/NA that contributes to the artifactual association with illness behavior.

The difference between transient versus stable aspects of negative emotions might also be an important distinction in this regard. S. Cohen and his colleagues (1995) found that both state and trait NA were associated with increased symptom reports following exposure to a respiratory virus. However, only the correlation of state NA with symptom reports could be explained as reflecting the development of more severe infections. The association between trait NA and symptoms was independent of objective measures of disease severity. In a related study (S. Cohen, Tyrell, & A. Smith, 1991), state but not trait NA was associated with increased risk of developing a verified respiratory infection following viral exposure. These findings raise the possibility that the actual arousal of negative emotions could influence health, but that some other feature(s) of the stable personality trait of neuroticism or the negative affectivity characteristic might be responsible for somatic complaints in the absence of disease. This interpretation again underscores the importance of ex-

amining the independent contributions of the facets or components of this broad trait (Carver, 1989).

Mechanisms of Association. The mechanisms possibly underlying the effects of N/NA on illness behavior have been detailed elsewhere (Cioffi, 1991; Watson & Pennebaker, 1989). Briefly, these include increased perception of somatic sensations, appraisals of benign sensations as possibly reflecting illness, and a corresponding lower threshold for seeking medical care.

Explanations for the possible association between N/NA and actual illness have primarily focused on the interactional stress moderation model (Cohen & Rodriguez, 1995). For example, a variety of studies indicate that stress and negative emotions can contribute to the suppression of immune responses (S. Cohen & Williamson, 1991; Herbert & S. Cohen, 1993; Kiecolt-Glaser & Glaser, 1995), thereby increasing vulnerability to infectious disease and cancer. In the case of fear, anxiety, and depression, cardiovascular psychophysiological mechanisms have been proposed. For example, both anxiety and depression have been found to be associated with reduced cardiovascular parasympathetic responsiveness and increased sympathetic reactivity (Carney, Freedland, Rich, & Jaffe, 1995; Hoehn-Saric & McCleod, 1988; Watkins, Grossman, Krishnan, & Sherwood, 1998). These mechanisms could contribute to the initiation and progression of CAD (Manuck, Marsland, Kaplan, & J. K. Williams, 1995), as well as the precipitation of acute cardiac events among individuals with advanced disease (Kamarck & Jennings, 1991). Thus, individuals high in N/NA would be expected to respond to potential stressors with more pronounced increases in negative emotions, with corresponding effects on pathophysiology.

Although rarely discussed in the literature on the health consequences of anxiety, depression, and other aspects of N/NA, the transactional stress moderation approach may also be relevant. For example, it is well established that depression is not only a consequence of stressful life experiences, but a cause of such events as well (Coyne, Burchill, & Stiles, 1991; Daley et al., 1997; Davila, Bradbury, Cohan, & Tochluk, 1997; Fincham, Beach, Harold, & Osborne, 1997; Hammen, 1991; Johnson & Jacob, 1997; Potthoff, Holahan, & Joiner, 1995). Through negative expectations regarding others and ineffective social skills, depressed persons are likely to engender resentment, conflict, and rejection in their social relations (Coyne et al., 1991). This environment would not only tend to maintain or exacerbate depression, but also would contribute to the psychophysiological stress responses believed to foster disease. Bolger and his colleagues (Bolger & Schilling, 1991; Bolger & Zuckerman, 1995) reported that neuroticism is related not only to greater emotional reactivity to negative events, but to greater exposure to such events as well, especially interpersonal conflicts. Thus, the stress engendering aspects of the various facets of N/NA are worthy of additional consideration.

Health behavior mechanisms connecting N/NA and illness have also been suggested (Cohen & Rodriguez, 1995). For example, this trait and its components have been found to be

associated with reduced exercise, poor diet, smoking, alcohol consumption, poor adherence to medical regimens, and poor self-care (Booth-Kewley & Vickers, 1994; Carney et al., 1995; Wiebe, Alderfer, Palmer, Lindsay, & Jarrett, 1994). However, at least some studies have found that health behaviors do not account for the statistical association between N/NA and illness (Martin et al., 1995). Although this result might question the accuracy of the health behavior model in this instance, limitations in the assessment of health behaviors might result in an underestimate of its impact as a mediating variable.

Research on the potential health effects of N/NA and its components has primarily been directed toward the description of these associations. As a result, less attention has been paid to the psychological underpinnings of this trait, as compared to the literatures on the TABP and hostility. However, should the epidemiological research support the importance of these characteristics, then the large literatures in personality and clinical psychology on the nature of N/NA and related disorders will prove valuable in explicating the nature of their effects on health and identifying potential targets for change in intervention efforts (Clark et al., 1994; Coyne et al., 1991; Kendall & Ingram, 1989; Rehm, 1989; Watson et al., 1994).

Dispositional Optimism/Pessimism

The notion that optimistic expectations contribute to good health has long been a part of cultural beliefs regarding psychological effects on illness. In the past decade, this hypothesis has also played an important role in the current resurgence of interest in personality traits as risk factors. From distinct theoretical perspectives, two independent teams of investigators have examined the health consequences of optimism versus pessimism (Peterson & Seligman, 1987; Scheier & Carver, 1992). Although the implications of the resulting literature have been the source of some controversy, this trait has emerged as a major focus in current research.

Assessment. The Life Orientation Test (LOT; Scheier & Carver, 1985) is a widely used measure of optimism versus pessimism. The LOT is intended to assess generalized "expectations that good things will happen" (Scheier & Carver, 1985, p. 223). The LOT is hypothesized to assess individual differences at a critical junction in the process of self-regulation during encounters with potentially stressful events—the point at which expectations determine the pursuit of active, problem-focused coping efforts as opposed to withdrawal and passive coping (Scheier & Carver, 1985, 1992).

Although this self-report scale has adequate internal consistency (Scheier & Carver, 1985; Scheier, Carver, & Bridges, 1994), there is some debate as to whether it assesses a single dimension or separate (although highly correlated) optimism and pessimism factors (Marshall, Wortman, Kusulas, Hervig, & Vickers, 1992; Scheier et al., 1994). The scale correlates significantly with measures of similar constructs (e.g., hopelessness), but in some instances these correlations are not significantly larger than its correlations

with other, conceptually distinct traits (T. W. Smith, Pope, Rhodewalt, & Poulton, 1989).

This issue is especially relevant in regard to the trait of neuroticism. For example, in an early study of this problem, T. W. Smith et al. (1989) found that the LOT was as closely correlated with measures of trait anxiety as it was with a second measure of generalized expectancies for positive outcomes (Fibell & Hale, 1978). This limited discriminant validity relative to neuroticism creates the interpretive ambiguities noted earlier. For example, previously reported correlations between optimism as measured by the LOT and physical symptom reports have been consistently shown to be largely (if not completely) attributable to this shared variance with neuroticism (Mroczek, Spiro, Aldwin, Ozer, & Bosse, 1993; Robbins, Spence, & Clark, 1991; Scheier et al., 1994; Smith et al., 1989). Although subsequent research has demonstrated that many correlations between the LOT and other outcomes (e.g., coping behavior, health practices) cannot be attributed to an overlap with neuroticism (Mroczek et al., 1993; Robbins et al., 1991; Scheier et al., 1994; T. W. Smith, Pope, Rhodewalt, & Poulton, 1989; S. E. Taylor et al., 1992), one important finding that served as an initial demonstration of the scale's utility in studying health (i.e., Scheier & Carver, 1985) does appear consequential to this methodological limitation.

A second approach to the assessment of pessimism is based on the attributional reformulation of the learned helplessness model of depression (Peterson & Seligman, 1987). In that model, the tendency to attribute negative events to internal, stable, and global causes (e.g., low ability) is seen as a contributing cause for depression. In contrast, the tendency to attribute such events to external, unstable, and specific causes is hypothesized to confer some resistance to the development of emotional distress. This attributional style can be assessed through either a structured, self-report inventory or a content coding scheme (Peterson & Seligman, 1987). Both techniques have been found to be reliable, although evidence of their convergent and discriminant validity is limited. Other measures of optimism, pessimism, and closely related constructs (e.g., fatalism, hopelessness) have been employed in studies of health, but they have been used less frequently.

Association With Objective Health Outcomes. As noted previously, correlations between optimism–pessimism and self-reports of illness or even physician visits might reflect the effects of shared variance with N/NA. There have been some studies using more objective indices, however. For example, Scheier et al. (1989) found that optimism was associated with a reduced likelihood of intraoperative myocardial infarction in a small sample of patients undergoing coronary artery bypass surgery. In a recent, larger replication (Scheier et al., 1999), optimism was associated with reduced likelihood of rehospitalization after bypass surgery. Peterson and his colleagues (1988) found that ratings of pessimistic attributional style predicted subsequent physician ratings of physical health in a sample of 99 initially healthy men who were followed for more than 35 years. Importantly, these effects remained significant even when initial ratings of physical and mental health were controlled. Jensen (1987) reported

that hopelessness, as measured by the Millon Behavioral Health Inventory (Millon, Green, & Meaher, 1979) was associated with metastasis and earlier death in a sample of 50 women diagnosed with breast cancer. In a study of patients undergoing radiation treatment for cancer, pessimism as measured by the LOT was associated with increased risk of death over an 8-month follow-up. Interestingly, optimism scores were not related to survival (Schulz, Bookwala, Knapp, Scheier, & Williamson, 1996). Similarly, Reed, Kemeny, S. Taylor, Wang, and Visscher (1994) found that in a sample of 74 men diagnosed with AIDS, self-reports of "realistic acceptance" of their prognosis (i.e., pessimism or resignation) predicted significantly shorter survival times during a 4-year follow-up.

One limitation of the studies described here is their reliance on small samples. Other prospective studies have examined the effects of optimism–pessimism in larger samples. Everson and her colleagues (1996) reported that a two-item self-report hopelessness scale predicted increased risk of early mortality, as well as the incidence of myocardial infarction and cancer in a study of more than 2,000 men. Importantly, these effects were significant even in analyses controlling for medical risk factors and self-reported depression. Recently, their measure of hopelessness predicted the progression of atherosclerosis; men with high hopelessness scores showed larger increases in carotid artery disease over a 4-year period, compared with less hopeless subjects (Everson, G. A. Kaplan, Goldberg, R. Salonen, & J. T. Salonen, 1997). Anda and colleagues (1993) found that a single item hopelessness scale significantly predicted fatal and nonfatal CHD in a sample of 2,800 initially healthy men and women. The single item scale was a better predictor of CHD events than items measuring other depressive symptoms. In analyses of an archival sample of 1,100 men and women, Peterson, Seligman, Yurko, Martin, and Friedman (1998) found that ratings of one element of pessimistic attributional style—global attributions for negative events—predicted mortality over a 50-year follow-up. The association was particularly strong for accidental and violent deaths.

These studies suggest that individual differences in optimism versus pessimism might be related to health. However, other studies have failed to find such effects (e.g., Cassileth, Lusk, & D. S. Miller, 1985), and the number of studies with positive results is small when compared with the literature on the TABP, hostility, and N/NA. Further, one recent study found that parental ratings of optimism and cheerfulness were inversely related to longevity in a sample of more than 1,000 children followed for 60 years (H. S. Friedman et al., 1993). Given the small number of independent effects, the inconsistent results, small sample sizes in some cases, and unknown psychometric properties of the scales used in the larger studies, conclusions about the apparent health consequences of this trait should be tentative.

Mechanisms of Association. The mechanisms posited as linking optimism and health have included elements of both the stress moderation and health behavior models (Peterson & Seligman, 1987; Scheier & Carver, 1992). For exam-

ple, Scheier and Carver (1985, 1992) argued that this generalized expectancy leads individuals to cope with potential stressors in distinct ways. For example, optimists are expected to persist in difficult situations and to rely on adaptive, active, and problem-solving coping strategies, as opposed to the passive and maladaptive strategies employed by pessimists. Research has supported this view, and the results apparently are not simply due to the confounding effects of other personality traits (e.g., Carver et al., 1993; Stanton & Snider, 1993; S. E. Taylor et al., 1992). These coping correlates of optimism accounted—at least in part—for an association between LOT scores and immune functioning (Segerstrom, S. E. Taylor, Kemeny, & Fahey, 1998). Pessimism has also been found to be associated with higher ambulatory blood pressure levels (Raikkonen et al., 1999). However, other psychophysiological mechanisms have not been studied in the context of optimism research.

Pessimistic individuals also appear to engage in unhealthy behaviors, such as noncompliance with medical treatment and less active self-care in response to illness (Lin & Peterson, 1990; Strack, Carver, & Blaney, 1987). The interpersonal impact of individual differences in optimism–pessimism are largely unknown. However, related research on depression (Coyne et al., 1991) would suggest that this central element of the transactional model might be useful in future studies of the potential impact of this trait on health.

Repressive Coping Style

Psychodynamic formulations of defense mechanisms, such as repression, figured prominently in the early psychosomatic theories (Alexander, 1950; Dunbar, 1943). The current period of interest in the health consequences of personality traits includes attention to a closely related construct: repressive coping. Interest in repressive coping dates to work by Weinberger, Schwartz, and Davison (1979). These investigators examined repressive coping as a potential explanation for the low correspondence between self-reports and physiological measures of anxiety and stress. The construct is generally defined as a tendency to avoid attention to and awareness of threatening events and related negative affects (Weinberger, 1990). This individual difference has been described not only as an explanation for desynchrony among channels of emotional response, but also as a risk factor for physical illness.

Assessment. The prevailing assessment procedure in this area involves the classification of subjects on the basis of two self-report instruments, the Taylor Manifest Anxiety Scale (TMAS; J. A. Taylor, 1953) and the Marlowe–Crowne Social Desirability Scale (M–CSDS; Crowne & Marlowe, 1964). Repressive copers are those individuals with low trait anxiety scores but high M–CSDS scores. These individuals are generally contrasted with groups described as low anxious (i.e., low TMAS, low M–CSDS) and high anxious (i.e., high TMAS, low M–CSDS). Some, but not all, studies include the fourth possible combination (i.e., high TMAS, high M–CSDS), described as defensive high anxious. Several studies attest to the validity of this classification system. For

example, Weinberger et al. (1979) found that repressive coping was associated with reduced self-reports of state anxiety but heightened physiological reactivity in response to a laboratory stressor. This group also displayed behavioral indications of the expected avoidant cognitive style. Subsequent studies have indicated that repressive coping is associated with the predicted pattern of high autonomic responsiveness but low self-reports of distress (Asendorpf & Scherer, 1983), and restricted recall of emotionally threatening events (P. J. Davis, 1987; R. D. Hansen & C. H. Hansen, 1988).

One recently recognized ambiguity in the assessment of this construct is the multidimensional nature of the M-CSDS. This measure includes one component that is clearly consistent with the conceptual definition of repressive coping—self-deception. However, the scale also includes a second component that apparently reflects the tendency to present oneself in a positive light to others (i.e., impression management; Paulhus, 1984). This raises the question of the target or intent of the repressive coping; are these efforts directed inwardly as a way to manage unpleasant emotional experiences, or are they directed toward the social presentation of emotional adjustment? Some recent evidence suggests that the intrapsychic versus interpersonal nature of this coping style is an important question (Barger, Kircher, & Croyle, 1997; Newton & Contrada, 1992).

The current psychosomatic literature includes a closely related construct—alexithymia (Sifneos, 1973). This personality type involves the inability to recognize or verbalize emotional experience, or to use it constructively. Such individuals are also described as restricted in other aspects of inner experience (e.g., body awareness, day dreaming, etc.). Related conceptualizations suggest that alexithymia might be involved in abnormal illness behavior (i.e., somatization) and psychological influences on actual disease. Thus, in contrast to the efforts to minimize emotional experience described in conceptualizations of repressive coping, alexithymia is seen as a basic deficit in emotional experience and related processes. Despite the availability of reliable and valid assessment devices, alexithymia has not been studied in the type of large, prospective studies that would permit evaluation of its effect on subsequent health (Linden, Wen, & Paulhus, 1995).

Association With Illness. Repressive coping has primarily been studied as a potential risk factor for cancer. Using a follow-up case-control design, Dattore and his colleagues (1980) found that veterans subsequently diagnosed with cancer ($n = 75$) differed from controls ($n = 125$) on the basis of high scores on an MMPI measure of repression and low depression scores. Subjects had completed the psychological assessment at least two years prior to the diagnosis of cancer.

Repressive coping has also been linked to more rapid disease progression among cancer patients. Jensen (1987) found that the repressive style, as assessed by the TMAS/M-CSDS typology, was associated with subsequent metastasis and earlier death in a sample of 52 women previously diagnosed with breast cancer. This effect was significant even when controlling possible confounding medical variables (e.g., disease staging) and the previously described effects of hopelessness.

An apparent replication of the effects of repressive coping on cancer incidence was reported in two European samples (Grossarth-Maticek, Siegrist, & Vetter, 1982). However, an unvalidated measure of emotional suppression was employed, and other features of the methods preclude firm conclusions (Scheier & Bridges, 1995). Additional evidence suggests that, consistent with the older psychosomatic view (Alexander, 1950), suppression of anger and aggressive impulses accelerates the development of essential hypertension (Perini, Muller, & Buhler, 1991) and carotid artery atherosclerosis (Matthews et al., 1998). However, other evidence suggests that high levels of either anger suppression or anger expression are associated with increased risk of developing hypertension (Everson et al., 1998). Helmers and her colleagues (1995) found that the combination of high hostility scores on the Cook and Medley (1954) Ho scale and high scores on the M-CSDS were associated with greater levels of ischemia in CAD patients, both in response to laboratory stressors and during ambulatory monitoring. These findings could reflect general consequences of hostility or anger, rather than repressive coping or suppression per se.

A related finding involves gay men who conceal their homosexual identity. Although not involving assessment of repressive coping per se, “closeted” HIV seronegative gay men have been found to be at increased risk of developing cancer and serious infectious illness over a 5-year follow-up period (Cole, Kemeny, S. E. Taylor, & Visscher, 1996). Among HIV seropositive gay men, concealment is associated with more rapid progression of the illness (Cole, Kemeny, S. E. Taylor, Visscher, & Fahey, 1996). Thus, concealment of information that could have potentially serious social ramifications posed a threat to health.

Mechanisms of Association. The prevailing view of mechanisms linking repressive coping and subsequent illness is an interactional stress moderational model. Several studies have supported the basic prediction that repressive coping is associated with greater autonomic reactivity during stressful situations (Asendorpf & Scherer, 1983; Barger et al., 1997; Brown et al., 1996; Newton & Contrada, 1992).

An interesting finding consistent with this view involves the physiological effects of disclosure of previously undisclosed traumatic events. Failure to disclose such events has been linked to subsequent illness (e.g., Pennebaker & Beall, 1986). Further, disclosure through writing or discussion appears to have salubrious effects on several physiological mechanisms (e.g., Pennebaker, Kiecolt-Glaser, & Glaser, 1988; Smyth, 1998).

Jamner, Schwartz, and Leigh (1988) suggested that the autonomic responsivity associated with repressive coping is mediated by enhanced central endogenous opioid activity, consistent with a constitutional predisposition approach. Finally, health behavior mechanisms have also been discussed. For example, avoidant coping strategies might interfere with the appropriate recognition of and response to early symptoms of illness. The resulting delays in receipt of needed care could have deleterious consequences (Jensen, 1987; Weinberger, 1990). To date, the interpersonal impact of the

repressive style has not been discussed at length in this literature. If subsequent epidemiological research suggests that this trait indeed contributes to illness, then transactional stress moderation mechanisms (such as the interpersonal correlates of repressive coping) might be explored.

Other Traits

Several other personality characteristics have figured prominently in the recent research in this area. However, the corresponding literatures lack the degree of epidemiological evidence regarding their health relevance that exists for the traits reviewed thus far. Clearly, Kobasa's (1979) description of psychological hardiness was a major impetus in the resurgence of interest in personality and health (Suls & Rittenhouse, 1987). In her framework, individuals characterized by an internal locus of control, a tendency to view major life changes as challenges rather than threats, and a sense of commitment in the major activities of their lives were hypothesized to be more resilient when exposed to stressful life circumstances.

Several studies found predicted associations among self-report measures of hardiness, life stress, and symptom reports (see Funk, 1992, for a review). Further, several studies demonstrated the predicted stress moderation effect on psychophysiological responses to laboratory stressors (Allred & T. W. Smith, 1989; Contrada, 1989; Wiebe, 1991). Other studies found evidence of effects of hardiness on self-reported health that were mediated by health behavior (Wiebe & McCallum, 1986). However, the degree of overlap between measures of hardiness and N/A raised questions about the extent to which an association between emotional distress and somatic complaints accounted for much of the relevant findings (Funk, 1992; Funk & Houston, 1987), and some evidence has been consistent with this view (e.g., P. G. Williams, Weibe, & T. W. Smith, 1992). Thus, although the conceptual impact of this model on the developing field has been considerable, compelling evidence that hardiness influences actual physical health is scarce.

Power motivation is another trait studied as a potential risk factor (Jemmott, 1987). Defined as the desire to have an impact on others by controlling, influencing, or even helping them (McClelland, 1979), power motivation has been found to be concurrently associated with high blood pressure, and to predict the later development of essential hypertension in a 20-year prospective study of 79 initially healthy young men (McClelland, 1979). This trait, assessed by responses to the Thematic Apperception Test (Jemmott, 1987), has also been linked to reports of illness and immunosuppression (Jemmott et al., 1983; Jemmott et al., 1990; McClelland, Alexander, & Marks, 1982; McClelland, Floor, Davidson, & Saron, 1980; McClelland & Jemmott, 1980).

As previously discussed, individual differences in social dominance have been found to be related to the development of CHD in both human (Houston et al., 1992) and animal research (Manuck et al., 1995). Further, attempts to influence or control others elicit the type of cardiovascular reactivity hypothesized to contribute to CHD (T. W. Smith, Allred, Morri-

son, & Carlson, 1989; T. W. Smith et al., 1996; T. W. Smith, Nealey, Kircher, & Limon, 1997). Thus, the limited yet provocative research on power motivation might be seen as another indication of the potential usefulness of further study of the vertical axis of the interpersonal circumplex as an influence on health.

Finally, although most of the research related to the health consequences of traits in the current prevailing personality taxonomies has focused on hostility, emotional distress, and to a lesser extent dominance, recent evidence suggests that conscientiousness and openness to experience may be important as well. In an additional analysis of childhood predictors of longevity, H. S. Friedman and his colleagues (1993) reported that conscientiousness, as rated by parents and teachers, was associated with greater longevity. Subsequent research indicated that although conscientiousness is associated with positive health behaviors (Booth-Kewley & Vickers, 1994), the beneficial effects of this trait on longevity could not be accounted for by the mediating effects of health behaviors, including reduced alcohol consumption, nonsmoking status, prudent diet, or avoidance of accidents and violence (H. S. Friedman, Tucker, Reise, 1995). Curiosity—a component of openness to experience—has been found to predict increased survival over a 5-year follow-up of older adults, a result that could not be attributed to other known medical or behavioral risk factors (Swan & Carmelli, 1996).

CONCLUSIONS AND FUTURE DIRECTIONS

As noted at the outset of this chapter, the literature on personality and health contains some areas of cumulative progress but some unresolved problems as well. These concluding sections summarize the emerging findings, outline the limitations, and suggest some directions for maximizing the yield of future studies.

Do Personality Traits Predict Subsequent Illness?

Despite the conclusions of previous critiques of research in this area (e.g., Angel, 1985), there is clear evidence that personality traits do indeed predict objective health outcomes. Quantitative and qualitative reviews have summarized evidence that hostility and the TABP are associated with "hard" signs of CHD (i.e., MI and SCD) and reduced longevity (Adler & Matthews, 1994; T. Q. Miller et al., 1991, 1996). These effects are statistically small, but given the scope and impact of the health outcomes examined, they are important contributions to an understanding of threats to public health. The results of several large, prospective studies examining objective health outcomes suggest that this relation does not reflect the effects of personality traits on simple illness behavior, and it does not reflect the effects of illness on personality.

The literature on the health effects of neuroticism or negative affectivity is more complex than it was even a few years ago. Although chronic negative emotions, such as anxiety and depression, are clearly associated with illness behavior in the absence of disease (Stone & Costa, 1990; Watson & Pennebaker, 1989), recent evidence suggests a more substan-

tial role as well. Considered either as an individual difference within the range of normal variation, or as a diagnosable emotional disorder, chronic negative affect has been found to predict objective health outcomes in initially healthy samples and among patients with established disease. This area of research might benefit from an updated quantitative review to examine the level of inconsistency and possible causes among the independent studies available. The tentative review suggests that this trait is a potentially important influence on health. However, there are negative results from large, well-controlled prospective studies. Further, the circumstances under which N/NA contributes to illness behavior as opposed to actual illness remain to be identified (C. Smith, Wallston, & Dwyer, 1995).

The evidence that pessimism influences health is intriguing and suggestive, but is somewhat more limited than is the case for hostility or negative affectivity. The clarification of methodological issues in previous research on this trait should pave the way for more definitive studies, and the accumulating evidence suggests that such studies would be worthwhile. Finally, despite its central place in the personality and health literature, the evidence that repressive coping contributes to illness is limited to a small number of studies, and some of them used personality measures of undocumented validity. Repressive coping with anger (i.e., anger suppression or "anger-in") may be unhealthy, but this might reflect more general consequences of trait anger. Thus, conclusions about the effect of repressive coping on health will require several additional, methodologically sophisticated studies.

Although there is clear evidence of a reliable association between some personality traits and illness, several interpretive ambiguities remain even in the areas with consistent results. The degree of information about the personality trait(s) actually assessed by the measures used in this research varies considerably. As a result, it is sometimes unclear as to the specific psychological characteristic(s) involved in the effect. Second, given the correlational nature of even the prospective designs, the possibility that biologic, psychologic, or socioeconomic third variables account for the observed covariation between personality traits and disease must be acknowledged. Finally, even if it is assumed that the observed associations indicate causal effects of personality traits on health, the mechanisms through which these influences might operate are only tentatively identified (Krantz & Hedges, 1987). Importantly, animal models permit more direct evaluation of some of the central causal hypotheses and specified mechanisms, and the results of that work support the models already outlined (e.g., J. R. Kaplan et al., 1994; Manuck et al., 1995).

Is There a Disease Prone Personality?

An influential review of the personality and health literature suggested that individuals characterized by chronic negative affect displayed a disease prone personality (H. S. Friedman & Booth-Kewley, 1987). Although the basis of that conclusion was criticized appropriately on methodological grounds (Matthews, 1988; Stone & Costa, 1990), the subsequent research has indicated that the conclusion might have merit.

However, the evidence regarding the unhealthy effects of chronic hostility, anger, and disagreeable behavior is more compelling. Therefore, the earlier description of a disease prone personality underemphasized an important personality trait—agreeableness versus antagonism in the five-factor model, or friendliness versus hostility in the interpersonal variation of this taxonomy. Neuroticism and antagonism are independent traits, but obviously co-occur such that people with high levels of both characteristics are described not only as distressed, cold, and hostile, but selfish and intolerant as well (Saucier, 1992). Thus, this combination of chronic distress and disagreeable social behavior might constitute a disease prone personality.

Are There Other Personality Risk Factors?

The five-factor model and the interpersonal variation of this taxonomy suggest that the current research on personality risk factors might be expanded. The provocative findings in which conscientiousness and openness to experience predicted longevity (H. S. Friedman et al., 1993; Swan & Carmelli, 1996) were discussed earlier. These dimensions should be pursued in additional research. Similarly, some evidence from epidemiological studies suggests that social dominance might be a second facet of the TABP that confers risk of CHD and measure mortality (Houston et al., 1992, 1997), and this finding has an important parallel in nonhuman primate research on psychosocial influences on CAD (Manuck et al., 1995). Thus, the vertical axis of the interpersonal circumplex should also be examined in future research.

There are two dimensions that do not fall clearly within the current personality taxonomies that might be useful in future studies. The first dimension, discussed from several perspectives, involves social and emotional competence. The concept of *social intelligence* (Cantor & Kihlstrom, 1987) lies at the intersection of personality and traditional definitions of intelligence. This construct refers to the "declarative and procedural knowledge that individuals bring to bear in interpreting events and making plans in everyday life situations" (Cantor & Kihlstrom, 1987, p. 3). Consistent with the cognitive-social approach to personality described earlier (Cantor, 1990; Mischel & Shoda, 1995), this model emphasizes the processes underlying individuals' construal of situations, the goals they pursue, and the flexibility and effectiveness of the strategies they employ in those pursuits. Further, individuals vary in their social "expertise" in specific contexts, such as vocational achievement or personal relationships. *Emotional intelligence* (Mayer & Salovey, 1995) is a somewhat more circumscribed construct, referring to competence in identifying and regulating emotions in oneself and others. Another closely related concept with greater similarity to traditional descriptions and assessments of personality traits is *ego-resilience* (Block & Kremen, 1996; Klohnen, 1996).

Although broad individual differences in social and emotional competence are difficult to describe and measure, it is apparent that persons differ in the extent to which they have the skills or competence to succeed in important life tasks. A further implication is that many life tasks will be particularly

difficult for individuals with less expertise, with the likely result of increased stress. Consistent with the general view of the psychophysiology of stress as a link between personality traits and illness, limitations in social intelligence or competence could confer vulnerability to disease. Thus, the study of personality traits as risk factors might be expanded to include increased attention to skill and adaptive competencies, especially in emotional and social domains (Ewart, 1991; 1994).

The second health relevant dimension that falls outside traditional taxonomies is *social support*. Social support is clearly associated with reduced risk of physical illness and increased longevity (Adler & Matthews, 1994; Berkman, 1995; S. Cohen, Doyle, Skoner, Rabin, & Gwaltney, 1997; Hazuda, 1994; Orth-Gomer, 1994). Further, low support is associated with the pathophysiological mechanisms believed to link psychosocial processes to illness (Uchino et al., 1996). Although the traditional view of this construct is that it represents characteristics of the social environment (S. Cohen & Wills, 1985), recent evidence suggests that social support might be more accurately conceptualized as a characteristic of the person. For example, social support is closely related to other stable personality characteristics including shyness, neuroticism, anxiety, and depression (e.g., B. Sarason, Shearin, Pierce, & I. G. Sarason, 1987; I. G. Sarason, Levine, Basham, & B. Sarason, 1983). Further, perceptions of social support appear to be stable over time (Newcomb, 1990; I. G. Sarason, B. Sarason, & Shearin, 1986), and to remain consistent across settings (Lakey & Lewis, 1994). Finally, perceptions of social support seem to be heritable to some extent, with genetic factors accounting for as much as half or more of variance in support perceptions (Kendler, 1997; Plomin, Reiss, Heatherington, & Howe, 1994). Thus, rather than conceptualizing and studying social support as something distinct from the personality traits identified as risk factors, a person-focused alternative view of social support might be useful (Pierce, Lakey, I. G. Sarason, B. Sarason, & Joseph, 1997). Better still, models and methodological strategies that integrate social and personality characteristics hold particular promise.

It may be that low social support and limitations in social intelligence or competence can be described, at least in part, through combinations of traits in the current personality taxonomies (e.g., low agreeableness, high neuroticism). However, related research and theory suggest that these processes probably cannot be simply reduced to those variables. As a result, a somewhat broader view of the array of health relevant individual differences could add to the understanding of the ways in which personality can influence health.

Can We Make Better Use of Personality Psychology?

The discussion thus far illustrates how consideration of current personality taxonomies such as the five-factor model can provide much needed conceptual organization to this area of research. These taxonomies also point to some traits that might have been neglected in the area. Further, the related assessment devices and the psychometric tradition in which

they are embedded can facilitate the evaluation and refinement of key measures of traits studied as predictors (Costa & McCrae, 1987a; H. S. Friedman et al., 1995; Marshall et al., 1994; T. W. Smith & P. G. Williams, 1992).

The second major emphasis in current personality psychology—the cognitive-social and interpersonal perspectives—also could make a major contribution to the study of personality traits as risk factors. As discussed earlier, these perspectives can be useful in identifying the mechanisms underlying the broad elements in trait taxonomies (e.g., Graziano, Jensen-Campbell, & Hair, 1996), as well as the psychological processes through which traits influence pathophysiology. Further, the constructs identified in these models (e.g., appraisal, coping strategies, social competencies, etc.) can be easily incorporated in the design of interventions.

However, perhaps a more far-reaching implication of the cognitive-social and interpersonal conceptualizations of personality is the blurring of the commonly held distinction between risk factors considered characteristics of the person (e.g., hostility) and those that are traditionally considered characteristics of the social environment (e.g., social support). The reciprocal relation between persons and social circumstances is a fundamental assumption of these models (Wagner et al., 1995), as is the assumption that these reciprocal patterns are evident over periods of many years (e.g., Caspi et al., 1989) and in specific, time-limited interactions (T. W. Smith, 1995). These assumptions pose a challenge to conceptualize risk without simple distinctions between personality and the social environment.

From this dynamic interactional perspective, risk is conferred not through specific personality traits, but through recurring transactions between persons and social environments (Revenson, 1990; T. W. Smith, 1995), such as the model of how hostility influences health presented in Fig. 9.7. In this elaboration of the previously discussed transactional model, hostile persons recurrently construct social circumstances that are both unhealthy (i.e., low in support and high in strain), and that maintain their own hostile interactional style. Hostility can be accurately described through the traits in personality taxonomies (i.e., low agreeableness and high neuroticism), but the “active ingredients” through which hostile persons create such an environment consist of the cognitive and behavioral processes identified in cognitive-social models of personality. Clearly, the description of the risk process linking hostility and health is incomplete without attention to the social context of hostility. In addition, the understanding of low support and high social strain as risk factors would be incomplete without attention to the ways in which individuals create and maintain those circumstances.

The interpersonal perspective in personality and clinical psychology may be of particular use in this reconceptualization of psychosocial risk. The interpersonal circumplex (see Fig. 9.1) provides a common conceptual and measurement framework for describing personality characteristics, social stimuli, and interactional behaviors (Benjamin, 1994; Kiesler, 1991; Wiggins, 1991). For example, both the personality trait of hostility and the environmen-

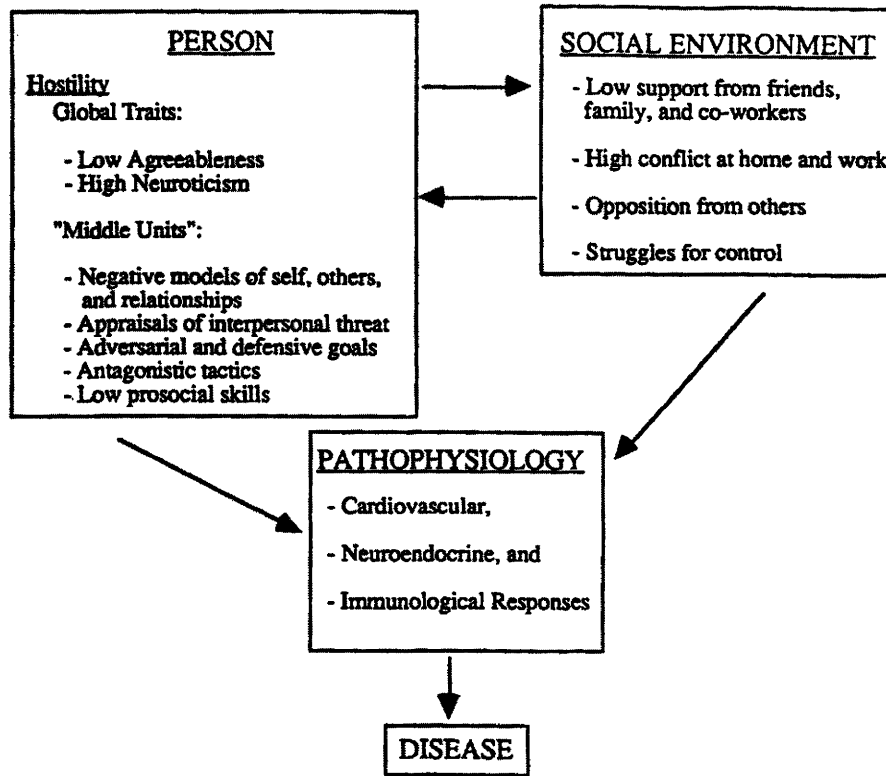

FIG. 9.7 The transactional model of the effects of hostility and the social environment on illness.

tal variable of social support can be located along the horizontal axis of the circumplex. Further, this perspective provides detailed models and assessments of the transactional processes linking persons and social contexts (Benjamin, 1994; Kiesler, 1996; Wagner et al., 1995).

Although the conceptual and perhaps treatment implications of the transactional view are clear, the implications of this model for epidemiological research are less obvious. Evidence from large prospective studies of personality and subsequent health is a critical component of research in this area. Simply put, nobody would pursue research on the traits without evidence that they predict objective health outcomes. Yet, typical analytic strategies in psychosocial epidemiology do not accommodate this reciprocal view of personality and social risk factors. Current practice in epidemiological studies of psychosocial risk factors reflects the traditional strategy of evaluating independent predictive utility, such as determining if smoking and blood pressure have statistically independent effects on CHD. Given that the causal processes through which psychosocial factors influence health may involve substantive relations among psychosocial characteristics, the practice of forcing statistical independence on naturally confounded variables seems likely to provide an inaccurate assessment of risk. That is, the traditional approach of examining statistically independent risk factors removes personality traits from essential elements of the surrounding so-

cial context (Revenson, 1990). Yet, in the transactional view, it is precisely this dynamic interaction of traits with contextual factors that influence the pathophysiology of disease.

An alternative analytic strategy would classify individuals in terms of naturally occurring patterns of personality and environmental characteristics, thereby providing a closer correspondence between specific statistical hypotheses and the transactional conceptual hypotheses about risk (Gallo & T. W. Smith, 1999). That is, multiple features of the hypothesized recurring cycles of personality—social environment transaction could be assessed and used to identify high and low risk groups (Wagner et al., 1995). For example, the global personality traits or even middle units of personality listed in Fig. 9.7 could be assessed along with the social environmental characteristics to which they are reciprocally related. Cluster analytic techniques could then be used to describe specific patterns of personality and social risk (Gallo & T. W. Smith, 1999), and included as predictors of subsequent health in prospective studies. Such naturally occurring groupings might reflect common adaptive and maladaptive interactional styles.

Are There Applications of Personality–Health Research?

The potential health benefits of modifying personality traits identified as risk factors are illustrated by the results of the

RCPD described earlier (M. Friedman et al., 1984; Powell & Thoresen, 1988). Enduring personality characteristics can be modified, and at least in that instance seemed to have had important consequences for subsequent health. Anger and hostility are amenable to treatment (Deffenbacher, 1994), as are other negative affects such as anxiety and depression (Chambless & Gillis, 1993; Hollon, Shelton, & Davis, 1993). Further, preliminary studies suggest such treatments may have positive effects on health (Gidron, Davidson, & Bata, 1999). Given the status of the related literatures, larger controlled trials examining the health benefits of interventions addressing these characteristics are justified, especially in high risk populations such as postinfarction patients.

The personality and health literature also has implications for primary prevention efforts. If traits such as (low) agreeableness and high neuroticism contribute to illness, then development of social and emotional adjustment and competencies should reduce risk. Attempts to prevent emotional disorders, antisocial behavior, and substance abuse in children and adolescents often focus on traits and processes that are similar to those discussed in models of the personality characteristics that confer risk of physical illness (Blechman, 1996; Blechman, Prinz, & Dumas, 1995; Caplan et al., 1992; Greenberg, Kusche, Cook, & Quamma, 1995; Tolan, Guerra, & Kendall, 1995). These prevention programs attempt to foster emotional self-regulation and social interaction competencies through educational methods. These interventions generally produce improved emotional adjustment, peer relations, and conflict resolution skills.

Although targeted toward mental health, this primary prevention technology may have beneficial effects on physical health as well. Thus, a final conclusion from the current research on personality traits as risk factors for physical illness is that the existing literature on primary prevention in the domain of social and emotional health may have valuable implications for the prevention of physical illness. Efforts to maximize the emotional and social adjustment of children and adolescents may contribute to their later physical health as adults.

Personality's Role in the Protection and Enhancement of Health: Where the Research Has Been, Where It Is Stuck, How It Might Move

Suzanne C. Ouellette
The City University of New York

Joanne DiPlacido
Central Connecticut State College

There is something engaging about research on positive health outcomes. Research that seeks to explain why some people thrive, or at least remain physically and psychologically intact in the face of arduous circumstances, catches on quickly. Whether it is called a sense of coherence, hardiness, optimism, resilience, or any one of a growing number of such terms, it is the personality characteristic that promises health in spite of hardship and inspires both scientists and ordinary folk. This chapter provides an overview of such research and offers encouraging yet cautionary advice about its future. Along with the gains of research on health protective personality characteristics, both specific conceptual and methodological shortcomings within and across work are pointed out on a number of different constructs. Also noted are more general ideological concerns about why and how such personality and health research is conducted. To address both the specific and the general critique, the chapter turns to contemporary trends within personality and the broader field of psychology for ideas about future personality and health research.

The first section contains summaries of work with some of the key constructs used in health research on positive out-

comes. As a unit of personality, each of these constructs represents a distinguishing characteristic in people's system of behavior and experience that is thought to be relatively long standing and expressed through their thoughts, feelings, and/or actions across the various areas of their life. The chapter reviews sense of coherence, hardiness, a set of control-related notions (including dispositional optimism, explanatory style, health locus of control, and self-efficacy), and affiliative trust. These personality constructs have been found to do one or more of the following: correlate directly with health; correlate with health-related behaviors; and minimize persons' likelihood of getting sick or sicker in the wake of stressors, including stressors that consist of acute and chronic illness conditions. For each of the personality constructs, there are basic definitions and a sketch of the theoretical background, measurement strategies, key findings, and a statement on unresolved issues.

The second section pulls back from the particular constructs to raise questions that apply to the whole research enterprise on personality and positive health outcomes. These have to do with gaps in the literature and ideological assumptions that emerge from but are typically not addressed in pub-

lished research reports. The ideological concerns are raised in the form of two dilemmas, a pair of "yes ... but" remarks. One involves assumptions about the relation between individuals and social structures, and the other involves assumptions about what constitutes the "good" that is implicit in the research. The call to tread carefully that is made here might indeed be issued for many health psychology topics, but it is particularly apt for research into positive outcomes. Findings from personality and health studies make their way into the popular media (e.g., Locke & Colligan, 1987) with great speed and the whole enterprise elicits remarkably high enthusiasm from new researchers. The quick popularity is encouraging, but researchers should remain wary.¹

The final section of the chapter seeks ways of addressing both the specific and general questions that have been raised. Recent discussions are consulted in the general personality psychology literature and insights about the historical and ideological dimensions of all psychological research are provided by feminist and critical psychology. To encourage investigators about the viability of research on personality and positive health outcomes that is inspired by general personality, feminist, and critical sources, examples of especially promising new empirical work relevant to health psychology are cited.

WHAT'S IN THE LITERATURE ON POSITIVE HEALTH OUTCOMES?

The seven constructs described here have all received considerable research attention and continue to appear in the literature. Some constructs that may be familiar to the reader such as Type A Behavior Pattern and trait hostility have been left out because they are covered elsewhere in this volume. More important, these constructs have more to do with why people

¹For one of us, there is more than a little ambivalence about those still almost weekly requests for a scale to measure hardiness, nearly 20 years after the first hardiness article and 10 years after the first of a series of articles sharply critical of hardiness measurement (cf. Ouellette, 1993). There is almost always a question about the relevance of the scale and even the construct for the group the investigator is seeking to study. A questionnaire designed for middle-aged, middle-class, male executives may not indeed work with a group of homeless children. Also, it is important that new researchers see the link between the latest wave of interest in thriving and resilience work with some older constructs like hardiness, but one also wishes for some new strategies for assessing these phenomena. The other of us approaches the audience of those interested in personality and health from the perspective of one in the early stages of a project on stress, stress resistance, and lesbian health. She is eager to publish findings on how personality (and other situation and structural) factors protect the health of lesbian women, but also keenly aware of the care with which these findings will need to be approached. Given the many unresolved methodological challenges in her chosen research area and even more important, a cultural and political climate in which discrimination against gays and lesbians remains prevalent, whatever results there are on links between individual lesbians' personalities and their health will need carefully be interpreted. Without capturing personality findings through the lens of the broad sociocultural context in which they sit, she risks provoking more stigmatization and neglect of social causes of poor health.

get sick than with the ways personality functions to maintain or improve their health. This chapter attempts to keep the focus on the latter. Nonetheless, as is described in what follows, personality characteristics that are presented as protectors and enhancers of health are most frequently cast in measurement efforts simply as those that correlate with lack of illness, that is, low illness scores.

A selective set of studies for each construct that is thought to be representative of the typical empirical approach to that construct is presented here. The results illustrate the now long available discussion of the three basic models in which personality gets linked to health (F. Cohen, 1979). In one, a direct connection is posited between personality and actual physiological, biological, and/or neurological states that are in turn related to health status; here, for example, investigators correlate personality scores with cardiovascular activity or immunological function. A second model portrays personality in its influence on health-related behaviors; in this scheme, personality is linked with matters such as whether people exercise, how they eat, and the extent to which they engage in high risk behaviors like smoking.

A third model portrays the stress buffering role of personality. It guides investigations that seek to determine the ways that personality influences peoples' response to the occurrence of stress (i.e., the ways it minimizes or maximizes the likelihood that a person will become ill, or more ill, following an encounter with a stressful situation). It has become standard practice to claim personality as a stress buffer when a significant statistical interaction is found between the stress and personality variables. Also, at this stage of the research, this model typically displays personality in relation with stress appraisal, coping strategies, and other mechanisms thought to be relevant to the stress process. Along with theoretical overviews and statements of issues awaiting resolution, the discussion indicates the extent to which data on each of the constructs fill out one or more of these models.

Sense of Coherence

Sense of coherence represents the individuals' ability to believe that what happens in their life is *comprehensible*, *manageable*, and *meaningful* (Antonovsky, 1993, 1987, 1979). Antonovsky (1987) referred to his construct as a generalized dispositional orientation toward the world:

The sense of coherence is a global orientation that expresses the extent to which one has a pervasive, enduring though dynamic feeling of confidence that (1) the stimuli deriving from one's internal and external environments in the course of living are structured, predictable, and explicable [comprehensibility]; (2) the resources are available to one to meet the demands posed by these stimuli [manageability]; and (3) these demands are challenges, worthy of investment and engagement [meaningfulness]. (p. 19)

With his focus on salutogenic strengths, Antonovsky switched the emphasis from stress and its negative health consequences to a discussion of positive or adaptive coping in re-

sponse to stress. Antonovsky, a sociologist, was interested in both personality dispositions that foster health and their structural sources, particularly the sociocultural and historical contexts in which these dispositions are embedded (Antonovsky, 1991). He saw institutionalized roles, cultural values, and norms as influences on all of the following: the processes through which people deal with stressors, the actual occurrence of stressors, and the resulting outcomes of the stress process (Antonovsky, 1991).

Antonovsky's theory states that a greater sense of coherence leads to a person's effective coping with a multitude of stressors and thereby positive health outcomes. The sense of coherence construct was predicted to be a stress buffer: Under stressful circumstances, those individuals with a strong sense of coherence—in contrast to those with a lower sense of coherence—would be better copers, more likely to draw on their own resources (i.e., ego strength) and those of others (i.e., social support), and as a result enjoy better health and well-being.

Antonovsky designed a scale to measure sense of coherence (the Orientation to Life Questionnaire, OLQ). The full OLQ scale includes 29 items and a shorter 13-item scale is also available. Adequate reliability and validity of this scale has been reported (Antonovsky, 1993, 1987; Frenz, Carey, & Jorgensen, 1993). The results obtained through use of the OLQ scale provide support for only parts of the stress buffer model. Only direct relations (correlations) between sense of coherence and health promoting variables, and mainly self-reported health outcomes have been empirically demonstrated. And much of this work on the salutogenic effects of sense of coherence has focused on psychological rather than physical health.

A prospective study with a repeated measures multivariate analysis of variance (MANOVA) design found main effects for hassles and sense of coherence on depression and anxiety (R. B. Flannery & G. J. Flannery, 1990). A greater number of hassles led to greater distress, and a greater sense of coherence led to lower distress among students from adult evening classes. There were, however, no significant interactions between hassles and sense of coherence to indicate sense of coherence's stress buffering role. Similarly, greater sense of coherence was related to lower psychological distress among adult Cambodians in New Zealand, but did not moderate the relation between life events and postmigration stressors and psychological distress (Cheung & Spears, 1995). In a sample of homeless women and low income housed women, higher levels of sense of coherence were related to less psychological distress among homeless women but not low income housed women (Ingram, Corning, & Schmidt, 1996).

Less published work relates sense of coherence to physical health outcomes, and most of what exists relies on self-reports of symptoms. In a study of kibbutz members, sense of coherence was negatively related to reported physical symptoms in the previous month, as well as reported limitations in daily activities due to health problems (Anson, Carmel, Levenson, Bonneh, & Maoz, 1993). A study conducted by Bowman (1996) found sense of coherence to be negatively related to self-reported physical symptoms in both Anglo-American and Native American undergraduates. Bowman noted that this

study supported a fundamental assumption made by Antonovsky that people from different cultures may attain similar levels of sense of coherence, despite socioeconomic differences. It should be noted, however, that only college students from these two cultures were included in this study.

At least two studies have examined the salutogenic effect of sense of coherence among medical patients; specifically, individuals in recovery from elective surgery for joint replacement and patients living with the chronic illness of rheumatoid arthritis. At a 6-week follow-up of surgery patients, sense of coherence was positively related to life satisfaction, well-being, and self-rated health; sense of coherence was negatively related to psychological distress and pain (Chamberlain, Petrie, & Azariah, 1992). In a cross-sectional study of 828 patients with rheumatoid arthritis, lower sense of coherence scores were significantly related to more difficulty in performing daily living activities, more overall pain, and poorer global health status (Callahan & Pincus, 1995).

The mechanisms through which sense of coherence is related to health outcomes have also been examined. As predicted by theory, sense of coherence has been positively related to health enhancing behaviors such as use of social skills among Israeli adolescents (Margalit & Eysenck, 1990); social support availability among minority, homeless women in the United States (Nyamathi, 1991); and problem-focused coping among Swedish factory supervisors (Larsson & Setterlind, 1990). Sense of coherence was also negatively related to emotion-focused coping among Swedish factory supervisors (Larsson & Setterlind, 1990); HIV risk behaviors among U.S. minority homeless women (Nyamathi, 1991); and alcohol problems among older adults (Midanik, Soghikian, Ransom, & Polen, 1992). In addition to this review, the reader is referred to Antonovsky (1993) for a thorough review of the cross-cultural studies that examine the salutogenic effect of sense of coherence.

As can be seen from the aforementioned results, what is missing is solid empirical support for the stress moderating role of sense of coherence, and evidence for the complete mediational model linking sense of coherence and coping, social skills, health behaviors, or social support with actual physiological and biological health processes. Either these relationships for which Antonovsky provided an elaborate theoretical justification have not yet been tested, or obtained negative findings have not met the published page.

Hardiness

Hardiness, as conceptualized by Kobasa (later known as Ouellette), Maddi, and their colleagues (Kobasa, 1979, 1982; Kobasa, Maddi, & Kahn, 1982; Maddi, 1990; Ouellette, 1993), is a construct drawn from existential personality theory and is intended to represent a person's distinctive way of understanding self, world, and the interaction between self and world. Existentialism, both in its European forms and in the American version found in some of William James' work, disputes a view of the person as simply a passive victim of life's stresses and requires all investigation to begin with persons' subjective experience of life's demands. Drawing on

the existential notion of authenticity, as well as the psychological literature on adult development and on the notion of control (Kobasa, 1979), the originators of the construct said that people's hardiness is reflected in the extent to which they are able to express commitment, control, and challenge in their actions, thoughts, and feelings. Commitment refers to individuals' engagement in life and view of their activities and experiences as meaningful, purposeful, and interesting. Control has to do with individuals' recognition that they have some influence over what life brings. Challenge indicates an orientation toward change as an inevitable and even rewarding part of life that is matched by an ability to be cognitively flexible and tolerant of ambiguity. The dynamic interplay of all three in people's basic stance toward life is theorized to promote stress resistance and to enhance psychological and physical health (Kobasa et al., 1982). Hardiness is said to lessen the negative effects of stress by its influence on the perception and interpretation of stressful events and its promotion of actions that minimize the toxicity of those events.

There are several different scales designed to measure hardiness. Some are results of efforts to shorten and psychometrically strengthen the original hardiness measure (e.g., Bartone, 1989), whereas others (e.g., Pollock & Duffy, 1990), although interesting in their own right, have only weak connection to the original conceptualization of hardiness. The most frequently cited measures are the original five-scale composite test of hardiness (Kobasa et al., 1982), and the 36- and 20-item abridged versions (Allred & T. W. Smith, 1989; F. Rhodewalt & Agustsdottir, 1984; R. Rhodewalt & Zone, 1989). The reader is referred to Maddi (1990) and Ouellette (1993) for reviews of the existing hardiness scales and attempts to organize at least some of the hardiness measurement story. Key critiques of the measures are Funk and Houston (1987) and Funk (1992).

The original hardiness scales have been criticized for their lack of balance of positive and negative items, that may lead to acquiescent response biases, and their facilitation of a confounding of hardiness with neuroticism. In addition, in some studies, low internal reliability among the challenge items, and low correlations between challenge and the other two scales (control and commitment) have been reported. There have also been questions about whether a total unitary hardiness score should be used, or separate scale scores reflecting the three hardiness components. Factor analyses have not been able definitively to answer this question because some researchers have found evidence for a unitary single dimension, and others have found two- or three-factor structures (Ouellette, 1993).

These criticisms have led to a more recent, not as yet widely used, measure of hardiness called the Personal Views Survey (cf. Maddi, 1990). Findings with this newer test appear to be more promising (e.g., Florian, Mikulincer, & Taubman, 1995). These reports emphasize the need for investigators to check the structure and psychometric properties of the hardiness measure within their own samples, and to make use of newer statistical strategies, such as structural equation modeling, to examine the structure of hardiness. Nonetheless, one of the originators of the hardiness concept (Ouellette,

1993, 1999) strongly calls for the serious consideration of measures other than simple self-report as alternative or additional methods of capturing hardiness with all its complexities. Use of a breadth of measurement approaches is especially important given the need to address hardiness in contexts different from those populated by the largely male, White, and middle-class executives on which the original measurement efforts were based.

The majority of studies on hardiness have provided evidence for a general relation between hardiness and psychological or physical health—the higher the hardiness, the fewer the symptoms. Wiebe and Williams (1992) reported that the most consistent finding in the hardiness literature is the lower reported levels of both concurrent and subsequent physical symptoms among individuals high in hardiness compared to those who score low in hardiness. Fewer studies, following the initial prospective demonstration of a stress and hardiness interaction among business executives (Kobasa et al., 1982), have actually confirmed the specific stress buffering role of hardiness (for reviews see Funk, 1992; Maddi, 1990; Orr & Westman, 1990; Ouellette, 1993).

Like sense of coherence, hardiness has been examined in a variety of groups, many of which are contending with what most would agree would be high levels of stress. Nurses, for example, have applied the construct of hardiness not only to patients but also to themselves in their high stress work settings. The nursing research has found links between hardiness and burnout for nurses involved in various kinds of nursing care (Keane, Ducette, & Adler, 1985; McCranie, V. A. Lambert, & C. E. Lambert, 1987; V. L. Rich & A. R. Rich, 1987; Topf, 1989); the influence of hardiness on student nurses' positive appraisal of their first medical-surgical experience (Pagana, 1990); and the relation between hardiness and activity levels in the elderly (Magnani, 1990). Other researchers have found hardiness to be related to less burnout among elementary school teachers (Holt, Fine, & Tollefson, 1987); positive indicators of both objective and perceived health status for women living with rheumatoid arthritis (R. Rhodewalt & Zone, 1989); fewer negative health changes among disaster workers responding to a major air transport tragedy (Bartone, Ursona, Wright, & Ingraham, 1989); and more effective performance among recruits in rigorous training for the Israeli army (Westman, 1990).

Hardiness studies have also included demonstrations of possible mechanisms through which this personality construct may have its health promoting effects. Findings show that the higher individuals score on hardiness, the less likely they are to appraise events pessimistically as stressful and threatening (Allred & T. W. Smith, 1989; Wiebe, 1991). Links have also been reported between the components of hardiness and the use of particular coping strategies (Westman, 1990; Williams, Wiebe, & T. W. Smith, 1992). Importantly, Florian et al. (1995) recently demonstrated in a longitudinal study that the different components of hardiness, at least among Israeli army recruits, have different appraisal and coping consequences. The commitment dimension reduced threat appraisal and emotion-focused coping while it increased their sense that they could respond effectively to the stress. The control dimension

also reduced the appraisal of threat and increased sense of effectiveness, whereas it distinctively increased problem-solving coping and support-seeking strategies.

There is also some evidence that hardiness indirectly affects health status through its relation with health-related behaviors (e.g., Wiebe & McCallum, 1986). Less clear are the physiological and biological mediators and outcomes of hardiness. Investigators have examined a number of these, including arousal (Allred & T. W. Smith, 1989; Contrada, 1989; Wiebe, 1991) and immune function (e.g., Dillon & Totten, 1989), but results are few and not consistent.

There are clearly a number of points in the hardiness research endeavor at which an investigator could enter to make significant contributions. The lack of a consistent demonstration of a stress buffering effect needs to be approached in terms of measurement and conceptualization. With regard to the former, there are calls for both improvement in self-report scales and for other, in Robert White's terminology, longer ways of assessing hardiness (cf. Ouellette, 1999). With regard to conceptualization, there are a number of tasks needing attention. Given recent critiques and findings, what the originators of the concept called the dynamic constellation of commitment, control, and challenge needs to be better specified (Carver, 1989; Florian et al., 1995): What constitutes a constellation? Are high levels of all three components required for stress buffering, or can high levels of one compensate for low levels of another? A better specification is also needed of how people are to think about the ways hardiness operates in context in social settings (Wiebe & Williams, 1992). Kobasa (1982) reported differences between occupational groups in how hardiness relates to the health of the members of those occupations. Nonetheless, hardiness theory has yet to be elaborated sufficiently to explain these group differences. Finally, in drawing on existential approaches, the originators of hardiness had in mind an approach that would recognize the person and not just the variable (cf. Allport, 1961; Carlson, 1984; Ouellette Kobasa, 1990). The necessary idiographic, developmental, and historical work with hardiness awaits.

Dispositional Optimism

Scheier and Carver (1985, 1987, 1992) defined dispositional optimism as individuals' stable, generalized expectation that they will experience good things in life. Key in this theory is the principle that people's behaviors are strongly influenced by their beliefs about the probable outcomes of those behaviors. Outcome expectancies determine whether a person continues striving for a goal or gives up and turns away (Scheier & Carver, 1987). Optimistic outcome expectancies are theorized to lead an individual to engage in active behavior to attain a goal. Pessimistic outcome expectancies, on the other hand, are thought to lead an individual to give up and not engage in behaviors to attain the goal. With regard to optimism's role in influencing health, it has been hypothesized that optimism leads to more adaptive coping with stress. In general, optimists who believe they will most likely experience positive outcomes will engage actively in more prob-

lem-solving coping, whereas pessimists who expect bad outcomes will tend to engage in more avoidant coping.

Dispositional optimism is assessed with the Life Orientation Task (Lot; Scheier & Carver, 1985), a brief self-report questionnaire. Evidence for its sound reliability and validity can be found in Scheier and Carver's (1987) review. Dispositional optimism has been found to be related to better physical health outcomes and its positive role has been documented in many different samples. Among college students in the final weeks of the semester (a stressful time with final exams and final papers), optimists reported significantly less physical symptoms during the course of those weeks (Scheier & Carver, 1985). These same researchers have also gone beyond a reliance on self-reports of health status to find that among coronary artery bypass surgery patients, optimists when compared to pessimists were significantly less likely than pessimists to develop perioperative physiologic reactions that are considered markers for myocardial infarction (i.e., less Q-waves on EKGs and release of the enzyme AST), and were more likely to recover faster from surgery (Scheier et al., 1989).

In terms of mechanisms through which optimism influences health, a great deal of research has examined optimism's relation with coping. Among different populations, such as college students and men at risk for AIDS, optimists were found to be more active copers, whereas pessimists were more prone to engage in avoidant coping (see Scheier & Carver, 1987, 1992; T. W. Smith & Williams, 1992, for extensive reviews of this research). Fry (1995) found that, among female executives, higher optimism was associated with greater reliance on social support as a coping mechanism. Further, Aspinwall and Taylor (1992) found support for a mediational model, whereby optimism was related to coping, which in turn influenced both psychological and physical well-being among college students. Scheier et al. (1989) also found evidence for the mediational role of coping through which coping links optimism and physical health among coronary artery bypass patients. The reader can consult Schwarzer's (1994) review for more discussion of these and other studies on optimism and health outcomes.

Optimism has also been found to influence health through its relation with health habits. For example, among coronary artery bypass patients, optimists were more likely to take vitamins (Scheier et al., 1990, cited in Scheier & Carver, 1992); and among heart patients in a cardiac rehabilitation program, optimists were more successful in lowering their coronary risk through exercise and by lowering levels of saturated fat and body fat (Shepperd, Maroto, & Pbert, 1996). Among nonclinical samples, similar beneficial results with health habits emerge. Among college students, optimism was related to health enhancing behaviors (Robbins, Spence, & Clark, 1991), and among HIV seronegative men, optimists in comparison to pessimists had fewer anonymous sexual partners (Taylor et al., 1992, cited in Scheier & Carver, 1992). In another study examining safer sexual behavior patterns among heterosexual women, Morrill, Ickovics, Golubchikov, Beren, and Rodin (1996) found that women higher in optimism were four times more likely to adopt safer sexual practices at a 3-month follow-up than those lower in optimism.

Although many studies suggest that optimism is beneficial for physical well-being, inconsistent findings have been reported. There is room for additional support and clarification. In a study of patients recovering from elective joint replacement surgery (Chamberlain et al., 1992), optimism was positively correlated with measures of life satisfaction, and positive well-being, and negatively correlated with psychological distress and self-reported pain 6 months postoperatively; however, after controlling for presurgery levels of these variables, investigators found that optimism no longer significantly predicted health outcomes after surgery. In addition, like with hardiness, there have been serious questions about optimism's discriminant validity with neuroticism (T. W. Smith, Pope, Rhodewalt, & Poulton, 1989). Other critics have raised the important possibility that too much optimism (e.g., unrealistic optimism) could be related to negative health outcomes through people's unrealistic high expectations that good things will always happen (e.g., Schwarzer, 1994; Tennen & Affleck, 1987; Wallston, 1994). In this vein, Davidson and Prkachin's (1997) results highlighted how constructs of optimism (i.e., dispositional optimism and unrealistic optimism) are jointly important in predicting health promoting behaviors.

Explanatory Style

Explanatory style describes the causal attributions that individuals habitually make for the positive and negative events that happen in their life. An optimistic explanatory style is characterized by external, unstable, and specific attributions for negative events, and internal, stable, global attributions for positive events. A pessimistic explanatory style has the opposite pattern of causal attributions. Explanatory style, with its combination of cognitive and learning principles, is a construct with conceptual roots in American psychology similar to those of dispositional optimism. More specifically, explanatory style is a reformulation of learned helplessness theory, a theory proposed to account for individual differences in responses to uncontrollable events (Abramson, Seligman, & Teasdale, 1978). Researchers of explanatory style focus on the causal explanations for bad (or good) events rather than the causes of uncontrollable events. "A person who explains such events [bad] with stable, global, and internal causes shows more severe helplessness deficits than a person who explains them with unstable, specific, and external causes" (C. Peterson, Seligman, & Valliant, 1988, p. 24). Most of the research focuses on pessimistic explanatory style, and specifically one's attributions for negative events. Investigators have suggested, however, the importance of also focusing on attributions of positive events on well-being (e.g., Abramson, Dykman, & Needles, 1991; Anderson & Deuser, 1991; Gotlib, 1991). See C. Peterson and Seligman (1984, 1987) for an extensive review of the research on explanatory style and well-being, as well as its conceptual and methodological background.

Explanatory style, unlike most other personality constructs reviewed in this chapter that rely solely on self-report scales, can be measured through two very different modes of measurement. The first and most popular method is the

Attributional Style Questionnaire (ASQ), a self-report questionnaire that lists hypothetical events. Respondents are asked to imagine that each of the events has happened to them, and then to write down one major cause of the event. They then rate each cause along each of the three dimensions (internal-external, stable-unstable, global-specific) on a 7-point scale. Ratings are added within type of event and across dimensions to get a composite score. Reliability and construct validity has been found to be satisfactory (C. Peterson, 1991a, 1991b, 1991c; C. Peterson & Seligman, 1987).

The second technique is a content analysis procedure referred to as the CAVE (content analysis of verbatim explanation) technique (C. Peterson, Schulman, Castellon, & Seligman, 1992). This technique was developed in order to capture nonhypothetical events and more spontaneous causes of events. The CAVE technique examines verbal material (e.g., interviews, biographies, letters, diaries) for events and causal explanations of the events. Investigators search for and identify these causal explanations in the text and then score them along the dimensions of internality, stability, and globality. The CAVE technique's reliability and validity has been established (C. Peterson, Maier, & Seligman, 1993). More recently, C. Peterson and Ulrey (1994) successfully measured explanatory style with a projective technique that identified causal explanations in TAT protocols.

Research on explanatory style has mainly examined direct relations with physical and psychological health outcomes. For example, a pessimistic explanatory style has been found to be related to increased depression (C. Peterson & Seligman, 1984) and immunosuppression—ratio of helper cells to suppressor cells (Kamen-Siegel, Rodin, Seligman, & Dwyer, 1991). Several studies have been prospective in design. In a study of college students, a pessimistic explanatory style was related to greater reported illness symptoms after 1 month and doctor visits 1 year later (C. Peterson & Seligman, 1987). In another study of college students, Dykema, Bergbower, and C. Peterson (1995) found the report of hassles to mediate the relation between explanatory style and illness. A pessimistic explanatory style led to increased reports of hassles, which led students to appraise major life events as having more negative impact on their lives, which in turn led to more illness 1 month later. Illness was represented by a composite score that included the number of times students were reported ill, doctor visits, missed classes, and a self-reported health rating.

A link between explanatory style and health has been impressively found in a 35-year prospective study using the CAVE technique (C. Peterson et al., 1988). In this study, explanations for bad events were extracted from interviews with Harvard University graduates from the classes of 1942 through 1944, done when respondents were age 25. The interviews were scored using the CAVE technique. At various ages, throughout a 35-year time period, respondents' health was rated by a research internist based on an extensive physical exam. Men with a pessimistic explanatory style at age 25 were rated as less healthy later in life compared to men with an optimistic explanatory style; these findings were most robust when the men were at age 45.

C. Peterson and Seligman (1987) suggested that explanatory style is related to health through coping. Preliminary data from a cross-sectional study indicated that a pessimistic explanatory style as represented on the stability and globality dimensions was related to low self-efficacy, unhealthy health habits, and stressful life events—variables that were, in turn, related to reported illness symptoms and number of doctor visits. Keep in mind, however, that these mediating variables are not commonly reported as measures of coping, and in the case of self-efficacy and stressful life events, the variables are most often considered to be predictors of coping. Another possible mechanism linking explanatory style and health is perception of health problems. C. Peterson and De Avila (1995) found that perceived preventability of health problems mediated the relation between explanatory style and risk perception among a community sample of adults. Their findings suggested that an optimistic explanatory style entails more perceived control over health problems, and thereby leads individuals to engage in positive health behaviors and ultimately enjoy better health.

More longitudinal research on the mediational role of health behaviors, and coping, as measured with reliable and valid measures, needs to be conducted in order to better understand the path that links explanatory style to health. The investigator eager to advance the work on explanatory style and health also need note that in most of the research conducted to date only the stability and globality dimensions of explanatory style have predicted health and well-being. This raises important questions about the role of the internality dimension. C. Peterson and Seligman (1987) reported that internality is the least reliable dimension and shows the most inconsistent associations with other variables. As with hardiness, the multifaceted nature of explanatory style raises particular conceptual and measurement challenges (cf. Carver, 1989). Although many different correlates of explanatory style have been found, there continues to be serious questioning of its meaning and of how best it is to be measured (C. Peterson, 1991a, 1991b). To help researchers contend with all the questioning, an important tool for those seeking to enter this challenging domain is a 1991 issue of *Psychological Inquiry*, which includes a target article by Peterson in which an overview on the explanatory style construct is presented, and commentaries and reactions to his statement by experts in the field.

Health Locus of Control and Self-Efficacy

Health locus of control and self-efficacy are somewhat hesitantly included in a chapter on personality and health. K. A. Wallston (1992) made clear that health locus beliefs were never conceptualized to be as stable as generalized locus of control beliefs. Thus, it was not considered to be a personality construct; rather, it was conceptualized as “a disposition to act in a certain manner in health-related situations” (p. 185). Similarly, Bandura and his colleagues repeatedly emphasized the specificity of the self-efficacy notion: The person’s intended behavior needs to be specific to a particular situation in order for expectations of self-efficacy to predict whether that person engages in the behavior. A review of the research,

however, revealed threads of “personality” in empirical work with both constructs that are relevant to this chapter.

Health locus of control (HLC) refers to individuals’ beliefs about where control over their health is located, in internal sources such as a person’s own behavior or external sources such as powerful others. The introduction of HLC (B. S. Wallston, K. A. Wallston, Kaplan, & Maides, 1976) was an attempt to apply Rotter’s social learning theory to health-related behaviors. Rotter’s expectancy value theory of behavior stated that the potential for individuals to engage in certain behaviors in a given situation was a function of people’s expectancy about whether or not their engagement in a particular behavior would lead to a particular outcome in a given situation, and the value they place on that outcome. Accordingly, early work showed that HLC scores only predicted health-related behaviors when respondents in the research said they highly valued health (B. S. Wallston et al., 1976; K. A. Wallston, Maides, & B. S. Wallston, 1976). The focus on the values of health outcomes brings the investigator closer to the domain of personality (cf. Lazarus & Folkman, 1984).

With regard to measurement efforts, there has been an emphasis on the multidimensionality of HLC beliefs (K. A. Wallston, 1989; K. A. Wallston, B. S. Wallston, & DeVellis, 1978). The Multidimensionality Health Locus of Control Scale (MHLOC) measures internal beliefs about health, and external beliefs that are made up of two dimensions, chance and powerful others (K. A. Wallston, 1989; K. A. Wallston, B. S. Wallston, & DeVellis, 1978). The internal dimension measures people’s belief that health is affected by their own behavior; the powerful others dimension measures beliefs that powerful others affect health; and the chance dimension measures beliefs that luck, chance, or fate influence health.

Results generated by the HLC construct have been mixed. The majority of studies have examined the influence of health locus of control on health behaviors or habits, with the assumption that greater HLC would be related to more positive health behaviors. When reviewing the vast literature on HLC, some studies do indeed find that a more internal locus of control (belief that one’s health is controllable) is related to health promoting behaviors (e.g., exercise, eating healthy), which in turn leads to better health. However, there seems to be just as many studies that do not find an association between HLC and health behaviors. The reader is referred to K. A. Wallston (1992) for a good review of the theoretical underpinnings of the HLC construct, as well as results linking HLC to health behaviors.

K. A. Wallston (1991, 1992) discussed possible reasons for the lack of consistent findings in the literature and recalled the theoretical roots of social learning theory. Wallston is grappling with the need for a more elaborated view of what is happening in the health-related behavioral episode, and thereby, personality. Wallston noted that most of the research on HLC does not include a measure of health value. Value of the outcome was an important component of Rotter’s original social learning theory. In support of Wallston’s argument, one study found that value placed on participation of health promoting behaviors was more important in predicting health protective behaviors than locus of control; moreover, those who were

high in health value and had an internal health locus of control were the most likely to perform health protective behaviors (Weiss & Larsen, 1990). Unfortunately, this type of research comprises a minority of the studies examining HLC.

In spite of the lack of consistent results, the health locus of control construct has not been entirely abandoned. K. A. Wallston (1992) noted that HLC beliefs were never expected to predict a large amount of the variance of measures of health behaviors. He emphasized the need for "more complex and inclusive theoretical models" (p. 252) to better predict and explain health-related behaviors. In that vein, Wallston pointed out the important additional role that self-efficacy can play in explaining health-related behaviors. Importantly, it was a generalized self-efficacy—indicative of what is considered to be a personality construct—to which he referred. To capture this, Wallston's research team has developed a perceived competence scale to measure generalized self-efficacy (K. A. Wallston, 1989).

Self-efficacy, in its own right, has become a very popular and formidable social cognitive construct for many health researchers. Based on Bandura's (1977) social learning theory, self-efficacy represents the degree to which individuals believe that they have the capability to perform an intended behavior: The more people believe they can perform the behavior, the more likely they will be to engage in the particular behavior. Reviews of the self-efficacy and health literature have found in general that self-efficacy predicts a vast number of health behaviors (Holden, 1991; A. O'Leary, 1992; Schwarzer, 1994). Schwarzer (1994) reported that self-efficacy has predicted physical exercise behavior, smoking behavior, weight control, and sexual risk behaviors.

Self-efficacy has been measured with many different scales. Due to the behavior-situation specificity theorized by Bandura, many researchers have developed their own scales designed to measure self-efficacy in specific situations. More recently, however, other researchers have developed more traitlike versions of self-efficacy. These conceptualizations can be considered dispositional or generalized self-efficacy (Schwarzer, 1994). Refer to Schwarzer (1994) for a good review of these generalized self-efficacy constructs. Schwarzer discussed Snyder, Irving, and Anderson's (1991) construct of hope, C. A. Smith, Dobbins, and K. A. Wallston's (1991) perceived competence construct, and Jerusalem and Schwarzer's (1992) generalized self-efficacy construct as all measuring this dispositional or generalized self-efficacy. These authors believe, similar to Bandura, that specific behaviors are best predicted by specific behaviors. However, when trying to make predictions across a variety of different situations, general self-efficacy scales are thought to be better predictors (Schwarzer, 1994).

Motives—Affiliative Trust

The work on motive strength and health by McClelland and his collaborators offered the only contemporary approach to understanding how people's personal dispositions lead to better physical health that gave serious consideration to un-

conscious processes. In this approach, motives are measured by the content analysis of TAT stories. Much of this work on motives has focused on the negative health affects of the stressed power motive syndrome (see McClelland, 1989, for a review of this work). However, Affiliative Trust—Mistrust—an object relations construct—found in stories of positive rather than cynical relations has been related to better immune function and fewer reported illnesses (McKay, 1991).

McKay (1991) was interested in examining whether internal representations of relations (i.e., object relations) would be associated with immune function. Respondents were asked to write stories in response to TAT pictures, and their stories were scored for Affiliative Trust—Mistrust. Affiliative mistrust represents malevolent, or negative internal representations of relations which lead an individual to constantly experience loss, rejection, or disappointment. McKay theorized that "the fear that one will be abandoned or mistreated by others could have an immunosuppression effect through the same mechanisms that are involved in the connection between actual loss and decreased immune function" (p. 641). Benevolent, or trustful representations of relations, in contrast, could have an immunoenhancing effect.

Interrater reliability for the Trust—Mistrust scale showed good agreement between coders. Internal and test-retest reliability were moderate. The Mistrust subscale showed good construct validity, as did the Trust—Mistrust index, although to a lesser degree (the Trust—Mistrust index represented a composite of the Trust and Mistrust subscales). The Trust subscale, however, showed very little evidence of construct validity. See McKay (1991) for a full discussion of reliability and validity for the Trust—Mistrust scale.

Results indicated that greater Mistrust (representing malevolent object relations) was negatively related to helper-to-suppressor T-cell ratios (T4:T8), indicative of lower immune function. Greater mistrust was also related to greater reporting of all types of illnesses, including respiratory tract illnesses in the preceding year. Benevolent object relations indicated by high Trust—Mistrust scores were positively associated with better immune function (i.e., greater helper-to-suppressor T-cell ratios), and negatively related to reports of all illnesses and respiratory tract illnesses.

Unlike the other personality constructs discussed in this chapter, most of the research on motives and health has focused on physiological processes. It seems that this direct link with physiological processes would have stimulated a great deal of excitement. On the contrary, this work has been met with much skepticism. A possible bias against projective techniques as reliable and valid measures of personality within the field of health psychology has possibly prevented further testing of these provocative findings. Moreover, there have been serious methodological questions raised about McClelland and colleagues' reliance on S-IgA concentration (salivation) as a reliable and valid indicator of immune function (Valdimarsdottir & Stone, 1997). McKay's (1991) study using the more stable helper-to-suppressor T-cell ratios as a measure of immune function is an important response to the criticism.

CRITIQUE: STRENGTHS, WEAKNESSES, AND DILEMMAS

In the process of looking across and seeking to integrate the research on the reviewed personality constructs, a new investigator encounters a number of questions about the arena of personality and health that require attention. In addition, as the investigator considers where the field has been and where it can go next, there are two dilemmas to be confronted. These are depicted here in order to make the point that indeed something has been learned through a research focus on personality as a health promoting and enhancing factor and that learning has consequences beyond the simple accumulation of facts. There are policy-related and ideological implications to this work that investigators need to recognize and bring to a decision about whether to continue "business as usual" or consider some new ways of working with personality in health psychology.

To reduce the risk that this section of the chapter would become a litany of problems that does little more than discourage the eager new investigator, bore more seasoned readers, and dizzy everyone, the sources and intentions must be clarified. The checklist and dilemmas are inspired by available personality and health literature and a more general reading of contemporary psychology.

A CHECKLIST OF CONCERNS

What, Exactly, Is the Link Between Personality and Health?

Investigators need to be exact and modest about what it is that they are looking at when they speak of a link between personality and health. In the empirical knowledge now available, the amount of work illustrating the model linking personality to health behaviors and that portraying personality as a stress buffer vastly outweighs work supporting the model of a direct connection between personality and biological and physiological processes, especially if it is required that more than self-reports of health processes be measured. Much more is known about the strictly behavioral domain and psychological processes (i.e., about how personality relates to behaviors thought relevant to the maintenance of health and how it presents itself along side of stress in persons' lives), than is known about the biomedical aspects that accompany the psychological. Studies (Gruen, Silva, Ehrlich, Schweitzer, & Friedhoff, 1997) like one of women exposed to a stressful induced-failure task in which the personality attribute of self-criticism was found to be related to changes in plasma homovanillic acid (the metabolite of dopamine), as well as self-reports of stress and changes in mood, are relatively rare.

This is not pointed out to diminish the importance of the first two kinds of endeavors—they are potentially useful for health interventions (Brownell & L. R. Cohen, 1995; Cockburn et al., 1991; Rakowski, Wells, Lasater, & Carleton, 1991), risk reduction efforts (Morrill et al., 1996; Wulfert, Wan, & Backus, 1996), and counseling and clinical applica-

tions (Spalding, 1995). Rather, the intent is to encourage a recognition of all that is waiting for attention, and the need for interdisciplinary work involving social scientists and those trained in the biological and medical sciences to fill in the many undeserved gaps that still exist in the literature.

There are also limitations to the notion of personality as a stress buffer. Although they work with conceptual frameworks that strongly support the prediction of a stress-buffering role for personality, investigators have met serious difficulties in actually statistically demonstrating interactions between stress and personality variables, and thereby, the buffering function of personality. Although this has been made most specific about hardiness (Funk, 1992; Orr & Westman, 1990), the problem also troubles other constructs. The demonstration of the main effects of personality constructs on psychological and physical health indicators, at least through self-report assessments, are plentiful in the literature; but a significant interaction (stress \times personality) term, the result taken to be the hallmark of buffering, is relatively rare. In the majority of studies that present themselves as about personality and health protection or enhancement, the interaction is simply not tested for; in other studies, it is sought and sometimes, but not always, found.

How Does One Assess Health as a Positive Outcome?

Given the kinds of measures that are typically employed, it may be concluded that it is much easier to assess health conceived of as the absence of illness than health as a distinct way of being that involves more than just not being sick. From the earliest days of formal discussion of personality, stress, and health issues, it has been assumed that outcomes would come in at least three independent forms: no change in health, negative changes in health, or positive changes in health (what Dohrenwend termed "growth"; Dohrenwend, 1978). Antonovsky introduced the term *salutogenesis* to emphasize that he was after more than the absence of illness, Kobasa and her colleagues wrote about hardiness and executives who not only do not get sick but thrive under stress. Nonetheless, in the research, it is most often symptom checklists that are relied on to represent all of the outcomes. High symptom scores are taken to represent illness and low scores stand in for health. As a number of researchers have recently noted, there are both conceptual and measurement challenges needing attention with regard to how convincingly to approach a distinctive notion of health and thriving in empirical research (V. E. O'Leary & Ickovics, 1995; Park, L. H. Cohen, & Murch, 1996; Tedeschi & Calhoun, 1996).

How to Choose Among the Constructs?

The new investigator needs seriously to take both similarities and differences between the constructs available for personality and health research. For example, although most of the variables studied involve some element of perceived control over the environment (e.g., C. Peterson & Stunkard, 1989), there are serious differences between theorists in what they

say about control. Antonovsky's position stands out as the most distinctive. In each of his major statements on the theory of sense of coherence, Antonovsky (1979, 1987, 1991; Ouellette, 1998) detailed his differences with promoters of an internal locus of control. For him, work on locus of control and its emphasis on control as that which resides in the hands of autonomous, isolated individuals who perceive and enjoy a direct link between their voluntary actions and the outcomes they seek bore a strong cultural bias. In sense of coherence, he sought something other than a Western, capitalistic, and entrepreneurial perspective on human capability—something that could capture the ways in which a person experiences control as a result of trust and sense of community with others, something that could be experienced within a broad variety of cultures and socioeconomic circumstances. Another difference is represented by the notion of challenge. It is this component of hardiness that most distinguishes it from the other constructs reviewed. In fact, it has provoked a debate between Antonovsky (1979, 1987, 1991) and Ouellette (1998), whose theories overlap in many respects, about what keeps people healthy under stress. A third specific example of difference is easily illustrated through the affiliative trust construct. Here, there is an emphasis on unconscious aspects of the human experience. This stands in sharp contrast to cognitive social learning notions such as optimism and self-efficacy that emphasize what is in awareness and highly rational and deemphasize what is implicitly motivational and emotional (cf. McClelland, Koestner, & Wenberger, 1989).

Speaking more generally, it must be recognized that personality and health investigators have differed substantially in their essential theoretical commitments and have made, thereby, fundamentally very different assumptions about what constitutes personality. They differ on such matters as the complexity of personality and the degree to which it needs to be understood as that which emerges in and through social structures (cf. Antonovsky, 1991; Ouellette Kobasa, 1990). The new investigator is encouraged to look closely within the theoretical statements that support each of the constructs. It is within those statements, and not the scales where items across constructs often look remarkably the same or within recent adaptations of the construct in which confusingly radical redefinitions of constructs can emerge (e.g., Younkin & Betz, 1996), that one can find both the distinctiveness of the constructs and insights that have yet to be brought to empirical test (Gladden & Ouellette, 1997).

Is It All Neuroticism?

For a number of the personality constructs reviewed here, investigators have claimed a threat to construct validity because of the relation between those constructs and neuroticism (also sometimes referred to as negative affect; e.g., Funk, 1992). The most popular form of the claim goes as follows: If the personality construct under study does not continue to have an effect on health outcomes after the variance associated with neuroticism has been removed, then

that personality construct is redundant. Most of the pursuit of this idea has been empirical, with investigators relying on exploratory and confirmatory factor analysis and/or multivariate regression strategies. The results of these studies have been mixed. For example, some have shown that a construct like hardiness loses its effect once neuroticism is entered into the regression equation (Allred & T. W. Smith, 1989); others show the effect remains (e.g., Florian et al., 1995). The ambiguity also emerged in work that took a number of constructs into account. Some studies demonstrated that all of the constructs similar to those of this chapter load on one large factor that can be labeled "health proneness" (Bernard, Hutchison, Lavin, & Pennington, 1996); others argued for the independence of constructs. A study by Robbins et al. (1991), for example, showed there is no single master personality construct like neuroticism that is more successful than any other at predicting health outcomes. They demonstrated that if the aim is to sort out the effects of personality on actual health complaints and beliefs about the maintenance of health, it is necessary to include several different kinds of personality constructs in the research.

A conceptual approach also needs to be taken to the question about neuroticism and redundancy. As Lazarus (1990) put it, it is all a matter of the theory that the investigator favors:

The presumption by Ben-Porath and Tellegen, Costa and McCrae, and Watson is that negative affectivity (or neuroticism) is *the* basic factor in the claimed confounding. However, the argument could just as logically, and perhaps more fruitfully, be turned around so that appraisal of coping styles are treated as key variables in the relationship between negative affectivity (or neuroticism) and subjective distress or complaints about dysfunction. (p. 44)

Scheier, Carver, and Bridges (1994) suggested that optimism–pessimism can be understood, not as a variable better replaced by neuroticism, but as a subfactor within the broader dimension of neuroticism; and, in its role in coping and health, independent of other possible subfactors of this broader trait of neuroticism. Maddi and Khoshaba (1994) provided empirical support for Maddi's (1990) argument that the relation between hardiness and neuroticism is not the basis for the dismissal of hardiness, but that which was indeed predicted by the original hardiness theory. Hardiness was conceptualized as related to strain, and strain is that which is assessed through most measures of neuroticism.

There is much yet to be learned by taking seriously the variety in personality constructs that have been linked with health. Given the current emphasis on the five-factor model approach to personality (neuroticism is one of the five) and its use as a kind of gold standard in personality study (cf. Ouellette, 1999; Suls, David, & Harvey, 1996), however, there is fear that there will be pressure put on new investigators to see neuroticism as the simple answer to it all. Granted some form of negative emotion plays some role in illness processes. However, it is necessary to understand more about staying healthy than that it represents a lack of negative feelings.

To Whom Does the Link Between Personality and Health Apply and Does It Apply in the Same Way?

Although a remarkable diversity of respondent groups emerges in a look across the personality and health studies, there has been relatively little explicit concern in this literature for matters of race, ethnicity, class, sexual orientation, and other markers of diversity. This gap is especially striking because much of the basic literature has had to do with personality in interaction with stress and many of the markers of diversity have been themselves documented to be serious structural sources of stress in our society (Krieger, 1999; Meyer, 1995). Also, there are suggestions in the literature that the link between personality and health may hold for some groups, but not for others; and that the link may emerge in different ways for different groups. For example, Ingram et al. (1996) found that sense of coherence was related to distress among homeless women but not low income housed women. Kobasa (1982) found that the challenge dimension of hardiness was correlated with better reported health among business executives and lawyers but that former Vietnam army officers on their way to ROTC assignments reported more health complaints, the more they reported an orientation toward challenge. Others have noted that many of the hardiness results found in groups of men have not generalized to women (e.g., Schmied & Lawler, 1986).

The theories that support the sense of coherence and hardiness allow for and encourage the investigator systematically to look for such differences between groups. Note Kobasa and Maddi's early phenomenological emphasis on how individuals see their world. From an existential perspective, how individuals see the world is constituted by what they have at hand in their immediate and distant environments; and issues such as race, ethnicity, and job situation are part of this way of being in the world. Antonovsky defined sense of coherence as that which is shaped by the social structures in which people are socialized. Nonetheless, the research has yet to be done that explicitly features diversity, especially with regard to the issues noted earlier. New investigations are in order so that an understanding of personality can inform the resolution of long-standing questions such as: Why is it that members of minority groups in society are often in greater risk of poorer health than members of the majority group?

DILEMMAS TO THINK ABOUT

"Yes ... But" 1: Can There Be Agency Without Blame? Can There Be Structures and Persons?

"Yes": A focus on personality as health promoting and enhancing has expanded the biomedical model and enabled a recognition of health (as well as illness), the importance of psychological factors, and the person as an active agent.

"But": This focus on the individuals' role in their staying healthy has led to blame being placed on those who get

sick and a neglect of the social, cultural, and political causes of distress and lack of health.

The Yes. In what might be called the founding ideas behind the personality constructs reviewed, there is an emphasis on the search to understand the factors responsible for health in very trying circumstances. Antonovsky (1979) used the term *salutogenesis* to encompass data collected from persons who had survived the Holocaust and those in less profound but still troubling situations. The initial hardiness study (Kobasa, 1979) was done with business executives undergoing a major organizational change, the divestiture of American Telephone and Telegraph (AT&T). This company was "Ma Bell." Most of the executives had gone to work there, 20 plus years earlier, assured of a stable and predictable work environment. They never expected the break up that occurred. In contrast to then-popular emphasis in airline magazines and other media on the terrible effects of stress in peoples' lives, especially those of American icons like business executives, the empirical study showed that significant numbers of the executives were doing quite well in spite of their high stress levels at work and in other parts of their lives. Later, Kuo and Tsai (1986) used a hardiness, stress, and health framework to react against a literature on immigration that is filled with references to the bad things that occur when people come to a new country, such as identity crises. They provided documentation of immigrants who were doing quite well. Other examples of what is now popularly called resilience in the face of adversity can be found from research on adults living with a chronic illness and persons working in education and service provision (cf. Ouellette, 1993).

In a similar spirit is the formidable and still-growing literature based primarily in the developmental psychology literature on children who have remained resilient in a variety of circumstances, including serious childhood illness, homes with parents suffering physical and mental debilitation, poverty and other class-related problems (Anthony, 1987; Masten et al., 1999). O'Leary and Ickovics (1995) documented findings on what they called thriving from various research arenas and issued a call for more such investigations and particular attention to the many examples of women's ability to thrive in the face of strenuous circumstances.

To explain why it is that some persons stay healthy while others fall ill, researchers focused on personality. In choosing the kind of personality variables that were to be examined alongside of health, health-related behaviors, and stress, researchers were making a claim for a particular view of what it means to be a person. In their selection of constructs, they were emphasizing the extent to which persons are to be recognized as not simply passive recipients of what happens to them but active shapers of their worlds, including those situations relevant to their health. Their conceptual stance was clearly opposed to a strict behavioristic view that left no room for matters like personal choice and a psychodynamic one that associated the determination of behavior with unconscious patterns set early in an individual's life. As people see especially clearly in sense of coherence, hardiness, and all of

the control constructs, their interest was in understanding agency and the person as a source of change.

The But. For several years now, one of us has taught graduate students who represent diverse ethnic, racial, cultural, and economic backgrounds and who are committed to use social science tools to do something about serious social problems like racism, homophobia, sexism, and the stigmatizing of those living with serious illnesses like AIDS. With such an audience, she has come to know very well that look of wariness that comes over students' faces as she gives the lecture on sense of coherence, hardiness, self-efficacy, and related constructs. They fear the consequences of the focus placed on characteristics of individuals, especially characteristics that represent agency. They question what will come of those who do not stay healthy under stress: Will they be blamed for the distress and illnesses they experience? They also worry that the spotlight placed on individuals serves to keep in the dark those social structures likely to be responsible for the stresses: Might not the emphasis on some individuals' resilience and thriving distract those who are willing and able to change the social structures and processes that make up racism, homophobia, sexism, and stigmatization? Is it just the excuse those folks who are determined not to see any of this change happen are seeking?

And it is not only graduate students who raise these questions. Ryan (1971) elaborated on how easy it is for those in power to attribute problems to defects in individuals rather than to unjust social systems. He included policymakers, liberal-minded reformers, and academics among those in power and showed how all participated in this way of thinking. His critique of victim blaming ideology was profoundly influential and is still found useful by those seeking to address the variety of forms in which inequality persists in society (cf. Lykes, Banuazizi, R. Liem, & Morris, 1996). There is also the compelling work of Sontag (1978, 1988) on illness and its metaphors. She made clear the pain caused to people living with a serious illness by research that seems to say: "If only you had this or that personality or attitude toward life, you would be fine." She also made the important point that constructs about personality are metaphors that serve to neutralize and make manageable distressing realities like suffering and death. From her perspective, psychologists and social scientists of health provide a kind of opiate for the pain that is an essential part of the human condition. Thereby, she claimed, social scientists engage in a kind of social denial (cf. Ouellette Kobasa, 1989)

Yes and But. The extent to which the juxtaposition of the personality and health research and the positions of Ryan, Sontag, and many graduate students represents a dilemma is well expressed in R. Liem and J. H. Liem (1996). They cited a good deal of research, including their own, that demonstrates the health damaging and other serious consequences of unemployment; and they displayed the inadequacy of the image of the unemployed victim that this research creates. They presented examples of unemployed individuals who contest the

victim image and actively engage in resistance against the many threats to their welfare that are brought on by unemployment.

"Yes ... But" 2: Health as a Moral Value

"Yes": Research on personality as health promoting and enhancing recognizes the importance of structures and suggests some ways of changing them so that all can enjoy lower risk of illness and enhanced well-being.

"But": Underlying the effort to improve peoples' health are insufficiently examined assumptions about what health is and ideological commitments that are themselves shaped by social, cultural, and political forces.

The Yes. Many researchers interested in personality and health called for a view of personality that incorporates the social, cultural, and political structures through which personality is expressed. They have discussed how changes required for the enhancement of certain personality characteristics, and thereby, health would need to be instituted on both individual and group levels. For example, much of Antonovsky's last work was taken up with the consideration of how structural changes might be instituted that would increase sense of coherence as it is experienced both by individuals and groups; Bandura's (1995) most recent statement on self-efficacy and related agency constructs made clear their connection to broader social forces; and Ouellette Kobasa (1991) discussed how to foster particular environmental settings (i.e., community-based health advocacy organizations) that serve as special physical and social spaces for the expression of hardiness. All based their calls for change in the assumption that these changes will lead to the improvement in persons' health, an unquestionably worthy goal for all. Who could question it?

The But. Several recent commentators on the science of linking psychological and social factors to biomedical phenomena have pointed out the essentially value-laden nature of the enterprise. In this discussion, seemingly universal and invariant notions like that of health are revealed to be socially and culturally constructed, as are theories about personality and the links between personality and health (cf. Marcus et al, 1996). What they said about the intricacies of how negative health outcomes are defined also holds for the positive outcomes that have been simply assumed as good and desirable throughout this chapter. One needs to ask, however: Positive and enhancing according to whom, in what circumstances, and when? Massey, Cameron, Ouellette, and Fine (1998) caution that what some investigators claim to be unquestioning indicators of having been resilient—of having successfully coped with life's stresses, such as staying in school or not getting pregnant, may be resilience from the perspective of the researcher, but not from the perspective of those being studied. A study by Green (1994) also underscores the danger of assuming what the good is. In a very provocative study of Central American

women who have survived the horrors of war and oppression, Green showed how the experience of poor physical health—what many personality and health researchers would seek to help them minimize—is actually something they desire. Their symptoms are a way for these women to retain ties with their now-lost communities. To be healthy would be to lose all contact with the many who have died.

Yes and But. The claim that research on personality and health is infused with value judgments and shaped by social and cultural forces is not to be denied. The call here is for the discussion of values to be made more explicit and prominent in the literature. For example, why has more not been said by health psychologists about the fact that those variables identified by Western psychologists as what keeps people healthy—feeling in control, being committed, approaching the world optimistically, and so on—are also, in themselves, thought to be good ways of being in society. It is the socially undesirable variables like anger and hostility that make people sick. The job is not to make the research enterprise value free but rather to find ways to keep researchers ever-cognizant of the value judgments that are being made. Many of those who enter the arena of personality and health are those who are indeed seeking to use scientific tools for good ends, to find new ways of intervening in biomedical phenomena to relieve peoples' sufferings. The aim is not to discourage them but to have them recognize the complexity of all aspects of their work.

THE FUTURE FOR RESEARCH ON PERSONALITY AND HEALTH

The following is the basic message for future work: Key to the resolution of current concerns and dilemmas is the willingness of health researchers to take better advantage of the theoretical and methodological tools now available to them within the enterprise of personality psychology and the insights about the ideological and historical dimensions of their work provided by feminist (e.g., Stewart, 1994) and critical (e.g., Fox & Prilleltensky, 1997; Prilleltensky, 1997) psychology. This willingness will help ensure that more of the contributions and fewer of the limitations of research on personality as a health protective and enhancing factor will be realized. To support this message, the remaining pages are used to identify three interrelated ideas from the more general endeavors in psychology: the multifaceted nature of personality and personality psychology, the importance of transactions, and the usefulness of quantitative and qualitative research within local contexts. Key sources of these ideas are cited, some ways they can be connected to the concerns and dilemmas in health research are suggested, and some examples of their representation in empirical work are provided.

The Multifaceted Nature of Personality or There Is More to Personality than Traits

Much of health psychology seems to equate personality with traits and to be excessively preoccupied with the potential

promise of descriptive approaches such as the five-factor model (e.g., T. W. Smith & Williams, 1992; Suls et al., 1996; cf. Ouellette, 1999). This limited view is in contrast to the concerns of the general field. Several recent statements strongly make the point that personality can be seen, given available conceptual schemes and measurement strategies, as constituted by several different units of analysis. It is not all just traits. McAdams (1996), for example, reviewed personality research to illustrate three levels on which personality operates. Beyond traits or what McAdams called the "psychology of the stranger," there is what he called the "personal concerns" level of analysis on which he placed constructs such as Little's (1993) personal projects and Emmons' personal strivings (Emmons & McAdams, 1991). On the third level, McAdams placed personality conceived of as a matter of identity and life stories. Here, the emphasis is on those personality processes involved in meaning making (Bruner, 1990), narratives about the self through the life course (Cohler, 1991), and the dialogical self (Hermans, Rijks, & Kempen, 1993).

As discussed elsewhere, the presence of all three levels has serious implications for the ways personality and health research is done (Ouellette, 1999). The variety of ways of conceiving of personality provide important options for a response to the specific concerns raised about how investigators think about outcomes, the choice between constructs, the generalizability of personality and health findings, and both dilemmas. For example, the second and third levels allow the researcher seriously to take the structures in which personality resides. The best of the research on these levels shows that persons have concerns in particular settings (e.g., Ogilvie & Rose, 1995) and stories about self are told in historical and cultural space (Franz & Stewart, 1994). This broader view of personality in context enables researchers to assess and seek to understand how it is that personality works similarly or differently across different groups to protect and enhance health. It also helps in addressing the dilemma around dealing with structures and individual agency.

The personality constructs reviewed in the first part of this chapter unfortunately have too often been approached simply as personality traits. There are solid grounds, however, within the theories that support each construct for understanding them as having to do with other ways of thinking about personality. Each reflects aspects of all three of McAdams' levels. In taking the broader view of these constructs, the move is away from a simple descriptive or McAdams' stranger approach to personality and toward an understanding of personality processes at play in such events as a person's actual facilitation, perception, and response to stressors in the environment.

But how can researchers do personality and health research taking advantage of the many levels? The case for the usefulness of these other units or ways of understanding personality for health psychology research was well made by Contrada, Leventhal, and O'Leary (1990) in their review of Type A research. They integrated a great many findings through use of a conceptual model framed around self processes. Contrada and his coauthors effectively brought to-

gether the work of Glass, Matthews, Price, and others by showing that for each of these investigators, personality has fundamentally to do with particular cognitive structures or belief systems about self and world. Rapkin and his colleagues (Rapkin et al., 1994) provided another good example. They developed what they called the Idiographic Functional Status Assessment for the systematic observation of others' goals. This interview strategy enables researchers as well as clinicians to take into account the ways individuals and subsamples within samples differ in terms of what determines their quality of life. In a study of 224 people living with AIDS, what people said about such things as the difficulty in their pursuit of their distinctive goals related significantly to their well-being and other health outcomes.

It Is About Transactions and Not Just Interactions

A second important insight that goes back in psychology's history at least as far as to Dewey and Bentley (1949), but that has been recently proposed with renewed vigor in a number of areas of psychology, is the notion that when investigators study aspects of persons in their environment, they are not studying elements that can be understood as independent, isolated, or separable from each other; but rather, they are looking at dynamic units that are synergistically related to each other—persons are defined in terms of the environments in which they participate and environments only become meaningful as they are taken up by and made relevant to the persons and other organisms that reside within them.

This idea has particular importance to that elusive stress buffer effect that has been attributed to personality. In most of the research to date, researchers have worked with statistical models requiring the construct representing it to be independent of the stress variable if personality is to be a buffer or moderator of stress. A transactional approach, however, makes clear how self-defeating such a requirement is. The complaint being voiced here about multiple regression is similar to that raised 13 years ago by Lazarus and Folkman (1984) when they argued that the processes of stress and coping would never be understood through an analysis of variance strategy that put person, situation, and person by situation interaction into separate, independent cells. More recently, Coyne and Gottlieb (1996) claimed that researchers' failure to seriously take the Lazarus and Folkman point about transactions has led to hundreds of misleading and inconsequential coping checklist studies. A stance should be maintained in the research that recognizes that people and what happens to them in forms such as stressful life events are inseparable and essentially related.

Moving to an empirical level, there are studies that are beginning to move in the direction suggested by Dewey and Bentley. There are studies demonstrating the important ways that personality not only correlates with how people respond to stress but also shapes the actual likelihood of stress occurrence (Bolger & Zuckerman, 1995; T. W. Smith & Anderson, 1986; T. W. Smith & Rhodewalt, 1986). In a daily diary study of 94 students, Bolger and Zuckerman demonstrated that the personality characteristic of neuroticism determined both how persons reacted to stress and their exposure to stressors.

In their framework, a trait and process approach to personality are combined. Such work suggests not that researchers should give up on personality as a stress buffer, but rather that it is necessary to develop new ways of thinking about personality as that which goes beyond static traits. These new personality units of analysis must simultaneously represent what situations afford to persons and what persons make of situations (cf. Mischel & Shoda, 1995).

The perspective of transactions when used in a critical psychology framework also provides a way of addressing the debate over individuals and agency versus structures and social determinations (e.g., Prilleltensky, 1997). A transactional look at notions such as resilience and empowerment forces a recognition of personality constructs and persons in context. Health is never simply a matter of the success and rights of individuals in isolation but rather the integration and responsibilities of individuals in communities. A critical psychology perspective would find Antonovsky's critique of an internal locus of control and Antonovsky's interest in the promotion of coherent social structures as conducive to its aims for psychology (cf. Ouellette, 1998).

People in Local Contexts Have Much to Say About Their Health, Especially if One Gets Close Enough to Listen

Recent work has effectively and usefully taken the investigation of the relation between minority stress and health, from strict comparison studies that pit minority groups members against those in the majority, to studies within the minority groups themselves (examples include James, 1994; J. L. Peterson, Folkman, & Bakeman, 1996). These studies represent serious attempts at understanding both the distinctive stressors that result from minority status, and the unique and important ways in which these stressors combine with other psychosocial resources, including personality, to protect and enhance health. DiPlacido (1998) and Meyer (1995) examined these issues in the context of individuals' sexual minority status. Meyer (1995), as part of an attempt to understand why it is that in large-scale epidemiological studies gay men score no lower on mental health than do straight men in spite of the former's greater exposure to social stressors, found individual difference in mental health within a group of gay men. These differences were in turn related to discrimination, experiences of negative treatment in society, and internalized homophobia; the greater the degree of exposure to stressors associated with living a gay life in this society and the higher the internal state of self-rejection and shame, the greater the mental health problems.

Similarly, DiPlacido, in a pilot study, found what she called "internal stressors" (i.e., self-concealment of sexual orientation, and internalized homophobia), both resulting from heterosexism and homophobia, to be related to greater distress among lesbian and bisexual women. DiPlacido's work on lesbian and bisexual women (i.e., women who partner/have sex with women) marks an attempt at understanding stressors which result from having a double minority status

(as both women and women who partner/have sex with other women), and in some cases a triple minority status (lesbian/bisexual women from racial and ethnic minority groups). DiPlacido underscored the multiple levels of stressors and their effects on well-being among minority women who live in a social context of sexism, racism, heterosexism, and homophobia. Moreover, these multiple levels of stressors remain very much in focus as this researcher examines the social and personality influences that buffer the negative effects of minority stress on health outcomes. Many of these sexual minority women do indeed lead healthy, productive lives; but these lives go on within a negative sociocultural climate of hate and stigmatization.

Although these largely quantitative research efforts have produced important findings, the point here is to encourage the use of qualitative data collection and analysis strategies as researchers move closer to local contexts in personality and health research. Feminist and critical approaches in psychology have led psychologists finally to recognize what sociologists, anthropologists, and our other fellow social scientists have known for years; that is, there is much to be gained through the application of phenomenological and qualitative approaches and a close look at the contexts in which stressors are experienced. Their relevance is especially clear as investigators seek to resolve the ideological and value dilemmas noted earlier. For example, Burton, Obeidallah, and Allison (1996) summarized descriptive data from several ethnographic accounts based in the inner-city communities in which African American teens live. They made clear why and how researchers need radically to rethink the assumptions made about what are and are not normative adolescent stresses and adaptive and nonadaptive outcomes for adolescents. For many of the research participants, there really are no childhoods or adolescences as they have come to be known in certain segments of society. Notions like the innocence of childhood and the moratorium of adolescence make little sense in lives in which 8-year-old girls are staying home from school to be the primary care takers of infant siblings, 12-year-old girls are dating the same men that their mothers are dating, and 13-year-old boys who have experienced extraordinary violence do not worry about what they will do when they get older because getting older does not strike them as much of a possibility. The message from these data is not that there are no grounds for evaluating positive outcomes. But rather, the advice is that the researcher needs to entertain the possibility of a diversity of outcomes and use the insights of members of the local context in the construction of the lists of outcomes that can be called desirable. For example, spiritual development and involvement in religious activities—for which African American adolescents are rarely given credit and which the research literature typically portrays as a simple coping strategy (if it considers it at all)—is seen by community participants in the Burton work as the most important outcome or indicator of positive adjustment to stressors among teens.

Sabat and Harré (1992, 1994; Sabat, 1994) also demonstrated the effectiveness of phenomenological and qualitative approaches in health research, and the dangers of relying

strictly on researchers' and formal and informal caregivers definition of healthy functioning. Using records of conversations with persons living with Alzheimer's disease, both in treatment centers and at their homes, interviews with caregivers, and interviews conducted by social workers with Alzheimer's sufferers together with their caregiver, they used discourse analysis to reveal much about the experience of living with Alzheimer's and the construction of that experience. For example, their interviews revealed a higher level of cognitive functioning, one that includes a subjective experience of self, than has ever been recorded through standardized psychometric measures. In addition, they demonstrated how it is that professional and family caregivers shape the social self that the person with Alzheimer's presents to the world. That self is often minimized by those others in ways that lower self-esteem and contribute to the general loss of personhood often seen with Alzheimer's disease. The Sabat and Harré work demonstrated that a subjectively experienced sense of self, a key component of personality, is both present in those living with Alzheimer's and highly valued by those persons.

CONCLUSION

Twenty years ago, when the research literature said that not everyone falls ill in the wake of stressors and that a person's personality actually serves to promote and enhance health, it said something new. Now, such a remark is old hat. A lengthy list of personality constructs have been proposed and shown to be related to health variables. At this time, a good deal is known about how personality has its effect through mechanisms such as the appraisal of stressors and the use of particular coping strategies. The endeavor has reached a point at which researchers are no longer primarily debating whether personality is related to health, but rather, which personality construct is the most powerful one and how little one needs to know about personality to make health predictions. Hopefully, this chapter serves to celebrate what has been learned but also warns against the enterprise becoming too smug and too narrow. Serious concerns remain about how personality is related to health and what is to be made of the relation. New researchers are encouraged to continue the struggle after understanding and, in so doing, to take good advantage of what the broader fields of psychology, including its critical elements, have to say.

Social Comparison Processes in the Physical Health Domain

Jerry Suls

René Martin
University of Iowa

The famous 19th-century medical pathologist Rudolf Virchow argued that medicine is a social science. Virchow was thinking mainly of the role of socioeconomic factors and social conventions in the etiology of disease, but this chapter argues that even more fundamental interpersonal processes play an essential role in understanding why people become ill, how people decide they are ill, whether they seek formal medical attention, and how they cope with illness. This chapter focuses on how people's health-related thoughts, feelings, and behaviors are influenced by comparisons with other people. It begins with a brief survey of classic social comparison theory and recent extensions and then considers four areas of health psychology, researched over the past 25 years, in which social comparison has been strongly implicated.

A BRIEF SURVEY OF SOCIAL COMPARISON THEORY

Festinger (1954) provided the first systematic theory of comparison processes. He noted that people have the need to evaluate the correctness of their opinions and gauge their capabilities for action. In the absence of physical objective standards, people engage in comparisons with others to establish their standing. Festinger proposed that people prefer similar others for gauging the correctness of their opinions and adequacy of their abilities.

Since the initial presentation of the theory, it has undergone several extensions and reinterpretations (Latané, 1966;

Olson, Herman, & Zanna, 1986; Singer, 1966; Suls & R. L. Miller, 1977; Suls & Wills, 1991; Wheeler, Martin, & Suls, 1997). Schachter and Singer (1962) showed how social comparison extends to the interpretation of emotional states, a domain of clear relevance to the physical health domain where physical symptoms and trauma covary with affect. Mechanic (1972) emphasized how social comparisons with others play an important role in the interpretation of physical symptoms and health care seeking behavior.

Besides these extensions of the theory to domains beyond ability and opinion evaluation, the basic elements of the theory have also undergone refinement. From the inception of Festinger's theory, questions have been raised about how similarity of a comparison other should be best conceptualized. Goethals and Darley (1977) argued that comparisons are preferred with others who are similar by virtue of sharing attributes thought to be related to performance on the ability or opinion under evaluation. For example, for individuals to gauge their swimming performance ("How good am I?"), they should prefer to compare themselves with someone who is similar in body build, swimming experience, and level of motivation (Gastorf & Suls, 1978; Zanna, Goethals, & Hill, 1975). For individuals to predict whether they will be able to achieve a given performance ("Can I do X?"), they should want to learn the outcome of someone else who has already attempted the same goal and who has performed comparably to themselves in the past on a similar or related task (Wheeler et al., 1997).

The comparison of opinions is also more complex than Festinger proposed. Value-type opinions are personally relevant and lack an objectively correct answer. Because of their personal relevance, the views of others who share an individual's general perspective or background are most useful. On the other hand, beliefs refer to empirically verifiable facts. In this case, persons who are dissimilar on related attributes may provide a kind of "triangulation," so as to get a better "fix," or more objective view, by learning how someone with a different perspective thinks about the issue. Hence, value-type opinion comparison may be best served by comparisons with people who share related attributes (i.e., similar others), but belief-type opinion comparison may be preferred with persons who come at the issue from a different angle (Goethals & Darley, 1977; Gorenflo & Crano, 1989).

Thus far, the dynamics of social comparison for *self-evaluation* (i.e., the accurate rendering of abilities or opinions) have been considered. This was the main motivation served by social comparison according to Festinger. However, in recent years, there has been increasing recognition that comparison may also serve *self-enhancing* or *self-protective* motives (Goethals & Darley, 1977; Wills, 1981; Wood, 1989). Initial thinking suggested that the self-enhancement motivation for people who were experiencing a threat to self-esteem would be best served by comparing with others who were worse off (i.e., downward comparisons, to increase their self-esteem; Wills, 1981; Wood, Taylor, & Lichtman, 1985). More recently, this argument has been refined with the recognition that both upward and downward comparisons may increase self-esteem depending on the dimension under evaluation (Buunk, Collins, Taylor, Van Yperen, & Dakof, 1990; Collins, 1996; Major, Testa, & Bylsma, 1991; Taylor & Lobel, 1989). A third motive, *self-improvement*, has been also identified (Wood, 1989). In this case, people may prefer comparisons with persons who are doing better to inspire hope that their situation will improve or to learn information that will help them to improve themselves.

The impact of explicit comparisons made with others has been considered. However, recent research also indicates that people engage in implicit *projections* of opinion and personal attributes (Gerard & Orive, 1987). Goethals, Messick, and Allison (1991) called this "constructive social comparison," referring to "in the head" estimates about the nature of social reality, such as the distribution of abilities and particular opinions. Suls (1986) proposed that these self-generated estimates may actually short circuit actual social comparisons. Fabricated or constructed comparison information may take the form of the well-known phenomenon of attributed projection, or false consensus where a person's own opinion or behavior is also attributed to others (Mullen et al., 1985; Ross, Greene, & House, 1977). Such constructions also may be biased in self-enhancing directions because they carry fewer constraints of reality. In some cases, however, constructions about norms may have to suffice because it is impossible for the individual (short of systematic polling) to gather all of the necessary information to obtain an accurate rendering of the norm. Regardless of the source of these constructed norms, it appears that they possess a self-perpetuating nature, and peo-

ple may treat the constructed norm as veridical and behave in accord with them.

Three basic aspects of the study of social comparison processes have been described: the self-evaluation of abilities and opinions, the recognition that such motives as self-enhancement and self-improvement may also direct the comparison process, and the construction of fabricated comparison norms. Since the foundation of the group dynamics tradition (Lewin, 1958), social psychologists have sought to both identify basic social processes, such as interpersonal comparison, and illustrate how they have influence in real-world settings (Festinger, Schachter, & Back, 1950). The physical health arena is one such setting. The remainder of this chapter describes how study of the comparison process, particularly the three aspects of the process already surveyed, has enriched understanding in several areas of health psychology.

CONSTRUAL OF SOCIAL NORMS CONCERNING HEALTH-RELEVANT PRACTICES

A wide-range of lifestyle behaviors—such as smoking, alcohol, overeating, and seat belt use—have been associated with early mortality and morbidity. A major task of health psychologists has been to develop interventions to decrease the frequency of unhealthy behaviors and increase the frequency of healthy behaviors. Virtually all theoretical accounts of health-related practices posit that normative expectations about specific practices play a role in whether the behaviors are adopted. For example, Ajzen and Fishbein's (1980) theory of reasoned action posits that behavior is a function of the person's attitudes about the behavior and their perceptions of the subjective norm (i.e., others' opinions regarding the appropriateness of the behavior).

Evidence for social influence processes in health behaviors comes from many sources. For example, one of the most consistent predictors of alcohol and cigarette use among high school and college students is the students' perception of alcohol and cigarette use by their peers (e.g., Gerrard, Gibbons, Benthin, & Hessling, 1996; Graham, Marks, & Hansen, 1991; Kandel, 1980; Stein, Newcomb, & Bentler, 1988). Laboratory experiments and field studies indicate that people will move closer to the group's consensual position when they note a discrepancy between themselves and the group (Asch, 1956; Crandall, 1988; Schachter, 1951). For social influence to occur, of course, the individual must have identified (or think they have identified) the social norm. The general societal or cultural sentiments about a particular opinion or practice may be easily discerned (e.g., the general opinion about the unhealthy effects of smoking are well-known through the media). But the specifics of social norms regarding healthy and unhealthy practices may be harder to determine. Although society does not condone heavy drinking of alcohol, for example, there is no readily available definition of "drinking to excess." In the absence of comprehensive information about average use and the range of use, it is virtually impossible for individuals to obtain a precise idea of how much drinking other people, besides their closest companions, do. Each

person has available only a narrow slice of the population from whom to infer the norms about the larger group. In addition, there is an awareness that public behavior may not represent people's private views (Deutsch & Gerard, 1955). All of these considerations make identification of social norms concerning health behavior a difficult undertaking for lay people.

False Consensus Effect

The complexity of identifying social norms forces people to depend on simpler rules of thumb, or heuristics, to infer social norms. One rule of thumb is the availability heuristic (Kahneman & Tversky, 1973), which evaluates the frequency or likelihood of an event or behavior on the basis of how easily instances or associations come to mind. Hence, when a behavior is easy to recall, it tends to be perceived as common. This implies that particularly memorable or accessible instances of a behavior will inflate estimates of the general probability of such behavior. Because people's own behavior is probably most available or accessible, people are likely to distort the norm in the direction of their own behavior. This is demonstrated in the well-known false consensus effect (FCE; Ross et al., 1977), or people's tendency to overestimate their similarity to others. Specifically, people ratings of their own behavior tend to be positively correlated with their estimates of others' behavior.

The FCE represents a form of social projection, or a constructed social comparison norm, as described in the introduction. This self-generated social consensus provides the individual with a justification for their behavior. Evidence of the false consensus effect has been demonstrated in several health domains (e.g., Graham et al., 1991). Chassin and associates (Chassin, Presson, Sherman, Corty, & Olshavsky, 1984) found that adolescents' ratings of their friends' use of alcohol, cigarettes, and marijuana were positively correlated with their own current use. Suls, Wan, and Sanders (1988) found a FCE for a wide range of health relevant practices (e.g., substance use, seat belts, etc.) among college students. For example, smokers believed that more of their peers smoked cigarettes than did the nonsmokers (See Fig. 11.1a).

Above Average Effect

By itself, the FCE cannot fully account for normative pressures for performing health relevant behaviors. For example, entry into college is usually associated with a shift toward college-wide norms encouraging increased alcohol consumption (e.g., Friend & Koushki, 1984). But, if the individual used themselves as the anchor for the norm, as the FCE suggests, then no such shift should be exhibited. To understand this, false consensus must be distinguished from other social perceptual processes. FCE represents a positive correlation (usually of modest to moderate size) between ratings of self and ratings of others. Where individuals place their standing (above, below, or at the same level) on the relevant dimension in relation to others is a separate issue. Survey studies of junior high school students' self-ratings and estimates of others' alcohol and cigarette use reveal that, although relative

standing regarding cigarette smoking and alcohol use is correlated with the standing of peers (i.e., FCE), students consistently overestimated the degree to which their peers smoke cigarettes. This *overestimation* of friends' and peer use of unhealthy practices, such as smoking and alcohol use, is a highly reliable finding (Graham et al., 1991; Hansen & Graham, 1991) also found among college students and community-residing adults (Suls & Green, 1996). This perceptual bias has its complement; people also *underestimate* the degree to which others engage in healthy practices (Suls & Wan, 1987; Suls et al., 1988; see Fig. 11.1b). So, whereas people see themselves as sharing the same general perspective on particular practices (i.e., FCE), they also differentiate their position from others, seeing their behavior in a more desirable light (Taylor & Brown, 1988) ("above average").¹

What would lead people to infer that others engage in unhealthy practices more than themselves but engage less in desirable healthy behaviors? Witnessing others engage in excessive drinking or suffering the consequences of alcohol overindulgence should be much more salient than the absence of such behavior. Consequently, extreme instances of such behavior are more likely to be highly available and probably receive inordinate weight in estimating the social norm. Such memorable instances may be even more accessible than an individual's own behavior. More than accessibility is probably involved, however, because people also tend to underestimate the frequency of healthy practices on the part of others compared to the self. The overestimation of unhealthy practices and the underestimation of healthy practices may both be manifestations of the "above average effect," whereby people perceive that they hold a more desirable position than do most other people (Taylor & Brown, 1988). Logically, of course, it is impossible for everyone to be better than average (unless the distribution is positively skewed; Krueger, 1998), so this perception appears to represent the result of a self-enhancing motivation to be perceived as distinctive and superior.

The impact of the FCE and above average effect on health behavior may be substantial. Perceiving social support for one's behavior (FCE) may permit one to feel at least somewhat secure with unhealthy practices. At the same time, the above average effect provides individuals with false reassurance that they are not acting as irresponsibly as some others. This may also provide an explanation for the illusion of invulnerability (Weinstein, 1982), whereby people think they are at less risk of incurring disease than are their peers.

¹The above average effect represents a comparison of an individual's estimate of own behavior versus his/her estimate of other people's behavior. Another way to establish the existence of a self-enhancing bias is to compare the individuals' estimates of others' behavior with the actual norm in the sample (e.g., how much alcohol they consume on average during a specific period of time). Such comparisons with the actual norms reveal a false uniqueness effect (Suls & Wan, 1987; Suls, Wan, Barlow, & Heimberg, 1990; Suls, Wan, & Sanders, 1988); that is, people underestimate the actual number of others performing desirable practices and overestimate the actual number performing undesirable practices. Unlike the above average effect, "false uniqueness" is identified by comparing estimates of the norm to the actual norm; however, both biases appear to be connected to the same self-enhancing dynamic.

People believe that if others drink more excessively, use their seat belts less, and ingest more red meat, then that means they are probably at lower risk than them.

Pluralistic Ignorance

Reliance on simple heuristics and self-serving motivation may contribute to normative perceptions that do not reflect reality. But even if such psychological factors were not in evidence, social norms would still be difficult to identify with accuracy because public behavior may not be an accurate reflection of private belief. This fact leads to still another psychological phenomenon with strong implications for health norm perception. Pluralistic ignorance is a psychological state characterized by the belief that individuals' private attitudes and judgments are different from those of others, even though their public behavior is identical (Allport, 1924; D. T. Miller & McFarland, 1987). In essence, people take a public position on a social issue that misrepresents their private position. One classic example is described by Schanck (1932), who studied a small rural community in which virtually all of the members condemned use of alcohol and card playing publicly because it was part of church dogma, but did not hold such extreme views privately. In this case, public behavior was used to identify the social norm, but because everyone mistakenly assumed that public behavior reflected private sentiment, they drew incorrect conclusions about others' feelings. Interestingly, because of pluralistic ignorance, the status quo is perpetuated because "even if no one believes ... everyone believes that everyone else believes" (D. T. Miller & McFarland, 1991, pp. 287–288). What causes people to maintain the public behavior? One explanation is the fear of being different or deviant. Another is people's desire to behave in accord with the norms of their valued social group. Because everyone is publicly behaving in the same way (and such

comparison information suggests there is consensus favoring the public behavior), individuals assume that people agree with the prevailing sentiment and fail to recognize that social embarrassment or concern about not fitting in may also govern others' public behavior.

The role of pluralistic ignorance in college drinking practices has been studied recently (Prentice & D. T. Miller, 1993). Alcohol use by college undergraduates has become a major issue of concern because excessive drinking is a common practice on many college campuses and is associated with low academic performance, legal infractions, alcohol-related car accidents, and other negative consequences. Furthermore, entry into college is associated with an increase in alcohol consumption (Friend & Koushki, 1984). What accounts for the apparent peer support for excessive rather than moderate drinking? Many experts identify drinking as an important part of the identities of many college students and their social life. Despite the strong public norms favoring drinking on campus, Prentice and Miller noted students may privately hold misgivings about alcohol practices as they obtain firsthand exposure to sick roommates and inappropriate behavior associated with drinking. Students may privately have great misgivings about alcohol, but, believing that others are still comfortable with alcohol, they may perpetuate the norm by hiding their own concern. According to this reasoning, there may be pluralistic ignorance about students' concern with alcohol use on campus.

Indeed, undergraduate students at Princeton University who were surveyed about their own level of concern about drinking practices and their estimate of the level of concern of the average student or friends demonstrated evidence of pluralistic ignorance. Whether rating a peer or a friend, the students believed others were more comfortable with drinking than they were (see Fig. 11.1c). Prentice and D. T. Miller (1993) proposed that "individuals assume that other's outward display of comfort and ease reflects their actual feelings,

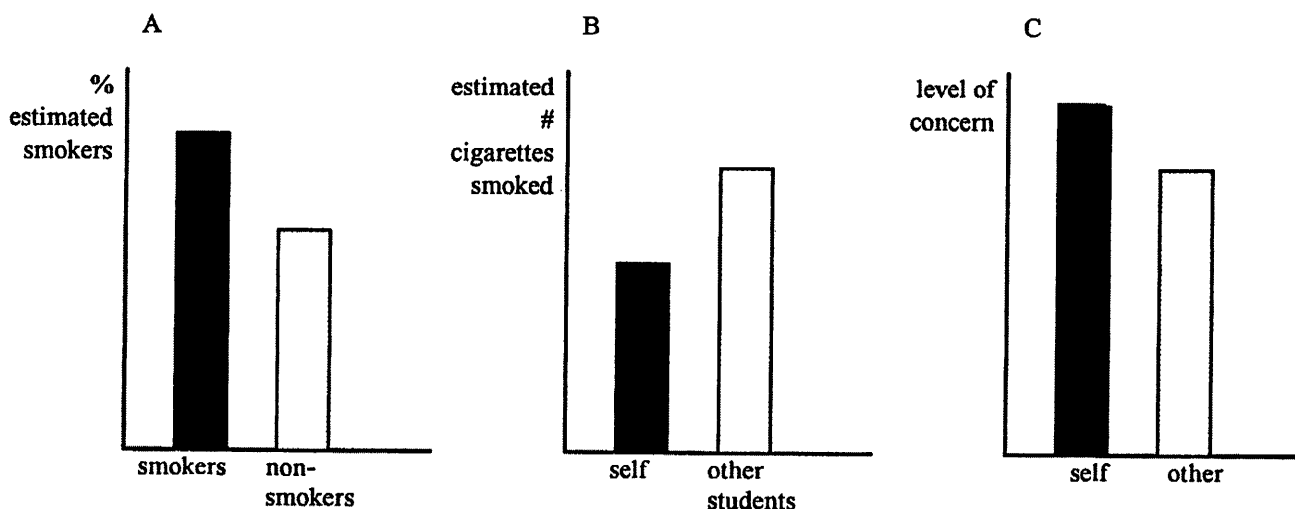

FIG. 11.1 False consensus (A), above average effect (B), and pluralistic ignorance (C).

even though those individuals' own identical behavior is somewhat at odds with their internal states" (p. 247).

In subsequent research, the relation between pluralistic ignorance and changes in drinking behavior on campus was assessed (Prentice & D. T. Miller, 1993, study 3). Both college men and women showed the pluralistic ignorance effect at the beginning of the academic year. Also, students' own level of drinking was uncorrelated with others' (projected) attitudes about drinking, suggesting that they were not complying with what they thought was the college norm favoring excessive drinking. However, by the end of the term, the college men reported the same low level of concern as their peers and the correlation between their own drinking and the perceived drinking norm had increased. This pattern of results suggested that the college men responded to their deviance from the perceived (and erroneous) norm by increasing their alcohol consumption. Women, on the other hand, showed no change in attitudes over time; they continued to perceive themselves as being more uncomfortable with campus drinking practices than were their peers and showed no correlation between their drinking behavior and others' attitudes. There are several reasons why the females may not have demonstrated the social influence shown by the men, but for reasons of brevity they are not considered here. Some data, however, may help shed some light on this interesting gender difference.

More on the Social Construction of Norms Concerning Health Relevant Practices

In several studies, Suls and Green (1996) examined the degree to which pluralistic ignorance extended to other health relevant practices. They wondered whether college students were privately very concerned about the level of illegal drug use, cigarette smoking, and unsafe sex practices on campus, but interpreted the nonchalance of their peers in a way that perpetuated erroneous social norms. They also wanted to examine the degree to which false consensus and the above-average effect characterized the socially constructed norms concerning a wide range of important health practices. Finally, they wanted to explore some initial data suggesting that gender differences in misestimations of social norms may have a significant impact on health behavior.

Nearly 1,000 college students enrolled at a large midwestern university completed surveys about the degree to which each engaged in certain practices and the degree to which they were concerned about the practices on campus. They were also asked about the degree they thought their friends and the average student engaged in these practices and were concerned about the practices on campus. Inquiries were made about alcohol use, driving while drunk, marijuana, cigarette smoking, bulimia, and condom use. Across all behaviors, students reported being more concerned about negligent behavior than they thought other students were. In other words, students misperceived the norm by thinking that others were less concerned than they were.

What accounts for this erroneous construal of the norm? The self-perceptions and estimates of others' frequency of en-

gaging in the various health relevant practices are informative about this question. Across practices, students perceived that they engaged in the unhealthy practices less frequently than did their peers. This provides additional evidence of the above average effect. Comparisons of students' estimates of other people's behavior with the actual reported behavior norms (taken from the same sample) also showed that students consistently overestimated the degree to which others engaged in unhealthy practices (i.e., false uniqueness; see footnote 1). These results suggest that Prentice and D. T. Miller's (1993) notion that everyone is observing identical behavior, which leads to the misestimation of the norm, requires revision. Suls and Green's health perception data indicate that students did not think they were behaving identically to others. Indeed, individual respondents perceived that they drank and engaged in all of the other negligent practices less than their friends. Obviously, everyone cannot be drinking less than their friends. Hence, some aspect of pluralistic ignorance is driven by a self-enhancing overestimation of how much others engage in undesirable practices. A few extreme cases also may be so vivid they lead to inflated estimates. Ironically, the erroneous representation of the social norm might acquire a life of its own and cause the individual to engage in unhealthy practices subsequently.

Gender Differences in Norm Estimation

In initial studies, Suls and Green (1996) found that, although both male and female college students exhibited pluralistic ignorance, the males reported somewhat lower levels of concern than did females. In subsequent studies, students were asked to answer about themselves and also to estimate the frequency and level of concern about several health relevant practices for male and female peers separately. For most health behaviors, male college students consistently rated their own level of concern as higher than other males and closer to their estimate of female students' level of concern. Males' self-reported frequency of undesirable behavior fell between their estimate of male behavior and female friends. Thus, surprisingly, there was evidence that males identified themselves with their perception of female norms, rather than with male norms. Female students also showed pluralistic ignorance and the above average effect with regard to their same-sex peers; however, they showed no identification with male attitudes or behavior (see Table 11.1).

TABLE 11.1
Level of Concern Regarding Unsafe Sex (i.e., failure to use condom) Among College Students

Target	Male Subject	Female Subject
Self	5.6	6.9
Average Male	4.0	4.4
Average Female	6.1	6.3

Note. Level of concern was measured on an 11-point scale, ranging from 0 ("doesn't bother me/them at all") to 10 ("bothers me/them very much").

This gender difference in norm perception has several potential implications. Male college students think their same-sex peers are less concerned and act more inappropriately than they do. Furthermore, males assume their concerns are frequently closer to those of females. This might create considerable sex-role conflict for males, particularly those concerned about maintaining a masculine image. There is speculation that concerns about maintaining a "macho" image may prompt male students to act in ways to reduce the (erroneous) discrepancy they perceive between themselves and their same-sex peers. This might explain why males in Prentice and Miller's study showed a decrease in concern and an increase in alcohol use. Although more research is needed, understanding gender stereotypes for health behaviors might help suggest ways to reduce unhealthy practices.

Normative Perceptions and Behavior Change

The knowledge gained from studying the perception of social norms regarding health practices has implications for health prevention programs. Misperception of peer substance use and other unhealthy practices functions as a passive form of social influence (Graham et al., 1991). Researchers have developed prevention programs in which erroneous normative perceptions about prevalence and acceptability of drug use among peers are corrected. In a study with junior high school students, Hansen and Graham (1991) found that normative education, which tried to correct the misestimation of drug use norms, was effective in reducing alcohol, marijuana, and tobacco use over a year's time. A comparison group treatment, involving resistance training to peer influence, was ineffective. Hansen and Graham observed that resistance training may fail because instruction in techniques to resist peer pressure communicates first that peer pressure exists and implies that most adolescents perceive substance use as common and acceptable.

Prentice and D. T. Miller (1993) strongly advocate group interventions. They noted that programs targeting the individual may not be fully successful because private attitudes may be changed, but social norms and public behaviors may be unaffected. Encouraging students to speak openly about their private attitudes within the group may, however, expose pluralistic ignorance. As social and health psychologists learn more about how people construe and misconstrue social norms, better interventions may be developed to encourage healthy and discourage unhealthy practices.

SYMPTOM INTERPRETATION, LAY REFERRAL, AND THE DECISION TO SEEK MEDICAL CARE

Social comparison processes also play a role in appraisal of symptoms and the decision to seek medical attention (Safar, Tharps, Jackson, & H. Leventhal, 1979; Sanders, 1982). Physical signs and symptoms occur frequently and most are ambiguous (e.g., a nagging headache, a bruise, heart palpitations). How do people decide when somatic sensations are indicative of illness and whether to go for treatment? In addition

to using commonsense models (H. Leventhal, Meyer, & Nerenz, 1980), past experience, and assessing the severity and likelihood that the symptoms are significant (Pennebaker, 1982), people also rely on members of their lay referral network for advice and social comparison (Friedson, 1961). Close to 70% of patients experiencing symptoms talk to at least one layperson about the symptoms and discuss what action should be taken (M. H. Miller, 1973; Suchman, 1965). Some aspects of this information seeking appears to involve direct social comparisons. Just as Schachter and Singer (1962) found that people label ambiguous physiological states by comparison with the emotions exhibited by others, people experiencing physical symptoms also may compare with others to determine if they are experiencing the same thing and how these sensations should be interpreted (Mechanic, 1972). Sometimes these comparisons are explicit, as when a person experiencing ambiguous physical symptoms asks friends if they are experiencing or have experienced the same sensations in the past. On other occasions, these comparisons appear to be made at a nonconscious level.

Suls, Martin, and H. Leventhal (1997) presented a model recently that integrates the literature on basic social comparison processes with the medical literature on lay referral. Three scenarios seem to cover most instances of comparison used in lay referral for symptom appraisal and the decision to seek formal care. The first scenario, called *symptom-induced social comparison* refers to cases when the individual experiences physical symptoms, forms a tentative opinion about them, and seeks out others with whom to compare that assessment (see Fig. 11.2a). In essence, this scenario involves the dynamics, described in the introduction, concerning social comparisons of opinions. Recall that the selection of a comparison other depends on whether the opinion is a belief or a value. However, symptom appraisal has elements of both beliefs and values. The individual wants to know whether the symptoms represent a definable medical condition (i.e., a potentially veridical entity). For belief-type opinions, dissimilar others provide valuable information because of the triangulation process, described earlier. In addition, someone with medical or health expertise should be most informative. Not only do they have a dissimilar perspective, but they also possess some expertise that may be considered objective. Recall that, according to Festinger (1954), objective or physical standards were the preferred source of information to reduce uncertainty; social comparisons were sought only when objective information was unavailable. In lieu of a physician or health care professional, the opinion of a lay expert (e.g., a neighbor who works part-time as a nursing assistant) will be useful. Hence, people may seek comparison with dissimilar others, especially those who have some kind of expertise, even if limited.

Value considerations also can figure in symptom-induced comparison. An illness may be manifested differently across people and many questions about illness are not answered by expert diagnosis, but rather with reference to a particular person's situation and life responsibilities. Someone with a similar physical constitution and background may provide a benchmark for interpreting one's symptoms.

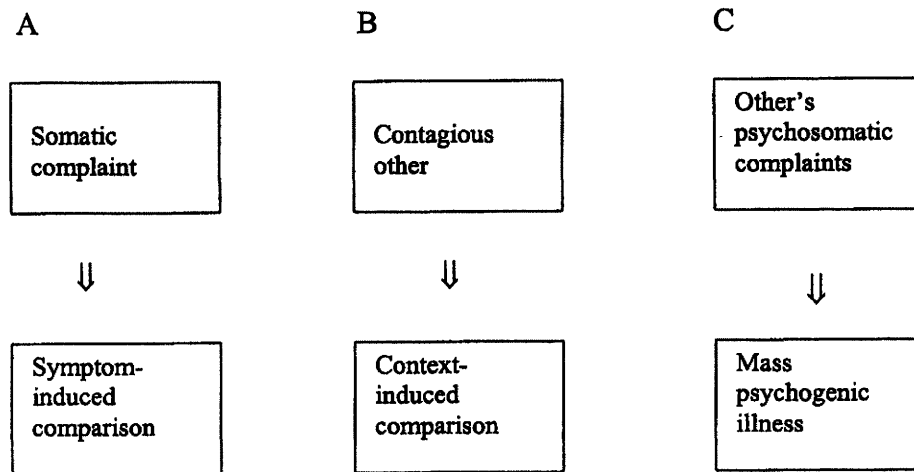

FIG. 11.2 Three scenarios for lay referral for health care.

Hence, symptom-induced comparison has elements of belief (“Are these symptoms indicative of a disease?”) and value (“Am I the kind of person who contracts this disorder?” and “How will these symptoms affect my lifestyle?”). As a result, both similar and dissimilar others may be sought as comparison others. Suls et al. (1997) reasoned that dissimilar experts should have favored status because they have the additional virtue of providing “objective” or expert criteria. In best of all possible situations, the “lay expert” would be someone of similar age, experience, and physical history, thereby satisfying value and belief concerns. Recent evidence involving surveys and interviews with young adults and senior citizens provided some empirical evidence for these predictions (Cameron, E. A. Leventhal, & H. Leventhal, 1993; Suls & Martin, 1995).

Context-Induced Social Comparison

The second scenario involves a situation in which the individual has had contact with someone who becomes verifiably ill with some contagious disorder or toxin. The awareness, via social comparison, of exposure to contagious or toxic elements induces symptom vigilance to ascertain whether signs and symptoms experienced match those presented by the ill target. In this scenario, comparison is prompted by the other person who is ill, rather than the initial manifestation of symptoms as described in the first scenario (see Fig. 11.2b).

The context-induced scenario resembles the comparison of abilities. There need be no exchange of opinions; merely being exposed to someone who is physically ill may prompt self-monitoring of relevant sensations in the same way that exposure to someone of superior ability may induce a comparison and consequent self-evaluation. In context-induced evaluations, comparers consider whether they have a particu-

lar set of physical symptoms, the meaning of which is provided by the proximity of a contagious other.

The choice of an appropriate comparison other depends partly on the nature of the health threat. For common contagious illnesses, almost any person with whom an individual has had contact or shared exposure is probably considered a relevant and similar comparison other. For certain illnesses, similarity may be defined by other factors. Exposure to someone with chicken pox may not induce symptom vigilance if individuals have had chicken pox in the past, because they know they now are immune to future episodes. Other disorders may involve environmental exposure to various toxins, so that relevant comparison with others who induce self-monitoring would have to share similar attributes and worksite exposure.

Context-induced comparison shares features of ability social comparison, but there is a notable difference. In the ability domain, comparison is prompted by people’s initial uncertainty about their standing. However, in the symptom evaluation domain, the illness of another person with whom they have shared contact or exposure creates the uncertainty regarding their own physical status and induces symptom monitoring.

Mass Psychogenic Illness

The third scenario involves widespread symptom perception among a group of individuals, even though there is no objective evidence of physical illness based on medical tests (see Fig. 11.2c). Such episodes tend to occur most commonly during stressful periods. Typically, the “illness” spreads among people with whom individuals work closely or know personally (Colligan, Pennebaker, & Murphy, 1982). The classic case is the so-called June Bug episode studied by Kerckhoff

and Back (1968), which occurred in an industrial plant. Victims (about 25% of the employees) reported nausea and feverishness, which sent some to the hospital, although no objective evidence of illness was found. The conclusion of health inspectors and Kerckhoff and Back was that the people who became ill showed a pattern of hysterical contagion in which psychosomatic symptoms of stress were mislabeled as markers of physical illness.

Like context-induced comparison, a social comparison process is induced by the social context, but here the symptoms are not really indicative of physical disease. Typically, in psychogenic episodes, people are already fatigued, anxious, and experiencing ambiguous symptoms (e.g., the June Bug episode occurred during a busy time at the plant). If others claim to have contracted a flu or been bitten by a bug, then this becomes a plausible illness label for another person's ambiguous state. As in the context-induced scenario, the information search preceding mass psychogenic episodes resembles the way in which people make ability comparisons. Similarity of environment and exposure of the comparison other with the "illness" are critical. Further, if the other has similar constitutional attributes, then this probably facilitates the attribution of illness in oneself because similarity may suggest a comparable level of vulnerability. Indeed, available evidence suggests that mass psychogenic illness tends to occur among persons who share personal attributes (Stahl & Lebedun, 1974).

Illness Delay. These three scenarios apply both to symptom appraisal, as described earlier, and the decision to seek medical attention ("Should I go to a physician?"). The framework provided may also explain why there is no straightforward conclusion about whether lay referral encourages or delays seeking medical attention. In the current scene of managed care, this is an important issue for theoretical and practice reasons. Sanders' (1982) review suggested that members of the lay network generally encourage seeking professional advice, but some empirical studies (Cameron et al., 1993) report that patients were advised by their relatives or friends to seek medical attention only about one half of the time.

Delay can arise from several features of comparison in lay referral. Experimental and anthropological research indicates that people rate disorders as less serious if they are more common (Clark, 1959; Jemmott, Ditto, & Croyle, 1986). Hence, symptoms that are prevalent among members of an individual's social network tend to be perceived as minor and less deserving of medical attention. In these cases, comparing with others who share the symptoms may delay seeking of medical attention.

In the mass psychogenic illness episode, however, if comparison others present so-called symptoms, others also may refer themselves for medical care. Sanders (1981) also found that, even if an objective test carried out by the individual suggested nothing was wrong, people were more apt to seek medical attention if members of their social network advised that they should do so. One interpretation of these results is that people are more likely to seek medical attention if peers give permission for them to assume the sick role.

The complex comparison dynamics involved in lay referral may explain why only about one third of people with physical symptoms needing attention refer themselves for medical consultation (Ingham & P. Miller, 1979; G. Scrambler & A. Scrambler, 1985). At the same time, a large proportion of people who do report symptoms to a health care provider have no demonstrable disease (Costa & McCrae, 1987). Both under- and overutilization of health care resources may occur as a function of social comparison processes operating in the lay referral network. More examination of these processes by health psychologists may be able to encourage appropriate self-referral for medical care.

AFFILIATION, COMPARISON, AND COPING WITH MEDICAL THREATS

Thus far, the chapter has considered the role that comparison processes play in the instigation of health-related practices and symptom appraisal. Interpersonal comparisons also play a role when people are actively coping with acute medical threats such as when they are awaiting medical procedures. People may affiliate and compare with others in their attempts to cope with impending medical threats, such as surgery.

Research on this topic was instigated by Schachter's (1959) pioneering laboratory studies on the effects of fear on affiliation (see Cottrell & Epley, 1977; Rofe, 1984, for reviews). Several experiments showed that people facing novel threats, such as electric shock, preferred to affiliate with others currently anticipating the same threat as themselves rather than alone or with others facing a different threat. These results are consistent with social comparison theory: People were experiencing uncertainty about the novel threat and were motivated to affiliate with similar others because they provided the best gauge for evaluating the appropriateness of their emotional state. For Schachter, emotional self-evaluation via social comparison was served by affiliating with others awaiting the same threat (i.e., a similar other). He acknowledged, however, that people might also want cognitive clarity about the impending threat to reduce uncertainty about the nature and dangers associated with the situation. Schachter differentiated cognitive clarity from emotional comparison even though both seem to involve social comparison. Seeking cognitive clarity was thought of in nonsocial terms by Schachter and focused on threat relevant information seeking. Emotional comparison processes were considered to be inherently interpersonal and focused on evaluating people's feelings.

The results of an early experiment by Schachter (1959) suggested that the need for cognitive clarity did not account for affiliation under stress (see Kulik, Mahler, & Moore, 1996). Also, Zimbardo and Formica (1963) found that high compared to low threat (of electric shock) subjects indicated a greater preference for awaiting threat in the presence of someone also facing the same threat than someone who had already experienced the threat. If cognitive clarity were the motive for affiliation, it would seem to be best served by someone who just experienced the threat. The conclusion drawn by Zimbardo and Formica was that emotional comparison was

the primary motive. This and later research seemed to reinforce that people prefer to affiliate and exchange information with other persons facing the same threats. Indeed, social support groups are frequently assumed to be so popular and, presumably effective, because they allow people who have the same problem to share their feelings.

Subsequent research (R. L. Miller & Suls, 1977; Rofe, 1984) has found that affiliation preferences are not necessarily as straightforward as Schachter contended. Although emotional comparison seems to explain Zimbardo and Formica's results, the experimenter in their study told subjects they could not talk with the potential affiliate. Hence, cognitive clarity may not have been a motive in the experiment because it was essentially blocked by the experimenter's instructions (see Kulik & Mahler's 1997 critique). In real-world contexts, however, communication is unlikely to be prohibited, so cognitive clarity may be an important motivation for social comparison under threat. There are several reasons why cognitive clarity may be an important consideration. Problem-focused efforts would be enhanced by talking to others who had more experience with the threat, had some expertise or skill, or simply served as successful role models. Several studies of ability-related affiliation (R. L. Miller & Suls, 1977; Nosanchuk & Erickson, 1985) demonstrated that individuals preferred more talented associates to work with on challenging tasks, presumably because of the clarity they could provide.

Kulik and his associates reported a series of studies reexamining affiliation under threat in real-world medical settings that explore the emotional comparison versus cognitive clarity question. In one study, Kulik and Mahler (1989) asked men hospitalized for coronary bypass procedures whether they would prefer assignment to a roommate who was awaiting bypass surgery (like themselves), a roommate who was back on the main ward recovering after bypass surgery, or whether they had no preference. Contrary to the emotional comparison notion, patients most often preferred a roommate who was already recovering from the surgery. Presumably, this was because such an individual could provide more cognitive clarity about the procedure and its sequelae. Indeed, comments from patients confirmed this interpretation ("It's more helpful for me to talk to someone who's already had it, because the guy that's waiting doesn't know anything about it, only what he's told"; Kulik & Mahler, 1997, p. 231). Laboratory research also confirms that cognitive clarity seems more critical for affiliation than emotional comparison. For example, individuals awaiting cold pressor pain spent more time watching and discussing the threat with someone who was threat experienced (had already undergone the cold pressor) than with someone who was threat inexperienced (Kulik, Mahler, & Earnest, 1994).

An important question for health care providers concerns what types of affiliations influence hospital recovery. If cognitive clarity is more important than emotional comparison, then assignment to a postoperative roommate should promote better adaptation than a fellow preoperative roommate. An initial study by Kulik and Mahler (1987) found that coronary bypass patients reported less anxiety prior to surgery, walked

more after surgery, and had a shorter hospital stay if assigned preoperatively to a roommate who was postoperative, rather than preoperative (Kulik & Mahler, 1987). A recent extension (Kulik et al., 1996) compared patients who waited alone with patients assigned to a roommate who was similar or dissimilar in type of operation (cardiac vs. low threat noncardiac) and either similar or dissimilar in operative status (preoperative vs. postoperative). In this study, the patient adapted better if a roommate had a similar (i.e., cardiac) problem. Also, patients were less anxious prior to surgery and had shorter postoperative stays if assigned to a roommate who was postoperative. In short, a roommate who presumably provided the greatest cognitive clarity (a postoperative cardiac roommate) was associated with the fastest recovery and the situation with the lowest cognitive clarity (no roommate) was associated with the slowest recovery. Although patients made some emotional comparisons (e.g., discussing their emotions about surgery prior to surgery), roommates talked about many irrelevant topics so emotional comparison was not the predominant preoccupation that Schachter's theory would predict. Second, although patients made more emotional comparisons under high than low threat with a roommate facing the same surgery, the rate of comparison did not vary as a function of the type of surgery, a finding contrary to the emotional comparison hypothesis. There was evidence of some emotional contagion; patients became more alike in their level of anxiety regardless of the similarity of the roommate's problem (Kulik, Moore, & Mahler, 1993). Emotional comparison theory would anticipate this should occur in accord with the similarity of the patients. Since this did not occur, Kulik and Mahler (1997) believed the results may best be seen as evidence for a primitive emotional contagion (Hatfield, Cacioppo, & Rapson, 1993). Although this contagion could be the result of comparison, it may also reflect a more general mimicry of facial expressions, vocalizations, posture, and body movements.

The processes that underlie the affiliation preferences and health outcomes of awaiting medical procedures with others remain to be disentangled. At the least, however, the findings suggest that information seeking via comparison may be more important to patients waiting for surgery than gauging their emotions. In this regard, and contrary to Schachter's hypothesis, fellow patients who have already recovered from surgery may create better adaptation and shorter hospital stays for the preoperative patient than assignment to preoperative patients. Further, assignment to roommates of preoperative patients may create an emotional contagion that is deleterious to patients and staff. Research to date suggests that comparison for cognitive clarity may be more critical than comparison of emotions. Hence, this may be a case where problem-focused coping on the part of the patient can be encouraged in an attempt to adapt to acute medical threats. More research needs to be conducted, however, to ascertain whether all types of postoperative patients are of equal benefit. Cognitive clarity may be undermined if a postoperative patient is a neurotic complainer or suffering postoperative complications. In any case, for health psychologists, roommate assignment is an intriguing and poten-

tially cost-effective measure to facilitate comparison in the interests of cognitive clarity and encourage adjustment in hospital.

COPING WITH CHRONIC MEDICAL THREATS VIA SOCIAL COMPARISON

Some medical threats are not acute but involve long-term adaptation to serious, and even life-threatening illnesses. Since the mid-1980s, health psychologists have actively studied the use of social comparison as a coping strategy by patients adapting to chronic health problems. One of the major inspirations for these efforts was Wills's (1981) theory that people who are threatened make downward comparisons; that is, they compare themselves with others who are worse off in order to feel better. Thus, for Wills (1987), downward comparison was an emotion-focused coping strategy (see also Gibbons & Gerrard, 1991). These ideas received support in a seminal study of women with breast cancer conducted by Wood et al. (1985). When asked how well they were adapting, nearly 80% of breast cancer patients reported adjusting somewhat better or much better than others. Among patients who did not know another woman who was in worse condition, they chose to imagine others who were adapting poorly (Taylor, Wood, Lichtman, 1983), a result reminiscent of the fabricated or constructed social comparisons discussed earlier in the section on "Norm Construction."

Since the publication of this research, there have been scores of studies assessing comparisons made by persons suffering from a variety of medical or other problems, including parents of medically fragile infants (Affleck & Tennen, 1991), patients with rheumatoid arthritis (Affleck, Tennen, Pfeiffer, & Fifield, 1988; Blalock, B. M. DeVellis, & R. F. DeVellis, 1989), physical disability (Buunk, 1995), persons trying to quit smoking (Gibbons, Gerrard, Lando, & McGovern, 1991), cardiac patients (Helgeson & Taylor, 1993), as well as cancer patients (Buunk et al., 1990; Molleman, Pruyn, & van Knippenberg, 1986). The general outcome has been that persons undergoing such health threats report a high degree of downward comparison; also, downward comparisons tend to be associated with higher emotional well-being, a result consistent with downward comparison theory. For example, arthritis patients mentioned more downward than upward comparisons (Affleck & Tennen, 1991).

However, Taylor and Lobel (1989) identified contradictory findings that did not support the predictions of downward comparison theory. In some reports (e.g., Molleman et al., 1986), medical patients under threat appeared to compare or desire affiliation with people doing better than themselves. To explain this discrepancy, Taylor and Lobel proposed that people may engage in upward affiliation to facilitate problem-focused coping by gaining information or finding hopeful or inspiring examples for identification. Downward comparisons (which need not involve actual contact), in contrast, serve as an emotion-focused strategy that improve affective well-being. This perspective seemed attractive because some empirical evidence indicates that

people rate themselves as superior to others on comparative ratings scales, but choose to affiliate and seek information from others who are superior (see Wood, 1989, for a review; also R. L. Miller & Suls, 1977; Nosanchuk & Erickson, 1985). Thus, Taylor and Lobel argued for a distinction between self-enhancement, which is served by downward comparisons, and self-improvement, which is served by affiliation with persons better off.

Not all of the evidence supports Taylor and Lobel's (1989) perspective, however (see Buunk, 1994). For example, persons in support groups for eating disorders and smoking show a preference for having others in their group who suffer more serious problems (Gibbons & Gerrard, 1991). These results suggest that sometimes people do prefer downward contacts, consistent with Will's downward comparison theory.

Recently, Wood and VanderZee (1997) proposed a reconciliation of downward comparison and Taylor and Lobel's theories. According to Wood and VanderZee, whether patients react positively or negatively to upward and downward comparisons depends on whether they believe they will improve or decline on the dimension of comparison (see Major et al., 1991). If patients believe their status will improve, upward comparison or contact will be pleasing, but if they believe they are unlikely to improve, then upward comparison should engender negative emotions. Conversely, if patients believe their condition will not decline, then downward comparison should be self-enhancing. However, patients who believe they are likely to worsen should find downward comparisons highly threatening. Hence, in this conception, both upward and downward comparisons can have either positive or negative effects. The patient's expectations of prognosis determine which outcome is most likely. Wood and VanderZee conducted a review of the available empirical evidence for their model with regard to cancer patients. Although some evidence is consistent with the model, they noted that too few studies provide a direct index of the perceived expectancy, the critical moderator.

Another related perspective on comparison and coping with chronic health threats has been presented by Buunk et al. (1990). Buunk et al., like Wood and VanderZee, also proposed that upward and downward comparisons can have negative or positive effects. They observed that when individuals learn that someone is worse off (i.e., downward comparisons), this may imply that they are not as bad off *or* that it is possible to get worse. When individuals learn that another is better off, this may imply that they are not doing as well as some others *or* it is possible to improve. In studies of cancer patients and couples experiencing marital distress, Buunk et al. found that persons high in self-esteem were better able to focus on the positive implications of both upward and downward comparisons. People with low self-esteem, in contrast, tended to draw conclusions from both upward and downward comparisons that were discouraging. People with high self-esteem tend to more optimistic, so the findings are consistent with Wood and VanderZee's analysis.

Before the relative merits of the theoretical approaches to comparison and coping can be determined, another problem needs to be resolved. Virtually all of the evidence regarding

comparisons and well-being in medical populations is based on cross-sectional, correlational methodologies. Hence, inferences about causation, confounding, and possible third variable explanations cannot be ruled out. In addition to noting this methodological problem, Tennen and Affleck (1997) argued that reports of relative standing or scores from comparative rating scales do not necessarily represent the result of downward coping efforts, but merely comparison conclusions. These conclusions may be accurate, rather than biased, because some patients will be doing well and will be veridically "better off" than others (Affleck et al., 1988). Although Tennen and Affleck are correct that longitudinal studies are needed to distinguish between comparisons and outcomes, all comparisons need not be effortful or intentional to be helpful. Patients may contemplate that "things could be worse" without intending anything beforehand; nonetheless, once patients have the thought they may seize on it for comfort.

Similarly, constructed norms may buoy a patient's spirits even if they are based on no concrete explicit comparisons. For example, Suls, Marco, and Tobin (1991) interviewed a sample of 100 senior citizens, many of whom were coping with serious chronic illnesses. After rating their health on a 4-point scale (excellent, good, fair, poor), respondents were asked to "report about the kinds of information that 'came to mind' in thinking about their overall level of health," such as whether they thought about how their health compared to someone else, to a group, with their health some time in the past, or based on direct feedback information from someone else. Sixty-seven percent of the sample reported that their health was "good" or "excellent," a result consistent with larger survey studies of elderly self-assessments of health (Levkoff, Cleary, & Wetle, 1987; B. S. Linn & M. W. Linn, 1980). Interestingly, mention of social comparison was unrelated to health ratings. Temporal comparisons were related to ratings, but in a negative direction (i.e., mentioning temporal comparison was associated with lower self-ratings of health). Because no specific, explicit social or temporal comparisons were related to the positive self-ratings, it was not obvious what factors accounted for the overwhelmingly positive health assessments. Suls et al. proposed that rather than being based on specific comparisons, the health assessments were based on implicit comparisons with a fabricated, generalized other and a stereotypical notion that most of the elderly population is quite frail and ill. Although many of the elderly respondents had serious diseases, they evaluated themselves positively because of their general stereotypes rather than a specific comparison other.

In any case, longitudinal studies are needed that include intensive assessments of the prospective relation between comparison coping efforts and subsequent outcomes (Tennen & Affleck, 1997). In this way, researchers can obtain more direct evidence of the causal relation between comparison efforts and adaptational outcomes. In addition, measures of expectancy, in accord with Wood and VanderZee's model, should be included. More attention also needs to be paid to identification of specific evaluative questions served by a given comparison (Suls, 1999). Patients diagnosed with cancer might initially ask "Will I survive this?" Upward contact

with a longtime survivor may be useful and inspiring. But other questions are more specific ("Will I become nauseous or lose my hair after radiation therapy?") and probably are best answered by people who are closer in standing to themselves. Some important concerns are in the form of "Can I do X?" In such instances, individuals might compare themselves with someone who is similar in background attributes (age, gender) who has recently gone through the procedure (Wheeler et al., 1997). Available research has conceptualized upward and downward comparisons in global terms (better vs. worse). Patients, however, probably make finer distinctions among potential comparison others both with regard to background factors and current adaptation to disease.

Although the study of comparison processes among chronically ill patients has identified an important area of coping, health psychologists still do not know what social comparison opportunities should be made available to patients and how they should be implemented. Perhaps Kulik and his associates' efforts with regard to acute medical threats (reviewed earlier) may offer suggestions in this regard. Also, more attention to the specific day-to-day evaluative questions and concerns pressing on patients and members of their support network may facilitate this active line of health psychological research.

CONCLUSIONS

This chapter has reviewed four areas of health psychology in which the role of social comparison has been strongly implicated. Classic and contemporary social psychological comparison theories and research shed light on some important medical and public health phenomena, and also provide suggestions for possible interventions. There is good reason to believe that social comparison processes will be implicated in other health psychology domains because comparison is such a fundamental aspect of social behavior. Just as advances in cellular biology and medical technology have contributed significantly to medical science and health care, it is clear that Virchow's 19th-century observation was correct—medical science is grounded in a social field.

Social Networks and Social Support

Thomas Ashby Wills

Marnie Filer Fegan

Ferkauf Graduate School of Psychology and Albert Einstein College of Medicine

This chapter considers how social support is related to physical health, including research on mortality, morbidity, and recovery from illness. During the past 10 years there has been a large amount of research showing measures of social network structure, or measures of available supportive functions, to be related to various outcomes (Belle, 1989; S. Cohen & Syme, 1985; I. G. Sarason, B. R. Sarason, & Pierce, 1990; Pierce, B. R. Sarason, & I. G. Sarason, 1996; Vaux, 1988; Wills, 1990b). During this time, there have been substantial advances in recognizing how beneficial social support can be; at the same time, this research has raised intriguing questions about how social support works.

The theme of the chapter is how social support works, because at present this question is less understood. A number of different mechanisms have been suggested as the basis for which an abstract social variable, social support, is related to objective physiological intermediaries (e.g., blood pressure) and to disease endpoints (e.g., mortality from myocardial infarction). These suggested mechanisms are most interesting from the standpoint of health psychology because they represent an interface between psychological theories of stress, coping, and affect, as well as physiological models of disease processes. Although a plethora of mechanisms has been suggested, the current evidence on the mechanism of support effects is mixed and sometimes fragmentary, so at present there is no consensus for seeing one particular mechanism as most likely. Hence the goal here is to survey the range of evidence available on social support and to suggest the relevance of possible mechanisms where they are indicated by the evidence.

This chapter is organized first by concepts about social support and then by areas of research. It first defines basic

concepts and discusses conceptual issues where debate is still occurring. Then it describes the nature of five groups of mechanisms that have been postulated to account for the relationship between social support and health, and discusses briefly the approach for testing each mechanism. The chapter then covers evidence from several areas of social support research. It begins by surveying epidemiologic studies of morbidity and all-cause mortality, and then considers research on social support effects for three specific disease conditions: cancer, diabetes, and renal failure. The chapter then considers specific topics, such as social support effects among children and adolescents, social support effects during pregnancy, and social support effects in elderly populations. A final section summarizes the current findings and discusses some questions for further research.

CONCEPTS IN SOCIAL SUPPORT RESEARCH

Social support is broadly defined as resources and interactions provided by others that may be useful for helping a person to cope with a problem. Under this broad definition, however, several different perspectives on social support are encompassed, and these are reflected in different assessment approaches and research designs. One point of divergence is whether support is conceptualized as the number of persons an individual knows, or whether support should be conceptualized as the amount of effective resources available to an individual, irrespective of the absolute number of friends and acquaintances. Another area of divergence is whether it is adequate to obtain a global assessment of a person's support, or whether it is necessary to measure specific dimensions of sup-

port provided by persons from different life domains, including spouse, friends, and workmates. The broad definition also does not guarantee that social support is only effective for persons with many problems, because it is also possible that support is effective across the board, such that persons with relatively few problems show just as much benefit as persons with many problems. Finally, the “may” in the broad definition allows the possibility that interactions regarded as supportive by the deliverer may not always be so perceived by the recipient (Coriell & S. Cohen, 1995; Rook, 1990). These varying perspectives on social support have produced several different research approaches, each with its own advantages and limitations. Although we see some approaches as more useful than others, attention is given to all of these perspectives in the course of the chapter. The following sections discuss some basic terms and concepts in detail.

Structural Versus Functional Measures

First is the distinction between *structural* and *functional* aspects of support. Structural and functional measures involve different theoretical assumptions about the basis for effects of support, with structural measures giving emphasis to the total number of linkages people have in their community. Structural measures assume it is the quantity of established, regular social connections that is important, and that the range of connections with different parts of the community may also be informative. Structural measures include items asking about the existence of primary social relationships, such as being married or having relatives and children who live nearby. They also tap frequency of visiting with neighbors and talking with friends, either in person or on the telephone (or, these days, by Internet). Other items in typical structural measures tap the existence of normative social roles, such as being employed and belonging to community organizations. These items can be combined to produce indices for the total size of a person’s network, the number of different social roles a person occupies, and other indices such as the percent of kin in the network or the number of network members who know each other (Hall & Wellman, 1985). The goal of such indices is to provide a quantitative measure of the number of social network connections. Analyses for structural measures are typically based on the total score for social connections, but investigators have sometimes performed separate tests for component indices to determine whether particular types of social connections might be differentially beneficial for men and women (e.g., Berkman & Syme, 1979; House, Robbins, & Metzner, 1982). It should be noted that a structural measure does not ask about the quality of the existing relationships, nor does it ask about what resources the network members provide.

Functional measures are based on the assumption that it is the quality of available resources that is most important, hence these measures aim to assess the extent to which supportive functions are available to an individual (Wills, 1985). In contrast to structural inventories, functional measures ask about the availability of a particular function (e.g., ability to confide with somebody about problems and worries). They do not necessarily determine who the support comes from (al-

though some inventories do assess availability of emotional support from different sources), but rather focus on whether support is available if needed.

Functional inventories typically include multi-item scales to assess the perceived availability of each of several supportive functions. Scales for *emotional support* (also termed appraisal, confiding, ventilation, or esteem support) have items that ask whether there are persons with whom you can share fears and worries, persons with whom you can talk about problems freely, and persons who make you feel understood and accepted. Scales for *instrumental support* (also termed tangible, material, or practical support) ask whether there are persons who could provide assistance with financial problems (i.e., lending money), transportation, repairs, housework, or child care. Scales for *informational support* (also termed advice, guidance, or feedback) include items asking whether there are persons available who can provide useful information and can make suggestions about relevant resources and alternative courses of action. Scales for *companionship support* (also termed belonging) include items that ask whether there are persons available for companionship with various kinds of leisure activities, such as going to movies, sporting events, theaters or museums, hiking, or boating. From these scales, subjects would receive a total score for emotional support, for example, based on their cumulative responses to the availability of different aspects of this function. It is typical to find scores for the different dimensions of functional support substantially correlated; for example, individuals with higher scores for emotional support also tend to have higher scores for instrumental and informational support. Whether this is attributable to perceptual factors, personality influences, or individual differences in the ability to recruit supporters has not been entirely worked out (see S. Cohen, Sherrod, & Clark, 1986; Coble, Gantt, & Mallinckrodt, 1996); for this reason, investigators often test unique effects of different dimensions as well as the total functional support score.

There are two interesting facts about structural and functional measures: They are not highly correlated, and they are both related to health outcomes. The first fact is initially puzzling to some, who assume that the more persons an individual knows then the more support they must have available. The probable explanation for the low correlation of structural and functional measures is that the existence of a relationship does not provide much information about the quality of that relationship (Wills, 1991); it is possible that people with a relatively small social network may still have available a large amount of esteem support, instrumental support, and so on, because of the nature of their relationships. The fact that both structural and functional measures are related to health outcomes is still not well understood. There are reasons to believe that structural and functional support contribute to health status through different mechanisms, but this question has not been entirely explicated.

Main Effects Versus Buffering Effects

A second issue in social support research is whether social support is primarily useful to persons experiencing a high

level of life stress, or whether support is useful irrespective of a person's stress level. The issue is a basic one for social support researchers because it directs attention to the question of what kind of process is involved in the operation of support. This question has been examined in studies that include both a measure of social support and a measure of life stress, and therefore can test for whether effects of support are dependent on stress level (S. Cohen & Wills, 1985).

The first possibility is usually termed the *main effect model* because it is demonstrated by a statistical main effect, indicating that support is equally beneficial to persons with low or high stress. The second possibility, termed the *buffering model*, is demonstrated by a Stress \times Support interaction effect, indicating that the effect of support is much greater for persons at a high level of stress. The terminology derives from the portrayal of support as a buffer that protects a person from the potentially adverse impact of negative events. Whereas buffering effects have frequently been observed in studies that used good functional measures and sizable samples, main effects are more typical for structural measures, and a main effect model has been observed in some other conditions (S. Cohen & Wills, 1985; Wills, 1991; Wills, Mariani, & Filer, 1996).

Matching of Functional Support to Needs

A theoretical issue that has been prominent in research on functional measures is what is known as the *matching hypothesis* (S. Cohen & McKay, 1984; Cutrona & Russell, 1990). Given the definition that support functions are useful for helping persons to cope with problems, the question arises concerning whether particular functions are best matched with specific needs; if so, then the availability of specific functional dimensions would be particularly helpful for persons who had a specific need. For example, a subgroup of persons within the general population might have adequate self-esteem but experience high financial stress because of unemployment, low income, and so on. In this case, it might be hypothesized that the availability of instrumental support, including financial aid or in-kind services, would be the primary (or only) useful function for these persons. Situations can be imagined in which functions such as emotional or informational support would be most useful, and the effectiveness of the available support would depend on the match between the functions provided by individuals' relationships and the needs evoked by their problem.

The status of the matching hypothesis remains an intriguing question for research. There have been some studies showing that buffering effects occur only for situations predicted by the matching hypothesis (e.g., Peirce, Frone, Russell, & Cooper, 1996). However, studies with functional inventories typically find emotional support to be a broadly useful function (Wills, 1991), even in situations where it might not be expected to be particularly useful (e.g., Krause, 1987). Current research is trying to extend this work through delineating the support needs evoked by particular kinds of life events, and through developing and testing theory on how functional support actually works.

Where Support Acts in the Disease Process

A question of particular importance is where in the disease process social support acts. Does it act primarily to prevent development of risk factors among those who are healthy? Does it act to retard the onset of a clinical disease episode among persons who have accumulated risk factors? Or, does it reduce disease severity and speed recovery among those who have suffered a disease episode? Each of these models is important from a health standpoint, but would represent quite different modes of operation (Cohen, 1988).

An answer to the question depends on several types of findings. If support were strongly related to incident disease (onset of new illness among those initially healthy), this would imply that the protective effect of support occurs early in the disease process. If support were more strongly related to prevalent disease (cases of existing illness), this would imply that effects of support occur later in the disease process, either through reducing the severity of disease among those originally affected or by enhancing recovery from disease.

The question of where support acts in the disease process is not easily answered, because chronic diseases such as CHD have onset periods that span a decade or more, whereas infectious diseases like as upper respiratory infection have a period of a few days from exposure to infection to recovery. Long-term prospective research and short-term intensive studies each have advantages and disadvantages, and accordingly the question cannot be completely answered by any single study. A full understanding of the question requires cumulated findings from many sources, and is only beginning to emerge. The most recent evidence has shown social support strongly related to recovery from disease, but there is also some evidence for protective effects of support at earlier points in disease processes. This issue is discussed at several points in the chapter.

THEORETICAL MECHANISMS AND MODELS OF ANALYSIS

How is support related to health? In theory, social support could be related to physical health through several different mechanisms. These are not mutually exclusive but are discussed in terms of three general categories. In addition, alternative theoretical mechanisms are appropriately analyzed through different statistical models. The following section first describes two statistical issues relevant for testing different types of theoretical mechanisms, and then discusses theoretical mechanisms through which social support is currently believed to operate.

Statistical Models: Buffering Effect Versus Main Effect

As noted earlier, support could be beneficial to persons irrespective of their stress level, or alternatively, support could be most useful to persons currently experiencing a high level of stressful events. Evaluating these modes of operation requires

a study that includes reliable measures of life stress and social support, has adequate variability in both of these predictors, and has a reasonable criterion measure of health status. Testing the statistical models can be done with analysis of variance using dichotomized predictors and testing the Stress \times Support interaction effect, or in multiple regression using continuous predictors and testing the cross-product term for stress and support. The latter procedure is preferable because it typically increases statistical power (J. Cohen & P. Cohen, 1983).

Examples of a pure main effect, a partial buffering effect, and a complete buffering effect are presented in Fig. 12.1, which shows possible effects of social support at different levels of stress. If support operates as a main effect relationship, then persons with higher support have more favorable health status, and the effect of support is comparable at low stress and at high stress (Fig. 12.1A). If support operates as a buffering effect, then the impact of life stress on symptomatology is reduced for persons who have high social support. A partial buffering effect is presented in Fig. 12.1B. Here, high support reduces the impact of stress but there is still a significant effect for stress; that is, persons with high stress and high support still have significantly more symptomatology than persons with low stress and high support. A complete buffering effect is presented in Fig. 12.1C; here, support completely eliminates the effect of life stress so that persons with high stress and high support are not significantly different from those with low stress and high support.

Note that detection of most interaction effects has greater power requirements than detection of main effects (Aiken & West, 1991). For this reason, it is desirable for a study testing buffering effects to have a sizable sample in order to have adequate power for detecting this type of interaction (McClelland & Judd, 1993). It is still not uncommon to see studies that

found no significant interaction effect, and then rejected the buffering hypothesis, in situations where the sample was so small that power was inadequate for detecting this type of interaction.

Statistical Models: Direct Versus Indirect Effects

Another statistical issue is the distinction between direct and indirect effects (Baron & Kenny, 1986). It is possible that support acts directly on variables relevant for health status, such as blood pressure; in this case, support has a *direct effect* on the criterion. Alternatively, it is possible that beneficial effects of support are transmitted through an intermediary variable; for example, support could be related to more effective preventive health behaviors and this would result in sustained reduction in blood pressure. In this case, support has an *indirect effect* on the criterion, mediated through preventive behavior. Evaluating these modes of operation requires a study that includes measures of variables believed to be possible mediators of the effect of support. Testing for the existence of direct and indirect effects can be analyzed in procedures such as path analysis or structural modeling (B. M. Baron & Kenny, 1986; Wills & Cleary, 1996, 1999).

The distinction between direct and indirect effects is diagrammed in Fig. 12.2 with respect to hypothetical variables: a support predictor S, one or more possible mediators (Ms), and an outcome measure O. It is important to recall that social support is related to better health status in both cases. However, in a direct effect model, the support predictor S is related to the outcome O and its mode of action does not involve any intermediate variable (Fig. 12.2A). In an indirect effect model, the support predictor S is related to an intermediate variable M, which in turn is causally related to the outcome O;

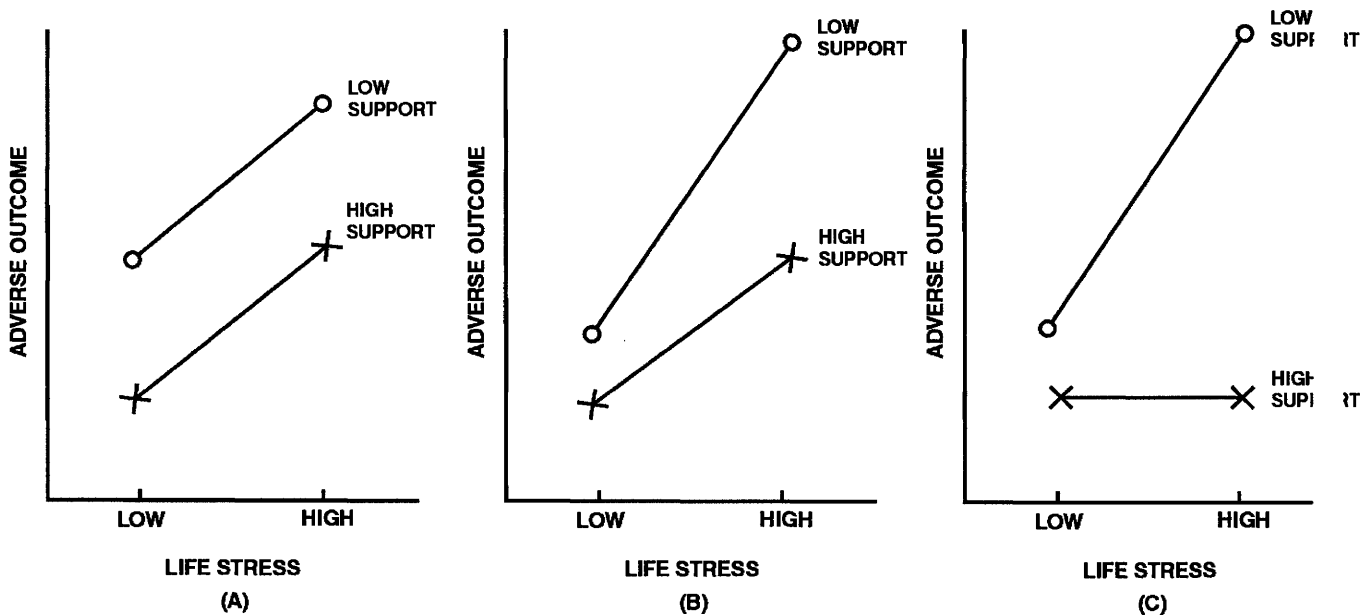

FIG. 12.1. Illustrations of main-effect vs. buffering results for persons with low vs. high stress and low vs. high support: (A) main effect result, (B) partial buffering result, (C) complete buffering result.

this is sometimes termed a *mediated relationship* because the effect of social support is transmitted through the mediator (Fig. 12.2B). Mixed models are possible, in which support has an indirect effect and also a significant direct effect (for more discussion see Wills & Cleary, 1996; Wills, McNamara, & Vaccaro, 1995).

Physiological Mechanisms

Seven mechanisms, which are illustrated graphically in various parts of Fig. 12.3, are described with respect to theoretical mechanisms. Two variant mechanisms posit that support acts directly on physiological variables. One mechanism posits that the presence of other persons has a calming effect that is essentially innate because of evolutionary processes for social species. Other things being equal, individuals would be more relaxed and in a more positive affective state when other persons were around, compared with when they were alone or isolated from others. This could be construed as a direct effect in that relaxed states and positive affect could be related to a range of physical variables conducive to health (Fig. 12.3A).

The second mechanism posits that good support is related to better immune system functioning (e.g., more proliferative T4 cells or natural killer cells) through reducing levels of depression and anxiety in times of stress. This would really be construed as an indirect effect because support acts on anxiety/depression which in turn acts on the immune system. To analyze this mechanism it is necessary to show that support is related to lower depression, which in turn is related to better

immune system function, which in turn is related to lower likelihood of infectious or other disease (Fig. 12.3B).

Appraisal and Reactivity Mechanisms

For the appraisal mechanism, it is posited that the knowledge that support is available to cope with problems makes persons appraise stressors as less severe. Because of the less severe threat appraisal, persons then would be less depressed/anxious when subjected to life stressors. This mechanism would be analyzed by measuring individuals' cognitive appraisals of stress and showing that these appraisals were linked to anxiety/depression. This would be construed as an indirect effect because the buffering effect of support occurs through altering the cognitive appraisal (Fig. 12.3C).

For the reactivity mechanism, it is posited that having support available makes persons less physiologically reactive (i.e., less change in heart rate and blood pressure) when subjected to acute stressors, and hence makes them less prone to disease conditions that are linked to cardiovascular reactivity, such as hypertension. Unlike the direct calming effect, this mechanism should be relevant only in times of stress, and would be analyzed by showing physiological reactivity was moderated by the availability of social support (Fig. 12.3D).

Behavioral Mechanisms

Linkage to Fewer Harmful Behaviors. One type of behavioral mechanism posits that high social support is re-

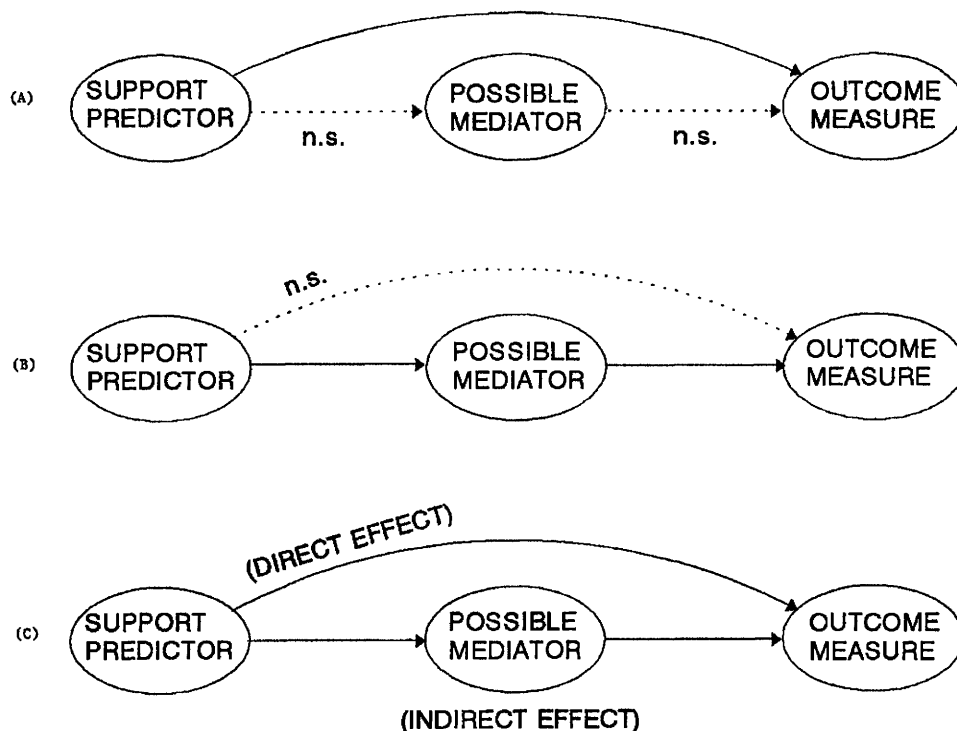

FIG. 12.2. Illustration of types of relationships between social support and health outcomes. (A) Direct effect. (B) Fully mediated effect. (C) Partially mediated effect.

lated to lower levels of harmful behaviors that are relevant for health risk (Fig. 12.3E). For example, persons with high support could be less likely to smoke cigarettes, or less likely to engage in heavy alcohol consumption and/or binge drinking (Wills, 1990a). In analyzing this mechanism it would be shown that support is related to lower levels of smoking and alcohol use, and that substance use is the primary causal factor in relation to subsequent adverse health outcomes.

Linkage to More Protective Behaviors. Two variant mechanisms posit that social support is linked to patterns of behavior that lead to better health outcomes. In one mechanism (Fig. 12.3F), it is posited that support is related to more help seeking in times of stress and greater access to preventive services in the community (e.g., cancer screening, regular physician visits). This would be expected to reduce mortality rates. In analyzing this mechanism it would be shown that support was related to more help seeking and medical service utilization,

and the latter was related to physical health status (Wills & DePaulo, 1991). The second mechanism (Fig. 12.3G) posits that having good social support enables persons to cope more effectively with problems and hence reduces anxiety/depression in times of stress (Thoits, 1986). This mechanism would be analyzed by showing that support is related to patterns of coping with problems, and coping in turn was related to less anxiety/depression and better physical health.

EPIDEMIOLOGIC STUDIES

Research with large samples from the general population initially drew wide attention to social support through demonstrations that support was prospectively related to lower mortality (Berkman & Syme, 1979; House et al., 1982). Subsequent studies broadened the base for the field through demonstration of similar effects across age groups and national populations.

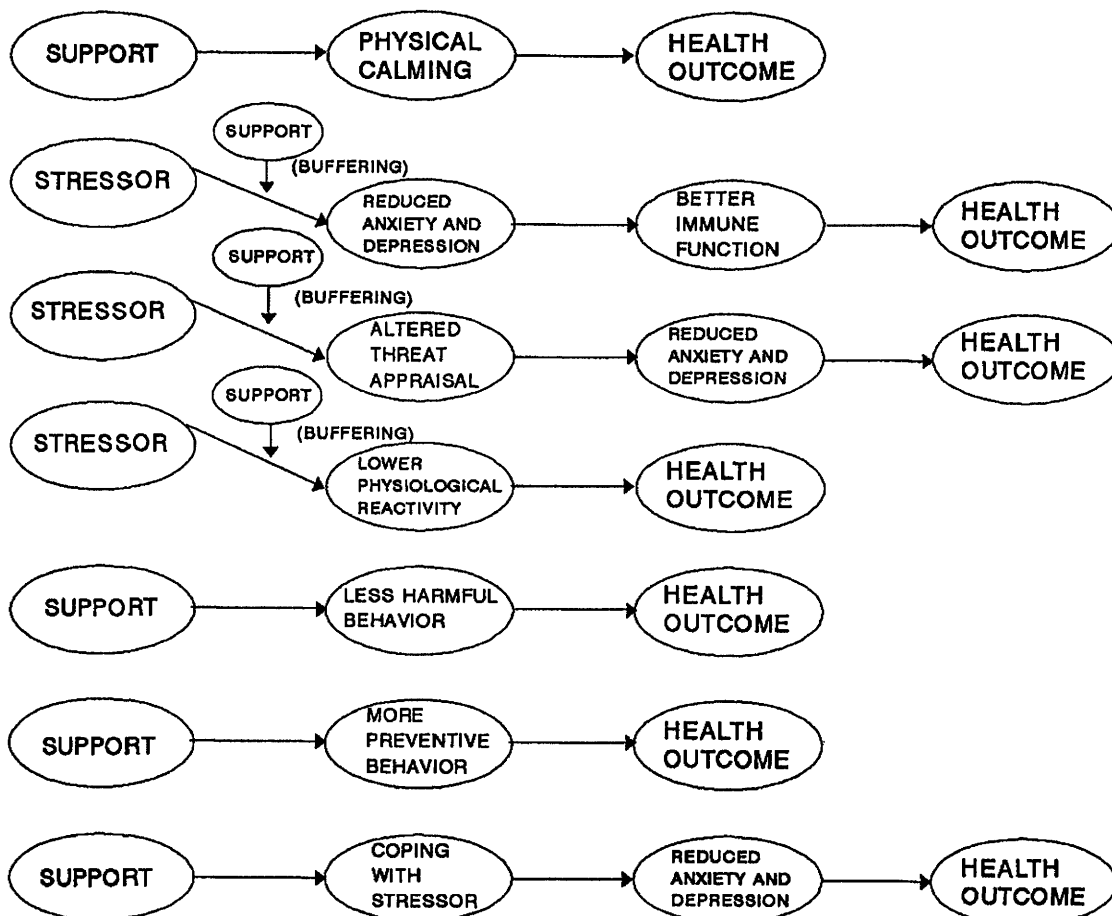

FIG. 12.3. Illustration of possible theoretical mechanisms of support–health relationships. (A) Support acts directly on physiological variable. (B) Support has an indirect effect on immune function, mediated through anxiety/depression. (C) Support has an indirect effect on anxiety/depression, mediated through cognitive appraisal of stressors; anxiety/depression is then related to health outcome. (D) Support reduces physiological reactivity when a stressor is encountered; reactivity is then related to health outcome. (E) Support is indirectly related to health status through a relation to health-harmful behavior, which is then related to the health outcome. (F) Support is indirectly related to health status through a relation to preventive behavior, which is then related to the health outcome. (G) Support is indirectly related through influencing coping, which then affects level of anxiety/depression.

These studies are discussed in some detail because they are essential for understanding the epidemiologic evidence on social support and health (House, Landis, & Umberson, 1988). The focus is on prospective studies in which a sample of participants is examined at a baseline measurement; the sample is then followed for a period of several years, and the health status of the participants at the follow-up point is determined. The studies typically include measures for demographics and baseline health status, used as control variables to test the possibility that low support at baseline is attributable to a demographic third factor (e.g., low income) or is a consequence of preexisting illness. Significant effects of social support are commonly found with control for possible confounders, so all this evidence is not discussed in detail. This section first discusses studies of prevalent disease conducted with general population samples and samples of elderly persons, and then discusses studies on incident disease and recovery from illness.

Social Networks and Mortality in General Populations

A number of prospective studies using social network measures have been conducted, with follow-up periods ranging from 5 to 9 years (Berkman & Syme, 1979; Blazer, 1982; B. S. Hanson, J. T. Isacsson, Janzon, & Lindell, 1989; House et al., 1982; G. A. Kaplan et al., 1988; Orth-Gomer & Johnson, 1987; Schoenbach, B. H. Kaplan, Fredman, & Kleinbaum, 1986; Welin et al., 1985; Welin, Larsson, Svärdsudd, B. Tibblin, & G. Tibblin, 1992). The social network measures indexed the existence of a range of social connections as described previously. The outcome was mortality status at follow-up as verified through death certificates, usually with close to 100% ascertainment. The results consistently showed number of social connections to be inversely related to mortality rate, and although results tend to be stronger for men than for women, significant effects have been observed for both genders. In some cases, the investigators analyzed the network measure as a total scale (e.g., G. A. Kaplan et al., 1988; Orth-Gomer & Johnson, 1987), whereas in other studies analyses were performed both for the total network score and for each of the component items (Berkman & Syme, 1979; House et al., 1982). Most component items show significant relationships to mortality, indicating that effects are not simply driven by a particular aspect of social networks.

Researchers have examined the question of whether the effect of social networks represents a *gradient effect*, with progressive reduction in mortality for each higher level of social connections, or a *threshold effect*, such that elevated mortality is found only for persons with few social connections and no effects are observed at higher levels. The studies are somewhat divided on this, with some investigators reporting results that resemble a threshold effect (e.g., House et al., 1982). However, other studies have shown a clear gradient effect, with a continuous reduction in mortality rates across increasing levels of social connections (e.g., Berkman & Syme, 1979; G. A. Kaplan et al., 1988; Welin et al., 1985), and some studies have found gradient effects for specific causes of

death (e.g., cardiovascular disease) occurring together with threshold effects for mortality from cancer (Welin et al., 1992). The repeated findings of gradient effects suggest that the protective effect of social network does not occur just for a small group of socially isolated persons.

Functional Support and Mortality

Although the initial research in the area predominantly used structural measures, some studies have tested whether functional measures have value for predicting mortality. Blazer's (1982) study of a U.S. elderly sample included both structural and functional measures; results indicated that a measure of perceived support (e.g., availability of a confidant, availability of instrumental assistance) was a strong inverse predictor of mortality, independent of a variety of demographic and biomedical controls. Here the structural measures were nonsignificant when tested with the functional measure, suggestive of an indirect effect, with social connections contributing to greater emotional and instrumental support and the latter being proximal protective factors. These findings were extended in European studies. B. S. Hanson, J. T. Isacsson, Janzon, and Lindell (1989) included scales for the perceived availability and adequacy of emotional support and of instrumental/informational support. They found a significant effect for the former measure: Men with low emotional support had 2.5 times the risk of mortality over the study period, controlling for demographic status and a variety of biomedical variables.

Buffering effects were analyzed with data for male participants from the Malmö study (Falk, B. S. Hanson, Isacsson, & Ostergren, 1992). Both structural and functional measures were tested as possible buffers in relation to a measure of stress from job strain. The job stress measure itself showed a significant relationship to higher risk of mortality. Results for the support measures showed a relative risk of 3.6 for men with high stress and low emotional support, and 1.2 for those with high stress and high emotional support; thus a buffering effect was demonstrated. An analogous effect was found for the structural measure (termed *social participation*; from B. S. Hanson et al., 1989), with risks of 2.6 and 1.3, respectively. Hence, in this study, both the structural measure and the functional measure showed evidence of buffering effects, although the measures were not analyzed together.

A recent analysis from the Gothenburg study also tested for buffering effects with an all-male sample (Rosengren, Orth-Gomer, Wedel, & Wilhelmsen, 1993). A measure of 10 negative life events was obtained at a baseline assessment together with an interview designed to assess the availability of emotional support from close relationships and from a variety of peripheral social relationships (termed *social integration*, but not directly analogous to a social network measure). Over four levels of life events the range of mortality rates was 15.1 for men with low emotional support and 1.2 for men with high emotional support; hence these data indicate a buffering effect of emotional support with respect to mortality. For the social integration measure, no buffering effect was found.

Support and Health in Elderly Samples

Research focusing on health in samples of older persons is of additional importance because the burden of chronic illness is greater among these persons. Research conducted in recent years has corroborated the relevance of social network measures for the health status of elderly persons. For example, Seeman, G. A. Kaplan, Knusden, R. Cohen, and Guralnik (1987) analyzed data from a 17.5 year follow-up of subjects from the Alameda County study who were age 38 or older at baseline. They found that the overall social network index was inversely related to mortality for both men and women. A study conducted in an urban area in Finland (Jylhä & Arö, 1989) followed an urban sample and obtained multi-item scales for social contacts (i.e., frequency of visiting) and outside-home social participation (similar to Welin's scale for outside-home activities) in addition to single-item measures for marriage, children, and loneliness. A continuous score for social participation was inversely related to mortality, again with significant results for both men and women. A study with a U.S. national sample (Steinbach, 1992) found a social participation index prospectively related to lower likelihood of both institutionalization and mortality, and these findings were obtained with control for demographic characteristics and health status at baseline. Persons with higher social participation were half as likely to experience an adverse outcome. Another study focusing on a sample of rural elderly in France (Grand, Grosclaude, Bucquet, Pous, & Albarede, 1990) observed protective effects for a social network scale indexing membership in community groups; a scale for close relationships (marriage and children) was marginally significant, but this was probably attributable to a sample size that was relatively small in comparison to other studies.

Beneficial effects of social support have also been indicated in research conducted with Asian populations. For example, Ho (1991) conducted a 2-year follow-up with a sample in Hong Kong age 70 or older. Measures were obtained for marital status, social contacts, community integration, participation in family and community events, and instrumental support. All of the social network indices were inversely related to mortality, but the instrumental support measure was nonsignificant. A study based on a representative national sample of Japanese elderly (Sugisawa, Liang, & Liu, 1994) is of interest because the investigators tested for both direct and indirect effects of support. This study used structural measures, including scales termed *social contact* (average frequency of visiting with children, relatives, and friends) and *social participation* (organizational membership and attendance), and also obtained a brief functional scale indexing the availability of caring and confiding. The investigators tested whether support measures were related to health status through intermediate variables including functional disability and cigarette smoking. Some evidence for indirect effects was observed; for example, social contacts and social participation were inversely related to functional disability, and being married was inversely related to cigarette smoking. The social participation scale showed a direct effect, that is, it was inversely related to mortality independent of all the interme-

diated variables (and of demographic and biomedical controls). These analyses suggest indirect effects for marriage and social contacts, operating through different pathways than the direct effect for social participation.

Social Support and Incident Disease

The previous section covered studies that showed a relation between social support and prevalent disease (i.e., mortality from cardiovascular disease, cancer, or other causes). What evidence is there that social support is relevant for disease onset? This question is addressed by studies of incident disease, examining (in longitudinal research) whether social support predicts onset of new disease among those who were initially healthy.

The number of studies on incident disease is still relatively small. One is a study conducted in Honolulu, Hawaii, in which a cohort of males of Japanese ancestry was followed over 7 years (Reed, McGee, Yano, & Feinlieb, 1983). A nine-item structural scale assessed social connections with relatives, coworkers, and religious and social organizations. The social network score was significantly inversely related to existing disease at baseline (i.e., prevalent disease) and this was true for several types of disease including myocardial infarction and angina. Analyses for 7-year onset of heart disease among those initially disease free showed social network to be inversely related to new disease, but analyses with biomedical controls reduced this effect to nonsignificance. In contrast to this are findings from a study in Gothenburg, Sweden (Orth-Gomer, Rosengren, & Wilhelmsen, 1993), where the study group was 736 men who were ascertained to be disease free at baseline and were followed up 6 years later. Both a score for emotional support and a score for social integration were significantly inversely related to incident heart disease, analyzed with biomedical controls. The marginal results in the Honolulu study may have been attributable to the fact that heart disease is less common in Japanese populations, so the lower rates make it difficult to detect the smaller number of disease onset events.

A study examining both prevalence, incidence, and survival from illness was conducted by Vogt, Mullooly, Ernst, Pope, and Hollis (1992), who followed a sample of HMO members over a 15-year interval and used medical records to determine both prevalent and incident disease, including cardiovascular disease (ischemic heart disease, hypertension, stroke) and cancer. A 26-item inventory administered at baseline assessed social connections with family, friend, and community networks, and was scored for three indices termed network size, network scope, and frequency of interaction. Health measures and outcomes were assessed through search of HMO records and state vital statistics. The network scores were independent predictors of 15-year mortality; the strongest effect was for network scope, with a relative risk of 6.7 for those in the lower versus upper thirds of the distribution. However, incidence analyses, predicting 15-year disease hazard among those disease free at baseline, were largely nonsignificant; only network scope was related to significantly lower incidence for one disease. These investigators

were also able to analyze predictors of survival through examining the subsequent experience of persons with a new disease episode. Findings indicated that higher network scores predicted increased survival; this was found for heart disease, cancer, and stroke. The contrast between results for incidence and survival analyses drew attention to a possible role of social support for enhancing recovery from illness.

Support and Recovery from Illness

Because evidence showing social support inversely related to mortality is strikingly consistent but evidence for a relation of support to disease onset is minimal, the question of social support and recovery from illness assumes particular theoretical importance for understanding the way support operates. Evidence on this question is available from several previous studies and has been a focus of recent research. In studies of recovery, the participants typically are patients recruited at the time of hospitalization for a disease episode; the criterion variable is degree of recovery from disease or survival time after an initial disease episode. The available studies vary considerably in characteristics such as sample size, length of follow-up, and nature of the support measures. Here emphasis is given to studies with larger samples and longer follow-up times, although some attention is given to other studies that illustrate interesting points.

A study with strong design characteristics was conducted by Williams et al. (1992). The investigators followed a large sample of patients for an average of 9 years after intake. At intake all the participants had significant coronary artery disease, as indicated by angiography findings showing greater than 75% stenosis of at least one major artery. The support indices included being married, having a confidant, and visiting with friends and relatives. The predictive analyses focused on survival time after intake and included a medical risk score composed from 10 physical variables measured at intake and shown empirically to be significant predictors of survival. Results showed that patients who were unmarried and without a confidant had a significantly lower survival rate (50%) compared with those having high support (82%); control analyses showed this result was independent of medical risk and of the patient's economic resources. The findings of Williams et al. (1992) were consistent with a study of an all-male sample followed for 3 years (Ruberman, Weinblatt, Goldberg, & Chaudhary, 1984), which found elevated mortality for persons with a high score on life stress and a low score for social networks (based on visiting friends and relatives, and belonging to a social club, fraternal organization, church, or temple). This latter result suggests a stress buffering effect for social networks, but Ruberman et al. (1984) did not conduct a formal test for interaction. Other studies have used a specific indicator, marital status, and have indicated that survival times after myocardial infarction are longer for married individuals (Chandra, Szklo, Goldberg, & Tonascia, 1983; Wiklund et al., 1988). It is noteworthy that several of these studies found significant protective effects of support for both men and women.

A report by Berkman, Leo-Summers, and Horwitz (1992) from their study of elderly persons is of interest because it is

based on a community sample followed over time (as in Vogt et al., 1992). These investigators focused on a group of 165 participants who were hospitalized for acute myocardial infarction during the ongoing study. A noteworthy aspect is that the support measures were from an interview conducted prior to the illness episode, unlike other studies where support measures were typically obtained after hospitalization; so these data are truly prospective. Support measures included a social network index and a three-level functional index reflecting the number of persons who were available to talk about problems. Results showed that persons with greater emotional support were more likely to survive over a 6-month period, and emotional support was related to survival at all points during the follow-up interval. Persons with high support were about three times as likely to survive compared to those with low support, an effect size comparable to effects for several medical risk factors measured in the study. A similar trend was noted for the social network index but was not significant.

Several studies have obtained criterion measures directly assessing the patient's extent of recovery from heart disease, such as physical activity limitations and recurrent symptomatology. King, Reis, Porter, and Norsen (1993) measured different aspects of functional support in a sample of coronary artery surgery patients followed for 1 year after the operation. Predictive analyses showed esteem and companionship support most consistently related to outcomes (i.e., greater well-being, less functional disability, fewer angina symptoms); some effects were also observed for instrumental support. Helgeson (1991) obtained structural and functional measures with a sample of myocardial infarction patients followed for 3 months to 1 year after the illness. A functional measure (emotional support from spouse) was inversely related to angina symptoms and rehospitalization and positively related to perceived health; the structural measure was not significantly related to any criterion. A series of reports by Kulik and Mahler (1987, 1989, 1993) was based on a sample of patients recovering from coronary bypass surgery. The investigators obtained a measure of general emotional support from spouse through a rating of marital satisfaction and a recording of the proportion of days the spouse visited the patient in the hospital. Results showed that the combination of good marital relationship and high visiting was related to less pain medication usage after surgery and faster release from the hospital. Data from 13-month follow-up indicated emotional support predicted better quality of life, more ambulation, and less cigarette smoking at follow-up. Marital status was not significant in these analyses when its correlation with emotional support was statistically controlled, suggesting an indirect effect. It should be noted that functional support is also related to recovery from mental illness, with or without concomitant psychotherapy (see, e.g., Billings & Moos, 1985; Cross, Sheehan, & Khan, 1980; Dadds & McHugh, 1992; Moos, Finney, & Cronkite, 1990), but there is relatively little research on this topic.

Research on social support and recovery from cancer is more complex (see Helgeson, S. Cohen, & Fritz, 1998; Reifman, 1995). The epidemiologic research in this area has been dominated by studies of marital status, which is at best a

proxy for functional support. The literature includes a study of 1,262 persons followed for a 10-year period, which found marriage related to longer survival time for breast cancer (Neale, Tilley, & Vernon, 1986), and a study of 25,706 cases with various types of cancers (J. S. Goodwin, Hunt, Key, & Samet, 1987), which found a survival advantage for married persons, controlling for the fact that married persons were likely to be diagnosed at an earlier stage of cancer (which suggests a behavioral mechanism). However, several studies have found no significant survival effect for marital status (e.g., Cassileth et al., 1985; LeMarchand, Kolonel, & Nomura, 1984), and although these tend to be with smaller samples with more severe disease and shorter follow-ups, they indicate some inconsistency in the literature.

Marital status is only one index of social connections, so it is important to discuss studies that have obtained more extensive measures of social networks. Two studies have found social network measures related to longer survival time, one with a sample of 208 patients followed for 20 years (Funch & Marshall, 1983) and one with a community-based sample of 339 cancer cases followed for 17 years (Reynolds & G. A. Kaplan, 1990). This research is augmented by evidence from studies with smaller samples and follow-ups, which show cancer survival time related to measures of social participation (Hislop et al., 1987), contacts with friends (Waxler-Morrison, Hislop, Mears, & Kan, 1991), and social integration (Ell, Nishimoto, Mediansky, Mantell, & Hamovitch, 1992). These studies found social network measures predicted survival time with control for demographics and for medical variables such as stage at diagnosis. The minimal evidence for support effects on cancer incidence (Helgeson & Cohen, 1996) contrasts with the general robustness of findings on survival time, and indicates this as a promising area for investigation.

SPECIFIC AREAS OF RESEARCH

The following sections discuss some specific areas of research on social support. The aim of this section is both to show the scope of research efforts and to give consideration to the mechanisms of how support works.

Specific Disease Conditions

Social Support and Adjustment to Cancer. The potential role of social support for helping persons with cancer has been a significant focus of research. This has been true both because of the severity of the disease and because adjustment involves both issues of coping with emotional distress and of dealing with interpersonal relationships. Research on how social support facilitates adjustment to cancer has included studies on specific support functions as well as several intervention studies with peer support groups (see Helgeson & S. Cohen, 1996).

Several studies have examined how supportive functions from family members and medical professionals may be relevant for persons with cancer. These studies concur in finding that emotional support is the function desired from family

members, particularly with respect to discussing fears and concerns about the disease (Dakof & Taylor, 1990; Dunkel-Schetter, 1984; Rose, 1990). In contrast, patients want informational support from medical professionals but do not want it from family members. An important aspect of this research has been the finding that emotional support may be inhibited in family settings through a reluctance of family members to talk about the disease, because of fear that it will be upsetting to the patient; but it is exactly this aspect of support that patients themselves say they find most helpful. Probably for this reason, the patients in these studies rate emotional support from family members as helpful but sometimes inadequate, and report they may keep their thoughts and feelings to themselves because other people do not want to hear them.

Social support has been shown related to indices of better adjustment to illness, such as reduced anxiety, increased self-esteem, or better functional ability. Emotional support has been found related to better adjustment in breast cancer patients in both concurrent studies (e.g., Zemore & Shepel, 1989) and longitudinal research (e.g., Northouse, 1988). In the few studies that compared different support functions, emotional support is typically shown to be related to adjustment but effects for instrumental support are sometimes nonsignificant (e.g., Primomo, Yates, & Woods, 1990). It should be noted that there has been little research using multi-dimensional functional inventories with good psychometric properties, and conclusions about the differential effects of support functions accordingly are somewhat qualified. Investigators have suggested that effects of emotional support on adjustment to illness are mediated through reduced emotional distress and improved coping (cf. Ell et al., 1992). Although this inference is plausible, explicit mediation tests of these mechanisms have not been conducted.

The evidence showing support measures related to reduced emotional distress and increased survival has motivated several intervention studies designed to enhance the well-being of cancer patients. Methodological characteristics in this literature are quite variable and several studies used brief interventions or lacked reasonable control groups (see Helgeson & S. Cohen, 1996). Two studies with true randomized designs and intensive interventions have shown positive results. A notable study by Spiegel, Bloom, Kramer, and Gottheil (1989) involved a peer support group conducted over a 1-year period for patients with advanced breast cancer. The group sessions were facilitated by a professional leader and were intended to provide emotional support through frank sharing of feelings and experiences, as well as expressions of reassurance and caring. A 10-year follow-up of the sample found that support group participants had significantly increased survival time compared with control participants. Analyses were conducted to test whether the survival advantage was attributable to reduced emotional distress, but these results were inconclusive.

A randomized study by F. I. Fawzy et al. (1990, 1993) was conducted for patients with melanoma. The patients received education about the disease, received instruction from staff members about stress reduction and coping strategies, and

participated in group discussion with other patients and a group facilitator. Results indicated that patients who received the intervention showed reduced psychological distress, enhanced immune system function (e.g., natural killer cell activity), and increased survival at 6 years. Similar to the Spiegel et al. (1989) study, this research involved a true randomized design, and the results of these two studies together have been provocative.

This discussion is not meant to minimize the impact of educational interventions, which focus on providing information about the disease and its treatment. These have been shown to have a significant effect on treatment compliance and survival time in cancer patients (e.g., Richardson et al., 1987; Richardson, Shelton, Krailo, & Levine, 1990). Some studies included group educational experiences (Helgeson & S. Cohen, 1996) and a study by Helgeson, Cohen, Schulz, and Yasko (1999) found a group education condition had more beneficial effects than a peer support condition.

Social Support and Adjustment to Arthritis. Arthritis is a chronic disease that involves unpredictability and interference with daily activities as well as recurrent pain. Supportive relationships, particularly with spouses, may be relevant for facilitating adjustment to the disease (Melamed & Brenner, 1990; Revenson, 1994). As in studies of cancer patients, investigators have examined what types of interactions with spouses or friends are perceived as supportive or nonsupportive. For example, Lanza, Cameron, and Revenson (1995) interviewed arthritis patients about perceptions of recent support episodes. Coding of responses indicated that instrumental support was most frequently reported as helpful (e.g., "friend came and cleaned my whole house"); emotional support was second (e.g., "Spouse understood how I felt"). In the category of unhelpful episodes, lack of instrumental support was mentioned most often (e.g., "Husband expected me to do the laundry which I couldn't"), whereas critical remarks and lack of understanding were mentioned less often. Comparable to other studies, spouses were mentioned as most often providing helpful emotional support and physicians as providing helpful instrumental support.

Studies of the contributions of support to adjustment among arthritis patients have included several types of outcomes. Functional measures are shown to be related to higher self-esteem (Fitzpatrick, Newman, Lamb, & Shipley, 1988), more positive affect (Affleck, Pfeiffer, Tennen, & Fifield, 1988), and greater life satisfaction (Smith, Dobbins, & Wallston, 1991). In addition, longitudinal studies have shown social support related to decreased depression over time (Brown, Wallston, & Nicassio, 1989; Fitzpatrick, Newman, Archer, & Shipley, 1991; Smith & Wallston, 1992). Goodenow, Reisine, and Grady (1990) compared a social network measure with a composite functional measure for predicting several outcomes. They found that the functional measure was related to better adjustment in home and family domains. For predicting depression, the social network index was inversely related to depression in zero-order correlations, but this effect disappeared when the functional measure was

added; this implies that the effect for the structural measure was mediated through greater functional support.

In a somewhat different design, Revenson and Majerovitz (1991) studied spouses of arthritis patients, comparing a measure of received support from the spouse with a measure of received support from network members. The study tested buffering effects of support measures for the stressor of disease severity. Results showed a buffering effect for network support but not for spouse support. In this case, the measures were for received support (not perceived availability of support) and the support provider was ill, so it is not clear whether these data are contradictory to the other study. A related study (Revenson, Schiaffino, Majerovitz, & Gibofsky, 1991) showed independent, opposite effects for supportive behaviors (positively related to adjustment) and problematic interaction behaviors, negatively related to adjustment. This study also found an interaction, with depressive symptoms particularly elevated among persons receiving less supportive behaviors and more problematic behaviors.

Indirect effects were tested by Manne and Zautra (1989), who investigated mediational effects for different aspects of support. These investigators obtained a measure for a 10-item composite of emotional and instrumental responses presumed to be helpful for persons with arthritis, together with an index of responses predicted to be unhelpful, namely, the number of critical remarks made by the spouse during an interview. Analyses indicated independent and opposite contributions for the two scales; support was related to better adjustment and criticism was related to worse adjustment. The authors tested for mediation and found that the support score was related to more cognitive coping (which was related to better adjustment) whereas criticism was related to more avoidant coping (which was related to worse adjustment). Thus mediation of support effects through coping was demonstrated and different pathways were demonstrated for supportive and unsupportive behaviors.

Social Support and Adjustment to Diabetes. Diabetes is a chronic illness in which extensive self-care efforts are necessary, and failure to comply with the daily preventive regimen may lead to adverse physical complications. Because glucose metabolism may be upset by negative emotional states and the preventive regimen for diabetes involves continued interactions with other persons, social support may be of considerable relevance for adjustment to this disease condition.

A study by Littlefield, Rodin, Murray, and Craven (1990) examined buffering effects of social support on depression among a sample of individuals with Type I diabetes, using a measure of stress from disease-related disability. Marital status was used as the structural measure. A functional index was obtained through an inventory for emotional and instrumental support; this was analyzed as a difference score assessing the discrepancy between the amount of support patients desired and the amount of support they received. The majority of respondents (70%) thought they received as much support as they needed, or more; hence the discrepancy score distribution was cut into a group with a positive discrepancy score (labeled as adequate support) and a group with a negative discrepancy

score (labeled as inadequate support). Multiple regression analysis indicated a Support \times Disability interaction effect: Disability was strongly related to depression among persons with inadequate support, but the effect of disability was considerably reduced for persons with adequate support. These results show a buffering effect of functional support.

Krause (1995) set out to examine the association of social support, stress, and diabetes mellitus. Interviews were conducted with a community sample of individuals age 65 or older; of this sample, 143 indicated they currently had diabetes. Stress was assessed in terms of the stressful life events in the preceding year that occurred in connection either with highly valued social roles (e.g., spouse, parent) or in less valued roles. Social support was indexed through a measure assessing how often emotional support was received. Findings from logistic regression models, with control for demographic variables and obesity, a risk factor for Type II diabetes, indicated the risk of having diabetes increased with number of undesirable life events but emotional support reduced this effect. The buffering effect of emotional support was found to be significant for stress from highly valued social roles. Krause hypothesized that support could be acting in part to restore individuals' perceptions of control in their important social roles, although perceived control was not directly measured in this study.

A study by Griffith, Field, and Lustman (1990) tested the association of social support, stressful life events, and glucose control. A sample of adult subjects (40 insulin dependent and 40 non-insulin dependent) was randomly drawn from a central registry. Social support was indexed by a visual analogue scale assessing the degree of satisfaction with support received from "those people important to you." Blood samples drawn as part of an annual evaluation were analyzed to determine glycosylated hemoglobin (HbA1c) level, which provides an index of glucose control during the past 6 to 8 weeks. Analysis of variance showed a buffering effect of social support: Under high stress, individuals with high levels of support satisfaction had better glucose control, but this did not occur under low levels of stress.

A related study with adolescents was conducted by C. L. Hanson, Henggeler, and Burghen (1987) to test the relation of family support to adherence with the diabetic regimen. Interviews were conducted with adolescents with Type I diabetes and their mothers. Parental support was indexed through the adolescent's perception of parental behaviors that are supportive of the diabetic treatment, and adolescents also completed a competence scale assessing four domains: cognitive, social, physical, and self-esteem. Stress was indexed by the adolescent's perception of life changes in the family and their own lives during the past year, and metabolic control was assessed by averaging the patient's HbA1c levels at the time of the clinic visit and at some point during the year prior. Self-report and observational methods assessed five areas of adherence behavior (e.g., diet, glucose testing, foot care). Findings from multiple regression showed that low stress and high adherence were independently associated with better metabolic control. Parental support was correlated with better adherence, which in turn was correlated with better metabolic control; this pattern is

suggestive of an indirect effect for support, although mediation was not specifically tested. An interaction effect on metabolic control was not found for parental support, but a buffering effect was found for peer social competence. Parental support is believed to help the adolescent in a main effect manner through continuous monitoring and supervising of their regimen, which increases the likelihood of adherence. The buffering effect of peer competence was attributed to the fact that interference with the diabetic regimen may derive from peer activities (e.g., going out for a hamburger and Coke), hence well-developed social skills may enable adolescents to cope better with these kinds of temptations.

Some complexity of results was found by R. M. Kaplan and Hartwell (1987) in analysis of longitudinal data from an intervention study on diabetes control involving a sample of individuals with Type II diabetes. Individuals were assigned to one of four group intervention programs (diet, exercise, diet plus exercise, and diabetes education). Support indices were obtained from Sarason's Social Support Questionnaire, which provided scores for both network size and for satisfaction with functional support. Results generally indicated opposite predictive effects of support for men and women. At baseline, support satisfaction among men was associated with less worry about diabetes and worse glucose control, but among women support satisfaction was associated with more worry and better control. A different pattern was noted for participation in the treatment program; for women, larger network size was related to less participation whereas no correlation was observed for men. Outcome was indexed by change scores reflecting differences between values for baseline and follow-up variables. Support satisfaction was not related to outcome, but network size was. Among men, larger network size was related to less change in glucose control and blood lipids; among women, these effects were smaller and generally nonsignificant. It was suggested that large networks may involve obligations that interfere with successful management of health behaviors.

Social Support and Hemodialysis. The health status of patients with kidney failure may be sustained through renal dialysis. The procedure is a demanding one because it involves continued effort by the patient, as well as strict compliance to dietary changes necessary to maintain electrolyte balance. Therefore, social support may be relevant for helping patients to meet the demands of this treatment regimen. The role of family support in renal dialysis has been studied by several investigators. Devins et al. (1990) administered Berkman's social network index and other structural measures to a sample of dialysis patients and analyzed relationships to survival over an average 46-month follow-up. Most support indices were nonsignificant, although an index of leisure activities was related to greater survival time.

In contrast, significant results were found by Christensen and colleagues (Christensen et al., 1992; Christensen, Wiebe, Smith, & Turner, 1994) in studying the role of a functional measure of family support in a sample of hemodialysis patients followed over an average 44-month period. Estimated 5-year mortality rates were 18% for the high support group and 52%

for the low support group. The authors considered whether the survival advantage was attributable to support effects on depression or on treatment adherence. Though both mechanisms were plausible and Christensen et al. (1992) had previously shown support related to better adherence, neither depression nor adherence predicted survival in this study, hence the researchers were not able to conduct mediation analysis to suggest inferences about the causality of the effect.

Social Support and Adjustment to HIV Infection.

Social support has recently been investigated in relation to adjustment to HIV status, including psychological outcomes and physiological variables. Nott and Power (1995) studied the relationship between social support and various affect and coping measures in a 6-month longitudinal investigation with a sample of HIV-positive men. Support was assessed using the Significant Others Scale, which measures actual and ideal levels of emotional and instrumental support. A Medical Coping Modes questionnaire was also given to participants to examine the ways in which individuals coped with their illness. The data indicated that individuals received levels of support that were average to moderately high, relative to expectation. Results showed that support was related to higher levels of self-esteem and coping efficacy, and to lower levels of depressive symptomatology and perceived stress.

Pakenham, Dadds, and Terry (1994) studied the relationship of social support to coping and adjustment in a sample of 96 HIV-positive gay or bisexual men and a comparison group of 33 seronegative gay/bisexual men. Stress was operationalized as the number of HIV-related problems the subject had experienced, and a problem checklist was given to assess daily stressors in his life. A version of Vaux's Social Support Resources Scale was used to assess several structural indices (e.g., partner present vs. absent, network size, frequency of contact), and scores were obtained for the proportion of network members who provided emotional or instrumental support in relation to coping with being HIV-infected (or coping with the AIDS epidemic, for controls). Analyses controlling for stage of infection showed that greater emotional support and frequency of contact with network members were related to unfavorable outcome (lower CD4 count), whereas larger network size and proportion of close friends were associated with higher CD4 count, a favorable outcome. The researchers tested for interactions of support measures with the stress index, but little evidence for buffering was found. It was not clear how to account for the discrepant results, and replication of the findings was recommended.

Two studies have focused on social support in relation to progression of HIV infection. Theorell et al. (1995) studied a sample of HIV-positive males representing all infected cases with moderately severe or severe hemophilia in Sweden. Participants were initially studied in 1985, approximately a year after they had learned of their HIV status, and were followed through 1990. Support was measured with a version of Henderson's schedule assessing confidant support from close relationships, and progression of HIV infection over a 5-year period was indexed with CD4 cell counts. Results indicated that persons with higher support showed slower disease pro-

gression. The researchers related the findings to other studies showing more rapid disease progression for persons with negative emotional states (e.g., anxiety or depression), but these variables were not measured directly in the study, hence no test of mediation effects was performed.

Several dimensions of social relationships were measured in a study that invited participation from all known HIV-infected homosexual men in the city of Malmo, Sweden and obtained completed data from 69% of this population (Persson, Gullberg, Hanson, Moestrup, & Ostergren, 1994). The outcome measure was the mean CD4 cell count from readings obtained during the study period (median = 3, range = 1-7). Indices of network size, anchorage, and social participation were based on measures used in the original Malmo study of social support (B. S. Hanson et al., 1989). Analyses predicting CD4 count with control for age and medical treatment showed that individuals with more favorable outcomes had higher scores on one structural measure (social integration) and on one functional measure (instrumental support). Thus there is evidence that both structural and functional aspects of social networks may serve a protective role for HIV infection.

Support Effects for Children and Adolescents

The effects of social support among children and adolescents have recently been studied (see Sandler, Miller, Short, & Wolchik, 1989; Wills, 1990c). This body of literature contains more research using functional measures, which typically index a combination of emotional and informational support from parents, sometimes with parallel measures for support for peers. Some investigators have studied the effect of support on mental health outcomes (depression/anxiety symptoms or behavioral adjustment problems); others have studied effects of support in relation to adolescents' substance use. Research on social support at younger ages becomes theoretically more complex because individuals participate simultaneously in two different types of social networks—the family network and the peer network—and in some cases these different networks have opposite effects on outcomes (Wills, 1990c; Wills, Mariani, & Filer, 1996).

Studies with mental health outcomes have generally shown protective effects for parental support, sometimes including stress buffering effects, whereas effects for peer support are often not significant. Greenberg, Siegel, and Leitch (1983) tested contributions of parent and peer emotional support to indices of positive mental health (self-esteem and life satisfaction) in adolescents; they found that parental support showed stress buffering effects, such that the impact of negative life events was reduced for adolescents with high parental support. For peer support, the main effect was significant but smaller in magnitude and no buffering effect was observed. Dubow and Tisak (1989; Dubow, Tisak, Causey, Hryshko, & Reid, 1991) demonstrated a similar effect in a sample of younger children, with teacher-rated school adjustment and behavior problems as criterion variables. It was suggested that parental support was related to more active coping, which

itself had a stress buffering effect, but no explicit mediation test was performed.

A long-term prospective study by Newcomb and Bentler (1988) related a composite support index (primarily parental support) measured in middle adolescence to a range of outcomes measured 8 years later in young adulthood. Their results, obtained from structural modeling analyses, indicated support was a protective factor in relation to a variety of mental health and behavioral outcomes. The range of effects observed was surprising even to the investigators, who emphasized that the impact of support on adolescents is not restricted to a narrow domain. A 7-month prospective study by DuBois, Felner, Meares, and Krier (1994), conducted in early adolescence, showed a functional measure for family support related concurrently to higher grade point average and less conduct problems, psychological distress, and substance use; most of these effects remained significant in prospective analyses. This study tested what was essentially a three-way interaction among socioeconomic disadvantage, stress, and social support. The interaction results were consistent with buffering effects, as support had stronger relationships to criterion variables among the high disadvantage group, compared with the low disadvantage group. Buffering effects were found for support from school personnel as well as for support from family members, so this study demonstrates buffering effects for support that occurs outside of primary relationships.

Independent effects of social support and social conflict were demonstrated by Barrera, Chassin, and Rogosch (1993). Support from parents was related to higher self-esteem and fewer externalizing behavior problems, whereas support from friends was not consistently related to these criteria in multivariate analyses. Conversely, conflict with parents was related to lower self-esteem and more behavior problems (cf. Matthews, Woodall, Kenyon, & Jacob, 1996). Another study (Forehand et al., 1991) showed that support from a parent buffered the impact of family-related stressors, such as divorce or parental depression, on adolescents' mental health. A 1-year longitudinal study with a community sample of 13- to 16-year-olds (Farrell, Barnes, & Banerjee, 1995) examined the effect of family cohesion for buffering the effect of a particular stressor, father's problem drinking. Results showed prospective buffering effects. Father's drinking was related to increases in psychological distress, antisocial behavior, and heavy drinking over time for adolescents in families with low cohesion, but these effects did not occur for adolescents in families with high cohesion.

An interesting study of help seeking in adolescence was based on an Australian sample of secondary school students (Rickwood & Braithwaite, 1994). A functional measure assessed the availability of confiding relationships. The dependent measures asked whether the respondent had sought any help for a psychological problem in the previous 3 months and if so, whether it had been from informal networks or from a professional helping agent (doctor, school counselor, or mental health service). Results indicated that adolescents were more likely to seek help from informal networks than from professional sources (cf. Wills & DePaulo, 1991).

Logistic regression analyses indicated that high symptom level and female gender were predictors of help seeking, and confidant support was related to more help seeking, controlling for gender and symptom level. Thus, this study provides some evidence for a behavioral mechanism of how social support operates for emotional problems.

The relation of parental or peer support to adolescent substance use has also received attention. Functional measures, typically indexing good communication and emotional supportiveness from parents, have been shown in several studies to be a strong protective factor, related to lower likelihood of substance use (e.g., J. S. Brook, D. W. Brook, Gordon, White-man, P. Cohen, 1990; Dishion, Reid, & Patterson, 1988). Studies with measures of parental emotional support have indicated that parental support is inversely related to adolescent substance use and has stress buffering effects, such that the relation between life stress and substance use is considerably reduced among adolescents with higher parental support (Barrera et al., 1993; Wills et al., 1992; Wills & Vaughan, 1989). Peer support, in contrast, typically is unrelated to substance use and sometimes is positively related (Wills & Vaughan, 1989). Fondacaro and Heller (1983) showed that a protective effect of parental emotional support was observable in a college student sample, whereas social network indices were positively related to heavy drinking, probably because they reflected frequency of socializing and "party-ing." It should be noted that the predictors of adolescent substance use are quite similar to the predictors of HIV risk (Donovan & Jessor, 1985; Stein, Newcomb, & Bentler, 1994). This suggests that many of the effects reported here are likely to be relevant also for HIV risk (Leigh & Stall, 1993), but there has been little research on adolescent risk behavior with a focus on social support.

Mediation tests to indicate how social support works in adolescence were conducted in two studies that used different measures and samples. A study by Wills, DuHamel, and Vaccaro (1995) was based on a sample of adolescents surveyed at age 12.5. This study focused on a temperament model of substance use and also obtained a 4-item scale for parental emotional support. Structural modeling analysis indicated parental support was related to more behavioral coping and self-control, and to fewer deviant peer affiliations. These effects largely mediated the relationship between support and adolescent substance use, but an inverse effect for support going directly to substance use (net of all other variables in the model) was also observed.

A mediational analysis by Wills and Cleary (1996) used data from a sample of adolescents who were assessed on three occasions between age 12 and 15. In this study, support was measured with a 12-item scale that assessed emotional and instrumental support from parents, and a measure of major negative life events was included. Regression analyses showed Stress \times Support interactions for adolescents' tobacco, alcohol, and marijuana use at all three assessment points, consistent in form with buffering effects. Structural modeling analyses indicated the effect of parental support was mediated through multiple pathways, including effects on more adaptive coping, higher academic competence, less deviance

prone attitudes, and fewer deviant peer affiliations. Mediation through relations of support to more adaptive coping was an important pathway that was consistent with previous theory on resiliency effects (Thoits, 1986; Wills, Blechman, & McNamara, 1996). Interaction analyses in structural modeling showed that buffering occurred through two different processes: one in which support reduced the impact of risk factors (e.g., negative life events) and another in which support increased the impact of protective factors (e.g., behavioral coping). The results show that the effects of social support are mediated through multiple pathways to both risk and protective factors.

Social Support and Substance Use in Adults

A number of studies have examined how social network and social support measures are related to substance use among adults. Most studies show functional support measures to be protective in that they are related to lower likelihood of substance use or amount of use (e.g., less heavy alcohol consumption). The distinction between onset and maintenance of substance use becomes somewhat blurred in this literature because most studies do not show clearly whether support acts to prevent onset of use, reduces level of habitual use, or increases the likelihood of quitting. A theoretically interesting aspect of this research, however, is that the precise composition of the social network is quite important, because opposite effects may be observed depending on whether or not the network includes substance users (see Wills, 1990a).

Studies of general populations have suggested a protective effect for both structural and functional indices. A study of a national probability sample by Umberson (1987) found that persons who were married and/or had children showed lower rates of substance abuse as well as higher levels of some health protective behaviors (cf. Kirscht, 1983). These findings are consistent with data from several studies showing structural indices related to lower prevalence of cigarette smoking (Sugisawa et al., 1994; Waldron & Lye, 1989), and with data showing marriage and functional support related to lower levels of alcohol and tranquilizer use (Brennan & Moos, 1990; Timmer, Veroff, & Colten, 1985). A study of an urban African American sample (Romano, Bloom, & Syme, 1991) found interactions with gender such that a social network index was inversely related to smoking among women, whereas a 1-item emotional support measure was positively related to smoking among men. (In the latter case, it was suggested that the construct validity of the measure was in question.) This study also showed that a measure of perceived control over health was inversely related to smoking (cf. Wills, 1994), but Romano et al. did not explicitly test whether the effect of social networks was mediated through perceived control.

A test of the matching hypothesis for buffering effects was conducted by Peirce et al. (1996) with a community sample, using scales for emotional, instrumental, and companionship support. These were tested as buffering agents for indices of stress from financial problems, with change in alcohol use over a 3-year period as the criterion. For indices of problem drinking, instrumental support was indicated as a buffer because it

reduced the relationship between stress and problem drinking. The results were interpreted as consistent with the matching hypothesis in that instrumental support showed a buffering effect with respect to this financial stressor, whereas emotional support and companionship support did not.

Jenninson (1992) conducted a test of the buffering hypothesis for life stress and alcohol use in a sample of individuals age 60 and over. Life stress was indexed through questions pertaining to role loss (divorce, unemployment, etc.). Structural indices included marital status, group membership and church attendance, and presence of siblings and other family members. Findings indicated an increase in drinking among individuals experiencing traumatic life events such as unemployment, loss of spouse, or hospitalization of a relative. Several social network variables were found to reduce the relationship between life stress and excessive drinking; these included church attendance, quality of marital relationship, number of close friends and kin in the network, and support from siblings. These findings are similar to a recent analysis of data for elderly men from the Malmö study (B. L. Hanson, 1994). This analysis found that men who engaged in heavy drinking had less support from spouse, lower scores for community integration, and less frequent contact with friends and relatives. Hanson's (1994) study, however, did not test for buffering effects.

Several studies have identified social support as a factor that facilitates cessation of substance use or continued abstinence after cessation. This process was originally studied with both community-based samples and clinical samples of alcoholics; findings indicated that persons with greater emotional support from friends and family were more likely to stop drinking and remained abstinent for longer periods of time (Billings & Moos, 1983; Rosenberg, 1983). Similar results were shown in studies of opiate addicts, which found that individuals with greater emotional support from friends or relatives showed lower levels of illicit drug use and fewer adverse consequences, such as overdose (Rhoads, 1983; Tucker, 1985). The Tucker (1985) study also showed a buffering effect, such that negative life events did not lead to increase in drug use over time for persons who had high emotional support. In these studies, social network measures typically do not show significant protective effects. In fact, the studies by Rhoads (1983) and Tucker (1985) both found increased adverse outcomes among persons who had more close friends, if the friends were substance users.

The effect of social support in smoking cessation has received the most detailed study. The researchers recruit samples of smokers who are either committed to quitting on their own or are enrolled in formal smoking cessation programs; subjects are followed after the quit attempt so that effects of social factors on cessation can be determined (e.g., Coppotelli & Orleans, 1985; Mermelstein, S. Cohen, Lichtenstein, Kamarck, & Baer, 1986). For example, Mermelstein et al. (1986) followed persons during a clinic-based smoking cessation program and for 1 year afterward. They found that emotional support from spouse and friends was related to successful quitting and to abstinence during the first 3 months after cessation. However, the only predictor of long-term

abstinence was the spouse's smoking status: Persons were more likely to relapse if the spouse was a smoker. This finding is comparable to data from a study of long-term cessation in a community sample (B. S. Hanson et al., 1990). Participants were more likely to have quit smoking if they were married and their spouse was a nonsmoker, as compared to participants who lived alone. However, married men with smoking spouses had the lowest quit rate of all groups. This study also tested various structural measures and found that a measure reflecting formal and informal group memberships was related to a higher rate of quitting smoking; but a measure reflecting frequency of social contact showed the opposite effect, possibly because men with high rates of socializing were more likely to encounter smokers (cf. Fondacaro & Heller, 1983).

A comparative study by Havassey, Hall, and Wasserman (1991) investigated the relation of a range of structural and functional indices to relatively short-term (3-month) relapse status with three different samples from treatment programs: cigarette smokers, alcohol abusers, and opiate users. General functional measures tapped emotional support, instrumental support, and interpersonal conflict; specific measures indexed abstinence-specific support from a partner. Structural measures included both a social network index and a drug-specific structural measure that indexed how many persons in their network (spouse, friends, and/or household members) were users of the participant's problem drug. Results indicated that high social integration was a protective factor, related to lower likelihood of relapse, as was having a partner (vs. none). Abstinence-specific functional support also showed a significant protective effect, but the general functional indices were all nonsignificant. Drug use by network members was a significant risk factor, related to greater likelihood of relapse. Analogous results were found in follow-ups of participants in alcoholism treatment programs (Gordon & Zrull, 1991; Longabaugh, Beattie, Noel, Stout, & Malloy, 1993), which showed that abstinence-specific support enhanced recovery whereas perceived approval for drinking among network members undermined the recovery process.

Support and Pregnancy

Studies with somewhat different designs have examined the effects of social support during pregnancy. This research has included medical outcome measures such as pregnancy complications and infant's birthweight, both of which are of prognostic significance for the infant's health and development. Such research provides a valuable opportunity to bridge the social and physical domains during a period that is of crucial importance for the health status of both mother and infant (Lobel, Dunkel-Schetter, & Scrimshaw, 1992).

Collins, Dunkel-Schetter, Loebel, and Scrimshaw (1993) investigated the role of social support in a sample of economically disadvantaged women (65% Latina and 20% African American). Interviews were conducted on several occasions during pregnancy, and medical charts were reviewed after delivery to assess outcome measures. A structural index was derived from items on number of kin in network, number of close

friends, and whether the subject was living with the baby's father. A composite functional index was based on receipt of emotional, instrumental, and informational support during pregnancy; separate scores were also obtained for support from the baby's father and for support from health care providers. An inventory of stressful life events during pregnancy was obtained together with assessments of depression. Structural modeling analyses tested main effects of support on birth outcomes with control for two indices of medical risk. Results indicated the structural index was related to higher birthweight, the functional index was related to fewer labor complications and better infant developmental status at birth (Apgar score), and the indices of support from father and health care providers were related to better developmental status. A buffering effect was found for functional support in relation to infant's birthweight: Support was positively related to birthweight for women experiencing a high level of stressful life events but was unrelated to birthweight among women with low stress. An analogous buffering effect was also found for maternal depression. It should be noted that the results for structural and functional measures were independent effects, so these findings represent different ways in which social relationships contribute to improved birth outcomes.

The effects of social support in teenage pregnancy were investigated by Turner, Grindstaff, and Phillips (1990), with the rationale that additional stressors face adolescents during pregnancy and their risk for certain birth complications is increased. A sample of adolescent mothers was interviewed on two occasions, the first after confirmation of pregnancy and the second 4 weeks after the birth. Support was assessed with a composite functional measure assessing emotional, instrumental, and companionship support; separate scores were obtained for support from parents, partner, and friends. Birth outcomes were assessed in terms of birthweight and maternal depressive symptomatology. Multiple regression analysis, with control for medical risk factors, showed parental support to be positively related to infant birthweight and inversely related to depression. For prediction of maternal depression, two other variables (living with parents and friends' support) were also inversely related to depression. Turner et al. performed different tests for buffering effects and found a buffering effect for maternal depression among higher SES mothers, whereas for lower SES mothers, main effects of support were observed for both birthweight and depression.

A behavioral mechanism for relationships between social support and pregnancy outcomes was examined by St. Clair, Smeriglio, Alexander, and Celentano (1989) in a study of the association between social network structure and prenatal care utilization. The investigators conducted postpartum interviews with low income, inner-city women in an area in which many women failed to receive prenatal care. Social network structure was characterized by questions assessing three sectors: household, relatives, and friends. Analyses indicated that utilizers of prenatal care had a larger number of relatives in the network, were more likely to have frequent contact with friends (by telephone or visiting), and had fewer children in the household. In contrast, an index of emotional intimacy indicated that mothers who had high emotional inti-

macy with relatives were less likely to utilize care. Findings are reminiscent of other studies testing whether persons with dense, kin-centered networks are less likely to use preventive medical services (Broadhead, Gehlbach, DeGruy, & Kaplan, 1989; McKinlay, 1973).

Thinking about the role of social support for pregnant women has led to investigations assessing the impact of support interventions. A well-known Guatemalan study conducted by Sosa, Kennell, Klaus, Robertson, and Urrutia (1980) studied the effects of a supportive lay woman ("doula") who was present during labor and delivery. Participants were randomly assigned to either an experimental group or a control group. The experimental condition consisted of receiving constant support from the doula from admission through delivery in the form of physical contact, interpersonal interaction, and the presence of a friendly and sympathetic companion, whereas the control group received routine prenatal care. Outcome measures consisted of the length of labor, the presence or absence of birth complications, and the nature of maternal-infant interactions observed following delivery. Findings indicated that women with a doula had significantly shorter labor periods and fewer delivery problems; also, these women stroked, smiled, and talked to their infants more during interactions following birth. The authors suggested that the effects of the supportive companion may be physiological in nature; reduced maternal anxiety leads to lower levels of catecholamines, which facilitates uterine contractility (Zuspan, Cibils, & Pose, 1962) hence reducing delivery complications. These findings were replicated in a study by Kennell, Klaus, McGrath, Robertson, and Hinkley (1991) with a sample of low income women in Texas, including a condition with a person who observed the delivery but did not interact with the patient. Results showed beneficial effects of having a doula, and even participants with only an observer showed better outcomes in comparison to controls. The doula group used oxytocin less often to augment labor, received less epidural anesthesia, and had significantly shorter labor durations and fewer caesarian and forceps deliveries. In terms of infant outcomes, the newborns of the doula group remained in the hospital the least amount of time.

A nonreplication was reported by Villar et al. (1992) in a study conducted with women in four urban sites in Latin America (Argentina, Brazil, Cuba, and Mexico). The participants were women with one or more risk factors for delivering a low birthweight baby; they were randomly assigned to an intervention group consisting of 4 to 6 home visits from a nurse or social worker, in addition to routine prenatal care, or to a control group that received routine care. The home visits focused on health education by the visitor, who also suggested that the mother involve a support person (husband, mother, sister, friend, or neighbor) in the intervention activities—although such involvement was not documented. Outcome analyses indicated the groups did not differ significantly on variables such as preterm delivery; infants of experimental group mothers were somewhat heavier, but the differences were not statistically significant. The reasons for the nonreplication remain unclear; they could include the timing or nature of the

intervention, the focus on cognitive education, or the higher-than-average risk status of the mothers.

Support Effects in Elderly Populations

Paralleling the epidemiologic research on social support and health in the elderly is research investigating specific support effects among elderly individuals. These studies have involved a variety of support and stress measures. For example, Silverstein and Bengtson (1991) focused on intergenerational family relationships using 14-year longitudinal data from three generations in 328 families. Self-administered questionnaires focused on perceived emotional supportiveness for grandparents from their children (now adults), and support effects were tested in relation to stressors such as age-related physical decline and social losses. Logistic regression analyses suggested a buffering effect, showing that intimate ties to offspring were related to an increased longevity and decreased distress only among persons who had lost a family member or spouse. Silverstein and Bengtson suggested intergenerational relations help persons cope with disruptions in family memberships and partially compensate for the loss of support from other sources. Another analysis of data from the same sample (Silverstein & Bengtson, 1994) found interaction terms indicating that emotional support moderated the decline in well-being caused by health problems. Among widowed parents, instrumental support from children also moderated the decline in positive well-being associated with health problems and the decline in well-being associated with being widowed.

Several studies have examined effects of support in relation to specific stressors of the elderly. Cutrona, Russell, and Rose (1986) conducted a 6-month longitudinal study with a sample of 50 community-dwelling elderly. Support was measured with a multidimensional functional inventory, and life stress with a geriatric life events scale. Prospective analyses indicated support was related to improvement in physical health and reduction in depressive symptomatology. A buffer interaction was found for the mental health criterion, with support inversely related to depression only among persons who had experienced a high level of life events. Emotional support was the function most strongly related to physical health, whereas emotional and informational support both were related to less depression. A related prospective study by Phifer and Murrell (1986) also found a buffering effect, with the association between loss events and depression onset reduced among persons with more emotional and instrumental support.

The stressor of chronic financial strain was examined by Krause (1987) in a community sample of older adults. The stress measure assessed whether the individual had enough money for basic needs (i.e., food, clothing, etc.). Social support was indexed through the dimensions of emotional, instrumental, tangible help, and support provided to others. Regression analysis found that the stressor of chronic financial strain exerted a significant effect on depression, somatic symptoms, and positive affect. Several effects of social support were found for buffering the impact of financial strain. In particular, effects of financial strain on depressed affect and

somatic scores were reduced among individuals who received high levels of informational support. Emotional support also served as a buffer of financial strain in terms of the positive affect measure (i.e., less decrease in positive affect for those with higher support).

Effects of structural and functional support indices in relation to depression onset following a particular stressor were investigated by Tompkins, Schulz, and Rau (1988) in a sample of stroke patients and their support persons, interviewed three times over a 14-month period after the stroke. Functional measures included assessment of emotional, instrumental, or informational support, plus a global rating of satisfaction with the quality and quantity of social contacts with people in general. Structural indices included network size, frequency of contact, and gender composition. Patients were classified into depressed versus nondepressed groups on the basis of a cut of symptomatology scores at Time 2 and Time 3, respectively. Patients who became depressed were discriminated at baseline by having fewer members in the intimate network and being less satisfied with their contacts with people in general. Measures of post-stroke functional support did not predict depression, so it appears that a more broadly based support network is essential for enhancing adjustment in this population.

Potts, Hurwicz, Goldstein, and Berkanovic (1992) investigated effects of social support in a longitudinal study on preventive health behaviors among the elderly, using data from a survey of health care utilization among persons in an HMO. Health-related preventive and risk behaviors were measured by asking how frequently the respondent engaged in each behavior (e.g., exercising, consuming red meat, smoking, taking vitamins). Support was assessed with a mixed structural/functional scale that included frequency of contact with friends and family as well as items on availability of confidant relationships. Findings indicated that respondents with higher support scores were more likely to endorse health promotive attitudes and also were more likely to engage in six of eight preventive behaviors assessed. Thus this study provides some evidence for a behavioral mechanism of support effects.

Support and Physiological Variables

A number of studies have investigated how social support is related to physiological variables. These include measures of cardiovascular parameters (e.g., heart rate, blood pressure), sympathetic nervous system activity (e.g., catecholamines), and immune system function (e.g., proliferation of T-cells or NK cells). All of these variables have a plausible status as risk factors and accordingly provide a perspective on the mechanism of how social support is related to health (see S. Cohen & Herbert, 1996; Seeman, Berkman, Blazer, & Rowe, 1994; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). The studies typically include statistical controls for demographic factors that could be correlated with both support and physiological variables, and sometimes demonstrate that the effect of support is independent of medical variables. Although this body of literature contains great diversity in the support measures used

and the physiological indices studied, some consistencies have been observed.

One consistent finding is that social support is related to better cardiovascular regulation, particularly lower blood pressure. This has been observed in diverse populations and for both men and women (e.g., Dressler, Mata, Chavez, Viteri, & Gallagher, 1986; B. S. Hanson, S. O. Isacson, Janzon, Lindell, & Rastam, 1988; Kasl & Cobb, 1980; Knox, Theorell, Svensson, & Waller, 1985; Livingston, Levine, & Moore, 1991). Functional support measures typically have tapped support from spouse or family, but also include other sources such as coworkers or supervisors. Of the studies that indexed functional support from family and included a stress measure, all found significant stress buffering effects for family support. Interestingly, structural and functional measures both have been found inversely related to blood pressure (Uchino et al., 1996). Some studies have found support measures related to endocrine measures such as epinephrine or norepinephrine (Ely & Mostardi, 1986; Knox et al., 1985); the latter study used path analysis to suggest that the effect of support on blood pressure was mediated through lower heart rate.

A different paradigm is used in laboratory studies in which participants are exposed to mildly stressful conditions and social support is experimentally manipulated, typically with measures of reactivity in heart rate and blood pressure as the criterion. Results indicate participants who receive support show less cardiovascular reactivity (e.g., Gerin, Pieper, Levy, & Pickering, 1992; Lepore, 1995). In addition, buffering effects are found when subjects receive support from a friend or family member, but are not found when the support comes from a stranger (Gerin, Milner, Chawla, & Pickering, 1995; Kamarck, Annunziato, & Amateau, 1995). Because high reactivity is suggested as a risk factor for cardiovascular disease, these studies indicate a mechanism through which support could reduce risk for heart disease. Several investigators have examined whether the protective effect is mediated through reductions in perceived stress, but have found little support for this hypothesis (e.g., Lepore, 1995). It is worth noting that persons show lower blood pressure when in the presence of a family member in naturalistic conditions (Spitzer, Llabre, Ironson, Gellman, & Schneiderman, 1992), so a direct effect mechanism is not implausible.

Measures of social support have also been correlated with levels of three stress-related hormones: epinephrine, norepinephrine, and cortisol. Although the number of studies is small and designs are diverse, several studies have found functional measures related to lower catecholamine levels. Fleming, Baum, Gisriel, and Gatchel (1982) studied residents in the Three Mile Island area after a power plant accident and found that persons with high emotional support had lower levels of norepinephrine; a buffering effect was observed, with the impact of residential status (close to vs. far away from the plant) on catecholamine levels being reduced for persons with high emotional support. Seeman et al. (1994) studied a community-based sample of elderly persons who were screened to be in the top third of their age group on physical and cognitive ability. Results indicated that women with higher scores for social ties showed lower levels of norepinephrine. Results for

functional measures were significant for men: Those with high emotional support had lower levels of epinephrine, norepinephrine, and cortisol; results for instrumental support were in the same direction but were of smaller magnitude.

Relationships between social support and indices of immune system function represent another research area in which designs and measures are diverse, and this research is often conducted with highly stressed populations (e.g., caregivers for an ill family member). The greater variance of immune system assays combined with typically smaller sample sizes for the studies (attributable to the high cost of the assays) may be responsible for a higher proportion of studies with null results. Nonetheless, meta-analysis showed a significant effect for social support over the range of immune-system indices studied (Uchino et al., 1996). The support measures vary but typically index confiding and emotional support from close relationships. Studies with positive findings include studies of healthy subjects (Thomas, J. M. Goodwin, & J. S. Goodwin, 1985), spouses of cancer patients (Baron et al., 1990) and cancer patients themselves (Levy et al., 1990), and caregivers for Alzheimer's patients (Esterling, Kiecolt-Glaser, Bodnar, & Glaser, 1994; Kiecolt-Glaser, Dura, Speicher, Trask, & Glaser, 1991). As noted previously, two studies of patients with HIV have found social support related to less decline in CD4 cell counts (Persson et al., 1994; Theorell et al., 1995). Kiecolt-Glaser et al. (1991) found a stress buffering effect, with more longitudinal decline in immune function for caregivers with high chronic stress and low emotional support. Esterling et al. (1994) reported evidence for a mediation effect: Caregivers with poor immune system function (in this case, lower natural killer cell activity) made more visits to physicians for infectious illnesses, which suggests a linkage of social support to illness through alterations in immune system function. It should be noted that several studies have tested whether effects of social support on immune system parameters were mediated through changes in depression or perceived stress, and all these tests were negative. Although the tests were conservative ones because of small sample sizes, failure to find mediation through psychological distress suggests that alternative mechanisms may be more plausible.

CONCLUSIONS

This chapter has tried to provide a comprehensive picture of research on social support and health, being selective to some extent but trying to convey the "big picture" of what this work means to the researcher and clinician. The one single conclusion most relevant to all audiences is that social support is consistently shown to be related to better physical health. The evidence supporting this conclusion is persuasive because social support has been shown to predict lower mortality rate. This has been found in prospective studies where the sample was followed for long periods of time after the initial assessment; the effect is shown with statistical control for a wide range of variables that could be correlated with social sup-

port; and the protective effect of social support has been shown to occur for both men and women in a variety of national populations, including North America, Europe, and Asia. A more subtle—but important—point is that the effect sizes found for social support measures are sometimes comparable to effects found for medical risk factors. Whereas some persons tend to assume that risk factors such as cholesterol and blood pressure reflect true physical risk and must be many times more powerful than social factors, this is not always the case. A number of the studies discussed have obtained indices for support measures and biomedical risk factors, and have noted comparable effect sizes.

Is it Network Structure or Functional Support That Is Really Related to Physical Health? Recent research has blurred what previously seemed like a sharp distinction between the effects of structural indices and functional measures. Although early studies consistently reported that higher social network scores were related to lower risk of mortality, recent research has shown functional measures to be significant predictors of mortality as well, and several studies have shown stress buffering effects for functional measures with physical health as the outcome. The research continues to show social integration (i.e., through marriage, children, friends, relatives, formal group memberships, and informal group memberships) as a predictor of mortality, but evidence is building for measures of functional support as showing similar effects. In addition, the few studies that have addressed this question have suggested that the effect of social networks is mediated through the availability of functional support. This conclusion is tentative because of the indirect methods currently used to analyze the question, but on the evidence it cannot be dismissed.

Is Any Support Function Particularly Important? The evidence is clear that emotional support is the function most widely useful for adjustment and health. Across a wide range of methods, measures, and health conditions, it has been found that emotional support is related to better outcomes. This has been found even in conditions where other functions would be expected to be more relevant, such as elderly persons coping with financial stress, arthritis patients coping with physical limitations on daily activities, or cancer patients coping with threats to survival. The only qualification to this conclusion is that studies have tended to place the most emphasis on emotional support, and in a number of cases have made only minimal efforts to measure other functions. Yet, in the few studies with multidimensional inventories, the evidence clearly favors emotional support as the most useful function across a wide range of situations. This fact has profound implications for the understanding of supportive relationships.

Do Stress-Buffering Effects Really Exist? Buffering effects of social support have been found for a wide variety of stressors including job strain, financial stress, and disease se-

verity. Moreover, buffering effects have been demonstrated not only for depression but for outcomes including substance use, glucose levels, catecholamine levels, and infant birthweight. Given the volume of the evidence, it seems less relevant to question whether buffering effects exist and more relevant to determine how they occur.

Is Social Support Only Relevant for the Most Isolated?

The evidence is not completely definitive on this question; a few studies have reported findings consistent with a threshold effect, but several studies have shown a graded effect of support on mortality across the levels of support measured. This evidence argues strongly against the existence of an effect of support only for the most isolated. In the studies with threshold effects, the evidence is itself internally inconsistent, with both graded effects and threshold effects sometimes observed in the same study. The conservative conclusion is that social integration has beneficial effects for persons across different levels of support, and we think this conclusion should be maintained unless it can be clearly rejected.

Is Social Support Only Relevant for Middle-Aged Men?

The research considered here shows beneficial effects of social support over the range from age 10 to 80. A number of studies have been discussed that show comparable effects of social support for men and women, hence sufficient evidence has not been encountered to suggest that beneficial effects of support are a gender-linked phenomenon. The evidence contains suggestive indications of emotional support and confiding as being more relevant for women and a looser network of reliable alliances and companionship activities as being more relevant for men (Berkman, Vaccarino, & Seeman, 1993; Wills, 1998). However, there are enough exceptions to this pattern that sharp gender distinctions cannot be made with much confidence.

What About Negative Effects of Social Networks?

It has been noted that social relationships involve strains and conflicts and that persons may not always receive as much support as they expect. From these observations, some investigators have suggested that effects of social networks may be largely negative ones. This suggestion ignores two basic facts that recur in research on social support. One fact is that persons typically rate their support networks in quite favorable terms, indicating that they perceive a high level of supportive functions to be available and that they generally receive about as much support as they need. The second fact is the consistent finding that support is inversely related to mortality (and to several other indices of physical and mental health status) in large representative samples. Whatever the mix of supportive and conflictual aspects that exists in typical social networks, the evidence indicates that in the prevailing conditions of the natural environment the balance of effects of social networks is a positive one. While negative aspects in networks exist, effects of positive aspects seem greater.

Where in the Disease Process Does Social Support Act? This is the most frustrating question in social support research. Obtaining a clear answer is most difficult from a methodological standpoint and current evidence is only suggestive. The striking aspect of current research is the dearth of evidence showing relationships of social support to disease onset together with a fair amount of evidence showing social support related to recovery from disease. It is tempting to conclude that support might primarily act at this stage of the disease process, and this aspect of the evidence is compelling from an applied standpoint because it shows the substantial benefits of having good support after a disease episode. However, a conclusion that supports only acts at this stage could well be illusory, as methodological issues make it considerably more difficult to detect effects for disease incidence, and there is considerable evidence showing social support related to risk factors that must ultimately be related to disease onset. Thus further research on the role of support in disease onset may be an important area.

Have We Learned Anything About How Support Acts?

On this front there is both good news and bad news. The good news is that a substantial amount of research has been conducted during the last 10 years, and the research has provided evidence consistent with several different mechanisms. Social support has been related to measures of stress hormones and cardiovascular reactivity, which are relevant to risk for heart disease; to cigarette smoking and heavy alcohol use, which are known risk factors for heart disease and several types of cancer; to indices of help seeking and health service utilization that are of broad significance for prevention of physical and mental illness; and to indices of immune system function, which have been linked to infectious diseases and chronic illness. The bad news is that there have been relatively few tests of whether support effects are mediated through these mechanisms, and a few studies testing for mediation through emotional distress or perceived stress have produced generally negative results. This evidence is not damaging, partly because some studies with null results have had methodological limitations and partly because a few studies have clearly shown mediational effects. This is an area where much progress probably will be made in the next decade.

Have All the Interesting Questions About Social Support Already Been Answered?

The answer is "Hardly so." This chapter has addressed only a part of the developing research on social support, and many of the most interesting questions remain to be studied. There are surprisingly few studies that have obtained comprehensive measures for both social networks and functional social support, and more research is needed to compare the respective contributions of structural and functional constructs. Studies specifically designed for studying how the effect of social support is mediated will be of considerable value, and contributions will likely occur through studies that include measures of plausible psychological mediators, such as coping processes and perceived control, as well as measures of

neuroendocrine hormones or immune system parameters that have been linked to disease endpoints. Support effects for health of specific populations, such as children, have received only minimal attention in current research. Disease conditions where social support has important effects for both patients and caregivers, such as stroke (Tompkins et al., 1988) and Alzheimer's disease (Kiecolt-Glaser et al., 1991), have barely been considered in the present chapter, and represent areas where good research will continue to be informative. The effects of support for extreme stressors such as warfare have been little studied (see, e.g., Solomon, Mikulincer, & Hobfoll, 1987) and represent an area where social support effects could be even more significant than has been found for the kinds of stressors that have been studied in previous research. Intervention studies to enhance social support for persons with physical illness appear to have promise at this time, and further efforts in this area are greatly needed. Findings from support intervention research may be applied to helping persons who have been victimized through child abuse or crime (cf. Pynoos, Sorenson, & Steinberg, 1993), and similar efforts may have value for helping persons deal with stressors of international migration (Shuval, 1993) or natural disasters (Weisäth, 1993), which are areas likely to be of increasing importance in the current world.

University of North Carolina at Chapel Hill

Kate Lorig, a health educator at Stanford University, tells a story about encouraging people with arthritis to begin exercise programs. Often, she explains, they believe that exercise would be beneficial but they also believe that embarking on a successful exercise program is not something that they can personally do. She will ask them, "Could you exercise for 15 minutes a day?" If they say they cannot, then she asks them if they would be able to exercise for 10 minutes? (Or 5? Or 1?) Eventually, virtually everyone admits to being able to exercise at some minimal level. If individuals agree they could exercise for 1 minute, then she might ask them if they could exercise for 1 minute on five separate occasions during the day. If they agree, then she points out that what they have agreed they can do amounts to more than 30 minutes of exercise per week. From this beginning, people often progress quickly to achieving the 15 minutes of exercise per day that they initially felt incapable of doing. What has allowed them to progress from a state of inaction to a modest but significant change in their health behavior? Arguably, the critical factor is the perception that people have the ability to initiate and execute an exercise program. That is, they have a sense of self-efficacy.

In the quest to understand and regulate health behavior, few theoretical constructs have been enlisted as enthusiastically as self-efficacy. The concept has been discussed both as one of the major components of social cognitive theory and as a theory in its own right. Whichever approach is taken, it is clear that self-efficacy has generated a substantial amount of research and has been applied to understanding, predicting, and changing a vast range of human behavior—including behavior related to health and illness. Since its

promulgation in the 1970s, self-efficacy has become progressively more visible in the health literature. Entering the text word "self-efficacy" into the MEDLINE database reveals no citations between 1966 and 1975, 9 between 1976 and 1980, 75 between 1981 and 1986, 343 between 1987 and 1992, and 552 between 1993 and July 1997. Thus, it is clear that self-efficacy is a preeminent concept in contemporary health psychology.

Bandura (1995a, 1995b, 1997), the creator of self-efficacy and social cognitive theory, published two major books on self-efficacy that cover much of the research done in the area prior to 1997. In addition, Maddux (1995) published an edited book on self-efficacy containing reviews of self-efficacy in a number of domains, as well as a spirited interchange between Bandura and Kirsch about the relation between efficacy and outcome expectations. Another recent review of self-efficacy has been done by Schwarzer and Fuchs (1995) and, finally, Maibach and Murphy (1995) wrote a very helpful, user friendly article on measuring self-efficacy.

This chapter draws heavily on the aforementioned books and articles. It begins by discussing how self-efficacy has emerged from earlier social learning theory concepts and its present status as a pivotal aspect of social cognitive theory. Next, it discusses processes that mediate the influence of self-efficacy on behavior. This is followed by differentiating self-efficacy from other psychological constructs. It then examines factors that contribute to a sense of self-efficacy and summarizes issues related to its measurement. Finally, it presents a brief overview of studies examining self-efficacy and health.

ORIGINS OF THE SELF-EFFICACY CONSTRUCT

The concept of self-efficacy grew out of social learning theory, which in turn grew out of principles of operant conditioning. According to these principles, behavior is determined by the consequences (i.e., reinforcing, neutral, or punishing stimuli) it produces. Rotter's social learning theory carried the ideas underlying these principles into the realm of more complex, cognitively influenced, social behavior. Two critical determinants of behavior, according to social learning theory, are the value individuals place on a specific outcome and the expectancy that the behavior in question will produce that outcome. Thus, at the core of Rotter's theory is the individual's belief about what will result from a given action. If someone expects good things to result from a given action, that action has a higher likelihood of occurring than if the expectation is for a bad outcome. This is stated a bit more formally in Rotter's (1954) own words: "The occurrence of a behavior of a person is determined not only by the nature or importance of goals or reinforcements but also by the person's anticipation or expectancy that these goals will occur" (p. 102). In other words, people will behave if they believe their behavior will produce a desired effect. Within this framework, outcome expectancies are essentially beliefs about the way the world works, that is, about how contingencies are arranged or the relationships between actions and their consequences.

Rotter later introduced the idea of locus of control, which refers to the generalized belief that the occurrence of outcomes is under the control of oneself (i.e., internal locus of control) or outside of the self (i.e., external locus of control). Controlling forces outside of the self also included control of one's outcomes by chance and/or powerful other people. This idea was subsequently adapted specifically for health-related outcomes (B. S. Wallston, K. A. Wallston, Kaplan, & Maides, 1976; K. A. Wallston, B. S. Wallston, & R. DeVellis, 1978). Although the notion of locus of control recognized that individual perceptions of influence over actions were determinants of action, the perceptions in question still concerned outcome expectancies. Locus of control, like the earlier conceptualizations of outcome expectancies, primarily assessed beliefs about how the world works. The idea that "I make a difference in how the world works" was imbedded in the locus of control concept, but the emphasis on personal agency was not yet fully developed.

Bandura developed a separate social learning theory largely independently from Rotter (Woodward, 1982). Notable additions in Bandura's theory were imitation as a process through which behavior could be acquired and, later, the concept of self-efficacy. Bandura (1986) changed the name of his theory from social learning theory to social cognitive theory. This change reflected the broader scope of his theory and the central contribution of thought processes to motivation, action, and affect (Bandura, 1986). An extremely important conceptual advancement was Bandura's explicit distinction between outcome expectancy and what he termed *self-effi-*

cacy. He reasoned that individuals may believe that their own behavior would result in a certain desired outcome (thus, having a high outcome expectancy and an internal locus of control) but might feel incapable of performing that behavior. Such a perceived incapacity was described as weak self-efficacy with respect to the particular behavior. In contrast, if the belief that they are capable of performing a particular behavior is strong, then self-efficacy for the behavior in question is strong. Thus, Bandura's model made a distinction between beliefs regarding how the world works (i.e., outcome expectancies) and beliefs about what they are capable of doing (i.e., self-efficacy).

Why wasn't this distinction recognized earlier? Outcome expectancies alone may have appeared to be all that was needed. Asking "What do you think will happen if you do X," seemingly assumes that the ability to do X is not at issue, and for many behaviors this may be the case. But depending on how the question was asked and interpreted, and on what the behavior was, outcome expectancies might or might not capture the idea of self-efficacy. Thus, asking "If you stop smoking, will your health improve?" might evoke different answers depending on how it is interpreted. One person might reason, "well, I *can't* stop, so the answer is 'no,'" whereas another reasons, "well, if I *could*, I guess I *would*," and answer, "yes." Bandura's work revealed that recognizing self-efficacy as a distinct and essential determinant of behavior avoids ambiguity and thus has obvious utility. People who respond affirmatively when asked about whether quitting smoking will result in better health may give an answer that takes into consideration whether or not they feel able to quit. But, asking separately about whether quitting would result in better health (outcome expectancy) and whether individuals believe they can quit (self-efficacy) greatly reduces the chances for ambiguity or confusion. The extensive use of the concept of self-efficacy by clinical and research psychologists since its introduction attests to the recognized utility of distinguishing self-efficacy from outcome expectancies.

DEFINITIONS: SELF-EFFICACY AND OUTCOME EXPECTATIONS

Over the years, Bandura's definition of self-efficacy and discussion of its relation to outcome expectations has been elaborated and applied to increasingly diverse arenas of behavior. At one point, Bandura (1977b) defined outcome expectations as "a person's estimate that a given behavior will lead to certain outcomes" (p. 79). He then defined self-efficacy as "the conviction that one can successfully execute the behavior required to produce the outcomes" (p. 79). By 1986, the definition of self-efficacy was stated more broadly as "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances" (Bandura, 1986, p. 391). Over the same period of time, however, Bandura's definition of outcome expectations remained essentially unchanged as "a judgment of the likely consequence such behavior will produce" (Bandura, 1986, p. 391). Although his basic definition of outcome expectations

had not changed, Bandura tried to clarify what he meant by "outcome expectations" because he thought people were misinterpreting both what he meant by "self-efficacy" and the relation between self-efficacy expectations and outcome expectations. Of particular concern was the boundary between behavior and the outcomes it produces. To clarify his position on this issue, Bandura gave the example of an athlete who is confident that he can jump 6 feet. The strength of the athlete's confidence that he can jump 6 feet, he argued, is the efficacy expectation, and the outcome of "jumping 6 feet" is the praise and self-satisfaction the athlete receives on completing the act. Thus, according to Bandura, self-efficacy in this case would not be merely how confident the person felt about the ability to execute the multiple behaviors and subskills that go into a successful jump (e.g., the speed of running during the approach; the velocity of the push off from the ground). This is so because the sequence of subskills does not constitute the relevant behavior. Rather, the attainment of jumping 6 feet is the behavior. The successful performance of this athletic act is then rewarded by the outcomes of praise, admiration, and/or the satisfaction of doing something well. As Bandura (1986) wrote, "If an act is defined as a six-foot leap, then a six foot leap is the realization of that act, not a consequence of it" (p. 392). Bandura also emphasized that possession of skills alone does not guarantee successful execution of the act because competent functioning requires the ability to use those skills in appropriate combinations under diverse sets of circumstances.

As another example, a person prescribed a complex medication regimen may possess all the requisite skills to count out a week's worth of multiple medicines and cluster them into "morning," "noon," "dinner," and "before sleep" doses for each day. The person also may have seen pill boxes in drug stores that allow pills to be arranged in this way. Someone lacking the ability to apply skills in the appropriate combinations and contexts, however, may not recognize that a means of accomplishing their goal of taking the medicines as prescribed is to use these pill boxes. A more efficacious person, according to Bandura's definition, would be able to make the connection between their basic skills of pill counting and pill sorting and the availability of special pill boxes to achieve a system that greatly facilitates their medication adherence.

The example just described illustrates that mere possession of the requisite skills and the existence of external resources do not guarantee successful performance. Individuals' belief that they can coordinate the skills into an orchestrated behavioral sequence is also an important part of the equation.

In fact this belief that people can cope with the complexities of a complicated medication regimen operates partially independently of underlying skills (Bandura 1986, p. 391). Why? Because if people have low self-efficacy, they may never try a new approach to the problem, even though it would succeed if attempted. In contrast, people with high self-efficacy but fewer skills may have a resilient belief in their ability to achieve their goal. This may motivate them to persist in trying various alternative solutions until they eventually stumble onto one that works.

Bandura's (1997) discussion of self-efficacy reinforces the idea that the concept should be applied to coordinated behavioral sequences rather than subskills. He defined perceived self-efficacy as "beliefs in one's capabilities to organize and execute the courses of action required to produce given attainments" (p. 3). In addition, Bandura (1997) noted that the definition of self-efficacy encompasses not only the execution of behaviors and behavioral attainments, but also the perceived strength of individuals' ability to regulate motivation, thought processes, affective states, and the social and physical environment (Maibach & Murphy, 1995).

SELF-EFFICACY AS AN INTEGRAL PART OF SOCIAL COGNITIVE THEORY

Bandura asserted that to understand the impact of self-efficacy beliefs correctly and fully, they must be examined within the context of social cognitive theory, which includes three elements: the person, the person's behavior, and the environment. Each can influence the others in a process that Bandura referred to as "reciprocal causation." Characteristics of the person component include cognitive, affective, and biological factors, whereas behaviors include all the things that people say and do. Finally, the environment represents all factors outside of the person, including the social structure. This notion of reciprocal causation among the person, the person's behavior, and the environment leads to an examination of not just the ways people's environments influence their thoughts and/or behavior but the ways people's thoughts and/or behavior influence their environments.

Because self-efficacy is a belief, it is aligned most closely with the "person" component of Bandura's tripartite social cognitive theory; he viewed self-efficacy as the preeminent "person" attribute. Nevertheless, self-efficacy must be conceptualized in relation to relevant contexts, which can include elements of the person's behavior, their environment, and/or other aspects of the person. For example, 6 months after giving up cigarettes, individuals may have a strong sense of efficacy to refrain from smoking cigarettes if in a "no smoking restaurant" with friends who do not smoke. They may have a weaker sense of efficacy for refraining from smoking if in a bar drinking a soft drink with friends who are smoking. Efficacy might be further weakened if they have two alcoholic drinks in that same bar with those same smoking friends. Finally, efficacy would be weaker still if the person additionally had a terrible day at work and was feeling "down in the dumps." Thus, this emphasis on viewing self-efficacy within specific contexts anchors it to the individuals' environment (a smoking permitted bar vs. a smoking prohibited restaurant), the individuals' behavior (drinking alcoholic vs. a nonalcoholic drink), and other aspects of the individuals themselves (e.g., mood). In this example, the strength of self-efficacy to refrain from smoking varied according to levels of social influence, the physical environment, cues about the acceptability of smoking, and mood.

PROCESSES THAT MEDIATE THE INFLUENCE OF SELF-EFFICACY ON BEHAVIOR

According to Bandura (1997), self-efficacy is a powerful predictor of the kinds of activities people do, how long and how intensively they persist in doing them, and the amount of distress or satisfaction they experience in the face of life's opportunities, challenges, and hardships. Furthermore, self-efficacy even affects whether or not different people perceive the same event as an opportunity, challenge, or hardship. For example, someone who has high self-efficacy for successfully completing gross motor tasks requiring strength and coordination may view a recommended exercise regimen as a challenge to be faced with enthusiasm and strong expectations for success. A person with lower self-efficacy for this type of activity may view the same situation with dread, anticipating failure and embarrassment.

Bandura (1997) described four processes through which self-efficacy achieves its effects: cognition, motivation, affect, and selection. Each of these four processes can operate alone, but they usually "operate in concert, rather than isolation" (p. 116), and the mechanisms underlying each of the four overlap considerably.

Cognition

Self-efficacy is itself a cognition. However, other cognitions can mediate between self-efficacy and behavior. Self-efficacy thus can influence the way that people understand or interpret situations. For example, people who believe that they cannot solve a problem may come to believe the problem is inherently unsolvable. As a result, even if circumstances change, this interpretation may preclude effective action.

Motivational Processes

Motivational processes constitute the second major group of factors that mediate the influence of self-efficacy on performance. Bandura acknowledged, however, that motivational processes in humans involve a substantial cognitive component. Thus, beliefs about causal sequences can enhance or attenuate individuals' motivation to pursue a given behavior. He went on to describe cognitive activities associated with theories other than social cognitive theory that have motivational implications. These include attributions, outcome expectancies, and goal setting.

Attributions concern the causes that people ascribe for events that have already happened to them. For example, imagine that a woman who has not exercised in years finishes a 10-minute bicycle ride and experiences mild "windedness" and tightness in her calf muscles. Someone with a strong sense of efficacy for exercising more regularly might attribute these symptoms to beneficial health changes (e.g., "I'm exercising enough for an aerobic benefit and my legs are getting a good workout"), whereas someone with a weak sense of efficacy might attribute them to inherent

weakness (e.g., "I'm too out of shape to do this"). As a consequence, the former woman might continue to ride her bike regularly while the latter desists.

The second type of cognitive motivator is outcome expectancies. The outcomes that people anticipate from implementing a course of action should have motivational value. Bandura (1997), however, believed that outcome expectancies do not add much to the prediction of behavior over and above the contribution of self-efficacy because "efficacy beliefs affect the extent to which people act on their outcome expectations" (p. 126). Of course, a sense of self-efficacy is unlikely to lead to action if people believe that the action will not produce the desired outcome.

Goal setting, in the context of self-regulation, is the third motivator that mediates the influence of self-efficacy on behavior. Self-regulation refers to the "automatic and deliberate processes by which people control and direct their cognitions, emotions, and behaviors in the pursuit of their goals" (Barone, Maddux, & Snyder, 1997, p. 303). Self-efficacy can influence self-regulation in four ways (Bandura, 1997). First, self-efficacy influences what goals people set for themselves. Those people with higher self-efficacy in a particular domain of achievement will set higher goals than those with lower self-efficacy. Second, self-efficacy affects people's reactions to perceived discrepancies between their goals and actual performance (Barone et al., 1997). People with a high sense of self-efficacy will work harder and persist longer to attain their goals than people with low self-efficacy. Third, "self-efficacy in solving problems and making decisions influences the efficiency and effectiveness of problem solving and decision making" (Bandura, 1997, p. 291). Finally, self-efficacy influences whether or not a person will choose to enter goal-relevant situations.

Affective Processes

The third major group of processes that mediate the influence of self-efficacy are affective and consist of exercising control over thought, affect, and action (Bandura, 1997). First, with respect to thought, efficacy beliefs influence what stimuli people attend to (e.g., an elevator may go unnoticed by most people but not by someone with an elevator phobia), how people appraise situations cognitively (e.g., as a threat in the case of low self-efficacy and a challenge when efficacy beliefs are high), and whether past situations (e.g., a medical appointment) are remembered in positive, neutral, or negative terms. With respect to affect, efficacy beliefs influence "perceived cognitive abilities to control perturbing trains of thought when they intrude on the flow of consciousness" (p. 137). Thus, in essence, affective states may enhance or undermine self-efficacy through their cuing, motivational, and reinforcing properties. One of the objectives of self-regulation is fostering affective states conducive to the successful completion of desired actions. Finally, actions also can mediate the influence of self-efficacy on emotions. In essence, efficacy beliefs influence the types of actions that people take. The consequences of taking more effective courses of action will differ from those of less effective alternatives. Thus, actions are a

mechanism through which efficacy beliefs influence emotions. And these emotions, in turn, can mediate between self-efficacy and subsequent actions.

Selection Processes

The fourth major group of processes that mediate the influence of self-efficacy involve selection processes, that is, choosing environments into which people put themselves. These choices are heavily influenced by people's sense of efficacy to function in specific environments. People will avoid environments they believe exceed their capabilities and will gravitate toward environments they feel they can handle. People with higher self-efficacy are more likely to place themselves in challenging situations and persist in gaining mastery over those situations once they are in them. Moreover, these choices may have enduring consequences. Bandura (1997) noted that choices that often seem insignificant at the time end up, in hindsight, being crucial turning points in a person's life with major effects on people's life paths. An example of this is an adult who feels inefficacious with respect to classroom settings who thus fails to attend a lecture at a local school about cancer screening and neglects to recognize an important warning sign.

Thoughts on Mediational Processes

Bandura's point in discussing mediators of self-efficacy is to illustrate how various processes help to translate a given level of self-efficacy into a given behavioral performance. It is worth noting that factors other than self-efficacy will also influence cognitive, motivational, affective, and selective processes related to behavior. Thus, a full understanding of self-efficacy alone is unlikely to yield a full understanding of how each of these processes influences behavior. Moreover, characterizing these processes as mediators between self-efficacy and behavior amounts to acknowledging them as more immediate (although not necessarily more comprehensive) determinants of behavior. Thus, do not interpret the inclusion of concepts from other theories in the preceding sections as suggesting that social cognitive theory fully supplants the theories from which those concepts are derived.

HOW SELF-EFFICACY DIFFERS FROM OTHER CONSTRUCTS AND CONCEPTS

Bandura (1997) viewed personal efficacy beliefs as the pre-eminent factor in human agency. He briefly described a number of other person characteristics (e.g., locus of control, self-esteem, self-confidence) with the dual goals of showing how they differ from the construct of self-efficacy and demonstrating that they are not as powerful as self-efficacy in explaining, predicting, or intervening on human behavior. As noted earlier, the vast number of studies that have examined self-efficacy and the growing number of interventions that have self-efficacy as a cornerstone testify to its importance. Other evidence of the power of the self-efficacy construct has

been its addition to major models of behavior that had existed for a relatively long time without self-efficacy in them (e.g., the health belief model; Strecher & Rosenstock, 1977; theory of reasoned action; Montano, Kasprzk & Taplin, 1997) and the inclusion of self-efficacy in more recently developed theories of behavior such as Social Action Theory (Ewart, 1991) and the Cognitive-Social Health Information Processing (C-SHIP) Model (Miller & Diefenbach, 1998).

There are a number of constructs that have been mistakenly equated with self-efficacy. This has led to confusion at both the conceptual and operational levels. This confusion occurs, in part, because the personality traits, states, and processes that these concepts represent can both influence and be influenced by self-efficacy. This does not mean, however, that any of these concepts are equivalent to self-efficacy (Strecher, B. DeVellis, Becker, & Rosenstock, 1986).

Health Locus of Control

Health locus of control refers to a generalized expectation about where control for a person's health resides. Thus, health locus of control concerns the extent to which people think their health is controlled by their own actions and efforts, by the actions of others (e.g., physicians and nurses), or by fate or chance. In this scheme, health is an outcome and locus of control is concerned with the *perceived relation between actions and outcomes* (Maibach & Murphy, 1995). Self-efficacy, on the other hand, is concerned with the extent to which people feel capable of undertaking the specific behavior(s) that may or may not lead to a desired outcome. For example, individuals may firmly believe their health status (outcome) is influenced by what they eat (behavior) and thus that if they ate less fat they would live a longer and healthier life. They might, however, also feel incapable of restricting their consumption of fatty foods. Thus, people can view their own health as determined by their own actions (internal locus of control) but feel unable to carry out the actions that will lead to better health. The person caught in this dilemma has an internal locus of control but low self-efficacy when it comes to restricting fat consumption.

Self-Esteem

Self-esteem refers to "the overall affective evaluation of one's own worth, value, or importance" (Blascovich & Tomaka, 1991, p. 115). Blascovich and Tomaka further described self-esteem as part of the broader construct of self-concept. The latter includes both cognitive and behavioral as well as emotional aspects of people's self-representation. They also pointed out that self-esteem, especially when measured globally, tends to be quite stable across time and contexts. Although both self-esteem and self-efficacy concern an assessment of some aspect of oneself, the preceding definition highlights several key distinctions. Whereas self-efficacy has strong cognitive components, self-esteem is more evaluative and affective. It is, in essence, how individuals feel about themselves in a global sense. This "global sense" is the second key difference between self-esteem and self-efficacy. Although the latter is

specific to time and context, self-esteem is traitlike (i.e., relatively invariant). Despite these important differences, the two are not entirely independent. Perceiving oneself as efficacious in a variety of contexts is likely, over time, to exert a positive influence on self-esteem. Similarly, high self-esteem seems more likely than its opposite to engender a strong sense of self-efficacy in a novel situation. It seems unlikely, however, that either of these two variables will be determined primarily by the other in most circumstances. Thus, although it is possible to describe mechanisms that link the two, their differences are clear and the terms are by no means interchangeable. Bandura highlighted the distinction between the two concepts by pointing out that high self-efficacy for some tasks (e.g., being able to brush one's teeth well) will do little to enhance self-esteem and that low self-efficacy for others (e.g., not being able to ride a unicycle) will not compromise how individuals evaluate themselves globally.

Coping

Lazarus and Folkman (1984) articulated a comprehensive model of coping that shares some assumptions with the construct of self-efficacy and interfaces with it at several points. According to the Lazarus and Folkman model, two types of cognitive appraisal—primary appraisal and secondary appraisal—influence coping. *Primary appraisal* refers to categorizing a situation in terms of its meaning and significance for an individual's well-being. It involves formulating an answer to the question, "Am I in trouble or being benefitted now or in the future and in what way?" (p. 31). As a result of primary appraisal, a situation can be viewed as stressful, benign-positive, or irrelevant. There are three types of stressful primary appraisals: harm/loss, threat, and challenge. Secondary appraisal refers to an assessment of what might be, and can be, done when people conclude that either a threat or an opportunity exists. Self-efficacy is relevant for both primary and secondary appraisal. High self-efficacy for a situation can lead to a primary appraisal of that situation as benign, positive, or as irrelevant, but not as stressful. If a situation is appraised as stressful, then self-efficacy becomes a major, if not the major, component of secondary appraisal. Bandura (1997) noted that instilling a sense of or increasing a sense of self-efficacy can transform threatening situations into safe ones.

Self-confidence

Self-confidence describes "an overall evaluation of ability rather than an evaluation of capability with regard to certain tasks" (Maibach & Murphy, 1995, p. 40). According to Bandura (1997), although confidence refers to strength of a belief, it does not necessarily specify the cause of the certainty. For example, people can be extremely confident that they will live to age 90 based on the knowledge that all of their grandparents lived to this age. Thus, their confidence may have nothing to do with their beliefs about their behavioral capabilities. Perceived self-efficacy, on the other hand, refers to the belief in individuals' power to attain given lev-

els of performance. A self-efficacy assessment, therefore, includes both the affirmation of capability and the strength of that belief. Finally, self-confidence is a colloquial expression used in everyday language. Bandura cautioned readers to keep the term *self-confidence* in everyday language but to not equate it with self-efficacy, which is more precisely defined. Some of the confusion about the relation of self-confidence to self-efficacy probably arises from the fact that one way of measuring self-efficacy is to ask people to rate how confident they feel in their ability to do a specified activity. Although expressing self-efficacy in terms of confidence may be a useful means for researchers to communicate with respondents who are not theoreticians, it should not, Bandura asserted, be treated as a synonym for self-efficacy in formal discussions of the concept.

Generalized Self-Efficacy

Generalized self-efficacy refers to a "sense of efficacy that operates across all situations and domains of functioning" (Maibach & Murphy, 1995, p. 40). Maibach and Murphy (1995) noted that conceptualizing self-efficacy in this way is antithetical to the way Bandura defined self-efficacy because in social cognitive theory, self-efficacy must be tied to specific domains of functioning and specific contexts. Maibach and Murphy believed that this misguided idea of generalized self-efficacy evolved out of a misinterpretation of how the term *generality* is used in discussions of the three measurement dimensions of self-efficacy (i.e., level, strength, generality). As an example, individuals whose efficacy beliefs are high in generality may feel efficacious with respect to performing a behavior, such as avoiding high fat foods, in a variety of different settings. This is not the same, however, as feeling efficacious across multiple domains of behavior, such as dietary regulation, exercise, and avoidance of stress.

SOURCES OF SELF-EFFICACY

Beliefs about personal efficacy are learned from five major sources: enactive mastery or learning through personal experience; vicarious experience, which includes learning through the observation of events and/or other people; verbal persuasion; physiological state; and affective state.

Enactive Mastery

Bandura (1997) stated that enactive mastery experiences are the most potent source of efficacy information because they provide the most authentic evidence that individuals can do what it takes to succeed. Furthermore, Bandura noted, successive mastery over tasks required to engage in a behavior helps people develop and refine skills. In addition, it fosters development of a repertoire of coping mechanisms to deal with problems encountered. There is no one-to-one correspondence between performance and perceived self-efficacy, however (Bandura, 1997). Both successful and unsuccessful

experiences are cognitively processed and the way each experience is attended to, weighted, and interpreted will influence its impact on self-efficacy. Thus the extent that personal experience will alter people's perceived efficacy "depends on their preconceptions of their capabilities, the perceived difficulty of the tasks, the amount of effort they expend, the amount of external aid they receive, the circumstances under which they perform, the temporal pattern of their successes and failures, and the way these enactive experiences are cognitively organized and reconstructed in memory" (Bandura, 1997, p. 81). People with low self-efficacy in a particular domain may discount their successes as "flukes," whereas people with high preexisting self-efficacy may discount their failures as "flukes." All other things being equal, however, direct mastery experiences are the most potent source of efficacy information.

Vicarious or Observational Experience

Fortunately, people do not have to learn everything through direct experience but can learn from observing events and/or the behaviors of others in conjunction with the consequences that follow those events or behaviors. These events/people are referred to as "models." Bandura (1997) considered vicarious experience and modeling as the second most powerful source of self-efficacy information and, under some circumstances, vicarious experience and modeling can surpass the influence of enactive experiences.

There are four processes that influence the impact of observational learning: attention, retention, behavioral production, and motivational processes. First, an observer needs to attend to the model and Bandura cited a number of factors related to attributes of the observer (e.g., perceptual set, cognitive capabilities and preconceptions, arousal level, acquired preferences) and attributes of the event (e.g., salience, affective valence, complexity, prevalence, accessibility, functional value) that can influence what, if anything, receives attention. Next the person must retain the information that has been observed. This involves an active process of transforming information from discrete ideas into organized, symbolic form, such as general principles that can govern action in multiple situations. Behavioral production involves the translation into behavior of the principles that arose from attention and retention processes. The observer's physical capabilities and the number and complexity of subskills required to execute the behavior affect whether, and how well, individuals perform the modeled behavior. In addition, observers go through a self-regulation process whereby they monitor their skill at doing the behavior in light of their conception of how, and how well, the behavior should be done and then attempt to modify their behavior so that it better matches their conception of how it should be done. Finally, motivational processes influence the effect of modeling on the observer's self-efficacy. For example, people who are highly motivated to achieve a very high standard of performance may suffer a loss of self-efficacy if the performance of a model they view as comparable to them in ability falls short of this standard.

Verbal Persuasion and Social Evaluations

Verbal persuasion is the third source of efficacy information. If all other factors are equal, then verbal persuasion alone is a less powerful source of efficacy information than either enactive or vicarious experience. The right kind of verbal feedback from a credible source can significantly facilitate self-change efforts, however. Thus, positive feedback that is "within realistic bounds," focuses on achieved progress, highlights personal capabilities, and is delivered by a credible person can lead a person to try harder and persist longer. If a person is given the wrong kind of feedback, however, the results can be devastating. For example, feedback framed as a gain (e.g., you have progressed toward your goal by 75%) can enhance self-efficacy, whereas the same feedback framed as a deficit (e.g., you are short of your goal by 25%) can cause self-efficacy to plummet. Likewise, feedback that is overinflated will be discounted when individuals try out the new behavior and fall short of their goal. Bandura (1997) noted that it is easier to undermine people's efficacy through destructive feedback than it is to bolster self-efficacy through constructive feedback. Furthermore, he noted, that much of the feedback given in society is deficit oriented and destructive to a sense of efficacy. Finally, verbal persuasion works best in tandem with the other forms of efficacy enhancement (i.e., enactive experience, vicarious experience, and physiological and affective states).

Physiological State

People's physiological state can influence self-efficacy. Bandura noted that people are more apt to expect failure if they are highly physiologically aroused. This expectation occurs as a result of previous associations of physical arousal with impaired performance. People who experience sweaty palms and trembling knees as they are about to give a talk often find that their efficacy for public speaking plummets and their performance then may, in fact, be impaired. The presence of such arousal, however, does not automatically result in impaired performance. People who view their arousal not as a sign of incompetence at public speaking but as a sign of positive energy and heightened interest may find that their heightened arousal facilitates rather than impairs self-efficacy and may also result in a more dynamic presentation. Likewise, a sedentary person just starting an exercise program can interpret transient fatigue and mild aches as a sign of physical vulnerability and stop or they may see it as diagnostic of a neuromuscular system that is "coming alive."

Affective States

People's moods can affect their sense of self-efficacy. Positive mood states contribute to a heightened sense of self-efficacy and negative mood states contribute to a poorer sense of self-efficacy. When in negative moods people are more apt to recall and focus on past failures and shortcomings, whereas people experiencing a positive mood are more apt

to recall and focus on past success experiences. This mood relevant recall and focus has been shown to occur when a person is experiencing a naturally occurring mood state or is experiencing a mood that has been induced by an investigator in a research setting.

MEASURING SELF-EFFICACY

The measurement of self-efficacy has many features in common with the measurement of other psychological constructs and a few that are more specific. The general features include the avoidance of ambiguously worded items, use of multiple rather than single indicators, attainment of acceptable reliability, and demonstration of the validity of the measurement procedure. These are not discussed here. Readers may consult other sources (e.g., DeVellis, 1991; Nunnally & Bernstein, 1994) for a more general discussion of these and other technical measurement issues. The remainder of this section focuses on conceptual issues that have particular relevance to measuring self-efficacy.

Measurement in psychology typically involves obtaining some indication of the state of a construct that is not self-evident. The validity of the measurement process is the extent to which the manifestation obtained corresponds to the true state of the variable in question. One requirement for valid measurement, therefore, is that the data gathered correspond very closely to the concept they represent. This, in turn, requires that the concept be sufficiently clear to guide the development or selection of the measurement strategy.

Behaviors Versus Attainments

Should self-efficacy assess the person's confidence in doing something or achieving something? Although the early discussions of self-efficacy emphasized its impact on specific behaviors (Bandura, 1977a), self-efficacy is not restricted to overt, discrete actions. Self-efficacy with respect to goals, behavioral attainments, and self-regulation (i.e., thoughts, feelings, perceptions, and motivations as well as behavior) are an integral part of the most recent descriptions of the phenomenon (Bandura, 1997; Maibach & Murphy, 1995). The choice of measuring a specific behavior, behavioral attainment, or self-regulation should be based on the nature of the phenomenon under investigation. If the objective is to predict a specific action, then the self-efficacy assessment should probably correspond to the completion of that action. If the behavior in question is most reasonably defined in terms of a performance attainment (e.g., weight loss), then the attainment may serve as a marker for the behavior when assessing self-efficacy. In this case, self-efficacy would be assessed in relation to the goal of losing 8 pounds in 4 weeks and the outcome expectancy might include receiving complements on appearance, fitting into preferred clothes, and self-satisfaction about having achieved the goal.

Time Frame

Generally, self-efficacy assessments should focus on the present. Bandura (1997) highlighted the importance of asking

about what people believe they can do rather than will do. He noted that the former assesses self-efficacy and the latter assesses behavioral intention. Implicit in the "can do" wording is the notion of doing the behavior in question now. Confidence in a person's ability to act at an unspecified future time runs the risk of confusing self-efficacy and intention. One exception that Bandura (1997) acknowledged is a circumstance requiring sustained action over time, such as refraining from smoking. There is little utility in determining whether someone can refrain from smoking at a specific instant, as opposed to over some time interval. Thus, Bandura advocated wording self-efficacy items to assess confidence with respect to a specified time interval (e.g., not smoking for a week), when the attainment in question involves a sustained pattern of behavior.

Specificity

Self-efficacy is not a unitary attribute but a class of attributes. That is, self-efficacy will vary within the same individual across domains (e.g., self-efficacy for getting a new job vs. self-efficacy for refraining from smoking) and contexts (e.g., given different amounts of time to prepare a response or acting in familiar vs. strange physical settings). Before attempting to measure self-efficacy in a specific circumstance, that circumstance should be understood and explicated as fully as possible. Is the goal of the specific assessment to understand self-efficacy under relatively broad or relatively narrow conditions?

Specificity and breadth are both desirable aspects of assessment. Typically, one is achieved at the expense of the other and their relative merits will depend on the measurement goal. As a practical matter, little is likely to be gained by operationalizing self-efficacy at either extreme of this continuum. Extremes aside, greater specificity is usually preferable.

One potentially useful approach is to specify the domain of interest (e.g., adherence to a recommendation to avoid dietary saturated fats) and then to consider what types of situational factors might reasonably be expected to influence self-efficacy within that domain. Both Bandura (1997) and Maibach and Murphy (1995) recommended using a variety of methods, including open-ended questionnaires and elicitation interviews as a means of understanding the types of circumstances and performance demands that individuals may face. In thinking about situational influences, the criterion for inclusion should be what is reasonable or likely rather than what is possible. Thus, assessing efficacy under circumstances that pose real-world challenges to the respondent (e.g., eating in a restaurant with a limited menu, being a diner guest when a high fat meal is served) is likely to be useful. Possible but unlikely scenarios (e.g., having someone offer you \$100 to eat a pepperoni pizza) are less likely to correspond to the circumstances the respondent will actually face and, thus, will lower the validity of the assessment procedure.

Measurement Models

The preceding sections have suggested that how self-efficacy is measured should correspond with the reasons for measur-

ing it. Similarly, how the data yielded by measurement processes are treated should correspond with the assumptions underlying measurement procedures. An issue that is often overlooked in self-efficacy assessment is the correspondence between measurement procedures and measurement models. As an example, consider two different measurement strategies. In the first strategy, the purpose of having multiple items is primarily as a way of reducing error that might be associated with each individual item. The items themselves, however, are intended to get at essentially the same information. Three items that all gather similar information about self-efficacy for quitting smoking might be: "I am able to quit smoking successfully," "Giving up cigarettes is something I am able to do," and "I will be successful in my attempts to stop smoking cigarettes." Each asserts the same idea but in a slightly different way. Thus, it can be presumed (and could be empirically tested) that the items are equally sensitive detectors of self-efficacy for quitting smoking. An alternative perspective is to think about different items as tapping different levels of self-efficacy. For example, successive items might ask about confidence to refrain from smoking during a 2-hour movie in a theater, during a 2-hour meal with nonsmokers, and during a 2-hour meal during which all the other diners were smoking. In this case, the items represent a progression of challenges or barriers to the successful attainment of the behavioral goal. The investigator would probably expect the items to reveal different degrees of self-efficacy, in inverse proportion to the difficulty of the situation the item describes. Summing or averaging the items may not be the best means of capturing the information they can provide. Bandura stated a preference for items of the latter type, asserting that "to achieve explanatory and predictive power, measures of personal efficacy must be tailored to domains of functioning *and must represent gradations of task demands within those domains*" (Bandura, 1997, p. 42, emphasis added).

These two strategies for developing self-efficacy items reflect quite different measurement models. The first example corresponds fairly well to classical measurement theory based on an assumption of parallel, equally weighted items. The second is more like a Guttman scale (see Nunnally & Bernstein, 1994, pp. 72–75, for a brief description and discussion of limitations) or instruments based on item response theory (IRT; see Hambleton, Swaminathan, & Rogers, 1991, for a good general introduction). Methods for developing, validating, and reporting scales from these different models are not equivalent. On one hand, self-efficacy at a conceptual level seems well suited to psychometric methods derived from item response theory. That is, it seems reasonable to assume that, within a given domain of self-efficacy, there should exist items that are sensitive to progressively higher levels of the construct. On the other hand, these methods are fairly demanding and require large sample sizes. Nunnally and Bernstein (1994, p. 396), for example, recommended samples of from 200 to 500 for applying IRT, even with very short scales. Treating items that represent progressively higher levels of an attribute as if they all reflected the attribute equivalently introduces its own logical and technical difficulties. Although this issue cannot be re-

solved here, it is worth considering when choosing how to measure self-efficacy.

Maibach and Murphy (1995) provided several examples of measurement strategies. These usually include a description of a situation or a scenario that establishes the context of the behavior and a response scale. The latter begins with a statement that respondents are to indicate a degree of certainty that they can do each of the things indicated by statements that follow the response option scale. Immediately after this statement is a scale that typically has 11 numerical values (e.g., the numbers 0 through 10) accompanied by three verbal labels: "cannot do at all," "moderately certain can do," and "certain can do" located, respectively under the extreme left, midpoint, and extreme right of the row of numerical values. Maibach and Murphy's examples then list multiple items describing behaviors or behavioral attainments. For each of these, respondents are required to provide a number from the numerical scale, thus indicating their confidence in doing whatever the item states. A hypothetical tool for assessing smoking abstinence, developed on the basis of examples provided by Maibach and Murphy (1995), appears as Table 13.1.

Note that in this example, the behavior (refraining from smoking) has a specified duration (an hour). Also, self-efficacy is assessed in the context of three activities (having a snack, a cup of coffee, or a beer) that may differentially impact self-efficacy. In addition, these behaviors are described as occurring in different settings and social contexts. Thus, the self-efficacy assessments gathered are context specific and the contexts represent different degrees of how difficult it might be to refrain from smoking.

OVERVIEW OF STUDIES EXAMINING SELF-EFFICACY AND HEALTH

As mentioned at the beginning of this chapter, there has been an enormous amount of research in the area of self-efficacy and health and many of these studies have been summarized in detailed reviews that have appeared since 1985 (e.g., Bandura, 1995, 1997; O'Leary, 1985; Schwarzer, 1992; Strecher et al., 1986). Bandura (1997) devoted over 60 pages of his 600-page book to summarizing health functioning in relation to the biological effects of self-efficacy, including pain tolerance and biological markers of distress, the role of self-efficacy in health promoting behavior, and the role of self-efficacy beliefs in recovery from heart attacks. In the same book, he devoted another 40 pages to the health-related topic of athletic functioning and 40 more pages to a chapter that covers anxiety and phobic dysfunctions, depression, eating disorders, and alcohol abuse. Maddux (1995) included chapters on self-efficacy in relation to health behavior (Maddux, Brawley, & Boykin, 1995), physiological stress responses (O'Leary & Brown, 1995), recovery from heart attack (Ewart, 1995), addictive behaviors (DiClemente, Fairhurst, & Piotrowski, 1995), anxiety disorders (Williams, 1995), and depression (Maddux & Meier, 1995).

The overall conclusion emerging from these and other sources is that self-efficacy is an important variable for both health research and health interventions. The results of many

TABLE 13.1
Example of a Hypothetical Self-Efficacy Measure

Below are a series of situations. For each one, please indicate how confident you are that you could **refrain from smoking** for the entire time if you were to face that situation immediately after leaving this session today. Assume that each situation lasts for about one hour. Indicate your certainty by writing a number from 0 to 10 in the space following the description of each situation.

0	1	2	3	4	5	6	7	8	9	10
Cannot do at all			Moderately certain can do				Certain can do			
										Confidence Rating
1. I am at home alone having a snack.										_____
2. I am at home alone having a cup of coffee.										_____
3. I am at home alone having a beer.										_____
4. I am at home with nonsmoking friends having a snack.										_____
5. I am at home with nonsmoking friends having a cup of coffee.										_____
6. I am at home with nonsmoking friends having a beer.										_____
7. I am at home with smoking friends having a snack.										_____
8. I am at home with smoking friends having a cup of coffee.										_____
9. I am at home with smoking friends having a beer.										_____
10. I am at a restaurant with nonsmoking friends having a meal.										_____
11. I am at a coffee shop with nonsmoking friends having a cup of coffee.										_____
12. I am at a bar with nonsmoking friends having a beer.										_____
13. I am at a restaurant with smoking friends having a meal.										_____
14. I am at a coffee shop with smoking friends having a cup of coffee.										_____
15. I am at a bar with smoking friends having a beer.										_____

interventions and cross-sectional studies suggest a link between self-efficacy and the adoption of health promotive and disease preventive behaviors. Bandura's (1992) review of studies on coping with chronic health conditions concluded that the impact of therapeutic interventions on health behavior was at least partly, if not completely, mediated by self-efficacy. He drew the same conclusion when focusing on the personal change efforts among people who want to prevent illness and promote their own health. He viewed self-efficacy as critical at all three stages of health promoting behavior change: the initiation of change, generalized use of the change under different circumstances, and maintenance of the behavior change. More recently, Bandura (1997, pp. 279-313) cited an array of studies suggesting that greater self-efficacy increases the likelihood of initiating actions aimed at improving health, enhances people's responsiveness to health communications urging regulation of health behaviors, augments adherence to habit change programs and other forms of health promoting behavior, and reduces relapse to addictive behaviors.

Self-efficacy has also been shown to influence the extent of recovery following an illness episode and level of functioning among people with chronic illnesses. Ewart (1995) described a line of research focused on recovery following acute myocardial infarction (AMI). He reported that post-AMI men often have inaccurate self-appraisals of their physical capacities, leading to fear and underactivity that impede successful rehabilitation. Ewart found a number of ways to increase patients' self-efficacy for activity, which in turn lead to increased activity. For example, as these people took their treadmill test 3 weeks post-AMI, self-efficacy for physical activity was enhanced by having nurses and physicians provide reassurance and appropriate interpretations of internal bodily sensations. Self-efficacy was also enhanced through enactive mastery, whereby patients first identified the activities they feared and then were guided through those activities in small increments. Vicarious learning was promoted by having participants in the study observe other patients similar to themselves successfully performing the treadmill test. Ewart observed that changes in jogging self-efficacy follow-

ing the treadmill test were more predictive of activity level over the following week than was actual biological condition. He further noted that "self-efficacy appraisals are superior to functional exercise evaluation in predicting adherence to rehabilitative exercise regimens" (p. 208). He also found that people can have self-efficacy that is too high. Of those people in the top one third of the distribution on jogging self-efficacy, 57% were exercising beyond the recommended regimen and were therefore endangering their lives.

Another intervention based on self-efficacy and aimed at people with chronic illness was referred to at the beginning of this chapter: Lorig's Arthritis Self-Management Program (Lorig & Gonzalez, 1992). The goal of this group intervention is to improve the self-management and coping skills of people who have arthritis. The group leaders, many of whom have arthritis themselves, help participants set reasonable and achievable goals for behavior change. Goals are broken into small steps and participants are allowed to undertake only those behaviors for which their self-efficacy exceeds 70, on a scale with 0 being totally inefficacious and 100 being totally efficacious. In this way, participants are guaranteed success in enacting the behavior. The program capitalizes on modeling, furthermore, by having people who are coping well with arthritis as group leaders. Participants can also look to other group members for positive coping models. Verbal persuasion efforts by the group leader and other group members are also an important source of efficacy information in these groups. Finally, the group leaders help participants to examine and reinterpret the attributions they are making for their physical symptoms. For example, they are taught that some of the fatigue they attribute to their illness is, in fact, attributable to a lack of activity and that the remedy for fatigue is not inactivity.

Although self-efficacy can affect health outcomes via its influence on health behavior, it may also contribute to improved health in other ways. Bandura (1997, pp. 262-279) described correlational and experimental studies, suggesting that high self-efficacy mitigates psychological states such as stress that increase susceptibility to disease, dampens autonomic arousal in the presence of feared stimuli, correlates with alterations in catecholamine activation over the course of phobics' mastery of feared stimuli, reduces the production of opioids in response to pain (presumably, by attenuating the psychological distress resulting from the pain), and predicts greater pain tolerance following pain management training.

In a recent study, Benight et al. (1997) investigated the possibility that coping self-efficacy would buffer psychological and physiological disturbances in HIV-infected men following a natural disaster (Hurricane Andrew in Florida). A total of 36 HIV-positive men were assessed 6 months after the hurricane. Their psychological and physical status was compared to that of an age equivalent group of healthy men who had similar exposure to the natural disaster. They found that greater levels of self-efficacy for coping with the demands of hurricane recovery were related to less emotional distress and less posttraumatic stress disorder in both groups of men. Among the men who were HIV-positive, higher levels of coping self-efficacy were associated with better physiological re-

sponses as measured by lower norepinephrine to cortisol ratios (NE/C).

Wiedenfeld et al. (1990) examined the immune system impact of experimentally manipulated perceived self-efficacy to control a stressor. People with severe snake phobia were assessed during three phases of mastery development: baseline, an efficacy acquisition phase (during which they gained an increasing sense of coping efficacy through guided mastery), and a maximal efficacy phase. Participants who acquired coping skills more rapidly during the second phase showed immunoenhancement, whereas the small subset of people who acquired a sense of coping self-efficacy more slowly during the second phase showed immunosuppression. The authors concluded from this study that the development of skills to manage stress can enhance immunologic functioning.

It is an oversimplification, however, to characterize various biological processes as consistently health conducive or health disruptive. Heightened activity of the immune system, for example, may be a good thing or a bad thing, depending on the specific circumstances an individual confronts. Nonetheless, it is fair to say that the biological changes and states associated with greater self-efficacy often appear to be beneficial.

It would be inaccurate to suggest that all studies examining self-efficacy confirm its importance for understanding health and health behavior. One recent article, for example, found that self-efficacy did not mediate the effects of modeling on the ability to endure pain (Symbaluk, Heth, Cameron, & Pierce, 1997). Furthermore, subtleties and complexities underlying the operation of efficacy beliefs continue to emerge. Zautra, Hoffman, and Reich (1997) reported, for example, that efficacy beliefs for making positive events happen and for coping with negative events operate independently. Also, as noted earlier, it is possible for self-efficacy to encourage unhealthy behaviors, such as exercising too much during the recovery phase of an illness (Ewart, 1995). It is not difficult to imagine other circumstances where a high sense of self-efficacy for completing a risky behavior, such as handling venomous snakes, could compromise a person's well-being.

CONCLUSIONS

The bulk of evidence clearly establishes self-efficacy as a pre-eminent concept worthy of the theoretical and empirical attention it has received. Several characteristics of the construct justify this conclusion. First, it has emerged from a rich theoretical context. Thus, its similarities to and differences from other constructs can be more clearly understood. Its role in a cascade of events culminating in a specific behavior can also be more clearly understood because of its strong linkages to theory. Second, self-efficacy has undergone extensive empirical scrutiny. There are multiple examples of investigations intended to clarify the nature of the construct as well as reports demonstrating its utility in applied contexts. These latter studies also reveal a third important characteristic of self-efficacy: Unlike some other theoretically related constructs, such as locus of control, self-efficacy provides an excellent basis not only for understanding but also for devising interventions

to change health-related behaviors. A fourth, related, characteristic contributing to the importance of self-efficacy is its specificity. As the vignette at the opening of this chapter illustrated, the specificity of self-efficacy perceptions enables manageable intermediate goals to be established, further enhancing its utility to interveners. Finally, although its specificity mitigates against a single, universally accepted measure of self-efficacy, researchers and practitioners have found it relatively easy to devise methods of assessing the construct in ways that appear satisfactory.

Despite its clear utility, self-efficacy should not be expected to do everything. The proportion of variance in health behavior not explained by self-efficacy will often be considerable. Although the effects of some other constructs in health psychology on health behavior will be mediated by self-efficacy, others will not. Suggestions that self-efficacy fully captures the effects of outcome expectations, for example, seem forced. Broadening the definition of self-efficacy to subsume other constructs seems to contradict its inherent specificity, one of its most attractive features. These issues notwithstanding, self-efficacy remains a concept that will continue to find widespread utility in health psychology.

The Psychobiology of Nicotine Self-Administration

Neil E. Grunberg

Martha M. Faraday

Matthew A. Rahman

Uniformed Services University of the Health Sciences

Knowledge and perceptions of cigarette smoking and tobacco use have changed dramatically since health psychology began (i.e., over the past 25 to 50 years). A short half century ago, tobacco use was considered to be a behavior of choice and was commonplace in society. Most men smoked in public, some women smoked in public, and more women smoked in private. In the middle of this century, smoking was not considered by the general public to be a health hazard and was touted by tobacco companies and celebrities as an enhancer of good health. By the mid 1970s, the health care community's attitudes toward tobacco use had turned negative, but tobacco use still was common among men, was increasing among women, and was erroneously viewed by the public and by many health care professionals as a matter of free choice. During the last quarter of this century, the story of tobacco use has undergone a Dr. Jekyll to Mr. Hyde transformation. It has gone from the standard behavior of gentlemen and some ladies to the monstrosity of a shunned suicidal behavior that pollutes the environment and everyone near the smoker. Since the 1970s, it has become unquestionably clear that the behavior of tobacco use is the single greatest cause of death and illness in the world. Tobacco use results in cardiovascular diseases, many cancers, chronic obstructive lung diseases, increased morbidity, and immunosuppression. Since the 1980s, it has become well-known that tobacco use involves addiction to nicotine, that the use and abuse of to-

bacco also is a result of behavioral and biological actions of nicotine in addition to nicotine dependence per se, and that psychological and situational variables become associated with tobacco use and thereby contribute to the use and abuse of deadly tobacco products.

This chapter discusses those psychobiologic phenomena that are central to why people smoke and why it is so difficult to quit. The psychobiology of nicotine self-administration includes behaviors (e.g., self-administering nicotine) that are directly relevant to tobacco use; psychological and behavioral effects of nicotine that contribute to tobacco use (e.g., euphoria, mood regulation, attentional effects; changes in eating behavior and appetite); psychological phenomena that come to elicit nicotinelike effects (e.g., classical conditioning, operant conditioning, paired associations); and psychological consequences of nicotine abstinence (craving, increased appetite and feeding, irritability, sleep disturbances). As such, this chapter in the tobacco story is the domain of psychologists who are interested in behaviors that affect health and psychologists who study interactions of psychology and biology as they relate to health.

The first section presents evidence that humans and animals self-administer nicotine. The second section explains that nicotine self-administration is established by principles of reinforcement. The third section reviews effects of nicotine on the body that are believed to underlie the euphoric

and dependence effects of nicotine. The fourth section explains how several principles of learning theory interact with pharmacologic actions of nicotine to cement the addictive behavior. The fifth section reviews additional psychobiologic effects of nicotine that reinforce nicotine self-administration and that may help to explain individual differences in tobacco use. The sixth and final section discusses clinical implications of these findings and future directions for research regarding the psychobiology of nicotine self-administration.

HUMANS AND ANIMALS SELF-ADMINISTER NICOTINE

The most basic evidence for drug addiction is self-administration of the drug. With regard to nicotine, it is clear that humans and animals self-administer nicotine. The fact that people smoke cigarettes and use other tobacco products (e.g., cigars, chewing tobacco, snuff) is consistent with the interpretation that nicotine is the substance that exerts addictive and psychobiologic effects that maintain self-administration, but these behaviors do not necessarily mean that nicotine per se exerts these effects. In fact, tobacco contains roughly 500 chemicals and tobacco smoke contains roughly 4,000 chemicals in addition to nicotine (Dube & Green, 1982). Therefore, careful empirical studies have been conducted to determine that nicotine per se is self-administered. These studies include investigations with human and animal subjects. The advantage of human subjects is that they offer face valid evidence that humans indeed self-administer nicotine. The advantage of animal subjects is that investigators can isolate variables to focus on nicotine without the potential confound of attitudes, opinions, beliefs, biases, and so on. The additional advantage of animal investigations is that true experiments can be conducted (i.e., random assignment and manipulation of treatment groups; something that is unethical to do with addictive drugs in human subjects and with minors). Another advantage of animal investigations is that invasive analyses are possible, including brain dissection and neurochemical and molecular biologic assays of specific brain regions.

There are several types of human nicotine self-administration studies (Ashton & Watson, 1970; Deneau & Inoki, 1967; Goldberg & Henningfield, 1988; Goldfarb, Jarvik, & Glick, 1970; Henningfield, 1984; Henningfield & Goldberg, 1983, 1988; Henningfield, Miyasato, & Jasinski, 1983; Henningfield, Yingling, Griffiths, & Pickens, 1980; Jarvik, Glick, & Nakamura, 1970; Pomerleau, Fertig, & Shanhan, 1983; Russell, Wilson, Patel, Feyerabend, & Cole, 1975; Schachter, 1978; Schachter, Kozlowski, & Silverstein, 1977; Schachter, Silverstein, & Perlick, 1977):

1. Studies of humans smoking cigarettes in laboratory settings in which the smoking topography (e.g., number of cigarettes, number of puffs per cigarettes) and the nicotine yield of the cigarettes (i.e., based on pub-

lished data) are used to determine the extent to which nicotine was self-administered and the extent to which that self-administration reflects nicotine titration.

2. Studies of humans smoking cigarettes in natural settings in which the smoking topography is measured but the cigarettes have a manipulated amount of nicotine and the manipulated amount changes between groups or over time.
3. Studies of humans smoking cigarettes in laboratory settings with commercially available cigarettes in which the smoking behavior and topography is carefully observed and the nicotine yield is used to determine nicotine self-administration.
4. Human studies in laboratory settings where the smoking is measured by a machine (e.g., subjects smoke on a cigarette that is connected to a machine that measures number of puffs, duration of puff, interpuff interval, depth of inhalation) and the nicotine yield is known or manipulated.
5. Human studies in laboratory settings where smoking behavior is carefully measured, nicotine yield of cigarettes is known, and additional nicotine is administered (e.g., by intravenous infusion, oral ingestion, transdermal administration) to determine how nicotine self-administration and smoking are affected by nicotine administration via a separate source.
6. Human studies in laboratory settings where smoking behavior is carefully measured, nicotine yield of cigarettes is known, and nicotine excretion from the body is manipulated (e.g., by manipulation of urinary pH) to determine how nicotine self-administration and smoking are affected by nicotine availability.
7. Human studies in laboratory settings in which nicotine is self-administered intravenously.

There also are several types of animal laboratory studies of nicotine self-administration (Clarke & Kumar, 1984; Corrigan & Coen, 1989, 1991; Cox, Goldstein, & Nelson, 1984; Donny, Caggiula, Knopf, & Brown, 1995; Glick, Visker, & Maisonneuve, 1996; S. R. Goldberg, Speelman, & D. M. Goldberg, 1981; Hanson, Ivester, & Morton, 1979; Rose & Corrigan, 1997; Shoaib, Schindler, & S. R. Goldberg, 1997; Yanagita, Ando, Kato, & Takado, 1983): intravenous nicotine self-administration, intracranial nicotine self-administration, and inhalation of tobacco smoke.

The research has revealed that humans and animals self-administer nicotine, humans and animals titrate nicotine self-administration (i.e., the more nicotine is available in the body, the less is self-administered; the less the nicotine that is available in the body, the more is self-administered), and humans and animals increase nicotine self-administration over time demonstrating tolerance to this drug.

All of these studies indicate that nicotine is self-administered, but they do not reveal the underlying psychobiological mechanisms. To uncover these mechanisms, it is relevant to consider basic principles of reinforcement.

NICOTINE SELF-ADMINISTRATION IS ESTABLISHED BY POSITIVE AND NEGATIVE REINFORCEMENT

Humans and animals self-administer nicotine as a result of the consequences of this behavior following well-established principles of psychology (Hull, 1943; Skinner, 1938; Thorndike, 1911; Watson, 1924). *Reinforcement* occurs because nicotine has effects that result in continued and increased self-administration of nicotine. *Positive reinforcement* operates in that nicotine results in specific effects that are found to be desirable and thereby maintain and increase nicotine self-administration. These positive reinforcing actions include specific neurochemical changes that result in the following: euphoria, neuroendocrine changes that modulate reward and regulate physiologic processes, control of appetite and body weight, alterations in attentional processes, and psychosocial rewards (e.g., imitation of role models, acceptance of peers, etc.). *Negative reinforcement* operates in that nicotine offsets specific actions that are found to be undesirable and thereby maintain and increase nicotine self-administration. These negative reinforcing effects of nicotine self-administration include offsetting the unpleasantness of classic withdrawal symptoms (e.g., craving, irritability) as a result of nicotine abstinence and offsetting other undesired effects of nicotine abstinence (e.g., body weight gain, attentional difficulties, sleep disturbances). The psychobiologic reinforcing effects of nicotine that contribute to nicotine self-administration are discussed in the next three sections of this chapter.

NICOTINE'S CENTRAL NERVOUS SYSTEM (CNS) ACTIONS PRODUCE EUPHORIA AND DEPENDENCE

Tobacco smoking is a means to self-administer the addictive drug, nicotine. Similar to other addictive drug-taking behaviors, tobacco use is characterized primarily by highly controlled or compulsive use, psychoactive effects, and drug-reinforced behavior. In addition, addiction consists of stereotypic patterns of substance use, use despite harmful effects, relapse following abstinence, and recurrent drug cravings. Addicted individuals also may experience tolerance (i.e., over time the dosage necessary to obtain a desired effect increases), physical dependence (i.e., the substance is necessary in order for normal physiological functioning to occur), and euphoriant drug effects (U.S. Department of Health and Human Services, USDHHS, 1988). Addiction to nicotine is a process that occurs over time and requires the individual to initiate and maintain self-administration. Reasons for initiating and maintaining nicotine self-administration via tobacco product use include biological actions of the drug as well as psychological and behavioral drug actions. This section reviews the biological mechanisms and neurobiological underpinnings of nicotine addiction.

Nicotinic Cholinergic Receptors

The self-administration of nicotine via puffs on a tobacco containing product results in nicotine entering the body and reaching the brain within 15 seconds (USDHHS, 1988). Once in the body, nicotine has a half-life of about 2 hours. The drug acts throughout the body at nicotinic cholinergic receptors (nAChRs) at muscle end plates and in autonomic ganglia, and in the brain at nAChRs that regulate and modulate many neurotransmitter and neuroendocrine systems. It is thought that nAChRs in the brain are primarily responsible for biologic rewarding effects of nicotine (Balfour, 1994; Kellar, Schwartz, & Martino, 1987). Stimulation of nAChRs in the lung or at other peripheral sites also may contribute to rewarding effects of nicotine (Ginzel, 1987; Ginzel & Lucas, 1980).

The nAChRs all are similar in basic physical structure. They consist of five subunits arranged in a circle to form a channel. When an appropriate agonist binds to the receptor, the channel opens and allows the flow of positively charged ions (e.g., Ca^{2+} or Na^+ or other cations, depending on the receptor subtype). The five subunits consist of different types. The α -subunits (ranging from $\alpha 2$ to $\alpha 9$) contain sites where agonists (i.e., acetylcholine, nicotine) bind. The β subunits ($\beta 2$ to $\beta 4$) are believed to be primarily structural in function. These nAChRs are distributed presynaptically in certain regions of the brain, including the ventral tegmental area (VTA), nucleus accumbens (Nacc), medial habenula, interpeduncular nucleus, hypothalamus, and hippocampus.

There are several subgroups of nAChRs that differ in structure, binding affinity for nicotine, and function. The subgroups are defined according to subunit composition. Most binding sites in the mammalian brain consist of the $(\alpha 4)_3(\beta 2)_2$ nAChR subset (Lindstrom, Anand, Peng, & Gerzanich, 1995). These receptors are found presynaptically and modulate neurotransmitter release (Lindstrom et al., 1995; Nakayama, Okuda, & Nakashima, 1994). A small percentage of brain nAChRs are composed in part of $\alpha 7$ and $\alpha 8$ subunits. This subset of nAChRs appears to act as agonist-gated ion channels that allow calcium to enter the cell and initiate various second messenger cascades (Lindstrom et al., 1995). The function of many of these combinations is not yet known.

The fact that nicotine's effects in humans and animals on a variety of psychological states and behaviors vary with individuals and environments may be partially explained by the fact that each subunit combination results in a distinct pattern of sensitivity to nicotinic agonists. This structural and functional diversity allows nAChRs to mediate different effects in different tissues, with nicotine sometimes enhancing activity and sometimes antagonizing activity (Nakayama et al., 1994). In addition, studies in mice of different genotypes indicate that nAChR densities may underlie the extent to which nicotine exerts behavioral effects (Collins, Miner, & Marks, 1988; Marks, Romm, Campbell, & Collins, 1989; Marks, Romm, Gaffney, & Collins, 1986). As Balfour (1994) wrote, "Each smoker probably uses tobacco in a way which maximizes the properties that he/she finds most rewarding. These

may reflect both stimulation and desensitization of the heterogeneous population of nicotinic receptors now known to be present in the brain" (p. 1422).

Nicotine's Effects on Neurotransmitter Systems

Via actions at presynaptic ($\alpha 4$)₃($\beta 2$)₂ nAChRs, nicotine alters activity of many different neurotransmitter systems, including those of dopamine, norepinephrine, endogenous opioids, and serotonin. Most of the work done on mechanisms underlying nicotine addiction has focused on the dopaminergic system (Corrigall, 1991) because enhancement of dopamine neurotransmission in specific brain areas is believed to be fundamental to drug reward or euphoriant effects (Di Chiara, Acquas, Tanda, & Cadoni, 1993; Koob, 1992; Nestler, 1992), including effects of cocaine, heroin, amphetamines, and alcohol. In addition, cellular and molecular changes that occur in these brain areas as a result of repeated drug self-administration may contribute to drug dependence and addiction (Balfour, 1994; Koob & Bloom, 1988; Koob & Swerdlow, 1988). Regions of the brain that mediate reward effects are phylogenetically old and respond to natural stimuli, addictive drugs, and electrical stimulation. The natural stimuli that evoke dopamine release by neurons that originate in the VTA and terminate in the NAcc are associated with behaviors essential to the survival of the individual and the species such as feeding, sexual behavior, birth, care of offspring, and some social behaviors (e.g., mutual grooming) (Salamone, 1994).

Tolerance to nicotine's effects is, in part, mediated by increased numbers of nAChRs (Lindstrom et al., 1995) and also depends on cellular changes in the mesolimbic dopamine system that occur with repeated nicotine self-administration (Flores, Rogers, Pabreza, Wolfe, & Kellar, 1992). These changes are similar to those that occur in response to other drugs of abuse and may include increased synthesis of the enzyme tyrosine hydroxylase (the rate-limiting step in dopamine manufacture), increased rates of spontaneous firing activity in VTA neurons, and changes in the structure of cell bodies, dendrites, and axons (Balfour, 1994; Beitner-Johnson, Guitart, & Nestler, 1992; Gold & Miller, 1992; Koob & Bloom, 1988; Nestler, 1992; Ritz & Kuhar, 1993; Rosecrans & Karan, 1993). In the NAcc, chronic addictive drug use alters G-protein levels and second messenger cascades, biochemicals that control rates of neurotransmitter synthesis and release. These neuronal-level changes reflect the fact the mesolimbic dopaminergic neurons adjust to the repeated presence of nicotine in a compensatory way by developing tolerance. Normal physiologic functioning now occurs in the presence of the drug (i.e., "physical dependence"). However, once the drug is removed (e.g., by overnight abstinence from smoking or by abrupt smoking cessation), dopamine release in the NAcc virtually disappears and the individual experiences unpleasant withdrawal symptoms. It is important to note that classical drug reward effects from nicotine are a short-lived phenomenon. In the tolerant human or animal, nicotine is necessary to maintain normal functioning and to

prevent withdrawal. Subjective reward effects per se largely disappear with chronic nicotine administration.

Nicotine also affects the production and release of the endogenous opioid peptides beta-endorphin and enkephalins (Bacher, Wang, & Holtt, 1995; USDHHS, 1988). Some of nicotine's early reward effects may be regulated through these systems. In addition, these systems also may regulate nicotine's long-term maintenance effects (Bozarth, 1994; Corrigall, 1991).

Serotonin, which is implicated in the addiction process of other drugs of abuse (Grunberg, 1994), is also released by nicotine administration (USDHHS, 1988). The nAChRs have been found on a wide variety of presynaptic serotonin neurons located in sites at which nicotine has been shown to have an effect (Rosecrans & Karan, 1993; Yu & Weckler, 1994). Specifically, the serotonin receptor subtype 5HT₂ seems to be a principal player in this process, and may play a role in nicotine's effects on mood (Carmody, 1993; Kaplan, Sadock, & Grebb, 1994; Ribeiro, Bettiker, Bogdanov, & Wurtman, 1993), attentional processes (Carmody, 1993), and modulation of the dopamine reward process (Di Chiara et al., 1993; Montgomery, Rose, & Herberg, 1993). These actions may contribute to nicotine addiction. Upon nicotine abstinence (e.g., when quitting smoking), changes in serotonin levels may alter mood and attentional processes in ways that the individual finds aversive. For example, these altered serotonin levels may be manifested as depressed or anxious mood and inability to focus attention—commonly reported sequelae of smoking cessation. The individual's desire to alleviate these unpleasant symptoms may motivate the individual to resume smoking.

Norepinephrine (NE) also is released by nicotine (USDHHS, 1988). In addition, nicotine administration increases the activity of tyrosine hydroxylase, the rate-limiting step in NE formation, principally in the locus coeruleus (Mitchell, Smith, Joseph, & Gray, 1992). NE in the locus coeruleus functions to focus attention (Hodges et al., 1992). NE also interacts with serotonin in mood disorders (Kaplan et al., 1994). Some of nicotine's addictive characteristics may be mediated by interactions of the NE system with other biochemical systems as well (Mitchell et al., 1992).

Nicotine's Effects on Neuroendocrine Systems

Nicotine affects the hypothalamic-pituitary-adrenal axis (Stolerman, 1991; USDHHS, 1988). Increased levels of prolactin, corticotropin-releasing hormone, the pro-opiomelanocortin group of hormones (beta-endorphin, beta-lipoprotein, melanocyte-stimulating hormone), adrenocorticotropin hormone, growth hormone, vasopressin, and neurophysin I have been found after acute and chronic administration of nicotine in humans and animals. Nicotine also directly stimulates the release of corticosteroids from the adrenal cortex by direct activation of nAChRs on autonomic ganglia terminating on the adrenal glands. Nicotine also affects levels of plasma and hypothalamic insulin. All of these hormones play important regulatory roles throughout the

body and brain and may interact with neurotransmitter systems in the addiction process of nicotine.

CLASSICAL CONDITIONING, OPERANT CONDITIONING, AND PAIRED ASSOCIATIONS ALL CONTRIBUTE TO NICOTINE SELF-ADMINISTRATION

The powerful effects of nicotine to control behavior are evident in nicotine self-administration and the central effects of this extraordinary drug. Yet, this information does not completely capture the full extent of the hold that nicotine-containing products have on the nicotine addict. In addition to nicotine's direct effects to develop drug dependence and self-administration, nicotine self-administration is accompanied by psychological phenomena that reinforce the effects of the drug by becoming intertwined with the direct pharmacologic actions of nicotine. As a result, psychological, behavioral, and environmental conditions that become associated with nicotine self-administration come to elicit the same biological actions of nicotine itself. This result makes treatment of nicotine addiction even more complex and mandates the incorporation of psychological as well as pharmacologic strategies to treatment.

The major psychological phenomena that become associated with nicotine self-administration operate through classical conditioning, operant conditioning, and paired associations. *Classical*, or *Pavlovian*, *conditioning* refers to the phenomenon in which stimuli that initially do not elicit a given response (neutral stimuli, NS) eventually come to elicit those responses (conditional or conditioned responses, CR) when paired repeatedly with a stimulus that normally elicits the given response (the unconditional or unconditioned stimulus, US). In Pavlov's classic studies of digestive physiology in dogs, a tone (NS) was repeatedly paired with food (US) until eventually the presentation of the tone alone (now a conditional or conditioned stimulus, CS) resulted in salivation (CR; Pavlov, 1927). *Operant* or *instrumental* or *Skinnerian conditioning* refers to the phenomenon by which consequences of a behavior come to increase or decrease the likelihood of that behavior (Skinner, 1938; Watson, 1924). For example, a given behavior or stimulus that is followed by the provision of food (particularly to a food-deprived subject) is rewarded. A behavior or stimulus that is followed by an electric shock is punished. *Paired associationism* was a concept studied by Gestaltist psychologists that referred to the phenomenon by which stimuli "associated" in time or in space (e.g., experienced close together chronologically or spatially) come to be psychologically joined and bound together (Koffka, 1935; Köhler, 1929). For example, the co-occurrence of visual stimuli near each other results in a perception and memory of these stimuli "together."

All three psychological principles operate to reinforce and strengthen nicotine self-administration by binding together a wide range of stimuli and consequences of tobacco use with biologic actions of nicotine. In the case of nicotine self-administration, environmental (e.g., a bar, the sight of an ash-

tray or cigarette), psychological (e.g., stress, anxiety, dysphoria), situational (e.g., on a break, when resting, when partying), and social (e.g., with friends) variables and stimuli can become conditioned stimuli that come to elicit the same biologically based responses as does nicotine itself. As a result of conditioning to tobacco use cues, efforts to abstain from nicotine become increasingly difficult as these psychological principles of learning continue to elicit positive and negative nicotine-related effects. These psychological effects help to explain why treatment of nicotine dependence only with nicotine replacement products (e.g., nicotine gum, patch, nasal spray) is not as effective as many people expect when they know that nicotine is an addictive drug. Actually, it is the fact that nicotine is a powerful and addictive drug with powerful biological and psychological effects that increases the likelihood that psychological conditioning occurs. Treatment of nicotine dependence must include ways to offset and extinguish the conditioning effects of nicotine and that requires psychological and behavioral strategies.

OTHER PSYCHOLOGICAL AND BEHAVIORAL EFFECTS OF NICOTINE CONTRIBUTE TO NICOTINE SELF-ADMINISTRATION

In addition to nicotine's "classic" addictive properties, the drug's effects to alter many psychological states and behaviors contribute significantly to its self-administration and to individual differences in reported effects of nicotine-containing products. The multiplicity of these effects is reflected by the variety of reasons people report for smoking: to control appetite and reduce body weight; to alter attentional processes; to manage negative moods such as anxiety, depression, and feelings of hostility; to relax; to relieve boredom; and to alleviate and cope with stress (USDHHS, 1988). Research on these consequences of smoking indicates that nicotine is the agent exerting these effects. In addition, these effects have been demonstrated in experimental settings with human and animal subjects.

In addition, failure to maintain successful cessation is related to unwanted alterations in psychological states and behaviors that occur apart from feelings of craving nicotine. Specifically, individuals report relapsing because of body weight gain; alterations in attention; feelings of anxiety, depression, and irritability; and inability to cope with stress (Hughes, Higgins, & Hatsukami, 1990; Shiffman, 1979, 1982, 1985, 1986; Shiffman & Jarvik, 1976; USDHHS, 1988). Many of these effects also have been demonstrated in animals. The following sections review key work regarding effects of nicotine and effects of nicotine cessation on appetite control and body weight regulation, alterations in attentional processes, and interactions with stress. In addition, these sections highlight the role of individual differences such as gender and genotype in these effects. These sections include a more detailed review of specific empirical findings because these psychobiologic effects of nicotine that contribute to nicotine self-administration currently are receiving active research at-

tention and because these psychobiologic effects illustrate complex multivariate interactions among genotype, gender, environment, physiology, behavior, and cognition.

Appetite Control and Body Weight Regulation

For hundreds of years people have known that tobacco smoking reduces body weight, with the average smoker weighing approximately 7 pounds less than the average nonsmoker (USDHHS, 1988). Many smokers, especially adult women and adolescent girls, cite smoking's appetite and body weight-controlling effects as major reasons for initiating and continuing to smoke, despite the well-publicized health hazards, and report unwanted weight gain after cessation as a reason for relapse to smoking (Grunberg, Winders, & Wewers, 1991; R. C. Klesges, Elliot, & Robinson, 1997; R. C. Klesges & L. M. Klesges, 1988; R. C. Klesges, Meyers, L. M. Klesges, & La Vasque, 1989). Animal studies indicate that these effects are the result of nicotine and that cessation from nicotine results in increased weight gain (e.g., Grunberg, 1982, 1986). Further, there are sex differences in these effects with female humans and rats exhibiting greater weight changes as a result of nicotine administration than males, and greater weight rebounds in cessation than males (Grunberg, Bowen, & Morse, 1984; Grunberg et al., 1991; Grunberg, Popp, & Winders, 1988; Grunberg, Winders, & Popp, 1987). The underlying mechanisms for effects of nicotine and of nicotine cessation on body weight are related to alterations in food consumption, activity level, and metabolism. Of these three processes, food consumption exerts the greatest influence over nicotine-related body weight changes.

Food Consumption. Nicotine decreases consumption of sweet-tasting, high carbohydrate foods without altering consumption of other foods (e.g., salty, bland) (Grunberg, 1982; Grunberg et al., 1984; Grunberg, Bowen, Maycock, & Nespore, 1985; Grunberg, Popp, & Winders, 1988). When only bland food (e.g., standard laboratory chow) is available, male rats administered nicotine do not decrease feeding but female rats still exhibit decreased consumption, indicating that nicotine's effects to alter feeding are more potent in females (Grunberg et al., 1987). Studies of nicotine's effects on biochemical responses that mediate energy utilization indicate that chronic nicotine decreases peripheral insulin levels (Grunberg, Popp, Bowen, et al., 1988). Decreases in insulin result in increased fat, protein, and glycogen utilization; decreased fat storage; and may account for a decrease in preference for and consumption of sweet-tasting foods (Rodin, Wack, Ferrannini, & DeFronzo, 1985). Changes in feeding patterns also may be accounted for by the fact that nicotine increases insulin levels in the brain, specifically in the hypothalamus (Grunberg & Raygada, 1991). Increases in brain insulin have been implicated in food intake and body weight regulation (Woods & Porte, 1983).

Sex differences in feeding and body weight also are apparent in effects of nicotine cessation. When only bland food is available, male rats previously administered nicotine resume normal rates of body weight gain (i.e., increasing body weight

over time as the animal gets older), but absolute body weight remains lower relative to saline control animals (Grunberg et al., 1987). In contrast, when only bland food is available to females, rates of body weight gain and absolute body weight values of animals previously administered nicotine become indistinguishable from controls within weeks of cessation (Grunberg et al., 1987). When a variety of foods is available in cessation, including sweet-tasting, high carbohydrate foods, body weight of males previously administered nicotine remains decreased when compared to controls even though males increase consumption of sweet-tasting foods (Grunberg, Popp, & Winders, 1988). For females exposed to nicotine, however, access to sweet-tasting, high carbohydrate foods in cessation results in increased rates of body weight gain as well as absolute body weight increases compared to controls (Grunberg, Popp, & Winders, 1988).

The mechanisms for changes in feeding and body weight in cessation also may be related to changes in peripheral and central insulin levels. These mechanisms have been investigated in male rats, but not in females. Specifically, in cessation peripheral insulin levels increase and hypothalamic insulin levels decrease (Grunberg & Raygada, 1991). These changes are consistent with the observed effects of cessation in males on body weight (i.e., to return rates of body weight gain to normal) and feeding (i.e., to increase consumption when sweet-tasting foods are available).

Taken together, these findings suggest that the reason women are more likely to report using smoking as a means of controlling body weight and avoiding quitting to prevent body weight gain may in part be a consequence of greater female sensitivity to these nicotine effects. With regard to clinical implications, these results indicate that adolescent and adult women may need to learn alternative strategies for body weight and appetite control (e.g., exercise) to prevent initiation of smoking, and in cessation women should avoid consumption of sweet-tasting, high carbohydrate foods in order to prevent excessive body weight gain (e.g., by consuming low calorie, sweet-tasting foods; Grunberg et al., 1985).

Activity Level. Nicotine's effects on body weight also are in part the result of alterations in activity level. These effects are complex, and depend on sex and genotype (i.e., rat strain) of subject as well as on the subject's environment (Bowen, Eury, & Grunberg, 1986; Faraday, Rahman, Scheufele, & Grunberg, 1996; Grunberg & Bowen, 1985). In male Sprague-Dawley rats (an albino strain), chronic nicotine administration increased activity levels (Grunberg, 1982; Grunberg & Bowen, 1985; others) and in male Long-Evans rats (a nonalbino strain) nicotine administration decreased activity (Faraday et al., 1996). These effects in Sprague-Dawley males are consistent with nicotine's body weight reducing effects (i.e., increased activity levels results in increased calorie expenditure). Effects of chronic nicotine administration in female rats are similar across strains and are not consistent with nicotine's body weight-reducing effects (Bowen et al., 1986; Faraday et al., 1996).

These effects also may depend on subjects' environment. When subjects were housed in same-sex groups, chronic nic-

otine increased activity of Long–Evans males and females (Faraday et al., 1996). The finding that drug effects in rats vary depending on the context in which nicotine is administered is consistent with smokers' reports that nicotine can have opposite effects on arousal (e.g., calming, as well as invigorating, energizing, and relieving boredom). Importantly, regardless of sex, strain, or environment, nicotine administration reduced body weight, indicating that apart from and in spite of qualitative activity effects, the net result of nicotine administration is body weight reduction.

Effects of nicotine cessation on activity also depend on subjects' strain and sex. For males, strain is an important variable. Sprague–Dawley males decreased activity in cessation (Grunberg & Bowen, 1985), but Long–Evans males did not change activity levels (Faraday et al., 1996). As with effects of nicotine, females responded similarly across strains, and did not change activity levels in cessation (Bowen et al., 1986; Faraday et al., 1996). Again, these changes are consistent with increased body weight in cessation for Sprague–Dawley males only.

Taken together, these findings suggest that the extent to which changes in activity levels contribute to body weight effects of nicotine and nicotine cessation depend on the individual's sex and genotype, with genotype more important for males, and possibly on the environment in which nicotine-containing products are used. These results also underscore the special vulnerability that females may have to nicotine's body weight effects.

Metabolic Effects. Nicotine's body weight reducing effects in part are the result of changes in metabolism probably mediated by the actions of peripheral insulin. The effects of nicotine administration and cessation on body composition have been examined in male rats. Nicotine reduces body fat stores without altering body protein or body water when compared to controls and in nicotine cessation these proportions return to control levels (Winders & Grunberg, 1990).

Attentional Processes

Many smokers report that smoking enhances attentional abilities (USDHHS, 1988). In humans, empirical studies indicate that nicotine's attentional effects vary. Whether nicotine enhances, impairs, or has no effect on attention depends on many factors, including the complexity of the task, the timing of testing, the route of nicotine administration, and the nature of the subject pool. With regard to subject selection, results differ substantially depending on whether study participants were smokers who were in withdrawal (e.g., after a required overnight cigarette abstinence), smokers who were not in withdrawal, or nonsmokers. With smokers in withdrawal, tasks that index focused, selective, divided, and sustained attention generally indicate that nicotine administration returns performance to predeprivation baseline levels (for review, see Heishman, Taylor, & Henningfield, 1994). With nondeprived smokers and nonsmokers, nicotine enhances motor responding (e.g., quickness with which a subject depresses a key measuring reaction time) in tests of focused and

divided attention (Heishman et al., 1994). With a complex task (simulated driving in the context of a computerized game), nondeprived smokers performed more poorly (e.g., had more rear-end collisions) than deprived smokers and nonsmokers (Spilich, June, & Renner, 1992). Overall, these studies suggest that in the smoker nicotine ameliorates attentional deficits on simple task performance that occur with withdrawal and in the nondeprived smoker or nonsmoker there is little absolute enhancement of performance. On complex tasks, nicotine may actually impair performance in smokers.

The fact that individuals vary considerably in these responses suggests that nicotine's effects on attentional processes may be an example of the extent to which different individuals use nicotine to obtain different desired effects. That is, the extent to which nicotine's attentional effects contribute to self-administration and relapse from cessation may depend on the individual smoker. Studies with rats indicate that these individual differences in attentional responses to nicotine may be biologically based (e.g., mediated by genotype, including sex) and also may depend on subjects' environment.

Behavioral indices that reflect processes believed to underlie information processing (Swerdlow, Caine, Braff, & Geyer, 1992) and possibly attention (Acri, 1994; Acri, Brown, Saah, & Grunberg, 1995; Acri, Grunberg, & Morse, 1991; Acri, Morse, Popke, & Grunberg, 1994) in humans and in rats have been used to examine nicotine's effects. These indices consist of the acoustic startle reflex (ASR) and pre-pulse inhibition (PPI) of the ASR. The acoustic startle reflex is a characteristic sequence of involuntary, muscular responses elicited by a sudden, intense acoustic stimulus (Davis, 1984). Jumping in response to an unexpected car backfire is an everyday example of the startle reflex. The reflex is present in all mammals, including humans and rats, and is considered an index of reactivity to external acoustic stimuli. Because the reflex can be elicited using the same stimuli across species (Swerdlow, Braff, Taaid, & Geyer, 1994), the paradigm has face validity for generalizing from an animal model to human issues.

Pre-pulse inhibition (PPI) of the acoustic startle reflex (ASR) occurs when the startling stimulus is preceded by a nonstartling acoustic stimulus by a short interval (about 100 msec). The presence of the pre-pulse results in measurably reduced startle amplitude (Braff et al., 1978; Graham, 1975). In the example of a car backfire, the ability of this loud noise to startle would be reduced if the listener also heard the engine sounds immediately preceding the backfire. This reduction in startle amplitude is pre-pulse inhibition of the ASR. As with the ASR, the phenomenon of pre-pulse inhibition occurs in humans and in rats. Pre-pulse inhibition is believed to index an innate sensory-cognitive-motor "gating" mechanism that operates at a nonvolitional level and underlies the organism's ability to select relevant stimuli from the environment while screening out irrelevant information (Swerdlow et al., 1992). PPI also has been interpreted to reflect processes associated with attention (Acri, 1994; Acri et al., 1994; Acri, Grunberg, & Morse, 1991), and in humans PPI is negatively correlated with distractibility (Karper et al., 1996).

The effects of nicotine on ASR and PPI are qualitatively different in various rat strains. In Sprague–Dawley rats, nicotine administration enhances startle and PPI (Acri, 1994; Acri et al., 1991, 1994, 1995; Faraday, O'Donoghue, & Grunberg, 1999). This enhancement has been interpreted as analogous to the attentional enhancement reported by some human smokers when they smoke (Acri, 1994; Acri et al., 1994). Within the Sprague–Dawley strain, there are large individual differences in the magnitude of this enhancement, with some subjects exhibiting large increases and others exhibiting relatively small increases (Acri, 1994). In contrast, for Long–Evans rats, nicotine decreases startle and impairs pre-pulse inhibition, suggesting that for these subjects nicotine hampers information processing and attention (Faraday, Rahman, Scheufele, & Grunberg, 1998; Faraday et al., 1999). These varying responses within and across strains of rats are consistent with the variance of attentional responses to nicotine in the human literature. To the extent that these differences are biologically based, the mechanisms for the varying behavioral responses to nicotine are likely differences in central tissue sensitivity (e.g., differences in density, distribution, and/or affinity of nicotinic cholinergic receptors in the brain). Variations in receptor density have been implicated in similar behavioral differences in strains of mice, with the greatest nicotine effects associated with the largest numbers of nAChRs (Collins et al., 1988; Marks et al., 1986, 1989; Marks, Stitzel, & Collins, 1989), but similar studies have not been performed across rat strains. With the advent of progressively more sophisticated and noninvasive imaging technology in humans and in rats (e.g., positron emission tomography with receptor-specific radioactive labels, functional magnetic resonance imaging, and so on), it soon may be possible to document differential nicotinic cholinergic activity in living, behaving humans and animals.

Environment and sex of subject also influence whether the net effect of nicotine is an enhancement or an impairment of startle and sensory-gating. When Long–Evans rats are housed either singly or in same-sex groups, nicotine administration impairs sensory-gating for females regardless of housing condition (Faraday et al., 1998). For males, however, nicotine's effects depend on housing with impairment of singly housed subjects' PPI but enhancement of group-housed subjects' PPI. Again, these differential nicotine effects depending on the environment in which the drug is administered are consistent with the diversity of human uses of nicotine.

Overall, the human and animal literatures on nicotine and attention suggest that nicotine's psychological effects are highly individual. It is possible, therefore, that some smokers smoke to enhance attention, some smoke in spite of impaired attention because nicotine exerts other desired effects (e.g., body weight and appetite control), and still others smoke in order to blunt attention (i.e., to ameliorate hyperreactive or hypervigilant states). These individual differences are relevant in the context of prevention. Specifically, if individuals differentially experience attentional effects of nicotine, then the extent to which nicotine exerts desired

attentional effects (e.g., enhancement or blunting) may make initiation of tobacco use more or less likely.

In cessation from nicotine, some smokers report impaired attentional processes (Shiffman, 1979, 1982, 1986; USDHHS, 1988). Animal studies indicate that effects of nicotine cessation depend to some extent on rat strain. In Sprague–Dawley male rats, cessation results in startle responses similar to pre-drug baselines but reduced pre-pulse inhibition (Acri, 1994; Acri et al., 1991). This result in Sprague–Dawley males is consistent with human reports of impaired attention in cessation. In Long–Evans males and females, ASR and PPI responses return to baseline levels in cessation (Faraday et al., 1998). Because nicotine impairs attentional processes in Long–Evans rats, this return to baseline reflects a net improvement. As with the nicotine and attention literature, the nicotine cessation and attention literature also suggests that responses are individual-specific. This specificity may have important clinical implications. That is, for effective cessation, individuals who use nicotine to obtain particular attentional effects may need to learn alternative strategies to obtain similar effects without nicotine (e.g., learning to cope with distractions, learning to use relaxation techniques to attenuate hypervigilance). This custom-tailored approach to cessation may enhance success rates (Grunberg, 1995).

Interactions With Stress

It is well-established that stress and the use of addictive substances, including nicotine, are positively correlated. Epidemiologic studies and laboratory experiments indicate that under stress, smokers smoke more than when not under stress (Epstein & Collins, 1977; Rose, Ananda, & Jarvik, 1983; Schachter, Silverstein, et al., 1977; Shiffman, 1982, 1985; USDHHS, 1988). These reports may seem to be paradoxical given that nicotine, a sympathomimetic, increases physiological (e.g., heart rate, blood pressure) and biochemical stress responses (e.g., cortisol) in humans and in animals (Morse, 1989; USDHHS, 1988). Several explanations have been proposed for this dissociation between subjective experience and biologic responses known as Nesbitt's paradox (e.g., Parrot, 1998; Schachter, 1973): (a) Stress speeds nicotine excretion so that the smoker must self-administer more nicotine in order to obtain desired behavioral and psychological effects similar to those experienced in the nonstressed state; (b) nicotine's behavioral and psychological effects are different in the stressed state than in the nonstressed state; (c) nicotine alleviates the unpleasant subjective experience of stress (e.g., feelings of anxiety or irritability, inability to concentrate); and (d) individuals misattribute the symptoms of stress for symptoms of withdrawal (Grunberg & Baum, 1985; Grunberg, Morse, & Barrett, 1983; Schachter, Silverstein, et al., 1977; USDHHS, 1988). These explanations are not mutually exclusive and together probably account for why people smoke more under stress, and why different individuals are more or less vulnerable to increased smoking under stress.

The interaction of stress with nicotine's effects on attentional processes (as indexed by the ASR and PPI paradigm) in an animal model provides a useful exemplar for how these processes might occur. Importantly, there are sex and genotypic differences in these effects. Specifically, ASR and PPI responses in rats are altered by brief exposure to a mild physical stressor—immobilization for 20 minutes. The stressor is administered by placing the rat in a device that holds it firmly without pinching or causing pain. The stressful nature of the procedure appears to result from rodents' instinctual aversion to being unable to move freely. This stress procedure produces reliable peripheral biochemical changes in the form of elevated adrenocorticotropin hormone (ACTH), beta-endorphins, and corticosterone consistent with a stress response (e.g., Acri, 1994; Kant et al., 1983; Raygada, Shaham, Nespor, Kant, & Grunberg, 1992). These biochemical stress responses do not diminish with repeated exposure to the stressor and are similar in males and females (Kant et al., 1983).

In Sprague–Dawley males, exposure to this stressor increases startle and PPI (Acri, 1994; Faraday et al., 1999). In Sprague–Dawley females and Long–Evans males and females, however, immobilization has no consistent effects on startle and PPI (Faraday et al., 1999). These findings suggest that stress alone enhances information processing and possibly attention in Sprague–Dawley males and does not alter these processes in other subjects. When subjects are administered nicotine concurrent with the stress experience, however, there are dramatic changes in this pattern.

Specifically, in stressed Sprague–Dawley males administered a low dosage of chronic nicotine (6 mg/kg/day), stress and nicotine have additive effects on ASR and PPI (Acri, 1994). That is, these subjects exhibit more startle and more sensory-gating than nonstressed low dose nicotine-treated subjects (for which nicotine enhances startle and PPI) and saline-treated stressed subjects (for which stress increases ASR and PPI). In stressed Sprague–Dawley males administered a higher nicotine dosage (12 mg/kg/day), the effects of nicotine and stress cancel one another, and ASR and PPI responses are indistinguishable from nonstressed saline controls (Acri, 1994; Faraday et al., 1999).

This pattern of responses to the stress and nicotine interaction is consistent with several of the proposed explanations for why smokers increase smoking under stress. For example, if stress speeds nicotine metabolism, then behavioral responses to a nicotine dosage (12 mg/kg/day) that increases attention in a nonstressed subject might be attenuated when the subject experiences stress because of reduced nicotine bioavailability. These data also suggest that nicotine's actions under stress may be different than its actions in the nonstressed state. Specifically, nicotine is known to act on behavioral and biologic indices according to an inverted-U shaped function (i.e., at low dosages nicotine increases these indices and at higher dosages it decreases them). If stress also increases these indices (e.g., attentional processes), then low dosages of nicotine plus stress are likely to have additive ef-

fects but high dosages of nicotine plus stress are likely to push the organism over the top of the inverted U-shaped curve and result in reduced or normal responses. To the extent that increased reactivity and sensory-gating as a result of stress are experienced as unpleasant (e.g., as hyperreactive or hypervigilant states), then these data also are consistent with the idea that individuals self-administer nicotine in order to alleviate these effects.

For stressed Sprague–Dawley females administered nicotine, a different picture emerges. Specifically, stress by itself does not affect ASR and PPI in these subjects and nicotine alone enhances these responses. Together, stress and nicotine administration exert additive effects on ASR and PPI at both low and high nicotine dosages (Faraday et al., 1999). Therefore, for Sprague–Dawley females, stress in the presence of nicotine increases reactivity and sensory-gating above levels that result from nicotine administration alone. This sex difference in behavioral effects of the nicotine \times stress interaction suggests that, for Sprague–Dawley females, stress may even slow the metabolism of nicotine, resulting in enhanced effects of the same drug dosage when compared to nonstressed subjects who are administered nicotine. These results also are consistent with the idea that nicotine's effects under stress are different than in the nonstressed state.

In contrast, for Long–Evans males and females, concurrent stress and nicotine administration do not produce ASR and PPI patterns substantially different from effects of nicotine alone (Faraday et al., under review). These findings suggest that for this rat strain stress does not alter nicotine metabolism and that ASR and PPI effects of nicotine are similar during stress or not during stress. To the extent that interoceptive, subjectively experienced effects of nicotine (e.g., changes in attentional processes) serve as cues to the individual that a particular drug action is occurring, these results suggest that for some people the lack of stress-induced changes in these cues might result in the individual not experiencing stress. That is, these individuals would not perceive that nicotine's effects were altered when in a challenging or threatening situation and therefore would not be likely to increase nicotine self-administration. It is also possible that these subjects represent a subset of smokers for whom the effects of nicotine are powerful enough to make any effects of stress irrelevant.

Overall, human and animal reports indicate that stress may interact with smoking behavior in several different ways, and that there are sex and possibly other genotypic differences in these effects. This interaction is particularly relevant for effective cessation. Understanding the extent to which stress alters various psychobiologic processes that also are altered by nicotine is important to determining the individual's propensity for relapse to smoking under stress. For example, an ex-smoker who under stress increases food consumption, becomes hyperreactive, and feels anxious may be more vulnerable to smoking relapse because of nicotine's capacity to ameliorate these effects than an individual for whom these responses do not occur.

TOBACCO ABUSE CAN BEST BE TREATED BY UNDERSTANDING THE ROLE OF NICOTINE AND THERE IS A LOT OF NICOTINE PSYCHOBIOLOGIC RESEARCH TO DO

It is now clear that tobacco use is a form of nicotine self-administration and that psychological and biological variables interact to maintain this behavior. Overwhelming evidence that nicotine is addicting, however, does not mean that nicotine replacement alone will serve as a magic bullet to stop tobacco use. In light of the many psychobiologic interactions that are involved in tobacco use, psychological and pharmacologic strategies should be used together to treat tobacco dependence. Simply prescribing a nicotine replacement product without treating the behavioral and psychological variables involved in maintaining nicotine self-administration usually fails. Treatments that consider the multivariate aspects of tobacco use are likely to be more successful. In light of emerging evidence that individual differences (including sex and other genotypic differences) are most pronounced in some of the psychological effects of nicotine that contribute to nicotine self-administration, it is these psychobiologic effects that must be studied and considered in detail to develop the most effective treatments and prevention strategies to avoid tobacco use.

CONCLUSIONS

This volume provides examples of great progress in health psychology over the past 25 years. Understanding of tobacco use and the interaction of psychological and biological variables in nicotine self-administration is a particularly clear example of how multivariate focus on health and behavior problems has resulted in substantial progress that can result in improved health.

Obesity

Rena R. Wing

Betsy A. Polley

University of Pittsburgh School of Medicine

Obesity is a significant health problem in the United States. One out of every two Americans is either overweight or obese (Flegal, Carroll, Kuczmarski, & Johnson, 1998). Obesity is a major cause of morbidity and mortality, both independently and through its association with hypertension, diabetes, and hyperlipidemia. Although genetic factors clearly play a role in obesity, the dramatic increases that are occurring in the prevalence of obesity are the result of changes in lifestyle, including changes in both intake and exercise. This chapter briefly discusses epidemiological aspects of obesity and the health and psychosocial consequences of this disease. However, it focuses primarily on the behavioral factors associated with the development of obesity and lifestyle interventions that have been developed for prevention and treatment of this major health problem.

DEFINING OBESITY

Obesity technically means an excess of body fat, and is distinct from "overweight," which means an excess of body weight. However, except in rare situations, such as body builders (who may be overweight but not overfat), the two are highly related and consequently the terms are often used interchangeably.

Obesity is most commonly quantified using the Body Mass Index (BMI), which is weight in kg divided by height in meters squared. Although this measure does not actually assess body fatness, it generally is highly correlated with measures of body

fat. A BMI of 25–29.9 is used to define overweight and a BMI > 30 is used to define obese (Table 15.1).

Other measures of body fatness are used primarily in research settings. These include measuring skinfold thickness with calipers, using underwater weighing to measure body density, and using dual x-ray absorptiometry to measure lean body mass (Lohman, 1992).

PREVALENCE

Obesity is a major health problem in the United States, due to its prevalence and its association with morbidity and mortality. It is estimated that one of every two Americans is overweight or obese (Flegal, et al., 1998). Obesity increases with age, peaking at about age 50, and occurs more commonly in women than in men, especially in minority women. Approximately 55% to 60% of African American women and Mexican American women, from age 40 to 60, are overweight (see Fig. 15.1).

Despite all of the recent attention to obesity, the increased public interest in exercise, and the development of new low fat products, the prevalence of obesity is increasing, not decreasing (Kuczmarski, Flegal, Campbell, & Johnson, 1994). In studies conducted between 1960 and 1980, approximately 25% of Americans were overweight. Now, 33% of Americans are overweight. The exact cause of this increased obesity is unclear. It appears that dietary intake has not increased over this period (and intake of fat has decreased), raising the possibility that the increased prevalence of obesity is due to decreases in physical activity (Heini & Weinsier, 1997).

TABLE 15.1
Body Weights in Pounds According to Height and Body Mass Index

Height (in)	Body Mass Index (kg/m ²)													
	19	20	21	22	23	24	25	26	27	28	29	30	35	40

Note. Each entry gives the body weight in pounds (lb) for a person of a given height and body mass index. Pounds have been rounded off. To use the table, find the appropriate height in the lefthand column. Move across the row to a given weight. The number at the top of the column is the body mass index for the height and weight.

FIG. 15.1. Unadjusted prevalence of overweight by age and race/ethnicity for men and women, U.S. population age 20 or older, from 1988 to 1991. Reprinted from Kuczmarski, Fiegel, Campbell, & Johnson (1994).

There has also been an increase in the prevalence of obesity in children. Currently, approximately 27% of children (age 6–11) and 22% of adolescents (age 12–18) are obese (Gortmaker, Dietz, Sobol, & Wehler, 1987). This high prevalence of obesity in children is of particular concern, because overweight children typically become overweight adults (Epstein, 1993).

CONSEQUENCES OF OBESITY

Impact of Obesity on Morbidity and Mortality

Obesity increases the risk of developing coronary heart disease, diabetes, hypertension, and some forms of cancer. These risks of obesity are particularly strong in individuals under age 40 (Van Itallie, 1985). Several prospective studies, following large cohorts of subjects, have shown that individuals who are even modestly overweight have a greater risk of developing coronary heart disease (Garrisson & Castelli, 1985; Hubert, Feinleib, McNamara, & Castelli, 1983; Willett et al., 1995). In addition, gaining weight in adulthood increases the risk of coronary heart disease (Willett et al., 1995). Similarly, for diabetes, both current weight and weight gain since age 18 are strongly related to the chance of developing this disease (Colditz et al., 1990; Colditz, Willett, Rotnitzky, & Manson, 1995). In the National Health and Nutrition Examination Survey (NHANES II), overweight adults were about three times as likely to develop diabetes as nonoverweight adults; the risk of developing hypertension was also increased threefold in overweight adults (Van Itallie, 1985).

What is less recognized by many is the fact that obesity also increases the risk of certain forms of cancer, particularly hormone-dependent cancers (endometrial, ovarian, breast, cervical, prostate) and gastrointestinal/hepatic/renal cancers (colorectal, gallbladder, pancreatic; Manson et al., 1995; Pi-Sunyer, 1991).

The relation between obesity and mortality is complex and different studies reach different conclusions (Van Itallie & Lew, 1992). Some of the discrepancies between these studies are due to methodological problems, such as the failure to control for smoking (smokers are thinner and die earlier; thus, low body weight may appear to be a risk factor for mortality, whereas it is really smoking that is the risk factor). In the strongest studies, there appears to be an almost linear, continuous relation between BMI and mortality. For example, the Nurses Health Study followed over 115,000 women, from age 30 to 55 at study entry, for 16 years (Manson et al., 1995). The lowest mortality rates were seen in women with a BMI of 19 to 21 (equivalent to 15% below the U.S. average for women of similar age). Among women with a BMI of 32 or greater, the relative risk of death from cardiovascular disease was 4.1 and the risk of death from cancer was 2.1 compared to women with a BMI of < 19 (Manson et al., 1995). Weight gain of 10 kg since age 18 was also associated with increased mortality.

Effect of Body Fat Distribution on Health Consequences of Obesity

It has become increasingly clear that body fat distribution, as well as total body fat, contributes to the health consequences of obesity (J. Vague, Bjorntorp, Guy-Grand, Rebuffe-Scrive, & P. Vague, 1985). Abdominal obesity, where a disproportionate amount of fat is found in the abdominal areas, is associated with increased risk of hypertension, diabetes, coronary heart disease, and mortality (Pi-Sunyer, 1991). Abdominal obesity is seen most commonly in men, in those who are heavier, and also appears to be associated with high dietary fat intake, low exercise, and smoking; there also appears to be a genetic contribution to body fat distribution (Kaye, Folsom, Prineas, Potter, & Gapstur, 1990; Wing, Matthews, Kuller, Meilahn, & Plantinga, 1991a).

The most accurate way to determine the amount of fat in the abdominal area is to use sophisticated techniques such as computed tomography (CT scans) or magnetic resonance imaging (MRI). However, a very simple way of estimating abdominal obesity is to measure the circumference of the waist. A waist circumference of > 95 cm suggests high abdominal obesity (Lemieux, Prud'Homme, Bouchard, Tremblay, & Despres, 1996). Recent studies suggest that weight loss and increased exercise may each contribute independently to reducing abdominal obesity (Despres et al., 1991; Wadden et al., 1988).

Psychosocial Consequences of Obesity

Overweight individuals are exposed to significant prejudice and discrimination. Children as young as age 6 rate overweight children as lazy, stupid, dirty, and prefer not to play with overweight peers (Wadden & Stunkard, 1993). These prejudices exist throughout society, extending even to physicians who prefer not to treat overweight patients.

Gortmaker, Must, Perrin, Sobol, and Dietz (1993) documented important social and economic consequences of obesity that were greater than those seen with many other chronic physical conditions. A sample of over 10,000 individuals were studied first at age 16 to 24, and then followed prospectively for the next 7 years. Women who were overweight at age 16 to 24 were found, 7 years later, to have completed less schooling, to be 20% less likely to be married, and to have lower household income, independent of baseline socioeconomic status or aptitude test scores. Men who were overweight at age 16 to 24 were 11% less likely to be married. In contrast, the young people who had asthma, musculoskeletal abnormalities, and other chronic health conditions at baseline did not show any of these negative consequences. Although this study did not directly measure discrimination, it is likely that the stigma and discrimination associated with being overweight explain these results.

Given these findings of prejudice and discrimination against the obese, it might be expected that the obese would have higher rates of depression and psychological distur-

bances. However, in population-based studies, no significant differences in psychological measures between obese and lean subjects have been reported (Wadden & Stunkard, 1993). The only psychological effects seem to be very specific to obesity, with greater dissatisfaction with body shape among the obese and greater problems with binge eating. Binge eating disorder (BED), which was included in the appendix of *DSM-IV* and is characterized by periods of eating large amounts of food and a feeling of loss of control, occurs in less than 10% of individuals with BMI of < 30 but in over 40% of those with BMI > 34 (Marcus, 1993; Spitzer et al., 1992).

Benefits of Weight Loss

As already discussed, obesity clearly increases morbidity and mortality. To date there has not been a major clinical trial to show that weight loss decreases mortality, but there is extensive evidence that weight loss will lower blood pressure, reduce total and LDL cholesterol, increase HDL cholesterol, decrease triglycerides, and improve glycemic control (Kanders & Blackburn, 1992; Olefsky, Reaven, & Farquhar, 1974; Wing et al., 1987). Many of these positive effects may be related to the fact that weight loss improves insulin sensitivity, which is in turn associated with blood pressure, lipids, and glycemic control. Moreover, each of these changes occur after just modest weight losses of approximately 10% of initial body weight. Although larger weight losses produce greater benefits, small weight losses in even very overweight persons will produce significant improvement in these health parameters. Thus, individuals who are markedly overweight do not need to reduce to ideal body weight to experience health benefits; rather, such individuals should be encouraged to lose 10% of their weight (20 lb in a 200 lb person) and then maintain this weight loss as a way of improving their health.

There are also positive effects of weight loss on psychosocial variables. Behavioral weight control programs that assess mood before, during, and after participation in treatment show reductions in depression and anxiety over the course of the program (Wadden & Stunkard, 1993; Wing, Epstein, Marcus, & Kupfer, 1984). Although subsequent to treatment there is some worsening in mood, these measures usually remain below baseline levels.

Unfortunately, many individuals who try to lose weight will experience initial success followed subsequently by weight regain. Thus, researchers have been trying to determine whether such yo-yo dieting, or weight cycling, has negative physiological or psychological effects. The most recent prospective studies on this topic suggest that there are no negative effects of such voluntary weight cycles (National Task Force on the Prevention and Treatment of Obesity, 1994). When overweight individuals lose weight and then subsequently return to baseline, their lipids and blood pressure also return to baseline, but do not overshoot baseline. Weight cycling also does not negatively affect resting metabolic rate, the ease/difficulty of future weight loss efforts, or body fat distribution. Fewer studies have assessed psychological parameters, but these too do not appear to differ consistently between weight cyclers and nonweight cyclers (Foster,

Wadden, Kendall, Stunkard, & Vogt, 1996; Venditti, Wing, Jakicic, Butler, & Marcus, 1996).

In several epidemiological studies, it was observed that weight cycling increased the risk of all cause mortality, and particularly cardiovascular deaths (Blair, Shaten, Brownell, Collins, & Lissner, 1993; Lissner et al., 1991; National Task Force on the Prevention and Treatment of Obesity, 1994). However, more detailed analyses of these data suggest that these negative effects occur primarily in association with involuntary weight loss, and that voluntary weight losses may, in contrast, be related to improved health and decreased risk of mortality (Williamson et al., 1995).

CAUSES OF OBESITY

Genetics

Twin studies and adoption studies have consistently shown a strong genetic component to obesity (Bouchard, 1995; Stunkard et al., 1986; Stunkard, Harris, Pedersen, & McClearn, 1990). Although there continues to be discussion regarding the proportion of the variability in obesity that is attributable to genetics versus environment, many conclude that it is probably close to 50:50.

Bouchard and colleagues showed that genetic variation interacts with environmental manipulations in determining weight change (Bouchard et al., 1990). These investigators overfed 12 pairs of monozygotic twins 1,000 kcal/day extra for 100 days. They found marked variability between twin pairs in the amount of weight gained with overfeeding, but a high degree of concordance within twin pairs; thus, weight gain in one twin predicted weight gain in the other. Similar findings were observed with exercise (Bouchard et al., 1994), suggesting that the effect of these behavior changes on body weight may be mediated by genetic factors.

The recent discovery of the genes responsible for obesity in several animal models (specifically the *ob* gene, which codes for leptin, and the gene for the leptin receptor) has dramatically energized this field and led to a burgeoning of research on the regulation of body weight (Campfield, Smith, & Burn, 1996). A number of genes that may be related to human obesity are currently being examined. However, the importance of these genetic factors must be kept in perspective. The recent marked increases in the prevalence of obesity are not due to changes in genes, but clearly arise from changes in the environment. Similarly, as native populations become Westernized, their risk of obesity rises dramatically. These changes are due to adoption of a Western diet (sometime referred to as "Coca-Cola-nization") and decreased physical activity. This is well illustrated by a recent study comparing Pima Indians who live in the United States with a group of recently identified Pimas, from the same genetic background, who live in a rural area of Mexico (Ravussin, Valencia, Esparza, Bennett, & Schulz, 1994). These Mexican Pimas, who have no electricity, maintain an agrarian lifestyle and consume a traditional Pima diet. Whereas 50% of American Pimas are overweight, with a mean BMI of 35.5, the Mexican Pimas have an average BMI of only 25.1. Such data suggest

that genetic background may predispose some individuals to obesity or leanness, but environmental factors determine whether these predispositions will be manifested.

Environmental and Behavioral Factors

Body weight is regulated by the amount of energy taken in through eating and the amount of energy expended. When these two are in balance, weight is maintained. Energy imbalance will result in weight change. When there is an increase in eating or a decrease in expenditure, weight gain occurs; with decreased eating and/or increased expenditure, weight loss occurs. Each of these behaviors is briefly reviewed next.

Eating Behavior. Until recently it has been difficult to demonstrate that overweight individuals eat more than normal weight individuals. This is due to the fact that the only way of determining intake has been to ask people to self-report what they eat, a notoriously unreliable approach. Recent studies using the doubly labeled water technique to more objectively determine energy expenditure have allowed researchers to back track to estimate energy intake (Schoeller et al., 1986). (Because individuals who are weight stable must be in energy balance, there must be a balance between what is eaten and what is being expended.) With this more precise measure, it has become clear that overweight individuals eat more than normal weight, as would be expected for their heavier weight. In addition, studies with overweight persons who consider themselves "light-eaters" have shown that these individuals actually have much higher intake than they recognize (Bandini, Schoeller, Cyr, & Dietz, 1990; Lichtman et al., 1992).

There is also evidence that overweight individuals consume greater amounts of dietary fat than do leaner individuals (Rolls & Shide, 1992; Tucker & Kano, 1992). Fat has 9 calories per gram, whereas carbohydrates and protein each have 4 calories per gram. Thus, it is easy to overeat fat. In addition, several investigators have shown that overweight individuals prefer food stimuli with higher fat intake (Drewnowski, Brunzell, Sande, Iverius, & Greenwood, 1985; Drewnowski, Kurth, & Rahaim, 1991). This may be particularly true of overweight individuals who repeatedly lose and regain weight (Mela & Sacchetti, 1991). In addition, children's preferences for high fat foods appear to be determined not only by the child's own fatness but also by the fatness of their mother (Johnson & Birch, 1994), suggesting that one aspect of genetic vulnerability to obesity may be through increased preference for high fat foods. Other studies also provide evidence that genetic factors may influence taste preferences and percent energy derived from carbohydrates and fat (although genetic factors do not seem to play a large role in determining total energy intake).

Eating behavior is a complex phenomenon, controlled by many physiological processes, learning history, and sociocultural factors. One of the strongest determinants of food intake is preference; people eat what they like. Preferences may to some extent be innately programmed. Humans innately prefer sweet taste and may also exhibit an innate

preference for meat, for dietary fat, or both (Institute of Medicine, 1991). However, learning history and sociocultural factors also play a major role in determining food preferences. Rozin and Schiller (1980) showed that 6- to 7-year-old Mexican children will select a spicy hot snack over a sweet one when given a choice, despite the fact that there appears to be an innate aversion to chilis and a liking for sweets. Familiarity is also an important determinant of food preference, and it is possible to change food preferences by increasing familiarity with a previously novel food item (Birch & Fisher, 1996). Pairing foods with positive social contexts can also affect preferences such that foods served at holidays or used as rewards become preferred. In contrast, when children are coerced to eat a food, their preference for that food decreases. Thus learning history is an important determinant of food preferences.

Whether it is necessary to change food preferences in adults in order to change intake or how best to do so, is unclear. Studies with low sodium diets have shown that after repeated exposure to low sodium foods there is a change in salt preference in favor of lower sodium content. Thus, changing the behavior eventually changes the preferences (not the reverse). Whether this occurs with fat preferences is unclear.

Other factors that influence intake include the social environment, the foods available, and their prices. People eat more when in the company of others, and will model the consumption of their peers. Experimental studies have shown that intake of a subject can be increased by having a confederate consume more cookies from a buffet table (Wing & Jeffery, 1979). Variety of foods also affect the amount eaten. If only one type of food is available at a meal, people will eat some of this item and then gradually cease eating. However, if a new type of food is then introduced, consumption of the new food will increase, demonstrating a phenomenon called "sensory specific satiety" (Hetherington & Rolls, 1996). Thus one way to limit intake may be to limit the choices available at a given meal. A recent study has shown that increasing the variety of fruits available at a cafeteria and decreasing the costs of these foods leads to increased fruit consumption (Jeffery, French, Raether, & Baxter, 1994). Thus, cost, availability, and variety all influence intake without modifying preferences. Given the goal of improving eating habits of the American public as a whole, it is interesting to consider whether by making healthier foods more available and less expensive it would be possible to increase consumption of these foods and consequently preferences, rather than first trying to influence food preferences.

Energy Expenditure. There are several components to energy expenditure. Resting metabolic rate (RMR) is the energy expended when resting in bed in order to maintain various body systems, such as body temperature. RMR accounts for approximately 60% to 70% of total energy expenditure in sedentary individuals and is primarily determined by the amount of lean body mass. Overweight individuals have more lean body mass, as well as more fat mass, thus these individuals tend to have higher RMR than less overweight individuals.

The second component of energy expenditure (accounting for about 10% of expenditure) is the thermic effect of food, or the energy cost involved in metabolizing food. There is inconsistency regarding differences between obese and lean in this component of energy expenditure, but even if differences do occur they are small and represent an unlikely explanation for marked obesity.

The third component is voluntary physical activity. This component is the most variable. Although it accounts for 20% to 30% of total energy expenditure in sedentary individuals, it represents a larger component in those who are more active. A number of studies have shown that overweight individuals are less active than normal weight individuals, although not all studies are consistent (Pi-Sunyer, 1992). Recent studies suggest that overweight individuals not only spend less time doing physical activity, but they also spend more time doing inactive pursuits (such as watching TV; Ching et al., 1996). A number of studies have shown a direct association between hours of TV/day and prevalence of obesity (Gortmaker et al., 1996). This third component is clearly the most easily modified aspect of energy expenditure, and is a primary target of lifestyle interventions for prevention and treatment of obesity.

PREVENTION

As previously described, the problem of obesity is increasing in the United States. One approach to this problem is to try to prevent weight gain and the development of obesity by focusing either on entire populations or on selected individuals. In the public health approach, researchers have attempted to prevent weight gain in entire populations by providing education about nutrition, exercise, and weight; improving access to healthy foods and exercise; or offering incentives for healthy behavior to all individuals in a given community (Taylor et al., 1991), worksite (Henrikus & Jeffery, 1996), or school (Simons-Morton, Parcel, Baranowski, Forthofer, & O'Hara, 1991). Other programs are able to offer more intensive weight gain prevention interventions by focusing on selected individuals rather than large populations. For example, Jeffery conducted two randomized, controlled prevention trials. In the first study of 219 normal weight subjects, the intervention was provided via a monthly newsletter for 1 year (Forster, Jeffery, Schmid, & Kramer, 1988). Subjects were also asked to report their weight each month on a postcard, and received financial incentives for weight maintenance. The treatment was effective for men, but not for women: Men in the intervention group lost 4.7 lb and controls lost 1.4 lb; for women, the weight losses were 1.0 lb and 0.1 lb. The second study used a similar treatment, but included 1,226 normal weight and overweight subjects (Jeffery & French, 1997), and specifically included a sample of lower SES women. Over 1 year there were no group differences in weight gain, although there was a trend for men and higher SES women in the control group to gain more weight than those in the treated group (but among lower SES women, there was a trend for higher weight gain in the treated group).

A more cost effective approach may be to identify individuals who are at particularly high risk for weight gain, and tai-

lor the intervention to their specific situation. Several groups at high risk for weight gain include young adults, women in the menopausal transition, and recent ex-smokers. Weight gain prevention may also be particularly cost effective in groups for whom weight gain carries particularly adverse health risks, such as those at risk for developing diabetes. Before discussing these specific approaches, several methodological points are of interest. First, it is important to assess both acceptability and effectiveness of prevention interventions. Individuals who do not yet have a weight problem may be less willing to participate in interventions to prevent weight gain; the ideal time for weight gain prevention interventions would be when individuals are at high risk for weight gain, and are willing to make changes to prevent the problem.

Second, most prevention studies have analyzed group differences in mean weight gain, which is the analysis strategy commonly used in weight loss programs. However, prevention studies are not intended to produce large weight losses, but rather to prevent relatively small weight gains. Therefore there may be relatively small differences between groups in mean weight change. It may thus be more instructive to compare the treatment and control group on the percentage of subjects who maintain their baseline weight rather than comparing mean weight changes. However, few studies have used this analysis strategy.

YOUNG ADULTS

The risk of large weight gains is greatest during the young adult years. One study looked at the 10-year incidence of major weight gain in adults, defined as a weight gain of at least 5 BMI units, or about 30 lb, in 10 years (Williamson, Kahn, Remington, & Anda, 1990). Such major weight gains occurred most commonly in those from age 25 to 34, affecting 8.4% of women and 3.9% of men in this age group. In addition, the Dormont High School study found that between age 17 and 34, women gained 17 lb and men gained 38 lb (Yong, Kuller, Rutan, & Bunker, 1993).

There has been no research on why young adults gain weight, but this time period clearly encompasses many life changes that could influence eating and exercise habits. For example, most people make the transition from being students to being employed, and they often have dramatic changes in their living situations, either establishing their own residence or getting married and living with a spouse. Many individuals begin a family and are engaged in childrearing. Because they are busy in their new adult roles, they may have less time available for meal planning and food preparation and may also spend less time in organized sports activities.

There are no published studies to prevent weight gain in young adults, but a recent pilot study to prevent weight gain in normal weight women from age 25 to 35 compared weekly group meetings or a correspondence course to a no-treatment control group (Klem & Wing, 1997). At the end of the 10-week treatment, the women who attended weekly meetings had lost 4.7 lb, the correspondence group had lost 1.8 lb, and the control group had lost 0.8 lb. However, women ap-

peared to be more likely to participate in the correspondence course than the weekly meetings; 86% of women randomized to the correspondence group attended the initial orientation and enrolled in the study, compared to only 50% of women assigned to group meetings. These results suggest that from a public health perspective the correspondence approach may be as or more effective than the group meetings.

A similar study to prevent weight gain in young adult men focused on increasing their physical activity through weekly meetings and group exercise sessions or a correspondence intervention. After 4 months of treatment, men in the group program and the correspondence program had lost similar amounts of weight (1.9 vs. 1.3 kg, respectively), and those in the control group gained 0.22 kg (Leermakers, Jakicic, & Wing, unpublished study). Fitness changes were also somewhat better in the two interventions than in the control group, with no differences between the interventions. Further research is needed to determine what type of intervention will be most acceptable and effective in preventing weight gain in men and women in this high risk age group.

PREGNANCY

One life event common in the young adult years is pregnancy; difficulty in losing the weight gained during pregnancy may contribute to the development of obesity in young adult women. The recommended weight gain during pregnancy is 25 lb to 35 lb for normal weight women, with a higher range for underweight women and a lower range for overweight women (National Academy of Sciences Institute of Medicine, 1990). Most women lose this weight after the baby is born, and have a permanent weight gain of only 1 or 2 pounds. However, a subset of women retain far more weight, with the strongest predictor of permanent weight retention being excessive weight gain during pregnancy. For example, one study found that women who gained more than recommended during their pregnancy were 17.0 lb over their pre-pregnancy weights 6 months after delivery, and 31% were classified as overweight; in contrast, those who gained within the guidelines were only 8.4 lb above their pre-pregnancy weight and only 14% were overweight (Scholl, Hediger, Schall, Ances, & Smith, 1995).

The majority of studies that have attempted to prevent excessive weight gain during pregnancy have been in women who have comorbid health problems, particularly gestational diabetes. In women who develop diabetes during pregnancy, levels of glucose in the blood are no longer appropriately regulated by the body; therefore strict attention to diet and exercise are necessary to control blood glucose levels. Studies that have examined the use of a calorie-restricted diet to improve glucose levels in pregnant women with diabetes have also found that the rate of weight gain was reduced during the period of calorie restriction (Algert, Shragg, & Hollingsworth, 1985), suggesting that weight gain during pregnancy can be limited with calorie restriction with no adverse effects. Only one study has examined the use of calorie restriction, exercise, and feedback about weight gain to prevent excessive

weight gain in nondiabetic pregnant women. In this study, 61 normal weight women and 49 overweight women were randomly assigned to receive either standard pregnancy counseling or an individualized behavioral intervention designed to prevent excessive weight gain during pregnancy. Preliminary results show that the intervention reduced the number of normal weight women with excessive weight gain from 58% to 33%; however, the intervention was not effective for women who were already overweight before becoming pregnant (Polley, Wing, Meier, Sims, & DeBranski, 1997).

SMOKING CESSATION

Another key time for weight gain prevention efforts may be in the period following smoking cessation. Individuals who smoke weigh about 7 lb less than nonsmokers and smoking cessation is associated with about a 6 lb weight gain (Klesges, Meyers, Winders, & French, 1989). Concern about weight gain is thought to interfere with smoking cessation, especially in women; thus, some researchers have attempted to prevent this weight gain by offering weight control interventions in conjunction with smoking cessation interventions (Gritz, Klesges, & Meyers, 1989; Perkins, 1994). For example, Hall and colleagues (Hall, Tunstall, Vila, & Duffy, 1992) offered a 2-week smoking cessation program, then randomly assigned the 165 participants who completed the program to a control group, a support group for weight issues, and a more intensive individualized behavioral program to prevent weight gain. In the behavioral intervention, individuals monitored their weight daily, and restricted their calories in response to weight gain. They were also given an exercise prescription and taught behavioral strategies. At 6 weeks and 52 weeks, weight gains in the two prevention groups were no different from weight gain in the control group, but participants in the two prevention groups were more likely to return to smoking. Similar results were found by Pirie (Pirie et al., 1992), who provided weight control counseling at the same time as the smoking cessation intervention. Thus, efforts to combine smoking cessation programs with weight gain prevention programs have been unsuccessful in preventing weight gain, and appear to increase smoking relapse rates. Better results may be obtained by focusing on exercise, rather than weight loss, in the period surrounding smoking cessation (Marcus, Albrecht, Niaura, Abrams, & Thompson, 1991).

MENOPAUSAL TRANSITION

A high risk period for weight gain in women is the period surrounding menopause; women gain on average 1–2 lb/year between age 40 and 55. It was once thought that menopause itself caused weight gain, but recent studies show that weight gain occurs in this age group regardless of menopausal status or use of hormone replacement therapy (Wing, Matthews, Kuller, Meilahn, & Plantinga, 1991b), and is best correlated with changes in physical activity level (Owens, Matthews, Wing, & Kuller, 1992). It is particularly important to prevent weight gain in this age group because of the high risk of cardiovascular disease that occurs in postmenopausal women. In

the ongoing Women's Healthy Lifestyle Project, healthy perimenopausal women participated in a 20-week behavioral program that focused on reducing dietary fat intake and increasing moderate intensity activities, such as walking. They were also encouraged to lose modest amounts of weight (5–15 lb, depending on baseline weight status). Participants will be followed for 5 years, but 6-month results are now available (Simkin-Silverman et al., 1995). After 6 months, women in the prevention group had lost 10 lb on average, versus 0.5 lb in the control group. Women attended 11 of 15 sessions, and demonstrated improvements in risk factors such as diet and exercise habits, lipid profiles, and blood pressure. The researchers have not reported the percentage of women who gained weight in each group, but the dramatic differences in average weight change suggest that an intensive prevention program is well-accepted and successful, at least in the short term, for this group of women.

OVERWEIGHT CHILDREN

Finally, another approach to preventing obesity is to treat children and adolescents who are already developing weight problems. About a quarter of children in the United States are overweight, and a recent review found that about half of obese school-age children become obese adults, a risk four to seven times higher than that of their normal weight peers (Serdula et al., 1993). Thus, efforts to treat obesity in childhood may prevent adult obesity. Behavior change may be more effective in children because parents still have some degree of control over the children's eating, and can be trained to provide appropriate modeling and contingencies. Epstein and colleagues conducted a series of family-based behavioral treatment programs for overweight children, with remarkably good results, both short and long term (Epstein, 1996). In Epstein's programs, both parents and children attend weekly group meetings, and weight loss is promoted through: (a) a simple diet plan, the "stoplight diet," that promotes healthy food choices by categorizing foods as red, yellow, or green; (b) an exercise program; and (c) instruction in the use of behavioral techniques such as self-monitoring, social reinforcement, and modeling. As long as 10 years after these 6- to 12-month programs, treated children have decreased their percent overweight by approximately 8% to 15%, and untreated controls have increased their percent overweight by 8% to 12%, depending on the study (Epstein, Valoski, Wing, & McCurley, 1994). Children are most successful in these programs when they are treated with their overweight parents (and both are targeted for weight loss), and children tend to be more successful than their parents (Epstein, 1996).

OTHER HIGH RISK GROUPS

Several other groups are known to be at high risk for obesity, but there have been no systematic studies to prevent weight gain in these individuals. One well-documented group is the offspring of mothers with gestational diabetes. These infants are often overweight at birth, and although their weight may normalize in early childhood, they are at increased risk of be-

coming overweight in later childhood and adolescence (Pettitt et al., 1991; Silverman et al., 1991). For example, Silverman and colleagues found that by age 8, 50% of the offspring of diabetic mothers had weights greater than the 90th percentile (Silverman et al., 1991). Prevention efforts would be particularly beneficial in the children of diabetic mothers because both having a diabetic mother and obesity are risk factors for the development of NIDDM.

Because obesity is a strong risk factor for NIDDM, it might also be beneficial to prevent the development of diabetes by treating or preventing weight gain in those at risk for NIDDM, including those with a family history of NIDDM and/or impaired glucose tolerance. Several studies have shown that individuals with multiple risk factors for NIDDM can reduce their risk of developing NIDDM by losing weight (Pan et al., 1997; Torjesen et al., 1997). For example, a recent study offered a 2-year behavioral weight loss program to overweight, middle-aged individuals with a family history of diabetes (Wing et al., 1998). A no-treatment control group was compared to groups given diet only, exercise only, or diet plus exercise. Initial weight losses were better in the groups given diet instruction, but unfortunately, at 2 years there were no group differences in weight loss. However, in each of the groups a 10 lb weight loss reduced the risk of developing diabetes over 2 years by about 30%. Thus again even modest weight losses can have a dramatic impact on health.

In summary, it is quite possible to identify groups that are at high risk for becoming obese, but there has been very little research in the prevention of weight gain in these groups. Initial results suggest that this may be a promising area for research.

TREATMENT

Since the 1970s, behavioral approaches have been the treatment of choice for mild to moderate obesity. The goal of behavioral approaches is to help patients change their eating and exercise behaviors by teaching them to rearrange the antecedents (cues) and consequences (reinforcers) that control these behaviors. Behavioral programs are typically delivered in a closed group format, with weekly meetings for approximately 6 months, followed by less frequent contact. At each meeting, participants are weighed individually, self-monitoring records are collected and reviewed, and a lecture/discussion is presented. Topics include nutrition and exercise information (e.g., low fat eating, eating in restaurants, exercise in different weather conditions) and behavioral topics (e.g., self-monitoring of eating and exercise behavior, stimulus control, assertiveness).

The weight losses obtained during the initial phase of behavioral treatment programs have improved over the past 25 years, as documented by several reviews of this literature (Brownell & Jeffery, 1987; Wadden, 1993). Summarizing studies published between 1990 and 1995, Wing (1997) concluded that, on average, participants in behavioral programs will lose 9.7 kg over 26 weeks of treatment (Table 15.2).

However, in contrast to improved short-term results, long-term results have remained fairly constant. With current treat-

ments, patients maintain a weight loss of 5.2 kg at 1 year follow-up (Wing, 1997), or about 61% of their initial weight loss (Wing, 1997). Few studies have provided data for 3 to 5 years of treatment, but it appears that there is continued weight regain in these longer studies (Kramer, Jeffery, Forster, & Snell, 1989; Wadden, Sternberg, Letizia, Stunkard, & Foster, 1989). Consequently, behavioral researchers have been focusing on improving long-term weight loss and maintenance. The basic behavioral techniques used in standard behavioral weight control programs are described, and new approaches being used to produce longer lasting changes in diet, exercise, and body weight are highlighted.

BEHAVIORAL TECHNIQUES

Participants in behavioral weight loss programs are given calorie, fat, and exercise goals designed to produce a weight loss of about 2 lb per week. To determine an appropriate calorie goal for weight loss, current intake is estimated by assuming that the individual consumes 12 kcal/lb of body weight. Thus a 200 lb person would be estimated to be eating 2400 kcal/day to maintain their weight. In order to promote a weight loss of 2 lb/week, this intake must be reduced by 1,000 kcal/day or 7,000 kcal/week. Typically, behavioral programs use calorie goals of 1,000 to 1,500 kcal/day, with the higher goal reserved for individuals who weigh more than 200 lb. The fat goal may range from 20% to 30% of calories from fat, and is usually

prescribed to participants in grams/day to facilitate self-monitoring. If an individual was assigned a 1,000 kcal goal with 20% as fat, then 200 calories would be from fat; because one gram of fat has 9 calories, the participant would be given a fat gram goal of 22 grams of fat. The exercise goal has traditionally been set at about 1,000 kcal/week over current activity levels. Walking is the preferred type of exercise because it is easy and requires minimal equipment. A good rule of thumb is that 1 mile of walking expends 100 calories; thus, 1,000 kcals can be expended by walking 2 miles on 5 days each week. More detailed energy expenditure charts that take into account current body weight and indicate calories expended in a variety of other activities are often used in behavioral programs.

The cornerstone of behavior change is self-monitoring, in which patients track their progress toward calorie, fat, and exercise goals. Patients are asked to keep a diary of their eating and exercise behaviors, which is to be filled out throughout the day (rather than retrospectively). They are instructed to list everything they eat and drink, using food labels or a book of food composition to estimate calories and/or fat. Each type of exercise is also listed, including time spent exercising, and the number of calories expended. For each diary entry they are also encouraged to note the time of day and circumstances. The patient is then taught to use the diary to evaluate their current behavior, identify problems, and select specific behaviors to target for change.

After identifying a target behavior, goal setting is used to specify the desired change. Although the overall goals for weight loss are quite general (e.g., eat 1,500 kcal/day, <20% from fat, and exercise 1,000 kcal/week), the use of specific goals breaks the behavior change into small, achievable steps. Thus, a person whose diary shows they are exceeding their fat goal is more likely to succeed if they set a small, specific goal (e.g., "use jam instead of margarine on toast at breakfast"), rather than a general goal, such as "continue to lower fat intake."

Stimulus control techniques are a powerful tool for reorganizing the environment to support the desired behaviors. Patients are taught that it is difficult to consistently make good eating and exercise choices in an environment that does not support the desired behavior. Thus, they are instructed to reduce (or eliminate) cues that encourage overeating/high fat eating (e.g., "do not allow chips, desserts, or other tempting foods in the house"), and to make it as easy as possible to make good choices (e.g., "leave exercise equipment in a highly visible area," "have low-fat snacks readily available in refrigerator").

Finally, participants are also asked to change the environmental consequences of their behavior using positive reinforcers, such as positive feedback or financial contingencies to reward behavior changes.

DIET

Initially, behavioral treatment programs focused primarily on calorie restriction. More recently, participants have been given goals for calorie and fat, and asked to monitor and mod-

TABLE 15.2
Summary of Results (Mean + SD) of 14 Behavioral Treatment Studies 1990–1995

	<u>Total</u>
Studies	N = 14
Treatment Groups	N = 34
Subjects/Group at Entry	N = 33 ± 12
Initial Wt (kg)	92.8 ± 7.9
Duration Treatment (wks)	27 ± 13
% Completing Treatment	83 ± 13%
Weight Loss during Treatment (kg)	9.7 ± 4.1
Weight Loss/Week (kg/wk)	0.39 ± 0.15
Duration of Follow-up (Pre to Follow-up) (wks)	64 ± 17
Duration of Follow-up from Post Treatment (wks)	40 ± 11
# of Contacts during Follow-up	6.3 ± 5.0
% Completing Follow-up	76 ± 13%
Weight Loss (Pre to Follow-up) (kg)	5.6 ± 3.0
% of Initial Weight Loss Retained	60.3 ± 21.7

ify both aspects of their behavior. This change is due in part to the evidence that overweight individuals have higher consumption of fat (Rolls & Shide, 1992; Tucker & Kano, 1992).

Moreover, fat is energy dense compared to other macro nutrients (i.e., fat has 9 kcal/gram and carbohydrate and protein have only 4 kcal/gram), and thus it is easy to overeat when consuming a high-fat diet. In fact, several studies have shown that individuals who are asked simply to restrict fat, but are not asked to count or restrict calories, reduce both their fat and calorie intake and consequently lose weight (Insull et al., 1990; Kendall, Levitsky, Strupp, & Lissner, 1991)—although this may be a temporary phenomena. To determine whether calorie restriction is more or less effective than fat restriction, Jeffery and colleagues compared weight losses achieved by women who were given either a calorie goal only or a fat gram goal only (Jeffery, Hellerstedt, French, & Baxter, 1995). No differences in weight loss were observed over 18 months. However, two other studies (Pascale, Wing, Butler, Mullen, & Bononi, 1995; Schlundt et al., 1993) found evidence that better weight losses are achieved when subjects are given goals for both calories and fat. Thus, this is the strategy now used in most behavioral treatment programs. Fat modified foods (e.g., fat substitutes) have been recently developed and are now widely marketed. It has not yet been determined how the use of fat modified foods affects body weight and weight loss efforts.

Structured Diets: VLCDs and Balanced Structured Eating

Whereas most behavioral weight loss programs recommend balanced diets of from 1,000 to 1,500 kcal/day, some studies have included periods of very low calorie diets (VLCDs). VLCDs are diets of < 800 kcal/day, usually consumed as liquid formula. The simplicity of drinking several cans of liquid each day, and removing food entirely from the diet, makes such regimens effective for some individuals. In fact, VLCDs have been shown to produce weight losses of approximately 20 lb in 12 weeks (Wadden, Stunkard, & Brownell, 1983). However, the problem has been that the weight is often regained when foods are reintroduced to the diet. Wadden and Wing (Wadden, Foster, & Letizia, 1994; Wadden et al., 1989; Wing, Blair, Marcus, Epstein, & Harvey, 1994; Wing, Marcus, Salata, et al., 1991) have tried, in several randomized controlled studies, to develop strategies that would increase the long-term effectiveness of VLCD regimens. These investigators have used VLCD's within the context of long-term behavioral program (Wadden et al., 1994; Wing et al., 1994), continuing to see patients frequently after food intake resumed. However, despite continued contact and the fact that the initial weight losses are improved with the VLCD, in the long term (1–5 years later), patients treated with behavioral programs that included use of VLCD have weight loss comparable to those who were treated in behavioral programs with balanced 1,000 to 1,500 kcal/day diets throughout.

Wing and colleagues also tried to use VLCDs intermittently, alternating 12 weeks of VLCDs with 12 weeks of low calorie diet (Wing et al., 1994). They found that adherence to the second VLCD, and consequently weight loss during

the second VLCD, was very poor (Smith & Wing, 1991). Thus, again, overall the VLCDs added little to the low calorie approach.

Behavioral researchers continue to be intrigued with VLCDs because they are successful at helping patients achieve initial weight loss. Recent findings that liquid diets of 400, 600, and 800 kcal/day all produce identical weight loss (Foster et al., 1992) suggest that the advantage of these regimens may be in their simplicity and structure, not the very low calorie intake recommended. Behavioral researchers have thus tried to maintain the simplicity and structure of these regimens, but use higher calorie goals (900 or 1,000) to make these diets safer and allow their use over longer periods of time. Wadden and colleagues (1997) recently utilized a 900 kcal/day diet that consisted of 4 servings daily of liquid meal replacement (150 kcal each) and a prepackaged dinner entree (280–300 kcal) with salad. Subjects utilizing this diet as part of an intensive behavioral program lost 14.5 kg after 17 weeks and maintained the weight loss at 1 year. Similarly, subjects participating in a 10-center clinical trial of cardiovascular risk factor management who were given prepackaged foods lost more weight over 10 weeks than subjects who were allowed to select their own diets according to the American Heart Association (AHA) Step 1 and Step 2 guidelines (4.5 vs. 3.5 kg for men; 4.8 vs. 2.8 kg for women; McCarron et al., 1997).

Jeffery, Wing, and colleagues also showed that providing subjects with the food they are to eat or prescribing a meal-by-meal eating plan may improve weight losses (Jeffery et al., 1993; Wing, Jeffery, Burton, et al., 1996). In their first study on this topic (Jeffery et al., 1993), these investigators randomly assigned 202 overweight adults to either a no-treatment control group, a standard behavioral treatment (SBT), a SBT with food provision, a SBT with financial incentives, or a SBT with food provision and financial incentives. Subjects in the food provision conditions were given a box of food each week for 18 months. This food provision markedly improved weight losses. Subjects in the SBT condition lost 7.7, 4.5, and 4.1 kg at 6, 12, and 18 months, whereas those given food lost 10.1, 9.1, and 6.4 kg at these three time points (see Fig. 15.2). Thus, at 12 months, food provision actually doubled the weight losses. No effect of financial incentives was observed. These positive effects of food provision were replicated in a second study by these investigators. In addition, they found that simply telling patients exactly what to eat for each meal and providing them with a grocery list to purchase these foods was as effective as giving patients the food (Wing, Jeffery, Burton, et al., 1996). It appeared that subjects given meal plans plus grocery lists, as well as those actually given the food, changed the types of food stored in the home and reported a more regular pattern of meal eating and less difficulty with estimating portion size, finding time to plan meals, and controlling eating when not hungry.

All of these studies suggest that patients may find it helpful to be given some structure as they begin to learn new eating and exercise habits. Merely telling patients to consume 1,000 kcal/day with 20% as fat may be more difficult than providing examples of specific meal plans and eating patterns that satisfy these goals.

EXERCISE

The single best predictor of long-term maintenance of weight loss is exercise, and randomized trials consistently show better long-term results for the combination of diet plus exercise than for either intervention alone (Pronk & Wing, 1994). Exercise may improve long-term weight loss by both psychological and physiological mechanisms. Exercise increases caloric expenditure, and may also minimize loss of lean body mass, thereby lessening the reduction in resting energy expenditure observed with weight loss. In addition, exercise has been shown to influence mood state and may maintain or even suppress appetite, thereby making it easier for patients to adhere to their diet in the long term.

The benefits of exercise are observed most consistently in weight loss programs with moderate calorie restriction (diets of 1,000–1,500 kcal/day). Previous studies with very low calorie diets have often failed to show benefits of exercise, perhaps because of the large weight losses achieved with the diet alone. For example, Wadden and colleagues (1997) randomly assigned 128 overweight women to year-long programs focused on diet only (diet of 900–925 kcal), or diet combined with resistance training, aerobic training, or the combination of resistance and aerobic training. Weight losses across the four conditions were 16.5 kg at 24 weeks and 15.1 kg at 48

weeks; no differences were seen between conditions in weight, body composition, mood, or appetite.

Exercise predicts maintenance of weight loss, so the issue becomes how best to encourage overweight individuals to adopt and maintain a higher level of physical activity. One approach may be to encourage more flexible exercise routines. In working with overweight children, Epstein, Wing, Koeske, and Valoski (1985) found that a lifestyle exercise program, where children could choose the type of exercise and the time at which they exercised, was more effective than programmed exercise, where the same exercise had to be done on preset days and times. Jakicic, Wing, Butler, and Robertson (1995) extended this reasoning to adults and hypothesized that encouraging overweight women to exercise in several 10-minute bouts might be more effective than the usual 30- to 40-minute bout prescription. In this study, all women received the same diet, the same behavioral program, and the same exercise goals. However, the long bout group did their exercise in one 40-minute bout, whereas the short bout group was instructed to exercise in four 10-minute bouts. Thus, the short bout group could take a brief walk after each meal, or whenever they found a free 10 minutes. The short bout exercise prescription led to better exercise adherence; these subjects were more likely to exercise on any given day and completed more minutes of exercise over the course of the program (see Fig. 15.3). Their weight losses were also somewhat better. Interestingly, the short and long bout group had comparable improvements in cardiovascular fitness.

Another way to improve exercise adherence is to focus more on the environmental cues and reinforcers for this behavior. Wing and Jeffery, therefore, compared a standard behavioral group that was given diet and exercise goals but encouraged to exercise on their own, with a group given supervised exercise, or supervised exercise with a personal trainer to cue exercise, supervised exercise with financial incentives for attending sessions, or supervised exercise with a trainer and incentives (Wing, Jeffery, Pronk, & Hellerstedt, 1996). The personal trainer and the incentives both were effective in improving attendance at the supervised sessions and the best attendance occurred when both interventions were combined. However, despite better attendance at walk sessions, there were no differences in overall self-reported physical activity. Surprisingly, the best weight losses occurred in the group given diet and exercise goals and encouraged to exercise on their own. Whether this result derives from the benefits of home-based versus group (supervised) exercise (King, Haskell, Taylor, Kraemer, & DeBusk, 1991; Perri, Martin, Leermakers, Sears, & Notelovitz, 1997) or suggests that emphasizing exercise too much may detract from diet remains unclear.

Epstein and colleagues, in their work with overweight children, compared the effectiveness of increasing physical activity (as done in the aforementioned studies) with the effectiveness of decreasing sedentary activities (e.g., TV and computers). A treatment focusing on decreasing sedentary activities was found to produce greater weight losses, better dietary adherence, and increased liking for high intensity activities (Epstein et al., 1995).

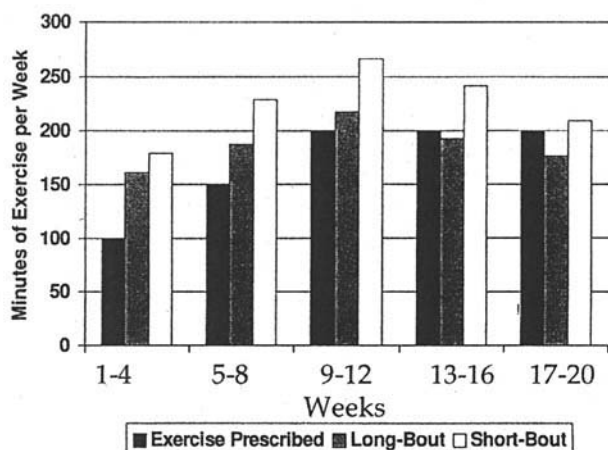

FIG. 15.3. Comparison of exercise adherence rates in overweight women during a 20-week behavioral weight loss program with exercise prescribed in long bouts versus short bouts. Adapted from data published in Jakicic, Wing, Butler, & Robertson (1995).

SOCIAL SUPPORT

Social support has also been investigated as a factor in changing eating and exercise behavior. Friends and family members not only provide social support, but also may model appropriate (or inappropriate) eating and exercise behaviors and serve as a “cue” for these behaviors. Thus, one common strategy is to ask spouses to participate in the weight loss program along with the participant, and to make the same changes in eating and exercise behavior. A recent meta-analysis showed a small positive effect of spouse involvement (Black, Gleser, & Kooyers, 1990), but results have been inconsistent. In a study of patients with type 2 diabetes treated with or without their spouses, Wing found a significant gender effect; women lost more weight when treated with their spouses, but men lost more weight when treated alone (Wing, Marcus, Epstein, & Jawad, 1991).

Other researchers have begun to investigate nonsupport, including coworkers, other participants, or friends. Jeffery (Henrikus & Jeffery, 1996) found that worksite interventions, including team competitions, improve long-term weight loss. Wing and Jeffery found that a “personal trainer” increased exercise adherence (Wing, Jeffery, Pronk, & Hellerstedt, 1996); the personal trainer was not a trained exercise physiologist, but a “paid” support person, who reminded the participant of exercise appointments and then walked with the participant. Wing and Jeffery (1999) recently conducted a pilot study to examine the effects of an intervention designed to increase social support through team building activities and group competitions, using participants who were recruited either as individuals or in groups of four acquaintances. They found the best weight losses in those individuals who were recruited with friends and provided with the social support intervention.

These data suggest that efforts to increase social support may be effective in both improving initial and long-term weight losses.

PHARMACOTHERAPY

In recent years, there has been tremendous interest in the pharmacologic treatment of obesity (National Task Force on the Prevention and Treatment of Obesity, 1996). This interest is spurred by the fact that long-term results of behavioral programs continue to be disappointing. There is also increased recognition that obesity is a chronic problem, requiring chronic ongoing therapy. Thus, investigators are beginning to consider long-term (perhaps lifelong) drug treatment for obesity, as would occur with hypertension or other chronic diseases. As part of this change in attitudes about weight loss drugs, the Food and Drug Administration (FDA) in 1996 approved dexfenfluramine for extended use in the treatment of obesity. Dexfenfluramine, which increases serotonin levels by stimulating the release and inhibiting the reuptake of central serotonin, became one of the most widely used drugs. In addition, the combination of fenfluramine (a serotonergic drug) and phentermine (a catecholaminergic drug) became extremely popular for the treatment of obesity. However, evidence suggesting that dexfenfluramine and fenfluramine might be associated with cardiac disease led to their rapid withdrawal from the market.

Despite this adverse experience with pharmacologic treatment of obesity, there continues to be great interest in developing a new drug for this disease. Several other drugs have recently been approved, including orlistat, which is a pancreatic lipase inhibitor, and sibutramine, which is a norepinephrine and serotonin reuptake inhibitor. These drugs appear to be modestly effective and have fewer risks. At present all that can be concluded is that there must be careful consideration of the risk-benefit ratio of each drug for each individual patient. Moreover, because these medications are typically considered adjuncts to behavioral lifestyle interventions, it will be important to determine how best to combine these two approaches.

MAINTENANCE

Given the major difficulty in producing long-term weight loss, researchers have specifically focused on questions related to the maintenance process. Based on Marlatt and Gordon’s relapse prevention model (Marlatt & Gordon, 1985), an effort has been made to identify specific situations that might pose problems for dieters and to determine whether coping skills are related to success in dealing with such relapse crises.

Researchers have identified three types of situations where dieters are at risk for overeating. These include situations involving food cues (e.g., being in a restaurant; family meal), situations involving affective cues (e.g., anger, depression) and situations involving boredom or transition (e.g., watching TV). These three high risk situations are quite similar to those identified by smokers.

Moreover, performance of a coping response appears to be related to surviving the relapse crisis. When subjects were asked if they had used any behavioral and/or coping strategies to keep them from overeating, the main difference between lapses that were successfully survived versus those that were not was the performance of any coping responses. Grilo, Shiffman, and Wing (1989) showed that behavioral coping strategies (such as leaving the room) and cognitive coping responses (devaluing the food) are equally effective in preventing lapses, but that the combination of a behavioral and cognitive strategy is the most effective response.

Given this, it is interesting to ask whether the ability to generate coping responses to hypothetical high risk situations would be related to success at long-term weight loss. The answer appears to be "yes." In a study by Drapkin, Wing, and Shiffman (1995), dieters were asked at the beginning of a weight loss program to listen to four scenarios describing high risk situations (i.e., family celebration with food, TV, anger, frustration at work). They rated the difficulty of each of these situations and generated as many coping responses to each scenario as they could. Participants who were able to generate more coping responses to the hypothetical situation subsequently lost more weight. Moreover, participants were able to accurately anticipate which situation would be most difficult for them. Participants who noted the negative affect situation as most difficult were later most likely to lapse in situations involving negative affect. These results suggest the possibility of individually tailoring treatment and teaching patients to deal with those situations that cause them personally the greatest difficulty.

Perri and colleagues have done the most systematic research on the maintenance process (Perri, Nezu, & Viegner, 1992). They showed, for example, that relapse prevention training followed by continued therapist contact improves long-term weight maintenance (Perri, Shapiro, Ludwig, Twentyman, & McAdoo, 1984). Relapse prevention training was provided to one group during the last 6 weeks of the treatment program; these participants were taught about the process of relapse, and practiced skills needed to identify and cope with high risk situations and to recover from acute lapses. Then, during the first 6 months after treatment, half of the participants were asked to maintain weekly contact with therapists by mailing in postcards with information about their progress, which was followed by a telephone call from the therapist. The group that received both relapse prevention training and continued therapist contact had significantly better weight maintenance than any other group, losing an additional 1.6 lb over the year of follow-up (compared to weight regains of 12.3 lb with relapse training only, and 6.5 lb with contact only).

Because so few participants in clinical weight loss programs go on to successfully maintain their weight loss, some researchers have begun to recruit and study individuals who have successfully lost weight and maintained the weight loss. Wing, at the University of Pittsburgh, and Hill, at the University of Colorado, developed a national registry of individuals who have successfully lost 30 lb (regardless of method) and maintained the loss for at least a year; registry members are recruited primarily through media coverage (i.e., magazine,

radio, newspaper). Although this is not a representative sample of all successful losers, it provides a rare opportunity to study weight maintenance. The initial cohort of 784 individuals in the registry reported an average weight loss of 66 lb, which they had kept off for 5 years. Nearly all of the registry members used both diet and exercise to lose weight and to maintain their weight loss (Klem, Wing, McGuire, Seagle, & Hill, 1997b). Reported calorie and fat intake were low (averaging 1,380 kcal/day with 24% as fat) and exercise levels were very high (2,800 kcal/week). These data suggest the continued importance of these two behavioral strategies for long-term weight control.

CONCLUSIONS

This chapter has broadly reviewed obesity, with a focus on areas relevant to health psychology. Obesity has long been a focus of health psychologists because behavior plays such an important role in the etiology and treatment of this highly prevalent disorder, which is associated with poor health outcomes, including heart disease and diabetes. Several areas of obesity research offer exciting new areas for research, including:

1. The interaction between genes, such as the ob and leptin receptor genes, and behavior in the etiology of obesity.
2. The determinants of food choice, including availability, cost, and preference.
3. Prevention of weight gain, both in the general population and in identified high risk groups.
4. The effect of low fat and fat modified foods on weight.
5. The use of exercise in weight control and weight maintenance (e.g., appropriate levels, how best to facilitate the adoption of exercise habits, decreasing sedentary activity).
6. The combination of behavior therapy with pharmacological agents.
7. Maintenance of weight loss.

Advances in genetic research and pharmacotherapy have heightened interest in obesity research, and it is vitally important that health psychologists continue to work with scientists and practitioners in these fields, using a multidisciplinary approach to further understand the determinants of obesity, and how best to prevent and treat this condition.

Alcohol Use and Misuse

Mark D. Wood
University of Rhode Island

Daniel C. Vinson

Kenneth J. Sher
University of Missouri-Columbia

Alcohol consumption is a complex, multifaceted phenomenon related to both objective drinking topographies such as quantity, frequency, and patterns of use, and to accompanying physiological, psychological, and social consequences. Adverse consequences from drinking may occur as a result of chronic misuse (e.g., pancreatitis, liver disease), or from single episodes of hazardous use (e.g., alcohol-related motor vehicle crashes). Although alcohol abuse and dependence often tend to be the focal points for discussion of alcohol-related problems, a burgeoning literature on the association between hazardous drinking (e.g., intoxication, heavy drinking) and various types of bodily trauma highlights the importance of recognizing that even “nonproblem” drinkers are placed at substantially increased risk as a function of alcohol consumption (Klatsky, Friedman, & Siegelau, 1981; National Institute on Alcohol Abuse and Alcoholism, [NIAAA], 1997). In this chapter we use the term *alcohol use* to describe any alcohol consumption, and group hazardous drinking, alcohol abuse, and alcohol dependence under the label *alcohol misuse*.

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (*DSM-IV*; American Psychiatric Association, APA, 1994) defines two major categories of alcohol use disorders: alcohol abuse and alcohol dependence. *Alcohol abuse*, or nondependent problem drinking, is characterized by one or more of the following as a result of alcohol use: (a) failure to fulfill major role obligations; (b) recurrent physically hazardous use; (c) recurrent alcohol-related legal problems; or

(d) continued use despite persistent alcohol-related social or interpersonal problems. *Alcohol dependence* is characterized by three (or more) of the following symptoms occurring at any time in a 12-month period: (a) tolerance; (b) withdrawal; (c) alcohol consumption frequently in larger amounts or over a longer period than was intended; (d) persistent desire to reduce intake or unsuccessful attempts to control alcohol use; (e) a great deal of time engaging in activities to obtain alcohol or to recover from its effects; (f) limiting or suspending important social, occupational, or recreational activities because of alcohol use; and (g) continued use despite persistent alcohol-related physical or psychological problems. Alcohol dependence is further subtitled as occurring with or without physical dependence (i.e., tolerance and withdrawal).

EPIDEMIOLOGY OF ALCOHOL USE, ABUSE, AND DEPENDENCE

Alcohol Use

There are two predominant methods for measuring alcohol consumption. Production and distribution statistics (e.g., tax records of total beverage sales) are analyzed to estimate per capita consumption at the population level, and surveys are used to examine consumption patterns among both the general population and various targeted subpopulations. Apparent per capita consumption represents an estimate of consumption calculated to include all individuals age 14 and

older and can be adjusted for the proportion of abstainers to yield a per drinker estimate of consumption (Williams, Stinson, Sanchez, & Dufour, 1998). Apparent per capita estimates do not include illicit or home production, tax-free personal imports or alcohol that is purchased but not consumed, and they do not provide information about the distribution of consumption patterns. Nonetheless, they provide valuable information about patterns of drinking by geography, time, and beverage type. For example, apparent per capita consumption decreased 20.7% from 2.76 gallons in 1980–1981 to 2.19 gallons of pure alcohol in 1996 (Williams et al., 1998). These levels are still considerably higher than the consistent per capita consumption levels near 2.0 gallons observed throughout the 1950s. Beer is the alcoholic beverage of choice in the U.S., accounting for 57.1% of per capita consumption, followed by spirits (29.2%) and wine (13.7%; Williams et al., 1998). The downward trend in consumption seen in the U.S. also has been documented in other countries (Smart, 1989).

Population-based surveys substantially augment information derived from aggregate statistics by providing information about sociodemographic variations in patterns of consumption, as well as incidence and prevalence rates of alcohol abuse and dependence. Survey data mirror aggregate statistics, with significant downward trends in consumption, proportions of current drinkers, weekly drinkers, and frequent heavy drinking (e.g., those reporting five or more drinks per occasion as often as once per week; Midanik & Clark, 1994; Williams & Debakey, 1992). However, these trends appear to vary as a function of ethnicity. For example, using data from national probability samples collected in 1984 and 1995, Caetano and Clark (1998) found significant decreases in frequent heavy drinking among White men, but relatively stable rates of frequent heavy drinking among Black and Hispanic men. Trends in drinking patterns among women showed less variability by ethnicity than those of men in this study. Despite encouraging trends overall, prevalence rates for frequent heavy drinking, alcohol abuse or dependence diagnoses, and alcohol-related morbidity and mortality remain high, and the social costs associated with alcohol use and misuse are staggering. For example, Midanik and Room (1992) noted that nine percent of adult men reported drinking five or more drinks at least one day a week while four percent reported eight or more drinks a day at least once a week. These numbers, potentially indicative of heightened risk for various negative outcomes at the low end, and of both negative consequences and alcohol dependence symptoms at the high end, were nearly twice as high among 18- to 29-year-old men.

Alcohol Abuse and Dependence

The prevalence of alcohol abuse and dependence in the general population has been examined in three studies: the Epidemiologic Catchment Area Study (ECA; Robins & Regier, 1991); the 1988 Alcohol Supplement to the National Health Interview Survey (NHIS; Grant et al., 1991); and the National Longitudinal Alcohol Epidemiologic Survey (NLAES; Grant et al., 1994). Past year prevalence for either

DSM-IV alcohol abuse or dependence was 7.41% in the NLAES sample, representing approximately 13.8 million people (Grant et al., 1994). Across the three studies, alcohol abuse or dependence diagnoses were between 2.5 to 5 times higher in men than women, with past year prevalence rates of *DSM-IV* abuse or dependence of 11.0% for men and 4.08% for women in the most recent of these studies (Grant et al., 1994). Grant et al. (1991) noted that gender differences were least pronounced in younger cohorts (age 18–29) and interpreted these findings as suggestive of increasing alcohol use disorders in women. Grant et al. (1994) observed the same convergence for men and women in the younger cohort, but more fine-grained analyses indicated that the pattern held only for non-Black women. There is also a large amount of variation in the prevalence of alcohol use disorders across the life span, with patterns differing across ethnic groups (Caetano, 1991; Helzer, Burnam, & McEvoy, 1991; NIAAA, 1993). These differences have implications for the high levels of alcohol-related morbidity and mortality exhibited among African Americans (Herd, 1991).

ECONOMIC COST OF ALCOHOL ABUSE

Two prevalent methods of estimating the economic cost of alcohol abuse¹ are the cost-of-illness method (e.g., Rice, Kelman, Miller, & Dunmeyer, 1990) and the external costs method (e.g., Heien & Pittman, 1993; Manning, Keeler, Newhouse, Sloss, & Wasserman, 1989). The cost-of-illness method includes estimates of: (a) medical consequences of alcohol consumption, treatment of alcohol use disorders, (b) morbidity costs (e.g., the value of lost productivity as a result of alcohol misuse), (c) mortality costs (e.g., premature deaths due to alcohol consumption) (NIAAA, 1993). In 1985, these costs totaled over \$70 billion (Rice et al., 1990). Others have suggested that estimates of external costs, that is the cost that alcohol abusers impose on the nonabusing population, represent a more useful approach because these estimates can be weighed against revenue generated from alcohol excise and sales taxes (Heien & Pittman, 1993; Manning et al., 1989). Heien and Pittman (1993) estimated the external costs of alcohol abuse in 1985 at \$9.5 billion. These estimates include: (a) \$6.62 billion for medical costs, morbidity, and mortality for victims (excluding passengers) of auto crashes caused by drinking drivers; (b) \$1.98 billion for victims of other accidents (e.g., fires, firearm accidents, falls, etc.); and (c) \$0.91 billion for property damage caused by alcohol abusing individuals and government costs for DWI enforcement and administration of the social welfare system. Manning et al. (1989) concluded that excise taxes accounted for only about half of the external costs of abuse. Despite increases in excise taxes on alcohol, there is still a considerable disparity between external cost estimates and revenue generated from excise and sales taxes on alcoholic beverages (NIAAA, 1993).

¹In this case the term "alcohol abuse" refers to any cost generating aspect of alcohol use or misuse and is not consistent with the clinical diagnostic criteria detailed earlier.

SCOPE OF COVERAGE

The remainder of the chapter focuses on health-related consequences of alcohol use, abuse, and dependence, as well as putative etiologic factors for alcohol use and misuse. First, a range of psychological, physiological, and social consequences of alcohol use and misuse are reviewed. Second, biological, psychological, and social-developmental factors related to alcohol use, as well as those implicated in the development of alcohol use disorders, are discussed.

HEALTH-RELATED CONSEQUENCES OF ALCOHOL USE AND MISUSE

Psychological Aspects of Alcohol Use and Misuse

Individuals with alcohol use disorders are more than twice as likely to exhibit another psychiatric disorder than are persons without an alcohol abuse/dependence diagnosis (Regier et al., 1990), but the nature of these beyond-chance associations are difficult to assess. Several possible states of nature exist, including: (a) alcohol disorder secondary to psychiatric disorder; (b) psychiatric disorder secondary to alcohol disorder; (c) common diathesis; (d) bidirectional influence; and (e) overlapping diagnostic criteria (Clark, Watson, & Reynolds, 1995; Schuckit, Irwin, & S. Brown, 1990). Comorbidity rates vary according to the population sampled, diagnostic approach, specific disorder, gender, and extent of other drug use (Ross, Glaser, & Stiasny, 1988; NIAAA, 1993). Our review of psychiatric comorbidity draws on data from clinical samples, the ECA Survey, and the National Comorbidity Survey (NCS; Kessler et al., 1994).

Comorbidity of Alcohol Use Disorders and Axis I Disorders

Anxiety Disorders. Among Axis I disorders, in both the ECA and NCS samples, anxiety disorders had the greatest rate of co-occurrence with alcohol use disorders (Kessler et al., 1997; Regier et al., 1990). It should be noted that the high levels of comorbidity between alcohol use and anxiety disorders are, in part, due to the relatively high population base rates of anxiety disorders. Because of these high population base rates, when expressed as an odds ratio² anxiety disorders demonstrate a modest association with alcohol use disorders (1.5; NIAAA, 1993). For individuals who met *DSM-III-R* alcohol abuse criteria, a recent NCS report noted lifetime prevalence rates for any anxiety disorder of 22.7% for men and 48.8% for women, with much higher lifetime prevalence rates of 35.8% and 60.7% in alcohol dependent men and women respectively (Kessler et al., 1997). In a recent prospective study,

Kushner, Sher, and Erickson (1999) presented strong evidence for reciprocal causal influences between anxiety disorders and alcohol dependence. Specifically, they found that having an anxiety disorder at Years 1 or 4 of their study quadrupled the risk for a new onset of alcohol dependence in Year 7. Conversely, they also found that alcohol dependence at Years 1 or 4 increased the risk for a new onset of anxiety disorders in Year 7 by three to five times.

Kushner, Sher, and Beitman (1990), in a review of comorbidity between specific anxiety disorders and alcohol use disorders, noted that while agoraphobia and social phobia co-occurred at roughly twice the community sample base rate for either disorder, the association between simple phobias and alcohol use disorders does not appear to exceed expected levels in the community. Further, although generalized anxiety disorder and panic disorder appear at greater than chance levels in alcohol-dependent samples, alcohol use disorders do not appear to be overrepresented in psychiatric samples of generalized anxiety disorder and panic patients, suggesting that the increased association in alcohol dependent patient samples is, in part, a function of alcohol withdrawal. Differential referral patterns may also account for the differences in comorbidity rates across different treatment settings. Schuckit and Hesselbrock (1994), examined studies published since 1975 on the relation between anxiety disorders and alcohol dependence. They concluded that although alcohol dependent individuals undoubtedly manifest more anxiety symptoms than individuals in the general population, evidence is equivocal and methodologically suspect with respect to the demonstration of significant levels of comorbidity for alcohol use and anxiety disorders (see Kushner, 1996, for an alternative perspective).

With respect to order of onset, Kushner et al. (1990) reported that phobias (simple, social, and agoraphobia) typically, but not invariably, antedate the onset of alcohol use disorders. However, for panic disorder, generalized anxiety disorders, and obsessive-compulsive disorders, they noted that no clear pattern emerges.

Although most commonly studied with respect to combat-related stress, post-traumatic stress disorder (PTSD) may occur as a result of exposure to a wide-range of traumatic stressors (e.g., robbery, physical assault, injury, accident), with different types of stressors carrying different implications for PTSD rates, severity, and comorbidity (Breslau, Davis, Adreski, & Peterson, 1991; P. Brown & Wolfe, 1994). Comorbidity rates among male veterans and female civilians presenting for substance abuse treatment have ranged from 35% to 46% (P. Brown & Wolfe, 1994; Kovach, 1986; McFall, Mackay, & Donovan, 1991). Helzer, Robins, and McEvoy (1987) using data from the St. Louis site of the ECA survey, noted that men with PTSD were almost twice as likely to meet *DSM-III* substance abuse disorder criteria, while women with PTSD were at nearly three times greater risk for *DSM-III* substance abuse disorders than women without PTSD. In an analysis, again using ECA data from the St. Louis site, Cottler, Compton, Mager, Spitznagel, and Janca (1992) found that the onset of drug and alcohol problems typically preceded the onset of PTSD symptoms. These data sug-

²An odds ratio depicts the relative risk of a comorbid disorder, given the presence of an alcohol use disorder, as compared with the risk of the comorbid disorder occurring in the entire population. A comorbidity proportion illustrates the number of cases of a comorbidity disorder per 100 cases of individuals with an index diagnosis.

gest a potential vulnerability to PTSD among substance users, perhaps due to a tendency to deal with stress through the use of ineffective coping strategies (e.g., substance use; P. Brown & Wolfe, 1994), although a common diathesis (e.g., risk-taking) cannot be ruled out.

Affective disorders. Individuals who met criteria for either alcohol abuse or dependence diagnoses exhibited 1.9 times greater risk for an affective disorder in the ECA study, while the proportion of respondents with an alcohol use disorder diagnosis with a comorbid affective diagnosis (13.4%) was nearly identical to the proportion of alcohol use disorders in the total ECA community sample (Regier et al., 1990). In the NCS sample, lifetime co-occurrence of alcohol abuse with any affective disorder was 10.2% for men and 34.5% for women. For alcohol dependence the comorbidity of these two disorders was even higher at 28.1% for men and 53.5% for women (Kessler et al., 1997). Additionally, alcohol use disorder and affective disorder comorbidity vary a good deal by specific disorder, with higher prevalence rates among individuals diagnosed with depression as compared to those with either dysthymia or mania diagnoses. In the NCS sample, in terms of relative risk, for alcohol abuse odds ratios for any affective disorder were lower than those observed in the ECA study (0.64 for men and 1.78 for women). However, for alcohol dependence, risks for an affective disorder were much more pronounced, with odds ratios of 3.16 for men and 4.36 for women (Kessler et al., 1997). Among clinical samples of those seeking alcohol treatment, major depression prevalence has ranged from 8% to 65% (Merikangas & Gelernter, 1990; Ross, Glaser, & Germanson, 1988). Order of onset appears to be moderated by gender, with depressive disorder preceding alcohol use disorders for 65% of women, and 41% of men (Hesselbrock, Meyer, & Keener, 1985).

Although the lifetime prevalence rate for bipolar disorder is much lower in the general population than the rate for major depression (0.8% versus 4.9% respectively), those with bipolar disorder in the ECA study were 4.6 times more likely to diagnose with alcohol dependence than those without a mood disorder, the highest odds ratio of comorbidity for any Axis I disorder (Regier et al., 1990). Evidence from clinical samples appears to reflect similar patterns (Hesselbrock et al., 1985; Ross, Glaser, & Germanson, 1988), although other research suggests that bipolar disorders are more prevalent among those meeting drug abuse or dependence diagnoses than alcohol abuse or dependent individuals (Brady & Lydiard, 1992).

Schizophrenia. An important feature of the ECA study is the inclusion of institutionalized individuals in sufficient numbers to examine comorbidity between substance use and more severe psychiatric disorders. Over 33% of schizophrenic individuals in the ECA study met criteria for alcohol abuse or dependence, compared to a community prevalence rate of 13.5% (Regier et al., 1990). Lifetime prevalence rates of substance use disorders in samples of schizophrenic patients have ranged from 10% to 65%, with demographic (e.g., age, S.E.S) and methodological (e.g., sampling and ascertain-

ment bias) differences across studies making more precise estimates difficult (Mueser, Bellack, & Blanchard, 1992).

Psychosexual Disorders. Psychosexual dysfunction is a common comorbid disorder, affecting 30% of those with alcohol use disorders in an alcohol treatment seeking sample (Ross, Glaser, & Germanson, 1988). Although few studies have examined gender differences for comorbidity of alcohol and psychosexual disorders, it appears that these disorders tend to co-occur more frequently in women than men (Ross, Glaser, & Stiasny, 1988).

Other Substance Use Disorders. Helzer et al. (1991) noted that much of the overall comorbidity between alcohol use and other psychiatric disorders is accounted for by the co-occurrence of alcohol and other drug use disorders. In the ECA study, 18% of individuals with a lifetime alcohol abuse or dependence diagnosis met lifetime criteria for drug abuse or dependence compared to only 3.5% of those without a lifetime alcohol use disorder. Similarly, in the NCS sample, for both men and women, the largest odds ratios of alcohol use disorders were with drug use disorders (Kessler et al., 1997). The risk for a psychiatric disorder is also substantially higher among those abusing multiple substances, as compared to either alcohol-dependent individuals or those in the general community (Helzer & Przybeck, 1988; Ross, Glaser, & Germanson, 1988).

A strong association between tobacco and alcohol use has been widely noted, prompting examination of the prevalence of comorbid alcohol and tobacco use disorder diagnoses in both alcoholic and general population samples. Among individuals with alcohol use disorders, it is estimated that smoking prevalence ranges from 75% to 90% (NIAAA, 1997). In a general population survey of young adults, Breslau, Kilbey, and Andreski (1991), noted that individuals with moderate nicotine dependence were 3.2 times more likely to meet criteria for lifetime alcohol dependence than were those without nicotine dependence. In a recent prospective, high-risk study, Sher, Gotham, Erickson, and P. Wood (1996) used structured diagnostic interviews to examine relations between alcohol use disorders and tobacco dependence over a three-year period during young adulthood. Among the study's most notable findings were cross-sectional and prospective relations between family history of alcoholism and both alcohol and tobacco use disorders, as well as significant reciprocal relations between alcohol use disorders and tobacco dependence.

Comorbidity of Alcohol Use Disorders and Axis II (Personality) Disorders

According to the *DSM-IV*, a personality disorder is "an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment" (APA, 1994, p. 629). It appears that personality disorders from the anxious-fearful (avoidant, dependent, obses-

sive-compulsive, and passive-aggressive) and dramatic-emotional (borderline, narcissistic, histrionic, and antisocial) clusters predominate in alcoholic samples (Alnaes & Torgersen, 1988; Poldrugo & Forti, 1988). Because of the very high rates of comorbidity between antisocial personality disorder (APD) and alcohol use disorders, APD is considered separately, and then the co-occurrence of alcohol abuse/dependence and other personality disorders is summarized.

Antisocial Personality Disorder. Alcohol use disorders are highly comorbid with APD in general population (e.g., Helzer & Przybeck, 1988; Kessler et al., 1997), clinical (e.g., Hesselbrock et al., 1985), and criminal (e.g., Lewis, Cloninger, & Pais, 1983) samples, even when overlapping diagnostic criteria are eliminated (Lewis, 1984). Prevalence of APD in alcohol dependent samples has ranged from 16% to 49% (Meyer & Kranzler, 1990). Prospective studies indicate, for men (and probably for women), that early conduct problems predict subsequent alcohol and drug disorders and APD (Hawkins, Catalano, & Miller, 1992; Nathan, 1988; Zucker & Gomberg, 1986).

Other Axis II Disorders. The overwhelming majority of studies of alcoholism and personality disorders have relied on clinical samples and thus are likely to overestimate comorbidity because patients with multiple diagnoses are more likely to be found in treatment settings (i.e., Berkson's fallacy, see Cohen & Cohen, 1984). However, the few studies that have examined comorbidity between alcohol use disorders and Axis II disorders also indicate extensive comorbidity (e.g., Drake, Adler, & Vaillant, 1988; Drake & Vaillant, 1985; Tausignant & Kovess, 1989; Zimmerman & Coryell, 1989). For example, in a series of reports, Drake, Vaillant, and colleagues reported prevalence rates of *DSM-III* personality disorders in a community sample of middle-aged men. Drake and Vaillant (1985) reported that 37% of the 62 men who met lifetime *DSM-III* criteria for alcohol abuse/dependence received a personality disorder diagnosis at age 47. Comorbid diagnoses of passive-aggressive, histrionic, and dependent personality were most common (all greater than 10% of the alcoholic sample; Drake et al., 1988). Furthermore, antisocial, borderline, histrionic, narcissistic, dependent, and passive-aggressive personality disorders were all more common among alcoholics than nonalcoholics in this community sample (Drake et al., 1988).

Relations Between Comorbid Diagnoses, Disorder Severity and Treatment Outcome

Generally, across both Axis I and Axis II disorders, the co-occurrence of alcohol and another psychiatric disorder or symptomatology is associated with a more severe alcohol disorder course and poorer treatment outcome (Hesselbrock et al., 1985; Litt, Babor, DelBoca, Kadden, & Cooney, 1992; Rounsaville, Dolinsky, Babor, & Meyer, 1987). Individuals with co-occurring alcohol use and antisocial personality disorders, for example, demonstrate earlier onset, more severe

course, higher relapse rates, greater treatment attrition, poorer overall prognosis, and deficits in occupational and social functioning compared to individuals with an alcohol use disorder only (Hesselbrock, Meyer, & Hesselbrock, 1992). However, some studies have found no differences in treatment outcomes among groups with multiple versus single disorders (Booth, Yates, Petty, & K. Brown, 1991; Brower, Blow, Hill, & Mudd, 1994; Powell et al., 1992).

It is important to recognize that comorbid individuals represent a heterogeneous group for which traditional treatment programs may be ill-suited. Treatment for a comorbid disorder also presupposes that psychiatric comorbidity is being recognized, which, particularly among individuals with affective or anxiety disorders, may not be the case. There is evidence supporting a model of bi-directional influence, which would suggest the need to treat both disorders simultaneously. Consistent with this notion, there are a few treatment outcome studies that suggest that addressing anxiety disorders in conjunction with alcohol treatment is efficacious in reducing symptomatology for both disorders (R. Brown, Evans, I. Miller, Burgess, & Mueller, 1997; Fals-Stewart & Schafer, 1992; Tollefson et al., 1992). With more severe psychopathology (e.g., schizophrenia), it has been suggested that increased attention needs to be focused on the psychiatric disorder itself. For example, efforts to alter aspects of the environment, such as living situations, as well as increases in family and social support could reap substantial dividends in the maintenance of treatment gains (Mueser et al., 1992).

ALCOHOL'S EFFECT ON PHYSICAL HEALTH AND ORGAN SYSTEMS

Alcohol abuse and dependence have adverse effects on almost all physical illness. Even in disease not directly caused by alcohol, alcohol abuse and dependence complicate the illness because of accompanying social and psychological problems, including noncompliance with medical treatment and follow-up. In this section, we focus on those biomedical diseases with which alcohol use is causally associated, either increasing or decreasing the risk of disease. We recognize, however, that the relationship between alcohol use and physical health is complex and that the social and psychological factors can be removed from the following discussion only artificially.

It's also important to note that alcohol's negative effects on morbidity can be ameliorated with relatively simple interventions over short periods of time. For example, in a recent clinical trial, alcoholic patients scheduled for elective surgery were randomly assigned to a control group, who received usual care, or an intervention group who received disulfiram 800 mg twice a week for four weeks prior to surgery. Postoperative complications were reduced from 74% to 31% (Tonnesen, Rosenberg, Nielsen, Rasmussen, & Hauge, 1999).

Alcohol Use and the Overall Risk of Mortality

By its direct adverse effects on health, alcohol accounts for over 100,000 deaths per year making it the third leading cause

of death in the United States (McGinnis & Foege, 1993; Shultz, Rice, & Parker, 1990; Stinson & De Bakey, 1992). About 15% to 20% of these alcohol-related deaths were ascribed directly to alcohol on the death certificate, with diagnoses such as alcoholic cirrhosis and alcohol poisoning. The rest of the deaths were due to diseases (about 40% of the 100,000 total) or injuries (about 45%) for which there is a quantifiable link with alcohol consumption. The assumptions underlying the calculations are debatable in several diseases, as we will review later. More important for clinicians caring for individuals, these calculations do not always provide enough information to allow an individual to calculate precisely how their use of alcohol affects their risk of sickness, injury, or death.

A complex relationship between alcohol use and the overall risk of mortality has been demonstrated in several prospective longitudinal studies (Ashley, Ferrence, Room, Rankin, & Single, 1994; Fuchs et al., 1995; Thun et al., 1997). The relative risk of overall mortality was lowest in light drinkers, those who consumed about one drink per day, and was slightly greater both in those who abstained and in heavier drinkers (Thun et al., 1997).

The effect of alcohol on mortality varies by gender and age. Women who drink face a lower risk of cardiovascular death than abstainers, but an increased risk of breast cancer death. Overall mortality is lowest around one drink a day, but primarily in women at highest risk of cardiovascular death (Fuchs et al., 1995). Because young adults have a lower basal risk of cardiovascular death and an increased risk of alcohol-related injury death, their overall mortality risk increases with alcohol consumption; among older adults, light to moderate drinking is associated with lower overall mortality risk (Scragg, 1995).

The reasons for the higher mortality risk for abstainers remain uncertain. It is not explained by confounding by smoking or other known risk factors for mortality (Gronbaek et al., 1994; Klatsky, Armstrong, & Friedman, 1992). In theory, it could be due to ex-drinkers and lifelong abstainers being classified together as non-drinkers, and there are some data supporting that hypothesis (Lazarus, Kaplan, Cohen, & Leu, 1991). However, other studies that analyzed lifelong abstainers and ex-drinkers separately found both groups at higher risk of coronary heart disease mortality (Klatsky, Armstrong, & Friedman, 1990) or total mortality (Boffetta & Garfinkel, 1990; Scherr et al., 1992). The issue continues to be unsettled with some recent cohort studies finding no cardioprotective benefit of light drinking (Hart, G. D. Smith, Hole, & Hawthorne, 1999), while another recent study indicates that risk of death from sudden cardiac death is reduced as a result of moderate alcohol consumption (Albert et al., 1999).

Mortality risk may vary by type of alcoholic beverage, with reduction of risk among wine drinkers, but not among drinkers of spirits (Gronbaek et al., 1995). The apparent benefit of wine consumption may be due to confounding by other lifestyle variables (Wannamethee & Shaper, 1999).

The previous studies all employed a longitudinal observational design, and may have found an association between light drinking and reduced overall mortality risk because of

unmeasured confounding variables. It is hazardous to extrapolate from their findings and advise current abstainers to start drinking. These studies do, however, raise important questions about whether and how light drinking affects cardiovascular disease risk, and about how clinicians and patients can assess and weigh those benefits against the health risks of drinking.

Alcohol and Heart Disease

Many studies have demonstrated an association between abstinence from alcohol and an increased risk of coronary artery disease, including myocardial infarction (heart attack) and sudden cardiac death. A meta-analytic study by Maclure (1993), found an L-shaped curve in which two drinks per week reduced the risk of coronary disease as much as higher doses. At two drinks per week, the risk of coronary disease relative to abstainers was 0.88 (95% confidence interval 0.83 to 0.92). Above that level, the curve was flat; even at seven or more drinks per day, the relative risk was 0.95 (95% CI 0.83 to 1.09). Maclure considered and excluded multiple possible spurious causes for the association. Furthermore, the higher risk for non-drinkers is not due to an increased risk of coronary disease among ex-drinkers, who might have stopped drinking because of illness, obscuring a decreased risk among life-long abstainers (Klatsky, Armstrong, & Friedman, 1990). Most studies published since Maclure's meta-analysis continue to confirm these conclusions (Albert et al., 1999; Doll, Peto, Hall, Wheatley, & Gray, 1994; Goldbert, Burchfiel, Reed, Wergowske, & Chiu, 1994). Others raise doubts about whether light or infrequent drinking confers any cardiovascular benefit relative to lifelong abstinence (Hanna, Chou, & Grant, 1997; Hart, G. D. Smith, Hole, & Hawthorne, 1999).

The mechanism by which low-level alcohol consumption might lead to a decreased risk of coronary disease is uncertain. There is considerable evidence that the effect is mediated by alcohol's effects on high density lipoprotein (HDL; Gaziano et al. 1993; NIAAA, 1997). Furthermore, alcohol's effect on plasma concentrations of endogenous tissue-type plasminogen activator (t-PA) may promote lysis of intravascular clots (Hendriks, Veenstra, Velthuis-te Wierik, Schaafsma, & Kluft, 1994; Ridker, Vaughan, Stampfer, Glynn, & Hennekens, 1994). Still other factors may be involved. In addition to possible long-term benefits, one case-control study found evidence for a short-term benefit, with the risk of a heart attack being reduced by consuming one or two drinks in the previous 24 hours (McElduff & Dobson, 1997).

Not all of alcohol's effects on the heart are beneficial (Moushmouth & Abi-Mansour, 1991; Preedy, Atkinson, Richardson, & Peters, 1993; Zakhari, 1991). Ethanol is toxic to cardiac muscle, and drinking over about six drinks per day substantially increases the risk of developing cardiomyopathy and congestive heart failure (Richardson, Wodak, Atkinson, Saunders, & Jewitt, 1986). The risk is greater in men than in women (Wu, Sudhakar, Jaferi, Ahmed, & Regan, 1976), and even smaller amounts of alcohol may damage cardiac muscle over time (Kupari & Koskinen, 1993). The mechanism of the injury and what makes the disease progress from

a reversible condition to a permanent one are unclear (Preedy, Atkinson, Richardson, & Peters, 1993).

Alcohol and Hypertension

Alcohol is associated with increased blood pressure (Marmot et al., 1994). In the Intersalt study, consumption of three to four drinks or more per day was associated with significantly higher systolic and diastolic blood pressure, two to five millimeters of mercury (mm Hg), in both men and women (J. Stamler et al., 1989). These results persisted after statistically adjusting for 24-hour sodium and potassium excretion, body mass index, and smoking. In both Japanese men (Wakabayashi, Nakamura, Kono, Shinchi, & Imanishi, 1994), and African American men and women (Strogatz et al., 1991), alcohol was associated with significantly higher blood pressure even at levels of consumption as low as one drink per day (Wakabayashi et al., 1994) or less (Strogatz et al., 1991), suggesting no readily identifiable threshold exists in the relation between alcohol and blood pressure.

Blood pressure may be more closely related to the frequency of drinking than the quantity (Russell, Cooper, Frone, & Welte, 1991), suggesting that studies that report only average consumption per day may obscure more complex relationships between alcohol drinking and blood pressure. The relationship between pattern of drinking and blood pressure, however, is not a simple one. Greater day to day variability in consumption was associated with higher blood pressure in the Intersalt study (Marmot et al., 1994), and a British study found drinking in the previous three days had more effect on blood pressure than more remote drinking (Maheswaran, Gill, Davies, & Beevers, 1991).

Randomized crossover trials in both hypertensive (Ueshima et al., 1993) and normotensive (Howes, 1994; Puddey, Beilin, Vandongen, Rouse, & Rogers, 1985) men and women have demonstrated a short-term pressor effect of heavy drinking. When drinking is reduced from three drinks per day or more to either abstinence or light drinking, blood pressure in these studies dropped by four to twelve mm Hg in four days to three weeks (Howes, 1994; Puddey, Beilin, Vandongen, Rouse, & Rogers, 1985; Ueshima et al., 1993). In a randomized clinical trial that focused on alcohol consumption (in addition to providing antihypertensive medication, which both intervention and control groups received), systolic blood pressure was significantly lower in the intervention group (11.9 compared with 4.6 mmHg in the control group; Lang, Nicaud, Darne, Rueff, & WALPA group members, 1995).

A reduction in blood pressure of this magnitude, although statistically significant, is small when one is considering any given individual. However, because hypertension is a highly prevalent condition and because of its association with stroke and ischemic heart disease, a reduction in blood pressure of this magnitude throughout a population would be associated with a 9% reduction in coronary heart disease mortality and a 14% reduction in stroke mortality (J. Stamler et al., 1989; R. Stamler, 1991). As reviewed by MacMahon (1987), approximately 5% to 7% of hypertension can be attributed to heavy alcohol drinking, more in men (11%) and little (perhaps as little as 1%) in

women. Drinking three to four drinks per day (for men) or two to three drinks per day (for women) increases the risk of having hypertension by about 40% to 50%, while six or seven drinks per day doubles the risk for both men and women (MacMahon, 1987; Witterman et al., 1990).

Alcohol and Stroke

Cerebrovascular accidents are of two kinds, *ischemic* strokes, in which blood flow to a part of the brain is stopped by a clot within an artery, and *hemorrhagic* strokes, in which bleeding in or around the brain occurs. The effects of alcohol drinking on these two types of strokes differ. The association between alcohol and ischemic stroke risk appears to be J-shaped. In a case-control study in New York City, consumption of up to 2 drinks per day was protective against ischemic stroke (odds ratio 0.55, 95% confidence interval 0.42–0.72). Results varied little by age, gender, and ethnicity (Sacco et al., 1999).

In contrast to ischemic stroke, the risk of hemorrhagic stroke increases monotonically with increasing alcohol consumption (Carmargo, Jr. 1989; Gorelick, 1989; Klatsky, Armstrong, & Friedman, 1989). The relationship appears to be linear rather than J-shaped, with increased risk at even low levels of consumption, although the magnitude of risk at low consumption levels is uncertain. At higher levels of drinking (five or more drinks per day), alcohol is associated with a four-fold increase in the risk of hemorrhagic stroke (NIAAA, 1997).

Alcohol and Cancer

Alcohol is associated with an increased risk of total cancer mortality, beginning at consumption levels of 3 or more drinks per day (Blot, 1992). At five drinks per day, the risk is 50% greater than for non-drinkers (Boffetta & Garfinkel, 1990).

In cohort studies, alcohol appears to increase the risk of breast cancer by approximately 9% per 10 g of alcohol (about 0.75 to 1 drink) per day (95% confidence interval 4% to 13%; Smith-Warner et al., 1998). One older meta-analysis found that the risk estimates were biased by the source of control patients, with studies that recruited controls from the community showing no effect (Roth, Levy, Shi, & Post, 1994). However, Longnecker and colleagues, considered this and other sources of bias and concluded that they were not sufficient to explain the findings (Giovannucci et al. 1993; Longnecker, 1994). Therefore, the association appears to be valid.

Because breast cancer and alcohol exposure are common, an association between the two is important. But as Schatzkin and Longnecker point out, "causality has not been established" (1994, p. 1101). A review by Rosenberg, Metzger, and Palmer (1993) also concluded that the evidence linking alcohol and breast cancer is weak and quite possibly due to confounding. The mechanism(s) underlying the association has not been found, and much work remains to be done. It is worth noting that the reduction in the risk of coronary disease (12% for a drink twice a week, 9% for one drink per day; Maclure, 1993) is of about the same magnitude as the increase in the risk of breast cancer (9% for a drink a day; Longnecker, 1994).

For several types of cancer, an association with alcohol is either absent or unclear. Even among alcoholics, no increased risk of several kinds of cancer was observed, including cancer of the stomach and bladder (Adami et al., 1992). For ovarian cancer, one study found heavy drinkers at decreased risk (Gwinn et al., 1986), while another found a significant overall trend of increased risk (La Vecchia et al., 1992).

For other types of cancer, the association with alcohol use is less controversial (Thun et al., 1997). The relative risk for oral and pharyngeal cancer, adjusted for smoking, increases from 1.2 with one to four drinks per week to 1.7 at five to 14 drinks per week to 8.8 at 30 or more drinks per week (Blot et al., 1988). Relative risks for laryngeal and esophageal cancer are similarly increased by moderate to heavy drinking (Steinberg & Tenner, 1994). An association with rectal cancer, particularly for beer, has been found, but is still considered speculative (Blot, 1992). Heavy alcohol drinking is related to cirrhosis and cirrhosis is related to hepatocellular carcinoma, but the relationship between heavy drinking and primary liver cancer is less clear (Naccarato & Farinati, 1991). Alcohol may act as a co-carcinogen in liver cancer along with other agents, possibly Hepatitis B virus or chemical carcinogens (Naccarato & Farinati, 1991).

Alcohol and Peptic Ulcer

Alcohol drinking is commonly assumed to increase the risk of gastritis and other inflammatory conditions of the upper gastrointestinal track mucosa, including peptic ulcer of the stomach or duodenum. Examination of the 1988 National Health Interview Study, however, revealed that much of that association is due to confounding with cigarette smoking; moreover, smoking is a modifier of the risk due to alcohol. Among non-smokers, each ounce of alcohol consumed per day was associated with a 13% increase in the risk of ulcer disease; among smokers, the increase was only 7% and was no longer statistically significant (Chou, 1994).

Alcohol and Liver Disease

The association between alcohol and liver disease is well established (Crabb, 1993). The spectrum of alcohol-related liver disease extends from acute fatty liver (a transient and reversible increase in the amount of fat within the liver) to alcoholic hepatitis (acute inflammation of the liver) to cirrhosis (permanent and often progressive scarring). While most people who consume large quantities of alcohol will develop acute fatty liver, only about 15% to 30% will develop cirrhosis (NIAAA, 1997). Why only certain individuals develop cirrhosis is unclear. While race does not appear to be a factor (Parrish, Dufour, Stinson, & Harford, 1993), risks of developing cirrhosis may vary by gender (Grant, Dufour, & Harford, 1988; Lieber, 1994), although see Klatsky and Armstrong (1992). If present, the gender difference may be due to variation in alcohol metabolism, including differences in gastric alcohol dehydrogenase activity and first-pass metabolism, both lower in women (Frezza et al., 1990). In addition, women have less body water per kilogram of body weight

and, therefore, attain higher blood alcohol levels for a given dose per kilogram (Lieber, 1994).

Generally, the risk of cirrhosis for women begins to rise at 20 grams of ethanol per day (1.67 drinks), but only at 60 grams per day for men (5 drinks; Grant, Dufour, & Harford, 1988; Lieber, 1994). Lower doses, however, may increase risk. In a longitudinal study of over 128,000 adults over three to ten years, Klatsky and Armstrong found that those who drank one to two drinks per day at baseline had an almost eight-fold increase in cirrhosis risk, rising to a 33-fold risk with six or more drinks per day. Usual beverage choice had no apparent effect on the risk (Klatsky & Armstrong, 1992).

The mechanism of hepatic injury remains uncertain. As reviewed by Lieber (1994), alcohol is metabolized to acetaldehyde by three intracellular systems. Both acetaldehyde and other by-products of the three metabolic pathways are toxic to hepatic cells. Malnutrition, while not a sufficient cause of cirrhosis in alcoholics, probably plays an important role in the progression of the disease (Grant, Dufour, & Harford, 1988; Lieber, 1994). Interactions with viruses (such as Hepatitis C virus) may be involved (Lieber, 1994). Genetic predisposition may also play a role (NIAAA, 1997) but cirrhosis is found across cultures and correlates with average per capita alcohol consumption (Grant, Dufour, & Harford, 1988; Parrish, Higuchi, & Dufour, 1991), suggesting that cultural and ethnic differences (and, by extrapolation, genetic differences) are not overriding.

Alcohol and Pancreatitis

Pancreatitis is an acute inflammation of the pancreas. It is often severe, with a complicated course. Heavy alcohol drinking is considered to be responsible for approximately 35% of the cases of acute pancreatitis, although that percentage varies widely by the population studied (Steinberg & Tenner, 1994); most of the remaining cases are associated with gallstone disorders. As with cirrhosis of the liver, which develops in only a minority of those who drink heavily, only 5% of alcoholics develop acute pancreatitis, for reasons as yet unknown (Singh & Simsek, 1990; Steinberg & Tenner, 1994). The relationship between the quantity and frequency of drinking and the risk of pancreatitis appears to be direct (Singh & Simsek, 1990), but the duration of alcohol abuse and quantity of consumption required before the risk of pancreatitis increases are uncertain. One study of patients presenting with a first episode of acute pancreatitis found that those who had drunk more than 1,000 grams of alcohol in the preceding week were more likely to develop complications (50% vs. 21%) and more likely to die (16% vs. none; Jaakkola, Sillanaukee, Lof, Koivula, & Nordback, 1994). This study, however, does not help define a drinking threshold at which risk of pancreatitis begins to increase.

As is true for hepatic cirrhosis, the mechanism of alcohol-induced pancreatitis is uncertain. Several mechanisms have been proposed and studied in animals and humans, including reflux of duodenal or biliary secretions into the pancreatic duct, blockage of the pancreatic duct by inflammation or other factors, and a direct toxic effect of alcohol (Singh &

Simsek, 1990). Nutrition may also play a role, although studies have reached conflicting conclusions about what that role might be. Studies in animals suggest that a diet high in protein or dietary fat increases the likelihood of pancreatitis (Singh & Simsek, 1990), but studies in humans have found no evidence of high protein or fat intake in patients with a history of alcoholic pancreatitis (Mezey, Kolman, Diehl, Mitchell, & Herlong, 1988; Wilson et al., 1985).

Alcohol and Hormonal Changes

Hormonal systems are complex in their regulation by internal and external stimuli and in their effects on other organs and functions. Alcohol's effects on hormonal systems are likewise complex. Much is known, primarily by animal studies, but the clinical implications and applications of this extensive knowledge are uncertain (NIAAA, 1997).

Long-term alcohol abuse is associated with changes in the hypothalamic–pituitary–gonadal (HPG) axis in both men (Emanuele et al., 1993) and women (Mello, Mendelson, & Teoh, 1993). Measurable effects have been seen in short-term studies in men, with increases in prolactin and decreases in testosterone levels (Ida et al., 1992). In a controlled clinical trial, women drinking two standard drinks per day had small but significant increases in estrogens at several points in the menstrual cycle (Reichman et al., 1993), but chronic heavy alcohol drinking is associated with decreases in estrogens, increases in prolactin, and disruption of the menstrual cycle (Mello, Mendelson, & Teoh, 1993).

Thyroid function can also be disrupted by alcohol abuse, with decreased levels of triiodothyronine (T_3 , the metabolically more active form of circulating thyroid hormone), possibly related to malnutrition or liver disease as much as to direct effects of alcohol itself (Jackson, 1993).

Alcohol and Cognitive Disorders

Acutely, alcohol has obvious effects on the brain (Peterson, Rothfleisch, Zelazo, & Pihl, 1990), among which are its effects on memory. Intoxication can cause a "blackout," a period of time when recollection is impaired. Blackouts are a type of anterograde amnesia similar to that caused by some benzodiazepines (Vinson, 1989). It has been assumed that an alcoholic blackout is an important early sign of alcoholism, but it is not infallible. In a 10-year longitudinal study of 230 young men, one or more blackouts at baseline had a sensitivity of 48% and a specificity of 81% in predicting the future development of alcohol dependence or abuse (Anthenelli, Klein, Tsuang, T. Smith, & Schuckit, 1994). Moreover, alcohol-induced blackouts are relatively common occurrences, particularly among some segments of the population. For example, in a recent national study, 26.7% of college students reported one or more alcohol-induced blackouts since the beginning of the current school year (Wechsler, Dowdall, Maenner, Gledhill-Hoyt, & Lee, 1998).

Following acute intoxication, after breath alcohol levels have returned to zero, there is little evidence of any lingering impairment in neuropsychological tests (Lemon, Chesher,

Fox, Greeley, & Nabke, 1993). In more complex tasks, such as piloting an aircraft, there may be more of a lingering effect (Yesavage, Dolhert, & Taylor, 1994).

Drinking moderately over many years may be associated with deterioration in cognitive function (Parsons, 1994), but possible effects are usually modest (Parsons, 1986). In one long-term cohort study, those who drank heavily (28 or more drinks per week) performed worse on cognitive tests and failed to improve on tests of verbal ability, whereas light and moderate drinkers did; but in neuropsychological tests, controlling for baseline performance, measures of drinking had little effect (Arbuckle, Chaikelson, & Gold, 1994). The effect of the quantity of drinking may be conditional on the frequency of drinking, with little effect among those who drink less often than three times a week (Parker, Parker, & Harford, 1991). Among community dwelling elderly, there appears to be little effect of light to moderate alcohol consumption (Hebert et al., 1993).

Alcoholism is associated with chronic brain diseases, especially Wernicke encephalopathy and Korsakoff psychosis (Victor, 1992, 1993). Wernicke encephalopathy is characterized by neurological signs such as ataxia, nystagmus, and confusion. Korsakoff psychosis is a combination of retrograde amnesia (an inability to recall remote memories) and anterograde amnesia (an inability to lay down new memories). Wernicke and Korsakoff syndromes usually occur together in varying degrees, and are probably due to nutritional deficiency and less to direct toxic effects of alcohol itself (Victor, 1993). Although it has been assumed that Korsakoff syndrome is preceded by Wernicke encephalopathy, there is evidence to the contrary (Blansjaar & Van Dijk, 1992). Improved nutrition, with vitamin replacement and abstinence from alcohol, is helpful and some of the signs of Wernicke–Korsakoff syndrome will resolve acutely (Victor, 1993). However, the amnesia (classic Korsakoff syndrome) will resolve in only about 20% of patients (Victor, 1993), and predicting which patients with Wernicke–Korsakoff syndrome will improve is difficult (Berglund, 1991).

Alcohol and Fetal Effects

Alcohol is a leading cause of preventable birth defects (NIAAA, 1997). Fetal alcohol syndrome (FAS) is defined by the presence of growth retardation, specific craniofacial anomalies, and behavioral and cognitive abnormalities. Neuropsychological abnormalities include attention deficits, impulsivity (Streissguth et al., 1994), and mental retardation (Spohr, Willms, & Steinhausen, 1993; Steinhausen, Willms, & Spohr, 1993). Alcohol's effects on fetal development vary by dose, the pattern of drinking, and the timing of exposure during pregnancy relative to stages of development of different parts of the fetal brain and other organ systems. Lesser degrees of involvement are called fetal alcohol effects (FAE; American Academy of Pediatrics Committee on Substance Abuse and Committee on Children with Disabilities, 1993; NIAAA, 1997).

The true prevalence of FAS and FAE are uncertain (NIAAA, 1997). The characteristic facial features can be

readily recognized by trained observers in the newborn period (Abel, Martier, Kruger, Ager, & Sokol, 1993), but many affected infants probably go unrecognized. Some of the abnormalities tend to resolve with time, but the effects on mental function have been shown to persist for more than a decade (NIAAA, 1997; Spohr, Willms, & Steinhausen, 1993; Steinhausen, Willms, & Spohr, 1993; Streissguth et al., 1994).

Because of the variety of abnormalities seen in fetal alcohol syndrome and the resulting heterogeneity in clinical samples, the threshold of drinking that causes them is uncertain. Approximately two drinks per day is known to be associated with FAE, although some infants exposed to higher alcohol doses in utero show no apparent effects (NIAAA, 1997; Streissguth et al., 1994a). Studies in mono- and dizygotic twins have shown greater concordance among identical twins, suggesting that genetic factors may play a role (Streissguth & Dehaene, 1993), but all races studied are about equally susceptible (Jacobson, Jacobson, Sokol, Martier, & Ager, 1993).

Alcohol and Injury

Alcohol use is frequently associated with injury. Blood samples are positive for alcohol in about one half of traffic and fire fatalities as well as a substantial proportion of other traumatic deaths (Hingson & Howland, 1993; NIAAA, 1997; G. S. Smith, Branas, & Miller, 1999). Injury deaths account for approximately 45% of all alcohol-related deaths and for 80% of alcohol-related years of productive life lost (McGinnis & Foege, 1993; Shultz, Rice, & Parker, 1990). In addition, alcohol is frequently cited as a factor in non-fatal injuries as well (NIAAA, 1997).

Unintended Injuries. Observational longitudinal studies have provided information about the risks of fatal injury associated with varying amounts of alcohol consumption. Two studies specifically examined deaths due to injuries and found that drinking more than an average of five or six drinks per day at baseline approximately doubled the risk of dying in the following eight or nine years, relative to people who drank fewer than five drinks per occasion (Anda, Williamson, & Remington, 1988) or lifelong abstainers (Klatsky & Armstrong, 1993). Both studies showed that lesser quantities of average drinking did not significantly increase the risk of fatal injury, but injury risk may be more related to peak rather than average alcohol consumption. Both reports acknowledged that subjects reporting light average drinking at baseline may have consumed significantly more alcohol before their injury, and that this could have spuriously led to an underestimate of alcohol's association with injury (Anda et al., 1988; Klatsky & Armstrong, 1993). Supporting this contention, a study from Finland found the risk of a fatal injury was lowest among men who drank only once or twice a year, and the risk in men with daily drinking was over three times as great as for non-drinkers. Differences in women were not significant (Vartiainen et al., 1994).

Case-control studies have yielded conflicting estimates of the association between alcohol and injury risk, particularly

in studies of hip fracture risk. Some studies have shown that alcohol use increases the risk of hip fracture starting at a threshold of seven or more drinks per week (Grisso et al., 1994) or two or more drinks per day (Hernandez-Avila et al., 1991). Others found no association (Cumming & Klineberg, 1994; Kreiger, Gross, & Hunter, 1992; LaVecchia, Negri, Levi, & Baron, 1991; Nelson, Sattin, Langlois, DeVito, & Stevens, 1992), and one found that daily drinking reduced the risk of a fall among elderly persons (O'Loughlin, Robitaille, Boivin, & Suissa, 1993). All these studies measured subjects' average alcohol consumption rather than consumption on the day of injury. Two case-control studies have assessed alcohol levels at or shortly after the time of injury. Honkanen et al. (1983), studying falls in a public place, and Zador (1991), studying fatal motor vehicle accidents, recruited control subjects at comparable times and locations as the case subjects' accidents. Both studies found that the risk of injury rose exponentially as blood alcohol level rose, with odds ratios of sixty (Honkanen et al., 1983) to several hundred (Zador, 1991) at blood alcohol levels over 0.15 grams per 100 ml blood.

The amount of alcohol that increases the risk of injury may be low, with measurable decrements in driving performance at levels as low as 0.01 g/100 ml (Roehrs, Beare, Zorick, & Roth, 1994). Yesavage et al. (1994) found pilot performance in a flight simulator was impaired even eight hours after inducing a blood alcohol level of 0.1 g/100 ml, when alcohol levels had presumably returned to zero. Data from a national survey also provide evidence that injury risk increases at an average consumption of one drink a day for both men and women, and with consumption of 5 or more drinks on one occasion as infrequently as twice a year (Cherpitel, Tam, Midanik, Caetano, & Greenfield, 1995).

A recent case-control study of skiing injuries found evidence that a hangover effect may be a more important risk factor for injury than acute intoxication (Cherpitel, Meyers, & Perrine, 1998). In addition, data from the National Alcohol Survey suggest that risk-taking disposition may also be more important than alcohol use (Cherpitel, 1999). Studies employing a case-crossover analysis, in which injured persons are compared to themselves on previous days (Maclure, 1991) may shed light on this issue (Vinson et al., 1995). In sum, the relationship between alcohol and injury is likely a complex one.

Intended Injuries. Some injuries are the result of interpersonal violence. The relationship between alcohol drinking and physical aggression is complex, but laboratory experiments show a dose-response effect that varies by individuals' predispositions to aggression (Taylor & Chermack, 1993). Epidemiologically, drinking and being a victim of violent crime are associated, but the nature of the association is unclear (Abbey, 1991; Amaro, Fried, Cabral, & Zuckerman, 1990; Muscat & Huncharek, 1991).

Suicide was unrelated to alcohol consumption in one longitudinal study (Paffenbarger, Jr., Lee, & Leung, 1994), but drinking more than three drinks a day was associated with a 3.5-fold increase in suicide risk in another (Ross, Bernstein, Trent, Henderson, & Paganini-Hill, 1990). In a study of 5,412

formerly hospitalized psychiatric patients, suicide risk among men and women who met alcohol or drug use disorder criteria was 11.9 and 60 times higher respectively than would be expected in a control population (Black, Warrack, & Winokur, 1985). It appears that recent heavy alcohol use, suicidal intent, lack of social support, depression, and medical problems all moderate the risk of suicide among alcoholics (Murphy, Wetzell, Robins, & McEvoy, 1992).

Social Consequences of Alcohol Use and Misuse

In addition to physical illness and injury, alcohol misuse has substantial negative consequences across social, occupational, and criminal justice spheres, ranging from consequences experienced by the abusing individual, his or her family, intimate others, co-workers and colleagues, to larger institutions such as the health care and legal systems. Further, these negative social consequences are important diagnostic determinants of alcohol abuse and dependence. Accordingly, next we summarize some of these consequences by examining relations between alcohol misuse and: (a) role performance in school and the work place; (b) family interaction, performance as a parent, and familial violence; (c) high risk behaviors; and (d) crime.

Alcohol and Role Performance

Well-publicized, reports of alcohol use among college students highlight significant, negative correlations between alcohol use and academic grade point average (Center on Addiction and Substance Abuse at Columbia University, 1994; Presley, Meilman, & Lyster, 1993; Wechsler, Davenport, Dowdall, Moeykens, & Castillo, 1994; Wechsler et al., 1998). However, research in this area is typically cross-sectional and statistically univariate. Hence, little is known about direction of causality, or whether the observed relations between alcohol involvement and poor academic outcomes remain when examined in conjunction with other known predictors of academic failure (which might covary with alcohol involvement). In a longitudinal study, Cook and Moore (1993), found that frequent high-school drinkers (more than one drinking occasion per week) completed, on average, 2.3 fewer years of college than those who were not frequent drinkers. P. Wood, Sher, Erickson, & DeBord (1997), in a five-year longitudinal study, examined relations between academic problems, *freshmen year* alcohol involvement, deviance, academic investment, campus involvement, and academic ability. Analyses indicated that modest bivariate prospective associations between freshmen year alcohol involvement and academic failure over the next six years were not observed when subsequent analyses controlled for, among other things, a history of conduct problems, intellectual ability and illicit drug use. More recently, M. Wood, Sher, and McGowan (in press), replicated and extended these results by prospectively examining relations between alcohol involvement *assessed throughout the college years* and early adult educational and occupational attainment. Consistent with the earlier study, when background variables and other known predictors of early adult role attainment were in-

cluded in analyses, significant prospective relations between alcohol involvement and educational attainment were reduced. In contrast to the earlier study, significant, albeit modest, prospective relations remained between college years' alcohol use and abuse and educational attainment after controlling for the effects of parental education levels, and individual differences associated with gender, family history of alcoholism status, and high school academic achievement and aptitude. Additionally, moderational analyses indicated that individuals who were successful in high school were more negatively affected by collegiate alcohol abuse than those with more marginal pre-college academic performance. While less consistent prospective relations were observed between college years' alcohol involvement and early adult occupational attainment, significant, prospective associations between college years' alcohol dependence and occupational attainment were observed in both bivariate and multivariate analyses. Taken together, results from these two studies suggest that alcohol use is but one of a range of psychosocial variables that researchers and institutional programs need to consider in order to better understand and ameliorate poor academic outcomes.

Alcohol misuse has demonstrated consistent positive associations with work place injury and absenteeism (Holder & Blose, 1991; Marmot, North, Feeney, & Head, 1993; Webb et al., 1994). Although there is limited evidence suggesting similar patterns for moderate-to-high levels of alcohol use (Gill, 1994; Jenkins, Harvey, Butler, & Thomas, 1992), at least one other study found no significant differences between work injuries and absences and high alcohol consumption (Webb et al., 1994).

There also appears to be an association between alcohol abuse or dependence and income, which is moderated by age. Mullahy and Sindelar (1992) found that young adults (ages 22–29) who met abuse or dependence criteria had slightly higher incomes than their nonabusing/dependent peers, with marked differences (in the opposite direction) appearing between age 30 and 59. These differences may be due to educational attrition among heavier drinkers (e.g., Cooke & Moore, 1993), followed by entry into the work force at an earlier age than lighter drinkers, whose income catches up and surpasses that of their alcoholic counterparts by age 30.

In sum, studies in the area suggest that whereas relations between moderate alcohol use and work place injury and absence are unclear, there is ample evidence to conclude that early identification and referral of problem drinkers could reduce work time lost due to accidents and absences, and could potentially benefit work place productivity. Further, the research by Mullahy and Sindelar (1992), and Cook and Moore (1993), suggests that a large amount of the impact of alcohol abuse or dependence on income may be due to its effects on educational attainment.

Alcohol and the Family

Sher (1991), reviewing the literature on alcoholism and family interaction, noted that some tentative conclusions are warranted. First, alcoholic families, compared to nonalcoholic control families, report greater conflict, less family cohesion,

expressiveness, independence, intellectual-cultural orientation, and active-recreational orientation. Importantly, it appears that these differences may persist only in the active phases of a parent's drinking, as they have not been found in studies comparing the family environment of recovered alcoholics with controls (e.g., Moos & Billing, 1982). Second, drawing most heavily on the work of Steinglass and associates, Sher (1991) concluded that it appears that alcohol can serve a variety of adaptive functions in the family (e.g., inhibition or expression of certain behaviors), and that there is a great deal of heterogeneity among the interaction patterns of alcoholic families.

An increased risk of injury is also seen among all ages of children whose parents are problem drinkers (Bijur, Kurzon, Overpeck, & Scheidt, 1992). Relative to children of nondrinking mothers, children whose mothers were classified as problem drinkers were 2.1 times as likely to have received injuries in the previous 12 months that required medical treatment or led to missing time from school. If the child's father was also a problem drinker, the relative risk increased to 2.7; but if only the father was a problem drinker, the child's injury risk appeared to be unaffected. These data suggest that some problem drinkers are deficient in providing adequate supervision to children under their care.

Alcohol misuse is a consistent correlate of familial violence, although as reviews of this literature have noted, a number of methodological problems preclude conclusions about alcohol's causal role in partner and child abuse (Collins & Messerschmidt, 1993; Hamilton & Collins, 1985; Miller, 1990; Steinglass & Robertson, 1983; Widom, 1993). Data on the relation between alcohol and family violence mainly come from three sources: (a) official records; (b) clinical samples; and (c) survey data; with each approach having particular strengths, weaknesses, and potential sources of bias.

A range of factors is important in understanding spouse/partner abuse, including both victim's and perpetrator's alcohol and drug abuse, marital conflict, and hostility (Leonard & Senchak, 1993, 1996; B. Miller et al., 1990). Cross-sectional research has also supported the role of men's aggression-related alcohol expectancies as a predictor of marital violence (Leonard & Senchak, 1993), but more recent longitudinal research with the same sample did not support hypothesized relations between men's alcohol-related aggressive expectancies and severe marital violence (Quigley & Leonard, 1999). When alcohol is present in a spousal violence situation, the most common pattern is drinking by both perpetrator and victim (Collins & Messerschmidt, 1993). Studies from the National Family Violence Surveys (Coleman & Straus, 1983; Kantor & Straus, 1987, 1989) have found consistent associations between frequency of husband's drunkenness and wife abuse. However, from these and other studies, it appears that the relation is curvilinear, with episodic drunkenness more strongly associated with both violence perpetration and victimization than infrequent, continuous, or near continuous drunkenness (Coleman & Straus, 1983; Hamilton & Collins, 1985).

In a review of the literature on alcohol and child abuse, Widom (1993) noted that despite the improved methodolo-

gies of more recent studies, the basic conclusions of earlier reviewers (e.g., Hamilton & Collins, 1985; Orme & Rimmer, 1981) remain unaltered. That is, the pattern of findings in this area are contradictory and methodological problems continue to hinder conclusions regarding the association between parent alcohol misuse and child victimization. Nonetheless, taken as a whole, results suggest that there is a link. Famularo, Kinscherff, and Fenton (1992), in analyses of randomly selected court records, found that parental alcohol abuse was significantly related to physical, but not sexual, abuse of offspring. In a case control study using ECA data, Kelleher, Chaffin, Hollenberg, and Fischer (1994) noted that parents who met alcohol abuse or dependence criteria exhibited levels of physical abuse and neglect 2.5 and 3.3 times higher than those of abuse or dependence criteria compared to sociodemographically matched controls. More generally, parents with any type of substance use disorder were 2.7 and 3.1 times more likely to have reported abusing their children than matched controls, after further controlling for other psychopathology (depression and antisocial personality disorder), number in household, and social support. The relation between alcoholism and child abuse also appears to be stronger than that of child abuse with other psychopathology (Famularo, Stone, Barnum, & Wharton, 1986).

Less is known about the prevalence of parental alcohol misuse among incest or extrafamilial sexual abuse victims. Russell, Henderson, and Blume (1985) reviewed several studies that reported very high rates of alcoholism among parents of incest victims. Hernandez (1992) compared incest and extrafamilial sexual abuse among adolescents with and without a family history of alcohol problems and noted that sexually abused adolescents were significantly more likely to have a substance abusing parent than adolescents who had not experienced abuse. Consistent with these findings, Sher, Gershuny, Peterson, and Raskin (1997) observed significantly higher levels across a number of specific types of sexual abuse among offspring of alcoholics as compared to controls. Additionally, Sher et al. (1997) found that many of a number of mild to severe childhood stressors more commonly experienced by children of alcoholics were related to alcohol use disorders in adulthood. At least for women, other studies also support the etiological significance of childhood physical and/or sexual abuse in the development of alcohol problems (B. Miller et al., 1990; B. Miller, Downs, & Testa, 1993).

In sum, research on the effects of alcohol misuse on the family is fraught with methodological limitations that make it difficult to discern the extent of a causal association between alcohol and family problems. Prospective studies using standardized diagnostic measures and multivariate analyses are needed to characterize more fully the temporal sequence of the association and to identify important mediators and moderators of relations between alcohol and family violence.

Alcohol and High Risk Behaviors

Risky Sex. Alcohol's disinhibiting effects on behavior have long been noted, as have its deleterious effects on judgment and decision-making processes. Anecdotal associations

between alcohol consumption and sexual behavior pervade our culture, and are not without empirical support, although it appears that expectations regarding alcohol's effect on sexuality are more powerful (at least at lower doses) than are pharmacological effects (Crowe & George, 1989). Across adolescent, young adult heterosexual, and adult homosexual samples, cross-sectional data show that those who drink more heavily are more likely to engage in risky sexual practices (Erickson & Trocki, 1992; McEwan, McCallum, Bhopal, & Madhok, 1992; Meilman, 1993; Stall, McKusick, Wiley, Coates, & Ostrow, 1986; Strunin & Hingson, 1992; Wechsler et al., 1994; Wechsler et al., 1998). Risky sex is defined here as unprotected vaginal or anal intercourse outside the context of an ongoing monogamous relationship. In contrast to cross-sectional results, one longitudinal study found that drinking was correlated with the frequency of risky sex only in between-subjects analysis and not in within-subjects analysis (Leigh, 1993). The association, therefore, may be due to confounding by other variables, such as generalized risk taking. Methodological limitations, and the inherent difficulty of conducting research in this area, make causal inferences regarding alcohol's role in risky sex extremely difficult. Leigh and Stall (1993), in a comprehensive review of the literature on alcohol and risky sex, noted that studies are limited by a necessary reliance on self-reports, introducing attributional, social desirability, and memory biases for both substance use and sexual activity that may be worsened when the two are examined in combination. They also noted that sampling characteristics such as time of data collection, geographic location, age, sexual orientation, and gender may influence the relation between alcohol use and risky sex. Leigh and Stall (1993) concluded that there is good reason to suspect that third variable explanations (e.g., sensation seeking or impulsive personality traits and situational factors) mediate much of the relation between alcohol consumption and high risk sexual behaviors, noting that studies have observed strong correlations between tobacco use (which is not typically ascribed causal status) and risky sex. Additionally, those studies that have controlled for extraneous variables have observed much attenuated or nonsignificant relations between alcohol use and high risk sexual behavior. They also caution that health education messages that assume a causal role for alcohol may be harmful because they potentially provide a means to avoid personal responsibility by "blaming the booze" (Critchlow, 1983).

In summary, empirical ambiguity surrounding a causal role for alcohol in the initiation of risky sex should not be taken to imply that messages about alcohol's deleterious effects on cognition and judgment should not be incorporated in prevention efforts. Instead, the association could be noted while attempting to minimize the acceptability of using intoxication as a means of excusing dangerous behavior (Leigh & Stall, 1993). Alternatively, as Leigh and Stall (1993) also noted, alcohol and drug abuse also may be viewed as potential markers of risky sexual behaviors in lieu of any demonstrated causal relationship.

Drinking and Driving. Data from the Fatality Analysis Reporting System (FARS), a database of over 800,000 fa-

tal motor vehicle crashes over a 20-year period indicate that between 1977 and 1996 there has been a 22% decrease in alcohol-related fatal motor vehicle crashes (Yi, Stinson, Williams, & Bertolucci, 1998). Despite these encouraging decreases, alcohol was still involved in 32.4% of all fatal car crashes in 1996. Moreover, after a 47% reduction between 1982 and 1995 in alcohol-related fatalities among the youngest cohort of drivers (ages 16–20), there was a slight (5%) increase in alcohol-related fatalities for this age group in 1996 (Yi et al., 1998). Examination of future FARS data will be necessary to determine whether the increase is merely a fluctuation or signals the beginning of a new trend.

Fell (1990) and Yi et al. (1998) suggested several possible explanations for the observed decreases in drinking and driving including: (a) increased public awareness of the problem; (b) media-covered implementation of stricter and swifter enforcement measures; (c) changes in drinking and driving laws (i.e., increases in the legal drinking age in 35 states between 1982 and 1988, zero tolerance laws in 43 states and the District of Columbia for drivers under 21, decreases in allowable BAC levels to less than .08 in 13 states by 1998); (d) prevention and intervention efforts that feature alternatives to legal deterrents (e.g., server training, designated driver programs); (e) a decrease in the population of young drivers; (f) an overall decrease in per capita alcohol consumption; and (g) overall safety improvements for vehicles and roadways, as well as increased use of seat belt and passive restraint systems. Further, a growing body of literature indicates that a number of factors other than alcohol use and alcohol problems distinguish drinking drivers from those who do not drink and drive, including personality traits (e.g., impulsivity, sensation seeking, hostility, social responsibility), and other individual differences such as alcohol outcome expectancies and driving-related aggression (McMillen, Pang, Wells-Parker, & Anderson, 1992; Stacy, Newcomb, & Bentler, 1991b). Additionally, there is a great deal of heterogeneity among drinking drivers along dimensions such as alcohol dependence, psychiatric severity, non-alcohol related traffic violations, and social instability (Wieczorek & Miller, 1992). Interventions tailored to these differences might lead to lower rates of recidivism for DWI/DUI offenders than has been seen to date.

Alcohol and Crime

The relation between alcohol and crime is complex, involving consideration of alcohol's anticipated and actual effects on the individual (e.g., expectations of increased aggression, impaired judgment, decision-making, and interpersonal skills), situational correlates (e.g., locale, time of day or night), and cultural factors (e.g., SES, widespread notions regarding alcohol's disinhibitory effects and its social cue properties). Alcohol involvement in crime is typically studied by event analysis (e.g., police or medical records or reports), or from the retrospective accounts of incarcerated offenders. Each approach has disadvantages, most notably incomplete or inaccurate records for the former method, and sampling and recall biases for the latter. The current state of knowledge is not such that causal inferences regarding alcohol and crime can be made.

Estimates of alcohol involvement prior to the commission of homicide have ranged from 7% to 85%, with most studies indicating greater than 60% of offenders had consumed alcohol prior to the offense (Collins, 1991; Collins & Messerschmidt, 1993; Murdoch, Pihl, & Ross, 1990; Pernanen, 1991; Roizen, 1997). For assault, Murdoch et al. (1990) summarized results from seven studies, noting that from 24% to 82% of offenders were intoxicated when the crimes were committed. Cordilia (1985) suggested that alcohol's association with the perpetration of property crimes differs according to whether the crimes are premeditated or opportunistic in nature.

Increasingly, researchers and prevention specialists are calling attention to alcohol's involvement in sexual assault. Koss, Gidycz, and Wisniewski (1987) examined the prevalence of sexual victimization in a national sample of college students and observed that 53.7% of women respondents had experienced some degree of sexual victimization (ranging from unwanted petting to rape), while 12.1% and 15.4% reported attempted rape and rape respectively. In another study from the same data set, Koss and Dinero (1989) found that respondent's alcohol use was one of four variables demonstrating predictive power for rape vulnerability, although as noted by Roizen (1997), the relationship between alcohol use and rape in this sample was not a strong one. Muelenhard and Linton (1987) in a survey of college men and women, noted that 55% of the men who reported they had committed sexual assault on a date indicated that they were either intoxicated or "mildly buzzed" at the time of the incident. Although methodological limitations, such as small and biased samples and reliance on retrospective accounts, preclude causal inferences, several explanations for the relation between alcohol consumption and sexual assault have been proposed. With respect to men who commit sexual assault, these include: (a) expectations of increased power and sexuality associated with drinking; (b) misattribution of a woman's friendly interaction as indicative of sexual interest; and (c) the tendency to use intoxication as a means of diminishing personal responsibility for behavior (Abbey, 1991). Because alcohol use, particularly heavy drinking, has marked deleterious effects on psychomotor and cognitive functioning, sexual assault victims are probably less capable of either physically or verbally thwarting an attack. Further, there are data indicating that a drinking woman is perceived as more sexually available (George, Gournic, & McAfee, 1988) and that bar victimization of women appears to be a frequent occurrence, with 32.6% of women surveyed in recent study reporting either attempted or completed rape associated with drinking in a bar (Parks & Miller, 1997). Research on sexual assault typically has been retrospective and most surveys have not assessed whether assailants and victims had consumed alcohol prior to the assault (Abbey, 1991; Roizen, 1997). Prospective and case control studies are needed to clarify alcohol's influence on sexual assault in order to guide education efforts as well as to better identify those at greatest risk.

Summary of Health Related Consequences of Alcohol Use and Misuse

Alcohol misuse is highly prevalent in the United States (and many other cultures) and is associated with a broad range of adverse health and psychosocial outcomes. Excessive alcohol consumption and alcohol use disorders have been shown to have deleterious effects on most organ systems, to be a major cause of fatal and nonfatal injury, and to contribute to a range of psychological and social problems (NIAAA, 1993, 1997). Against this backdrop of many deleterious consequences of alcohol misuse, there is some evidence for possible health benefits of light or moderate drinking (Albert et al., 1999; Friedman & Klatsky, 1993).

It is becoming increasingly clear that the relative risks and benefits of alcohol consumption are likely to vary across the life span. During adolescence and early adulthood, motor vehicle crashes represent the most serious consequences of alcohol use as well as the leading cause of mortality for this age group (NIAAA, 1993). Given the steep monotonic relationship between blood alcohol level and impaired driving, it is difficult to believe that any drinking during this period of life, no matter how socially normative, is likely to have positive benefits on overall health. On the other hand, CHD is the leading cause of mortality in middle age, and as discussed earlier, it appears that moderate alcohol consumption reduces CHD, presumably because of its effects on HDL and/or platelet function. The effects of alcohol on these two important health problems highlight several important issues with respect to alcohol and health: (a) the relation between alcohol consumption and various consequences is dose dependent, (b) the shapes of dose-response curves vary as a function of the health-related outcome under consideration and are not necessarily monotonic, and (c) the health consequences of alcohol consumption need to be viewed in a life-span developmental context.

Clearly, although a considerable amount is known concerning the effects of alcohol on health broadly defined, much more needs to be known with respect to elucidating the mechanisms underlying the consequences of alcohol use and misuse. Interpretation of many associations is complicated by a variety of third variables and unmeasured confounders and vulnerability factors that are important determinants of alcohol effects. Alcohol use is often accompanied by other "risky" or outright health-damaging behaviors and isolating unique effects of alcohol is frequently difficult. Similarly, as previously noted, many individuals who tend to misuse alcohol probably also tend to experience other psychological and social problems, and associations between alcohol consumption and many adverse psychosocial outcomes (e.g., disrupted family life, impaired work performance, crime, psychological disorders) are difficult to disentangle. Thus, clinicians are often limited in their ability to ascribe a causal role to alcohol.

PUTATIVE ETIOLOGIC FACTORS

Overview

An understanding of the prevalence and distribution of alcohol misuse in both the general population and at-risk subpopulations, as well as increased knowledge of alcohol's effects on physical and mental health are vital steps toward ameliorating human suffering and reducing the myriad negative health and social consequences of alcohol misuse. Contemporary alcohol researchers are also working to identify the biological, psychological, and social determinants of maladaptive drinking patterns. Next, each of these broad areas is addressed in turn while recognizing that most contemporary theories view alcohol use and misuse as being caused, maintained, and exacerbated by a combination of biological, psychological, and social factors.

Biological/Genetic Influences on Alcohol Use and Misuse

The observation that alcohol abuse and dependence tend to run in families has prompted a great deal of research aimed at identifying genetic mechanisms underlying alcohol use and the pathogenesis of alcohol use disorders. Studies utilizing behavior-genetic approaches in human samples, as well as animal studies, have amassed considerable evidence for genetic influences on alcohol use and misuse.

Behavior-Genetic Studies of Alcohol Use and Misuse

Behavior-genetic research can be loosely classified into five categories: (a) family studies; (b) twin studies; (c) adoption studies; (d) genetic marker studies; and (e) vulnerability studies. Family and vulnerability studies are not truly behavior-genetic in that they are not capable of separating genetic and environmental influences. The following summary of findings from behavior-genetic studies borrows heavily from more comprehensive recent reviews of this body of research (e.g., Ball & Murray, 1994; McGue, 1994; 1999; Merikangas, 1990).

Family Studies. Family studies have confirmed the long-standing clinical observation that alcohol use disorders tend to run in families (see Cotton, 1979; Merikangas, 1990 for reviews). For example, Dawson, Harford, and Grant (1992) noted that individuals who reported alcoholism in a first-degree relative (i.e., parent, sibling, or children) were at 86% greater risk for alcohol dependence than those without a family history of alcoholism.

True behavior-genetic studies attempt to explain behavior by partitioning variation in behavior according to genetic and environmental sources. In the simplest behavior-genetic model, the phenotype under study can be disaggregated into three components: (a) genetic effects; (b) shared environmen-

tal effects (e.g., parental SES); and (c) nonshared or unique environmental effects (e.g., peer influences).

Twin Studies. Twin studies are an important methodology for examining genetic and environmental influences for both alcohol use and alcohol use disorders. To the extent that alcohol use and misuse are genetically influenced, monozygotic (MZ) twins, who share 100% of their genetic makeup, would be expected to show higher concordance (agreement rates) for both alcohol use and alcohol use disorders as compared to dizygotic (DZ) twins, who are no more genetically alike than any pair of siblings. A number of assumptions need to be met in order to draw strong inferences from these studies. Nevertheless, studies are generally consistent in showing higher MZ concordance for both alcohol consumption and alcohol use disorders (Ball & Murray, 1994; McGue, 1994). In men, heritability estimates for alcoholism are consistent across studies and range from 50% to 60% (McGue, 1999). The studies differ somewhat in the extent to which genetic effects are generalizable to women, although shared environmental effects have been demonstrated consistently for both men and women (McGue, 1994). For men, by and large across the major twin studies, genetic effects have accounted for a greater share of the variance in alcohol abuse or dependence than shared environmental influences (McGue, 1994).

In contrast to some earlier studies, results from two more recent population-based studies suggest heritability for women is equal to that of men (Heath et al., 1997; Kendler, Heath, Neale, Kessler, & Eaves, 1992). In comparing their results with earlier findings, Kendler et al. (1992) suggested that previous female twin study participants, who were typically ascertained while seeking alcohol treatment, may not be representative of alcoholics in the entire population. McGue (1999) asserts, that taken as a whole, the literature supports the inference of genetic influence on alcoholism among women, but precise estimates of heritability risk cannot be drawn from existing data.

Adoption Studies. Adoption studies represent a powerful methodology for disentangling the genetic and environmental determinants of alcohol use and misuse. In a typical cross-fostering design, alcoholism in the adoptive home and alcoholism in the biological parents are orthogonally crossed. Adoption studies generally show an important role for genetics in the transmission of alcoholism in men, with more ambiguous findings with respect to alcoholism in women. Moreover, some of these studies have suggested genetic heterogeneity of at least two different types in the genetic predisposition to alcoholism (e.g., Cadoret, Yates, Troughton, Woodworth, & Stewart, 1995; Cloninger, Bohman, & Sigvardsson, 1981).

Studies conducted in Denmark, Sweden, and the United States all have found significantly higher rates of alcohol use disorders in adopted-away offspring of alcoholics. Goodwin, Schulsinger, Hermansen, Guze, and Winokur (1973) noted

that male adoptees with an alcoholic biological parent were at almost four times greater risk for alcoholism than a control group (18% vs. 5%) comprised of adoptees with either no family history of psychopathology, or of psychopathology other than alcoholism. Cloninger et al. (1981) found that alcohol abuse (at least one temperance board registration) was significantly higher among family history positive compared to family history negative adoptees (22.8% vs. 14.7%). Cadoret et al. (1995) noted direct genetic effects from biological parents to adopted-away offspring for drug abuse and dependency. Moreover, Cadoret and colleagues are the only investigators to observe an effect of adoptive parent alcoholism on offspring alcoholism, and have obtained these findings in men and women across multiple studies (McGue, 1994).

The interplay between genetic and environmental influences can be expressed with reference to two behavior-genetic processes: (a) gene-environment (G-E) correlations; and (b) G-E interactions. G-E correlations can be classified as *passive*, *reactive*, and *active* (Plomin, DeFries, & Loehlin, 1977). Passive G-E correlations reflect the degree to which environmental influences are not independent of inherited genes. Reactive, or evocative, G-E correlations refer to the differential reactions elicited from others by different genotypes. Active G-E correlations relate to the tendency for individuals to seek environments that complement their genotype. Each type of G-E correlation may play a role in the etiology of alcohol misuse, and could, presumably, relate to alcohol use more generally (Searles, 1988). G-E interactions are potentially important in the etiology of alcohol use and misuse as well. Cloninger et al.'s (1981) Type I alcoholism is an example of a G-E interaction. According to Cloninger and colleagues, environmental factors determine whether one type of genetic predisposition will result in alcoholism.

Taken together, twin and adoption studies have provided very strong evidence for the role of both genetic and environmental factors in the pathogenesis of alcohol use and misuse. Nevertheless, these methodologies also have been criticized with respect to issues such as poor measurement of environmental influences, and for inattention to nonshared environmental effects and indirect genetic effects such as G-E correlations and interactions (Reiss, Plomin, & Hetherington, 1991; Searles, 1988).

Genetic Linkage and Association Studies. The demonstration of major single gene effects for diseases such as Huntington's and muscular dystrophy has motivated a great deal of genetic research aimed at identifying specific markers for psychiatric disorders, including alcohol abuse and dependence (see McClearn, Plomin, Gora-Maslak, & Crabbe, 1991). A particular subtype of alcohol dehydrogenase (ADH) isoenzyme (the β subunit) has been found to vary in different ethnic groups and is associated with differential sensitivity to alcohol. For example, individuals with the β_2 subunit (approximately 65% of the Asian population) appear to oxidize alcohol faster than those with the β_1 subunit (most Caucasians) resulting in higher levels of acetaldehyde (alcohol's initial metabolite) which may lead to tissue damage (NIAAA, 1993). Genetic and ethnic variation in acetaldehyde

dehydrogenase (ALDH) isoenzymes also exist, and these are thought to be more important with respect to alcoholism. More specifically, it appears that Asian alcoholics have substantially lower rates of the ALDH isoenzyme (ALDH2) than Asian nonalcoholics, suggesting that this type of isoenzyme serves some protective function against the development of alcoholism (McGue, 1994, 1999).

Early reports of an association with the A1 allele of the dopamine DRD2 receptor gene and severe alcoholism (Blum et al., 1990) led to an intense concentration of research effort and some controversy in the field of genetics (see Holden, 1994). Uhl, Persico, and S. Smith (1992), in a meta-analysis of seven DRD2 studies, concluded that there appeared to be sufficient evidence to support an association between DRD2 alleles and substance abuse (on the basis of odds ratios averaged across studies). In contrast, Gelernter, Goldman, and Risch (1993) conducted a meta-analysis of all DRD2 studies subsequent to Blum et al. (1990), and found no significant differences between alcoholic and control groups on comparison of allele frequencies. They concluded that sampling error and/or ethnic variation between alcoholic and control groups are the most likely explanation in those studies demonstrating positive results. At this time it appears that the association between DRD2 A1 allele and alcoholism is not supported either with respect to the pattern of positive findings, or through identification of a physiological mechanism supporting its role in the etiology of alcoholism (McGue, 1999).

Genetic linkage studies attempt to identify within-family associations between a genetic marker and a particular disorder, which would suggest the existence of a disorder-susceptibility locus in close proximity to the marker site. Rising methodological concerns with regard to association studies have led to an increased focus on genetic linkage methods (McGue, 1999). The ongoing Collaborative Study on the Genetics of Alcoholism (COGA; Begleiter et al., 1995) is a systematic attempt to use linkage methods to identify specific genes contributing to the risk of alcohol use disorders. Reich et al. (1998) reported that several chromosomal regions showed suggestions of linkages with alcoholism. The strongest evidence of linkage was found on chromosomes 1 and 7, with more modest evidence on chromosome 2. Interestingly, there was suggestive evidence for linkage on chromosome 4 near the site of the alcohol dehydrogenase genes (ADH), which, as previously noted, appear to exert protective effects against alcoholism among some Asians. In another recent linkage study, Long et al. (1998) reported highly suggestive evidence for linkage at chromosome 11, with good (but more modest) evidence for linkage with alcoholism at chromosome 4, with the findings for the latter region partially overlapping the region identified by Reich et al. (1998). These studies have identified genetic regions that can be targeted in future replication attempts and are viewed as important first steps in the identification of genes that contribute to the risk for alcohol use disorders (McGue, 1999).

Vulnerability Studies. Vulnerability studies attempt to identify specific mechanisms of risk for alcohol misuse. Offspring of alcoholics are often utilized because they are known

to be at increased risk for alcohol use disorders, and can be examined prior to the age of risk for alcohol use or misuse. Numerous studies have found differences between children of alcoholics (COAs) and children of nonalcoholics (nonCOAs) in terms of their responses to alcohol, as well as across a range of cognitive, behavioral, neurophysiological, and biochemical measures (Sher, 1991).

A number of studies have compared the neurophysiological characteristics of COAs and nonCOAs. With respect to spontaneous electroencephalographic (EEG) activity in sober COAs, there have been some positive findings (e.g., Ehlers & Schuckit, 1991; Gabrielli et al., 1982), but taken as a whole, results have been equivocal for variation in EEG activity as a function of family history (Sher, 1991).

Event-related potentials (ERPs) are discrete waveforms elicited by direct sensory stimulation of a participant (e.g., a brief flash of light) or by engagement in a cognitive task (e.g., making judgments regarding the properties of a stimulus). COA/nonCOA differences have been demonstrated in the latter paradigm. Most notably, male COAs have been shown to have reduced P3 (a positive wave occurring approximately 300 msec after stimulus onset) amplitude compared to controls in both visual and auditory tasks. The P3 is thought to index cognitive processes such as stimulus evaluation, attentional resources, or memory updating processes, with its generators thought to be localized in the hippocampal region of the CNS. Polich, Pollock, and Bloom (1994), in a meta-analysis, found that COAs consistently demonstrated significantly decreased P3 amplitudes relative to controls. Age, task difficulty, and stimulus modality were all significant moderators of this effect. Although the P3 appears to reliably differentiate COAs from nonCOAs, it also appears to distinguish between individuals suffering from, or at risk for, a wide-range of psychiatric disorders, including schizophrenia and affective disorders. Thus, Polich et al. (1994) concluded that it is unlikely that the P3 is a *specific* biological marker for alcoholism.

In a review of vulnerability studies examining cognitive/neuropsychological functioning, Sher (1991) concluded that available data suggest differences in the cognitive functioning of COAs and nonCOAs, particularly relating to deficits in verbal ability and abstraction/conceptual reasoning among COAs. Studies conducted since this review have also suggested reliable differences in visuospatial learning related to temporal organization, attention, and informational encoding (Harden & Pihl, 1995; Schandler, Cohen, & Antick, 1992; Schandler et al., 1988). The etiologic significance of these observed differences is presently unclear, although several plausible hypotheses can be forwarded. For example, impaired verbal and problem-solving abilities may contribute to school failure, consequent loss of self-esteem, and adoption of a deviant role. Findings of impaired educational achievement among COAs are consistent with this notion. A second hypothesis is that cognitive deficits may lead to reduced coping abilities with consequent use of alcohol as a coping strategy. Another possibility is that alcohol consumption subjectively improves cognitive performance in some COAs and is thus reinforcing. This hypothesis is supported by results from several researchers who have reported that adolescent COAs tend to believe that

alcohol improves cognitive and motor performance (S. Brown, Creamer, & Stetson, 1987; Chassin, Mann, & Sher, 1988; Sher, Walitzer, P. Wood, & Brent, 1991).

In the search for a biochemical marker for alcohol use disorders, monoamine oxidase (MAO) has received the most empirical attention to date. MAO is an important enzyme in the breakdown of dopamine, norepinephrine and serotonin. In most studies, the human blood platelet is the source of MAO and is usually assumed to be an index of brain MAO activity. In studies comparing MAO activity levels in COA and nonCOA groups, there is general support for the hypothesis that low MAO activity may represent a predisposition for alcoholism. Research by von Knorring and colleagues (von Knorring, Bohman, von Knorring, & Oreland, 1985; von Knorring, Oreland, & von Knorring, 1987) suggests that low MAO activity may characterize only one form of alcoholism (the Type II alcoholism identified in the Swedish adoption studies). This hypothesis is also consistent with research demonstrating that low platelet MAO activity is associated with behavioral undercontrol traits such as sensation seeking and impulsivity (e.g., Fowler, von Knorring, & Oreland, 1980; Murphy et al., 1977; Perris et al., 1980; Sher, Bylund, Walitzer, Hartmann, & Ray-Prenger, 1994). However, results from a recent study indicate that MAO activity is associated with a range of factors such as cigarette and other drug use, other psychopathology, medical illness, metabolic factors, and, as noted above, personality traits (Anthenelli et al., 1998). Thus, MAO activity may be a consequence of alcohol or other drug use or a non-specific indicator of a range of disorders related to disinhibition and impulsivity (NIAAA, 1997).

The general hypothesis that differences in responses to alcohol may underlie COA vulnerability to alcohol misuse has been examined for alcohol metabolism, subjective intoxication, autonomic, electromyographic (EMG), and EEG activity. Differential sensitivity indexed by these measures could be related to both the negative (e.g., relief of negative affect) or positive (e.g., sensitivity to alcohol's euphoric effects) reinforcement properties of alcohol, or to decreased sensitivity to alcohol's aversive effects. For ethical reasons, it is desirable to exclude abstainers and naive drinkers from alcohol consumption studies. Thus, most studies cannot distinguish whether obtained differences are the result of initial sensitivity or acquired (e.g., tolerance) sensitivity. Taken as a whole, existing data suggest that there are no differences between COAs and nonCOAs with respect to absorption or elimination of alcohol (Sher, 1991).

The extant literature is equivocal regarding COA/nonCOA differences on alcohol's subjective effects. At least five studies have reported reduced subjective intoxication in COAs (Moss, Yao, & Maddock, 1989; O'Malley & Maisto, 1985; Pollock, Teasdale, Gabrielli, & Knop, 1986; Schuckit, 1980, 1984), while others have reported either no differences, or greater subjective intoxication in COAs compared to nonCOAs (de Wit & McCracken, 1990; Kaplan, Hesselbrock, O'Connor, & DePalma, 1988; Nagoshi & Wilson, 1987; Sher, Walitzer, Bylund, & Hartmann, 1989; Vogel-Sprott & Chipperfield, 1987). Newlin and Thomson (1990) have proposed that the seemingly contradictory literature on the direction of

COA/nonCOA differences in alcohol effects can be reconciled by considering the time course of intoxication. They have suggested that COAs are more sensitive to the effects associated with the ascending limb of the blood alcohol curve (when blood alcohol levels are rising), and less sensitive to the effects associated with the descending limb of the blood alcohol curve.

COA/nonCOA differences have been observed for indices of CNS (e.g., EEG) and peripheral nervous system (e.g. heart rate) functioning following alcohol consumption. Pollock et al. (1983) reported higher levels of fast alpha EEG activity (associated with self-reports of well-being) in intoxicated COAs compared to controls. Several studies have documented increased heart rate in COAs, compared to nonCOAs, subsequent to alcohol consumption, and it has been postulated that these increases might index an increased incentive value for alcohol (Finn & Pihl, 1987; Finn, Zeitouni, & Pihl, 1990; Nagoshi & Wilson, 1988). Generally, there is little evidence of COA/nonCOA differences following alcohol consumption on other autonomic measures such as finger pulse amplitude, blood pressure, and electrodermal activity (Sher, 1991).

Individual differences in the ability of alcohol to dampen autonomic responses to discrete stressors have been suggested as etiologically significant for the development of drinking problems. For example, persons for whom alcohol is particularly efficient in dampening stress responses may be more likely to drink alcohol in greater quantities (Sher, 1987). At least three studies have found that COAs demonstrate less heart rate reactivity to a stressor after alcohol consumption than nonCOAs (Finn & Pihl, 1987; Finn et al., 1990; Levenson, Oyama, & Meek, 1987). These findings are consistent with the notion that individuals with a positive family history of alcoholism receive greater reinforcement from alcohol consumption.

In summary, although no specific marker for vulnerability for the development of alcohol use disorders has yet emerged, there are encouraging findings. The cognitive processes indexed by the P3 may be etiologically important in the development of alcoholism even though reduced amplitude of the P3 is not specific to those at-risk for alcoholism. To the extent that the P3 indexes aspects of attention or memory updating, it could figure prominently in information-processing theories of alcoholism. MAO may represent a variable that distinguishes COAs and nonCOAs. The potential etiologic significance of MAO remains promising due to: (a) its association with alcohol abuse and dependence; (b) its link to neurotransmitters that appear to be associated with the development of alcoholism; and (c) its relation to traits predictive of alcoholism (e.g., aggression and impulsivity).

Sher (1991) noted, that two areas of consistency seem to emerge from studies of differential responses between COAs and nonCOAs. First, it appears that COAs are *less sensitive* to subjective intoxicating effects of alcohol, which may lead them to drink greater amounts of alcohol. Consistent with this notion, Schuckit (1994) reported that lower subjective responses to alcohol and less body sway in a baseline alcohol challenge study were associated with a fourfold increase in alcoholism 10 years later. Second, it appears, in seeming con-

tradition of the first conclusion, that COAs are *more sensitive* to some of alcohol's effects, such as stress response dampening and hyperreactivity to the stimulant properties of alcohol (e.g., Finn et al., 1990). Although these effects may seem incompatible, alcohol is known to have widely varying effects, and it is conceivable that the effects on subjective intoxication (in a nonstressed state) and autonomic stress responses are relatively independent. Newlin and Thomson's (1990) hypothesis that COA/nonCOA differences in alcohol effects can be resolved by consideration of the limb of the blood alcohol curve is intriguing, and if valid would suggest that COAs are doubly vulnerable to alcohol's effects. That is, their greater sensitivity to the reinforcing effects of alcohol, and decreased sensitivity to the negative effects of alcohol could lead to greater amounts of consumption with relatively fewer aversive side effects. Finally, the lack of specificity observed for measures such as P3 or MAO should not be taken to preclude their utility in understanding the etiology of alcoholism. Alcohol abuse and dependence are quite heterogeneous and, as reviewed earlier, frequently co-occur with other psychiatric disorders.

Animal Studies. Behavior-genetic studies with rodents have demonstrated a number of phenomena that may be important in understanding the determinants of alcohol-seeking behavior and the effects of alcohol in humans. The primary advantages of genetic animal models of alcohol abuse are related to experimental control, ethics, and cost. The major disadvantages stem from the difficulty in modeling important environmental antecedents of human alcoholism, and the fact that genetic animal models are, at best, only partial models of alcoholism (Crabbe & Phillips, 1990).

Selective breeding techniques have been used in the development of over a dozen rodent models of alcohol consumption and effects. For example, rats have been selectively bred for high and low preference for alcohol containing solutions (Crabbe, 1989; Li, Lumeng, McBride, & Murphy, 1992), with alcohol preferring strains often achieving high blood alcohol levels and expending considerable effort to obtain alcohol. Also, rats and mice have been bred for a variety of responses to alcohol, including sensitivity to stimulant and sedative effects and dependence-related phenomena such as tolerance and withdrawal sensitivity (Crabbe, Belknap, & Buck, 1994). These models, in addition to demonstrating how various aspects of alcohol-related behavior can be under genetic control, also offer the opportunity to study environmental effects on different genotypes and permit intrusive methods to assess neuropharmacological and neurophysiological correlates of these genetically mediated differences. For example, differences between alcohol preferring and nonalcohol preferring rats in monoaminergic and opioid functioning have been demonstrated using a range of techniques to study regionalized neuropharmacological functioning (Froelich, Zweifel, Harts, Lumeng, & Li, 1991; McBride, Murphy, Lumeng, & Li, 1990).

McGue (1999) suggested that animal models will likely make their greatest contribution to alcoholism etiology by helping to identify and characterize specific genes that influ-

ence individual differences in alcohol-related behaviors. For example, in recent years, a number of advances have been made in identifying variations in quantitative trait loci (QTL) for alcohol-related phenotypes in mice, many of which have homologues in the human genome that can be targeted in human genetic research (for reviews see NIAAA, 1997, and McGue, 1999). Additionally, transgenic approaches, which utilize genetically engineered animals to over- or under-express specific gene products, are increasingly being used to isolate the effects of individual genes on alcohol-related behaviors (Homanics, Quinlan, Mihalek, & Firestone, 1998; McGue, 1999; Wehner & Bowers, 1995).

Neurochemical Mediators of Alcohol's Effects.

Several neurotransmitter systems—including the monoamines (e.g., dopamine, serotonin), neuropeptides (e.g., endorphins, enkephalins), and amino acids (e.g., gamma-aminobutyric acid [GABA] and glutamate)—all appear to be affected by alcohol. Further, each of these neurotransmitters binds with multiple receptor subtypes, which may themselves be differentially affected by alcohol.

The monoamines, as well as GABA and the endogenous opiates, are thought to be associated with alcohol's reinforcing effects. Alcohol preferring rats have been found to have lower levels of dopamine and serotonin than alcohol nonpreferring rats in certain brain regions (Hwang, Lumeng, Wu, & Li, 1990; Li et al., 1992). In humans, individuals with alcohol use disorders have been found to have lower levels of serotonin metabolites (Gorelick, 1989; Roy Virkkunen, & Linnoila, 1990), and an inverse relationship between these metabolites and length of abstinence also has been noted (Banki, 1981). These findings have led some researchers to suggest that alcohol consumption may serve to increase alcoholic's serotonin to "normal" levels (Kranzler & Anton, 1994). Further, dopamine and serotonin agonists and antagonists have been shown to alter alcohol intake in rats and humans in predictable ways (Kranzler & Anton, 1994; Li et al., 1992; McBride et al., 1990). The relations between the monoaminergic neurotransmitters and alcohol's reinforcing effects are obviously complex and are not as yet totally understood. Nonetheless, the finding that decreased levels of serotonin and its primary metabolites are associated with alcohol use and problems is provocative given serotonin's association with mood and impulse control, both of which have been implicated as important aspects of proposed alcoholism typologies (e.g., Cloninger, 1987).

GABA is the major inhibitory neurotransmitter in the mammalian central nervous system, providing the brain with a means to control neuronal excitation. Alcohol's effects on the GABA_A receptor may be a mechanism for alcohol's anxiolytic, sedative, and motor impairment effects as demonstrated by GABA antagonists' ability to offset these effects (Korpi, 1994). The finding that an experimental drug (Ro 15-4513) counteracts ethanol's motor impairment effects elicited intense research efforts to define the parameters of the drug's effects and to identify other drugs that block alcohol's effects. Across several experiments, Ro 15-4513 has not been found to consistently affect the psychomotor stimulant, hypo-

thermia, or lethal effects of alcohol, suggesting multiple mechanisms for alcohol's effects (Korpi, 1994).

Glutamate, the central nervous system's major excitatory neurotransmitter, is implicated in alcohol's cognitive and motor impairment and amnesic effects through its action on two receptor sites: N-methyl-D-aspartate (NMDA) and α amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA; Lovinger, White, & Weight, 1989; NIAAA, 1993). Ethanol has been shown to inhibit NMDA receptor activation in neurons taken from several mice CNS regions, including the hippocampus, spinal cord, and neocortex (Lovinger et al., 1989). Alcohol's effects on AMPA receptors have been studied less frequently than NMDA receptors, but they appear to be less sensitive to alcohol and are thought to be involved in the decreased respiration and general anesthesia effects that occur as a result of extremely heavy alcohol consumption (NIAAA, 1993).

In a review of the literature on alcohol and glutamatergic transmission, Tsai, Gastfriend, and Coyle (1995) proposed a glutamatergic basis for alcoholism. They noted that, in addition to cognitive and motor impairment effects, many of alcohol's chronic and neurotoxic effects are the result of disturbances in glutamatergic neurotransmission. For example, they suggested that up-regulation of NMDA receptors, in response to chronic inhibition by ethanol, mediates withdrawal, the cognitive deficits associated with alcohol dementia and Wernicke-Korsakoff syndrome, and leads to cell death through chronic augmentation of postsynaptic neurons (an effect known as excitotoxicity). They also proposed that *decreased* (or down-regulated) glutamate receptor density occurring in the developing fetus in response to intrauterine alcohol exposure is a mechanism for fetal alcohol syndrome.

Converging evidence suggests that the endogenous opiates are an important mechanism for alcohol's reinforcing effects. Kranzler and Anton (1994) pointed to the following findings in summarizing the evidence for a role for endogenous opiates in alcohol use and alcohol use disorders: (a) lower basal levels of plasma and cerebral-spinal fluid beta-endorphins have been observed in alcoholics compared to nonalcoholics; (b) alcohol preferring mice have demonstrated lower levels of endogenous opiates prior to alcohol consumption; (c) basal beta-endorphin levels were found to be comparable for asymptomatic offspring of alcoholics and abstinent alcoholics, and were significantly lower in those with a family history of alcoholism than individuals without a family history of alcoholism; (d) after consuming alcohol, asymptomatic offspring of alcoholics exhibited a significantly greater increase in beta-endorphin levels, resulting in levels comparable to those demonstrated following alcohol ingestion by adult offspring of nonalcoholics; and (e) opioid antagonists (e.g., naltrexone) have been shown to reduce alcohol consumption, craving, and risk for relapse. It appears that the delta opioid receptor is an important receptor for alcohol's reinforcing effects (Froelich et al., 1991). Based on findings from controlled clinical trials that showed naltrexone in conjunction with therapy effectively decreased alcohol use and problems (O'Malley et al., 1992; Volpicelli, Alterman, Hayashida, & O'Brien, 1992), this opioid antagonist was approved for the

pharmacological treatment of alcohol dependence (as part of a comprehensive treatment program) by the U.S. Food and Drug Administration.

Several of the neurotransmitters discussed earlier, as well as others, are implicated in withdrawal and tolerance from chronic alcohol consumption. Increases in excitatory neurotransmitters, as well as reduced input by inhibitory neurotransmitters, are associated with alcohol withdrawal (see Glue & Nutt, 1990, for a review). Alcohol tolerance is thought to be at least partially the result of neuronal adaptation to the acute effects of alcohol (NIAAA, 1993). The down-regulation of GABA receptors appears to be important in both withdrawal and tolerance, as research has shown that sensitivity to GABA agonists decreases with chronic alcohol exposure (Dietrich, 1987). Adenosine, norepinephrine, and vasopressin are also implicated in the development and maintenance of tolerance (NIAAA, 1993).

PSYCHOLOGICAL ETIOLOGIC FACTORS

Psychological approaches to the study of alcohol use and misuse can be broadly classified into four categories: (a) personality theories; (b) cognitive/social learning theories; (c) psychopharmacological approaches; and (d) social interactional or developmental theories (Blane & Leonard, 1987; Leonard & Blane, 1999). The first three of these broad perspectives are summarized here and the last is reviewed in the subsequent section on putative social-developmental etiologic factors.

Personality Theories

Personality traits have maintained a near ubiquitous presence in psychologically based theories of alcoholism. Despite the apparent conceptual appeal of an "addictive personality," decades of empirical research have failed to identify a unique constellation of personality traits that characterize alcoholics. Nevertheless, there is convergent evidence for the etiologic significance of specific, broad-based personality constructs for alcohol abuse and dependence, particularly within the context of larger psychosocial models (see Sher, Trull, Bartholow, & Vieth, 1999, for a review).

There are a number of conceptual and methodological issues relating to the study of personality and alcohol that limit the confidence with which the results of given studies can be interpreted. For example, there is general consensus that alcoholism is both clinically and etiologically heterogeneous, and failure to consider relevant subtypes may mask possible relations. As noted earlier, individuals with alcohol use disorders are at increased risk for other psychopathology, making unambiguous attribution of personality characteristics to a particular disorder problematic. Additionally, ambiguity has often been more the exception than the rule with respect to operationalizing personality (see Nathan, 1988).

Relations between alcohol abuse or dependence and personality may be artifactually influenced by factors such as content overlap between purported personality measures and diagnostic criteria (e.g., drinking-related behavior) or by

"third variables" (e.g., gender, developmental stage; Sher et al., 1999). With respect to study designs, cross-sectional studies, the most frequently used methodology in the study of personality and alcoholism, are incapable of resolving whether personality factors are antecedents to, or consequences of, alcohol use disorders. Prospective designs, although useful with respect to the resolution of temporal precedence, are not immune to third variable alternative explanations.

Consistent with a more comprehensive review of this topic (Sher & Trull, 1994), this discussion is limited to three broad-band personality dimensions (i.e., neuroticism/emotionality, impulsivity/disinhibition, and extraversion/sociality), each of which have been found to be associated with alcohol abuse and dependence. Empirical support for this classification scheme comes from a study that factor analyzed 46 scales that purportedly measure basic dimensions of personality (Zuckerman, Kuhlman, & Camac, 1988). Others, notably Tarter (1988) and Cloninger (1987), used different, plausible, three-factor classification schemes, and we note also that the five factor model of personality may have utility in the prediction of alcohol use disorders (see Martin & Sher, 1994, and Sher et al., 1999).

There is consistent empirical evidence that alcoholics exhibit significant elevations on measures of neuroticism/emotionality (Barnes, 1979, 1983; Sher et al., 1999). The frequent co-occurrence of anxiety and alcohol use disorders also is consistent with a relationship between negative affect and alcohol use disorders (Kessler et al., 1997; Kushner et al., 1990). Findings from cross-sectional studies of COAs have been mixed, with some studies noting differences in measures of neuroticism/emotionality between high risk and low risk individuals (e.g., Finn & Pihl, 1987; Sher et al., 1991), whereas at least one other study found no differences (Schuckit, 1983). Additionally, another cross-sectional study found that harm avoidance, a measure conceptually similar to neuroticism, predicted negative alcohol consequences and alcohol dependence symptoms, but not quantity-frequency indices (Sher, M. Wood, Crews, & Vandiver, 1995). Historically, there has been less evidence from prospective studies regarding the importance of neuroticism/emotionality in predicting alcohol abuse or dependence, at least in men (e.g., Jones, 1968; Robins, Bates, & O'Neal, 1962; Vaillant & Milofsky, 1982). However, more recent prospective studies have found neuroticism/emotionality to be predictive of subsequent alcohol involvement (Caspi et al., 1997; Chassin, Curran, Hussong, & Colder, 1996; Cloninger, Sigvardsson, & Bohman, 1988; Labouvie, Pandina, White, & Johnson, 1990; Sieber, 1981). In sum, particularly when drawing on the relatively sparse existing database of prospective studies, the etiologic relevance of neuroticism/emotionality remains unresolved. Enhanced understanding of the role of neuroticism/emotionality in alcohol use disorders may be achieved by consideration of potential moderators of this relation (Sher et al., 1999). For example, there is some evidence that neurotic traits may be particularly etiologically significant for alcohol abuse and dependence among women (e.g., Jones, 1971).

Impulsive/disinhibited traits appear to be the most etiologically significant personality dimensions for alcohol use and misuse. This taxonomy includes such constructs as sensation seeking, aggressiveness, impulsivity, psychoticism, and novelty seeking (Sher & Trull, 1994). The high degree of comorbidity between alcohol use and antisocial personality disorders noted earlier is consistent with the high level of impulsivity and antisociality often exhibited by alcoholics (Regier et al., 1990). In cross-sectional high risk studies, COAs consistently differ from nonCOAs on indices of impulsivity, novelty seeking, antisociality, and aggression (Alterman et al., 1998; Sher et al., 1995). Most critically, prospective studies consistently indicate that traits such as aggression, conduct problems, impulsivity, unconventionality, and novelty seeking strongly portend the development of alcohol misuse, as well as other forms of substance misuse (Bates & Labouvie, 1995; Caspi et al., 1997; Cloninger et al., 1988; Hawkins et al., 1992; Pederson, 1991; Schuckit, 1998; Zucker Fitzgerald, & Moses, 1995; Zucker & Gomberg, 1986).

It should be noted that whether or not these personality dimensions constitute motivational traits or behavior has been the subject of some debate. Nathan (1988) suggested that it is primarily behavior that is etiologically significant for substance abuse and concluded that the evidence for the prognostic importance of personality traits more narrowly defined is largely nonexistent. Others (e.g., Zucker & Gomberg, 1986) have claimed that "antisocial personality is part of personality and it plays a significant etiological role" (p. 785). As Sher and Trull (1994) noted, the debate is largely centered on the question of how personality is operationalized.

Reviews of the literature suggest that extraversion/sociability does not tend to distinguish alcoholic and nonalcoholic individuals (Barnes, 1983; Cox, 1985; Lang, 1983). Further, high-risk, cross-sectional studies have not consistently demonstrated COA/nonCOA differences on measures of extraversion/sociability (Sher, 1991), although one study did find that sociability predicted substance use among adolescent COAs but not controls (Molina, Chassin, & Curran, 1994). However, there is some evidence from longitudinal studies to suggest that extraversion/sociability predict subsequent alcohol misuse (Jones, 1968; Kilbey, Downey, & Breslau, 1998; Sieber, 1981). Sher et al. (1999) suggest that the seeming paradox between the null findings in alcoholic samples and the positive findings in non-clinical samples may be resolved by consideration of the course of the disorder. Specifically, extraversion/sociability may be important risk factors for the *development* of alcohol problems, but there is evidence suggesting that this trait becomes increasingly "masked" as alcohol dependence increases (Kammeier, Hoffman, & Loper, 1973).

In summary, the existing literature indicates that impulsivity/disinhibition, and possibly neuroticism/emotionality, appear to be etiologically important for alcohol misuse. The role of extraversion/sociability is less certain, but there is some evidence supporting this trait as etiologically relevant in the development of alcohol problems. However, demonstration of significant correlations between personality dimensions and alcohol use disorders does little to establish

their importance in the etiology of alcohol use disorders. Current theorizing has evolved to the point where personality traits are typically viewed as important mediating or moderating variables within larger psychosocial etiologic models (e.g., Cloninger, 1987; Jessor & Jessor, 1977; Rogosch, Chassin, & Sher, 1990; Sher, 1991; Sher & Trull, 1994; Zucker, 1987; Zucker & Gomberg, 1986).

Cognitive/Social Learning Theories

The following section briefly summarizes recent research examining cognitive factors of putative etiological relevance in the development and maintenance of alcohol use and misuse. For a more comprehensive review of social learning theory approaches as applied to alcohol use and alcoholism, see Maisto, Carey, and Bradizza (1999).

Over the past 20 years, alcohol outcome expectancies, have figured prominently in the search for the psychosocial correlates and determinants of alcohol use and misuse. An outgrowth of learning theory and social learning approaches, alcohol outcome expectancies can be defined as beliefs that people have about the behavioral, cognitive, and emotional effects of drinking alcohol (Goldman, S. Brown, & Christiansen, 1987). A great many cross-sectional studies have found alcohol outcome expectancies to be strong correlates of both alcohol use and misuse for adolescents, college students, and adults, across drinking patterns ranging from abstinence to alcoholism (e.g., S. Brown, Goldman, & Christiansen, 1985; Connors, O'Farrell, Cutter, & Thompson, 1986; Fromme, Stroot, & Kaplan, 1993; Leigh, 1987; Leigh & Stacy, 1993; Mann, Chassin, & Sher, 1987; M. Wood, Nagoshi, & Dennis, 1992). Although more research has focused on positive rather than negative outcome expectancies, there is sufficient evidence to suggest that the latter also may be important predictors of alcohol use and misuse (Adams & McNeil, 1991; Leigh, 1989). Nevertheless, in studies involving direct comparison of these two types of expectancies, positive outcome expectancies have wielded greater prediction on indices of use and problems (Fromme et al., 1993; Leigh & Stacy, 1993; Stacy, Widaman, & Marlatt, 1990).

Researchers also have begun to examine outcome expectancies as mediators (Sher et al., 1991) and moderators (Cooper, Russell, Skinner, Frone, & Mudar, 1992; Kushner, Sher, M. Wood, & P. Wood, 1994) of relations between alcohol use and misuse and other psychosocial constructs. Studies of adolescents and children have supported the hypothesis that alcohol outcome expectancies play a role in the initiation of drinking in that they are present, presumably via vicarious learning, prior to personal drinking experience and predict subsequent alcohol use (Christiansen, G. T. Smith, Roehling, & Goldman, 1989; P. Miller, G. T. Smith, & Goldman, 1990; G. T. Smith, Goldman, Greenbaum, & Christiansen, 1995).

Comparatively few prospective studies examining relations between alcohol outcome expectancies and alcohol use and misuse have been conducted. Nonetheless, the small body of existing literature supports a role for outcome expectancies in the etiology of alcohol use, and perhaps in the escalation of

drinking to problematic levels. Outcome expectancies have been identified in children as young as age 8, become more homogeneous in older age groups, and, at least for early adolescents, increase over time (Miller et al., 1990; G. T. Smith et al., 1995). In contrast to these findings, a four-year prospective study of college students, observed significant decreases in alcohol outcome expectancies during young adulthood (Sher, M. Wood, P. Wood, & Raskin, 1996). Combining this study with those described above, the literature suggests that outcome expectancies are initially formed through vicarious learning, are augmented by early alcohol use (as well as numerous other social influences), and then are subsequently tempered by more substantial experience with alcohol. Prospective studies also have provided empirical evidence regarding reciprocal influence between alcohol outcome expectancies and alcohol use (Bauman, Fisher, Bryan, & Chenowith, 1985; Sher et al., 1996; G. T. Smith et al., 1995), suggesting a potential role for outcome expectancies in the escalation of drinking to problematic levels. Alternatively, at least one other study (Stacy, Newcomb, & Bentler, 1991a) did not find evidence for reciprocal influence, perhaps due to a substantially longer follow-up interval. Thus, it appears that alcohol outcome expectancies play a role in the initiation of alcohol use, and alcohol use in turn strengthens outcome expectancies.

Additionally, researchers are beginning to apply contemporary cognitive theory and methodology to the study of alcohol outcome expectancies (see Goldman, DelBoca, & Darkes, 1999 for a review). Rather, Goldman, Roehrich, & Brannick (1992), in an application of semantic network theory, used multidimensional scaling techniques to categorize expectancies along dimensions of social/positive to antisocial/negative and sedative versus arousing effects. They found that for light drinkers, the most highly endorsed effects were related to sedation, whereas heavy drinkers endorsed more arousing effects. They also noted that negative expectancies seemed to be less frequently accessed, suggesting they are further along the activation network and thus are presumably less likely to influence drinking behavior.

In sum, alcohol outcome expectancies appear to be etiologically significant for alcohol use and misuse. Research and theory in this area has begun to move beyond static descriptions of relations between outcome expectancies and drinking behavior, and instead examine the role of alcohol outcome expectancies within the context of larger psychosocial models. For example, Sher (1991) suggested that outcome expectancies may be etiologically important as either mediators (e.g., of individual differences in alcohol sensitivity), or moderators (e.g., of relations between more distal psychosocial variables such as negative mood states and drinking behavior). Finally, the modification of outcome expectancies has potential implications with respect to prevention and intervention efforts. To this end, Darkes and Goldman (1993, 1998) provided evidence for the effectiveness of an intervention challenging social and sexual outcome expectancies in decreasing drinking levels over brief (2-week) follow-ups.

Drawing from motivational models of alcohol use and misuse (e.g., Cox & Klinger, 1988), psychosocial research has examined cross-sectional associations between particular

types of drinking motives and alcohol use and problems in adolescent, college student, and adult samples (Carey & Correia, 1997; Cooper, 1994; Cooper, Frone, Russell, & Mudar, 1995). In a college student sample, Carey and Correia (1997) found that negative reinforcement motives demonstrated stronger associations with alcohol problems than did positive reinforcement motives. Cooper (1994) found support for a four-factor measure of drinking motives derived from the model proposed by Cox & Klinger (1988), with subsequent analyses indicating that both negative (coping) and positive (mood enhancement) motives were associated with adolescent alcohol use and problems. Cooper et al. (1995) extended the earlier study by examining relations between mood enhancement and coping motives and patterns of alcohol use and problems in both an adolescent and adult sample. Consistent with the hypothesis that negative reinforcement motives would be more predictive of pathological drinking patterns, in both samples coping motives were related to both alcohol use and problems, while enhancement motives were related to alcohol use but not directly related to problems.

Coping skills also have been identified as an important psychosocial determinant of alcohol use and misuse. From a social learning perspective, alcohol misuse may occur when environmental stressors overwhelm coping abilities, particularly in conjunction with higher levels of positive alcohol outcome expectancies (Abrams & Niaura, 1987). Wills (1986) noted an inverse relation between perceived coping skills and alcohol use among adolescents in both cross-sectional and longitudinal analyses. Further, he found that coping moderated life stress-alcohol use relations, with a strong relation demonstrated at lower levels of coping and weaker relations at higher levels of coping. Cooper, Russell, and George (1988) found that positive alcohol outcome expectancies moderated the relation between coping strategies and alcohol use, such that individuals with high outcome expectancies who used avoidant styles of coping with negative affect were most likely to cope by using alcohol. These results have also been replicated in a college student sample (Evans & Dunn, 1995).

Psychopharmacological Approaches to Alcohol Use and Misuse

Motivation to drink can result from either the positive or negative reinforcement properties of alcohol. The tension-reduction hypothesis (TRH; Cappell & Greeley, 1987; Greeley & Oei, 1999) is the most prominent example of the latter class of negative reinforcement approaches to understanding alcohol use and misuse. Basically, the TRH postulates that: (a) alcohol is tension reducing and (b) in stressful situations individuals will be motivated to drink. Empirical evidence for the TRH is mixed, at least in part due to differences in operationalization of key variables (e.g., tension), and methodologies (e.g., cross-sectional vs. prospective, experimental vs. correlational; Pohorecky, 1991).

Contemporary refinements of the TRH have focused on examinations of relations between experimentally elicited stress and alcohol consumption, and have more explicitly incorpo-

rated the notion that the stress reducing effects of alcohol are centrally (e.g., CNS) mediated (Sayette, 1993; Sher, 1987). In the following we summarize the stress response dampening model (Levenson, Sher, Grossman, Newman, & Newlin, 1980; Sher, 1987), as well as two other psychopharmacological models that draw heavily on information-processing explanations of alcohol's effects—the attention-allocation model (Steele & Josephs, 1988; 1990), and the attention-disruption model (Sayette, 1993).

Sher (1987) noted that the stress response dampening (SRD) model is essentially a scaled down TRH, in which alcohol is hypothesized to reduce responsivity to a stressor and thus is particularly reinforcing in certain stressful situations. SRD effects have been most consistently demonstrated with respect to cardiovascular response, but have been observed with other physiological, self-report, and behavioral measures as well (Sayette, 1993; Sher, 1987). Evidence for the etiologic significance of stress response dampening comes from studies that have found that individual differences in susceptibility to alcohol use disorders (i.e., behavioral undercontrol personality traits, family history of alcoholism) are associated with increased sensitivity to alcohol's stress dampening effects (Finn & Pihl, 1987; Levenson et al., 1987; Sher & Levenson, 1982; Sher et al., 1994). Although the mechanism(s) of the SRD effect are unclear and critical tests of the model have not been conducted, it has been suggested, consistent with many of the findings reviewed under neurochemical mediators of alcohol's effects, that GABA and possibly norepinephrine are implicated in alcohol's tension reducing effects (Sher, 1987).

Steele and Josephs (1988, 1990) proposed that whether alcohol is stress reducing or stress inducing is contingent on both alcohol's effects on information processing and environmental factors. They labeled the phenomenon "alcohol myopia" and described it as a narrowing in the ability to retrieve a range of perceptual cues to those most immediate and salient in a given situation. While questions remain with regard to specific aspects of the theory, empirical tests of the model have typically yielded positive results (Sayette, 1999). Steele and colleagues consistently demonstrated that in conjunction with moderate doses of alcohol, pleasant or neutral distraction (e.g., rating slides of famous paintings) leads to reductions in self-reports of state anxiety during a countdown period to a self-disclosing speech. Demonstration of alcohol's anxiogenic effects in lieu of distraction has been less consistent, but nonetheless has been noted (Steele & Josephs, 1990). The attention-allocation model is more comprehensive than previous models in that it proposes an explanation for both the anxiolytic and anxiogenic effects of alcohol, but does not explain demonstrated SRD effects in the absence of distracting activity (Sayette, 1993). Nevertheless, given the positive results to date, future research that investigates relations between this construct and other risk factors for alcohol misuse could yield valuable information on the etiology of alcohol use and misuse.

Sayette (1993) proposed a model hypothesizing that SRD effects are mediated by disruption in the appraisal of stressful information and accompanying impairment in the ability to

integrate it with related information from long-term memory. Sayette argued that if a stressor is sufficiently appraised, alcohol's effects will be anxiogenic; but if encoding of the stressor is disrupted, alcohol will be anxiolytic. Direct tests of the model have yet to be conducted (e.g., measurement of disruption of cognitive appraisal in conjunction with SRD). Nonetheless, the model appears to resolve some existing discrepancies in the literature by consideration of a range of factors, including the temporal ordering of alcohol administration and stress manipulations, the implications of dosage and stressor differences, and alcohol's known deleterious effects on the encoding of information.

There is a fairly large body of human and animal research examining the latter postulate of the TRH—that stressful situations will result in increased alcohol consumption. Cappell and Greeley (1987) noted that in both humans and animals, experimentally-induced *conflict* has typically resulted in increases in alcohol consumption, while more ecologically valid laboratory paradigms (e.g., social anxiety stressors) have yielded less consistent results. Sher (1987) concluded that the likelihood that stress will lead to alcohol consumption is qualified by a number of psychological and social factors, particularly the availability of alternative means of coping and the consideration of the potentially negative consequences of alcohol consumption.

Two studies have reported results supportive of the stress-induced drinking aspect of the TRH for men. Lang, Pelham, Johnston, and Gelernter (1989) examined subjective distress and alcohol consumption among participants who interacted with children trained to behave in both "normal" and "deviant" (Attention Deficit Disordered/Conduct Disordered) styles. Both men and women exhibited significantly higher levels of subjective distress as a function of interacting with the "deviant" child, but only men drank significantly more alcohol in this situation. Stasiewicz and Lisman (1989) randomly assigned undergraduate men to be exposed to either an infant crying or a smoke alarm, followed by a taste-testing task. Participants who heard the infant crying reported higher levels of distress and consumed significantly more alcohol than those exposed to the smoke alarm.

Neither the original tension reduction hypothesis, nor the subsequent models of alcohol consumption were proposed as comprehensive models of alcohol use and misuse. Nonetheless, they have been important in understanding some of the conditions under which alcohol consumption can be reinforcing and in linking these reinforcing effects with putative vulnerability factors.

SOCIAL-DEVELOPMENTAL PUTATIVE ETIOLOGIC FACTORS

Theories on the initiation, maintenance, and escalation of alcohol and substance use have included social factors as both direct and indirect influences (Jessor & Jessor, 1977; Flay & Petraitis, 1994; Kandel, 1973; Kaplan, 1980; Zucker & Gomberg, 1986). In large part due to the observation that al-

coholism tends to run in families, studies of family environment and interaction comprise the largest area of inquiry in this domain. However, other social variables, most notably peer and mass media influences, have been linked to alcohol use and misuse.

Familial Influences on Alcohol Use and Misuse

The family, as a primary and initial agent of socialization, obviously exerts a myriad of direct and indirect influences on the developing individual. A range of familial factors have been found to relate to either the intergenerational transmission of alcohol use and misuse, or to poor adolescent or adult adjustment more generally. These include parental monitoring, communication, cohesiveness, social support, parent and sibling attitudes toward alcohol use, familial conflict, parental loss through divorce or separation, disruption of family rituals, unfair and harsh disciplinary practices, and parent and sibling modeling (Barnes, 1990; Barrera, Chassin, & Rogosch, 1993; Bennett, & Wolin, 1990; Catalano et al., 1992; Duncan, Duncan, & Hops, 1994; Harburg, Davis, & Caplan, 1982; Holmes & Robins, 1987; Isohanni, Oja, Moilanen, & Koironen, 1994; Kandel & Andrews, 1987; Zucker, 1976).

Essentially, each of the factors listed can be classified as related to either parental nurturance, control, or modeling (either directly through imitation of behaviors or indirectly through the adoption of attitudes, expectations, or family rituals; Barnes, 1990; Jacob & Leonard, 1994). Researchers have begun to conduct more fine-grained analyses to examine potential mediators and moderators of relations between family factors and alcohol use, and have extended these investigations to racially heterogeneous samples.

Chassin, Barrera, and colleagues, in a programmatic series of studies, have examined mediational and moderational factors in relations between family history of alcoholism and adolescent substance use and psychological symptomatology. Chassin, Rogosch, and Barrera (1991) found higher levels of both substance abuse and psychological symptomatology among offspring of current alcoholics compared to controls. Barrera et al. (1993) examined the effects of social support and social conflict conjointly and found that their effects were largely independent. Lack of social support from parents was predictive of substance use, whereas conflict predicted general externalizing behavior, but not substance use. Chassin, Pillow, Curran, Molina, and Barrera (1993) demonstrated that decreased parental monitoring and environmental stress-negative affect appear to underlie the link between a family history of alcoholism and adolescent substance use. They also observed a direct effect, consistent with a modeling interpretation, from mothers' alcohol use to adolescent substance use. Taken together, these findings suggest multiple pathways for substance use in at-risk individuals. Parental alcohol abuse appears to be related to offspring substance use directly by social learning, and indirectly by decreased parental monitoring and environmental stress, both of which serve to increase the likelihood of affiliation with drug-using peers. This affiliation is, in turn, strongly associated with drug use by offspring. Molina et al. (1994), examined whether the observed relations between par-

ent monitoring and stress-negative affect were moderated by family history status. They found no evidence for differential relations, instead noting significant relations between these factors regardless of family history status, suggesting prevention efforts would equally apply to those with and without a family history of alcoholism.

Sher and colleagues, utilizing data from an ongoing longitudinal study of young adults at low and high risk for the development of alcoholism, examined potential mediators of the family history-substance use disorder relation in two recent studies. Sher et al. (1997) found that retrospectively assessed childhood stressors (e.g., verbal, emotional, physical and sexual abuse) demonstrated consistent and often robust relations with family history status. This study also observed significant associations between several childhood stressors (most notably embarrassment, emotional, physical, and sexual abuse of the participant, exposure to verbal abuse of other family members) and lifetime alcohol use disorder diagnoses. Additional analyses indicated that childhood stressors partially mediated the family history—alcohol use disorder relation, although the magnitude of the mediational effect was not large. Erickson, Sher, and P. Wood (1997) used state-trait analyses to prospectively examine alcohol expectancies, childhood stressors, and a vulnerability index (comprised of broad-band “constitutional” predictors of family history status) as mediators of the family history—substance use disorder relation. They found consistent evidence for a mediational role of alcohol expectancies and the vulnerability index across alcohol, other drug, and tobacco dependence, while childhood stressors mediated relations between family history of alcoholism status and tobacco dependence.

Overwhelmingly, research to date on familial influences on alcohol use and misuse has been conducted using predominantly White samples. As noted earlier, descriptive statistics regarding alcohol use, misuse, morbidity, and mortality among minority populations are available from the epidemiological literature, but until relatively recently little has been known about whether observed social influence factors generalize to minority populations. Barnes and colleagues, utilizing a general population sample that oversampled Blacks, reported on familial influences on alcohol use and misuse among black and white adolescents. In both cross-sectional and longitudinal analyses, they observed that high parental monitoring and social support were important protective factors for adolescent alcohol abuse and deviant behaviors more generally (Barnes & Farrell, 1992; Barnes, Farrell, & Banerjee, 1994). Although for the most part the lack of higher order interactions observed by Barnes et al. (1994) suggests that familial influences are similar for Black and White adolescents, some interesting interactions did emerge. Specifically, religiosity may insulate Black adolescents from abuse, and peer drinking appears to be a stronger influence for deviant behaviors among White rather than Black adolescents. Catalano et al. (1992), noted that patterns of drug use *initiation* differed among ethnic groups and sexes, even after controlling for socioeconomic factors. They also noted that family factors appear to exert the greatest protective influence for Black youths and the least protective for Whites.

Imitative modeling of parent or sibling drinking behavior is one of the most straightforward hypotheses regarding the intergenerational transmission of alcohol misuse. Whereas there is evidence to suggest its importance for the initiation of alcohol and other substance use (e.g., Chassin et al., 1993; Kandel & Andrews, 1987), it also appears that relations between parent and offspring drinking habits vary systematically. For example, Harburg and colleagues, in a series of studies, found evidence for imitative modeling effects associated with abstaining and light drinking parents, and “fall-off” (i.e., negative modeling or nonimitative) effects associated with heavy drinking parents (Harburg et al., 1982; Harburg, DiFranceisco, Webster, Gleiberman, & Schork, 1990; Harburg, Gleiberman, DiFranceisco, Schork, & Weissfeld, 1990; Webster, Harburg, Gleiberman, Schork, & DiFranceisco, 1989). Additionally, McCord (1988) demonstrated that father-son transmission of alcoholism was more likely when the alcoholic father was held in high esteem by the mother.

Studies examining the moderating role of family interactions on the later expression of alcoholism among offspring of alcoholics have uncovered some provocative findings. Wolin and colleagues, using semistructured interviews with both parents and adult offspring, assessed the extent to which “family rituals” (e.g., celebrating holidays, taking vacations) were disrupted by an alcoholic parent’s drinking. Families were classified as either “distinctive” (little or no family ritual disruption) or “subsumptive” (family rituals subsumed by an alcoholic parent’s drinking). Wolin and colleagues (Wolin, Bennett, & Noonan, 1979; Wolin, Bennett, Noonan, & Teitelbaum, 1980) found that subsumptive families and, to a lesser extent intermediate families, tended to produce alcoholic offspring whereas distinctive families did not. An additional study reported that offspring of alcoholics who exhibited high levels of “deliberateness” in establishing and maintaining rituals in their own families were less likely to experience alcohol problems themselves (Bennett, Wolin, Reiss, & Teitelbaum, 1987). As Sher (1991) previously noted, these findings are compelling, but await replication in larger samples with systematic attempts to eliminate potential third-variable explanations. Additionally, prospective studies are needed to more clearly elucidate the temporal ordering of effects.

Peer, Social Network, and Broader Sociocultural Influences. In a review of family and peer influences on adolescent alcohol use, Jacob and Leonard (1994) noted that the study of peer influences has, in large part, received its impetus from observed associations between: (a) early peer rejection and the development of delinquent behavior in childhood and adolescence; and (b) adolescent alcohol involvement and association with deviant peers. They also noted that although there is little doubt that substance use by friends, particularly close friends (e.g., Morgan & Grube, 1991), is among the strongest predictors of adolescent substance use, the question of whether the mechanism for these effects is one of self-selection versus peer influence remains unresolved. Toward this end, two recent studies (Curran, Stice, & Chassin, 1997; Wills & Cleary, 1999) examined selection versus socialization (peer influence) mechanisms in adolescent substance

use. In both studies consistent evidence was observed for peer influences mechanisms, with more modest evidence for selection effects observed in one study (Curran et al., 1997), but not the other.

Joint investigations of peer and family influences have indicated that there are multiple pathways to adolescent alcohol use and misuse, and that the importance of these pathways is likely to vary at different developmental stages (Chassin et al., 1993; Duncan et al., 1994; Gerrard, Gibbons, Zhao, Russell, & Reis-Bergan, 1999; Kandel & Andrews, 1987). Kandel and Andrews (1987) compared the influences of parents and peers on adolescent drinking and drug use and concluded that peer influences were much more important with respect to adolescent frequency of drinking. Alternatively, for the initiation of alcohol use, parent factors played a larger role than peer influences, although the total amount of variance explained was quite small (7%), making inferences regarding the substantive importance of these findings difficult. Kandel and Andrews also noted, consistent with Chassin et al. (1993), that closeness to parents was a protective factor, both directly through alcohol use and indirectly through decreased likelihood of affiliating with drug-using peers. Ary, Tildesley, Hops, and Andrews (1993) observed that both parent and peer attitudes and drinking behaviors were prospective predictors of adolescent alcohol use. Duncan et al. (1994) suggested that the relation between family influence and childhood/adolescent alcohol use may be curvilinear, waxing in late childhood and middle-to-late adolescence, and waning in early adolescence when peer influences assume greater importance.

Social influence factors of another sort have been noted in research with college students. Baer, Stacy, and Larimer (1991) found that college students’ misperceptions regarding drinking norms exist across several reference groups including best friends, immediate living group, and for students in general. They noted a strong tendency for individuals to nearly always perceive close friends and members of social reference groups as consuming alcohol more frequently than themselves. Although the particular mechanisms related to this effect are not clear, the findings suggest that these misperceptions could influence heavier drinking or insulate individuals or groups against recognition of hazardous drinking.

Mass Media Effects on Alcohol Use and Misuse. Alcohol commercials and portrayals of alcohol consumption are extremely prevalent features of the mass media landscape. For example, in 1990 and 1991, average alcohol advertisements per television hour ranged from 5.7 during major professional sports events to 0.22 during situation comedies, with an average of over 6 drinking acts per hour of prime time television (Grube, 1993). Content analyses of commercials and prime-time fictional television programs indicate that drinkers tend to be characterized as attractive, affluent, sociable, have high social status, typically experience positive and seldom experience negative consequences (Grube, 1993; Wallack, Grube, Madden, & Breed, 1990). One survey indicated that 73% of the general public agreed that alcohol advertising was a major influence on underage drinking (Grube & Wallack, 1994).

Empirically, much less is known about the effects of high levels of exposure to alcohol advertising and alcohol portrayals on actual alcohol consumption, drinking norms, and alcohol outcome expectancies. Smart (1988) reviewed the effects of alcohol advertising on overall alcohol consumption by examining: (a) advertising bans and restrictions; (b) correlational studies of exposure to advertisements; (c) econometric studies (correlations of advertising expenditures with aggregate measures of alcohol consumption); and (d) experimental studies. He noted that methodological problems severely limited the interpretability of findings, but generally concluded that there was little evidence to suggest any more than weak associations between advertising and alcohol consumption. Nonetheless, he suggested that more carefully designed econometric, experimental, and prospective studies would be useful additions to the extant literature.

Typically, researchers in the area have tacitly assumed that mere exposure to alcohol ads or portrayals (often indirectly assessed) is sufficient to elicit attitudinal and behavioral changes. Grube and Wallack (1994) suggested, in accordance with information processing theory, that advertisements may only affect attitudes and behaviors when they are attended to and remembered. To this end, they investigated relations between awareness of television beer advertising, drinking knowledge, alcohol outcome expectancies, and intentions to drink as adults among a group of 10- to 14-year-old youths. In conservative analyses, they demonstrated: (a) awareness of alcohol advertising was significantly associated with increased knowledge of brands and slogans and with positive beliefs about drinking; (b) alcohol outcome expectancies mediated the relation between alcohol advertising and intentions to drink as an adult; and (c) awareness of ads was *not* significantly related to negative beliefs about alcohol. These findings indicate that cognitive variables (e.g., alcohol outcome expectancies) may be an important mechanism of influence for mass media effects, and suggest prevention efforts should not ignore alcohol advertising as a potential source of social influence.

CONCLUSIONS

In reviewing etiological factors in alcohol use and misuse, several important issues need to be highlighted. First, alcohol is a drug that affects most of the neurotransmitter systems that have been identified as playing key roles in motivating and regulating human behavior. The neuropharmacological consequences of alcohol consumption are likely to play a key role in both alcohol-seeking behavior and determining the amount an individual consumes on a given occasion. Second, there are large individual differences in the likelihood that persons will misuse alcohol. Many of these individual differences are probably determined by genetic factors. However, the mechanisms describing how heredity exerts its effects are currently unknown. Although available research suggests that vulnerability is associated with differential sensitivity to alcohol effects, other genetically mediated mechanisms that do not rely on individual differences in ethanol sensitivity are also quite plausible (Sher, 1991). Third, at present, the strongest correlates (both cross-sectionally and prospectively) of alcohol use

and misuse are psychological constructs including certain behavior patterns (especially those characterized by impulsivity) and alcohol outcome expectancies. Fourth, social influences ranging from the family, to peers, to mass media and other cultural and political variables all appear to exert important influences on alcohol use. A comprehensive understanding of the etiology of alcohol misuse will require an understanding of how these diverse factors influence alcohol consumption both independently and in combination.

The broad range of biopsychosocial determinants of alcohol consumption and problems have important implications for development of techniques for preventing and treating alcohol misuse. Although intervention in alcohol problems is discussed elsewhere in this volume (see Altman & Goodman, chap. 36), it is worth noting here that interventions have been developed that target biological, psychological, and social variables. For example, at the biological level, there appears to be therapeutic benefit to employing pharmacologic agents that reduce craving and antagonize some of the reinforcing effects of alcohol (O'Malley et al., 1992; Volpicelli et al., 1992). At the psychological level, attempts to modify individually held beliefs about the consequences of alcohol consumption (i.e., alcohol outcome expectancies), although preliminary, show promise (e.g., Darkes & Goldman, 1993; 1998). At the social level, interventions that attempt to change perceived drinking norms appear to be an important component of multi-component prevention programs (e.g., Baer, 1993; Marlatt et al., 1998) and have demonstrated efficacy in universal prevention efforts with college students (Haines & Spear, 1996). Against this background of efforts targeted at individuals, social policy interventions (e.g., increasing the drinking age, decreasing permissible blood alcohol levels for drivers, stricter enforcement and harsher penalties of drinking and driving laws) have been shown to be particularly important in reducing certain alcohol-related problems (e.g., alcohol-related motor vehicle crashes). Thus, it seems likely that the effective prevention and treatment of alcohol misuse will involve interventions at each level of biopsychosocial organization.

ACKNOWLEDGMENTS

Preparation of this chapter was supported in part by a grant from the Alcoholic Beverage Medical Research Foundation and Grant R29 AA12241 from the National Institute on Alcohol Abuse and Alcoholism to Mark D. Wood, Grant R37 AA7231 from the National Institute on Alcohol Abuse and Alcoholism to Kenneth J. Sher and by an award from the Generalist Physician Faculty Scholars Program of the Robert Wood Johnson Foundation to Daniel C. Vinson.

We gratefully acknowledge Heather Gotham and Matt Kushner, who provided valuable comments on an earlier draft.

Crosscutting Issues

Stress, Health, and Illness

Angela Liegey Dougall

Andrew Baum

University of Pittsburgh Cancer Institute

The customary introduction to stress suggests that it is still a matter of scientific debate, despite the fact that it is a common and influential state. It shares aspects of mind and body, representing a good instance of more holistic integration of these constructs. It is also a crosscutting process, influencing a wide array of illnesses, health behaviors, and aspects of health and well-being. Despite the general lack of a consensus on a precise definition of stress or the best approach to measuring it, there is considerable evidence to suggest that stress has important effects on physical and mental states, pathophysiology of disease, and performance (for reviews see Baba, Jamal, & Tourigny, 1998; Biondi & Zannino, 1997; S. Cohen & Williamson, 1991; McEwen & Stellar, 1993). This chapter considers conceptual models of stress, the broad array of behaviors and bodily systems involved in the stress response, and the impact of stress on chronic disease processes. Differences in the consequences of acute and chronic stress, as well as the implications of observed differences between them are also explored.

THE STRESS CONSTRUCT

Perhaps the most difficult aspect of studying stress is deriving a widely accepted definition of it. Most theorists agree that stress is (or can be) adaptive, that it is associated with threatening or harmful events, and that it is typically characterized by aversive or unpleasant feelings and mood. Beyond this, there are few areas of universal agreement. Some theorists have argued that stress can be positive, but others have insisted that it is a fundamentally aversive state (e.g., Baum, 1990; Selye, 1956/1984). Some have pointed out apparently simultaneous biological and psychological activation, sug-

gesting that stress is an emotion, and some have described stress as a general state of arousal associated with taking strong action or dealing with a strong stimulus (e.g., Baum, 1990; Mason, 1971). Stress has been variously defined as a stimulus, as a response, and as a process involving both. It has been described as both specific and nonspecific responses to danger with little evidence to support one or another contention. However, it appears to be a fundamental component of adjustment and adaptation to environmental change, and as such has assumed a critical role in theories of human evolution. From these many notions have come a few major theories of stress that reflect integration and synthesis of prior theories and that describe a pattern of responses to threat, harm, or loss.

Biological Theories of Stress

A history of the stress concept could begin with early philosophers, but modern stress theory really began with Cannon's work early in the 20th century. Cannon (1914) was interested in the effects of stress on the sympathetic nervous system (SNS) and with application of the concept of homeostasis to interaction with the environment. Stressful events elicited negative emotions associated with SNS activation and disequilibrium in bodily systems. This activation was associated with the release of sympathetic adrenal hormones (i.e., epinephrine, norepinephrine), which prepared the organism to respond to the danger posed, characteristically by fighting or fleeing. This early description of stress did not consider the measures of activation or persistence, focusing solely on SNS arousal and release of sympathetic hormones.

Selye (1956/1984) focused his attention solely on the activation of the hypothalamic-pituitary-adrenal cortical (HPA) axis. Initially interested in the effects of hormonal extracts, Selye (1956/1984) discovered a "universal" response to stressful events that included adrenal hypertrophy, lymphoid involution, and ulceration of the digestive tract. He characterized stress as a nonspecific physiological response to a variety of noxious events and argued that, regardless of the stressor presented, the same response was seen, driven by activation of the HPA axis.

In contrast to these more focused approaches, Mason (1971) argued that stress affected many biological systems and that responses were based on the type of stressor presented. He concluded that stress was a unified catabolic response with the primary purpose of maintaining high levels of circulating blood glucose and providing the organism with energy to sustain resistance. Although he viewed emotional reactions as nonspecific, he maintained that responses in endocrine pathways followed response patterns that were specific to the stressor.

Whereas these early biological models of stress were typically narrow in focus and ignored or only hinted at important psychological aspects of stress, their importance can be illustrated in several ways. The systems that received most attention in these early theories were the SNS and the HPA axis. Both are arguably principal drivers of stress responding and persist today as focal points in studies of physiological responses during and after stress. Work by Cannon and Selye accurately identified these systems as integral parts of the stress response and focused attention on consequences of prolonged or excessive activation of these systems as primary consequences of stress. Mason recognized the integrated nature of these responses as well as the broad panoply of responses characterizing stress. Sympathetic arousal and activation of the HPA axis are hallmarks of the stress response and have been used as manipulation checks for stressors and explored as mechanisms underlying stress effects on the body.

These theories of biological activity offered some insights into psychological aspects of stress. Cannon's (1914) notion of critical stress levels suggested that organisms had thresholds, or limits, on normal or nonpathogenic responses to threat and his discussion of emotional stress suggested that emotional stimuli and responses were important in stress as well. In addition, stressors were stimuli that had to be recognized as a threat in order to elicit a response. Selye (1956/1984) argued that adaptive energy or the capacity to adapt to stressors is limited and depletion of adaptive reserves can have consequences, an idea consistent with notions of life change, stressful life events, and aftereffects of stress (e.g., S. Cohen, 1980; Holmes & Rahe, 1967; Rahe, 1987).

As critical as they are for understanding bodily responses to threat or challenge, these theories were also important because they introduced the notion that the nervous and endocrine systems jointly produced the arousal state characteristic of stress. Cannon incorporated emotional activation in his physiological model of stress, but Selye did not consider more psychologically relevant events or dynamics directly.

Despite this, Selye was responsible for popularizing the construct and made stress theory more accessible and readily integrated into independent and parallel theories in the psychological literature on stress.

Psychological Theories

Psychological theories of stress that developed largely independent of work on its biological bases, focused on variability of response to stressors. Lazarus (1966) emphasized the contribution of the individual to the interaction with an environmental stressor. Like Mason, Lazarus argued that people actively perceived and reacted to stressors and there was considerable individual variation in this experience. The occurrence of an event alone was not sufficient to induce stress. Instead, the notion of appraisal, or cognitive interpretation of the stressor, was introduced and integrated into a transactional model. For stress to be experienced, it was necessary for an individual to appraise the event as threatening or harmful. Stress appraisals then elicited negative emotions, but unlike other models, it was the appraisal of the event, and not the emotional reaction, that determined subsequent physiological and behavioral responses. Additional appraisal processes were used by the individual to determine what available coping strategies could be used to deal with the situation and whether the problem should be attacked or accommodated.

The primary appraisals and perceived stress in this theory were important because they suggested that psychological variables or CNS activity mediate the relation between stressful events and bodily reactions. Rather than an unidirectional process originating from the occurrence of a stressor, Lazarus conceptualized stress as a dynamic process in which an individual was constantly reappraising the situation as new information was obtained. Lazarus and Folkman (1984) later expanded on this model and defined stress as the "particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (p. 19). Central to this model were the processes of cognitive appraisals and coping, both of which mediated this relation and determined stress-related outcomes.

The model of stress proposed first by Lazarus (1966) and then by Lazarus and Folkman (1984) focused on the transactional process between the individual and the environment. However, Hobfoll (1989) argued that such a definition was circular in nature and hard to test. In order to make the stress relation more specific, he based his conceptualization of stress on a model of conservation of resources. Individuals actively sought to gain and maintain resources, and stress occurred in response to the actual loss, threat of loss, or lack of gain of these resources. Individuals reacted to either real or perceived loss of resources by trying to minimize the amount of loss experienced. Although this model was more parsimonious than the Lazarus and Folkman (1984) model, it was still consistent with their general framework of appraisals of loss or threat leading to stress.

Defining Stress

A unifying theme in many of these theories is adaptation and adjustment to changes in a person's environment. Selye (1956/1984) argued that life involves constant change and adaptation. Much of this is minor and hardly noticed, not unlike the continual adjustments a person makes to the steering wheel of a car while driving it. The grooves and bumps in the road represent an uneven environment that requires small changes in steering to maintain a straight path not unlike minor or routine stressors that are encountered every day. Major stressors present dangers more similar to oncoming cars; they require more dramatic and memorable efforts to avoid collision or driving off the road. Each adjustment involves a specific response (e.g., the minor adjustment of the wheel or more effortful maneuvering to avoid other cars). Each also appears to have a nonspecific component, composed largely of SNS and HPA arousal and bodily "support" for cognitive or behavioral adjustments. When these adjustments are more substantial or sudden, they may also affect mood and behavior. Regardless, this nonspecific arousal both motivates and supports coping, making it faster, "stronger," and more effective in accomplishing the adjustments needed to adapt. Collectively, the specific coping directed at threatening, harmful, or otherwise upsetting situations and the nonspecific activation supporting these responses may be considered "stress."

There remains considerable variability in the way stress is defined or conceptualized. Consistent with the previous emphasis on adjustment and adaptation, stress can be described as "a negative emotional experience accompanied by predictable biochemical, physiological, and behavioral changes that are directed toward adaptation either by manipulating the situation to alter the stressor or by accommodating its effects" (Baum, 1990, p. 653). When challenged or threatened, both specific adjustments and supportive nonspecific activation are likely and both continue until the source of stress is eliminated or the individual has successfully accommodated its effects. In this context, stress is an adaptive process with the goal of either altering a stressful situation or adjusting to and minimizing its negative effects. When confronted with a stressor, the body responds in ways consistent with a catabolic fight or flight reaction. Negative health effects occur when these emergency responses are extreme or prolonged. Additionally, variability in the stress process occurs through the influence of factors that affect appraisal of stressors and coping efforts.

Methodological Approaches

Although these general and more specific models of stress models have guided many studies, individual researchers' operational definitions of stress have varied. Historically there has been an emphasis on the stimulus or stressor end of the model, often either measuring outcomes after an organism confronts a particular stressor or counting the number of accumulating life events. Other researchers focus on the emotional, physiological, or behavioral responses to stressors and use these responses to predict physical and mental health.

More researchers are beginning to integrate these two elements and incorporate measures of person characteristics, such as appraisal and coping, to more accurately predict who is more resilient or more vulnerable to stress.

Stimulus-based approaches often compare groups of organisms either exposed or not exposed to a particular stressor. Acute stress is often manipulated in the laboratory using administered stimuli such as noise, immobilization, and electric shock (in animals) and challenging mental tasks or threatening situations (in humans). Naturally occurring events are also examined, such as residential crowding, ambient noise, natural disasters, or life threatening accidents. Differences across levels of exposure allow researchers to determine the impact of the stressor on physical and mental health outcomes. Another common approach is to ask participants to indicate which of a list of events occurred within a given time frame (e.g., 6–12 months). Participants can also rate each event on the amount of adjustment required to adapt to the stressor. The relations observed between life event measures and outcomes were consistent but usually modest, with life events generally accounting for less than 9% of the variance in outcome measures (for reviews see Rahe, 1972; Sarason, de Monchaux, & Hunt, 1975; Zimmerman, 1983).

Substantial improvements have been made in the prediction of outcomes through the use of personal interviews, such as the Life Events and Difficulties Schedule (LEDS; G. W. Brown & Harris, 1989). Through the use of interview techniques, specific information regarding the actual event and its context can be gathered and rated by objective reviewers. Therefore, many of the response errors and sources of bias inherent in self-report measures can be minimized. Unfortunately, extensive training of interviewers and raters, as well as costs associated with lengthy individual visits with study participants, limit the feasibility of this approach. However, the incorporation of the contextual meaning of the events rather than just the occurrence of the event has increased the magnitude of the relations found between life stress and outcomes. Using this method, researchers have demonstrated that life events and chronic difficulties contribute to the risk of developing many mental and physical conditions, such as depression, schizophrenia, anxiety, myocardial infarction, multiple sclerosis, abdominal pain, and menstrual disorders (for a review, see G. W. Brown & Harris, 1989). More recently, chronic stress measured in this way has been linked to susceptibility to viral infection (S. Cohen et al., 1998). Clearly, identification of objective predictors of mental and physical health outcomes is valuable for the prediction of stress consequences. However, such an approach reveals little about the way stress works or why it has these effects.

Other theories and measures of stress focus more intently on responses, arguing that it is the response that is most closely linked to outcomes or consequences and the extent to which the event is experienced as stressful is a better metric than is the event itself. In controlled laboratory settings or in naturalistic environments, researchers can measure cognitive, behavioral, and physiological changes before, during, and/or after a stressor. Changes in these response systems can then be correlated with physical and mental health outcomes.

Individual difference variables or other factors affecting how stressful events are experienced are also important predictors of both responses and outcomes. Situational factors affecting appraisals of stressors and a person's ability to resist them, as well as individual differences in appraisal or response, are critical determinants of outcomes.

There are many important intervening variables that affect interactions of the perceiver and the situation and affect appraisals of severity or the likelihood of successful adaptation. Among the more frequently studied stress mediators are perceptions of control, predictability, coping, and the availability of social support (Aldwin & Revenson, 1987; S. Cohen & Wills, 1985; Glass & Singer, 1972; Lazarus & Folkman, 1984; Skinner, 1995; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Individuals with greater perceptions of control and more social support, as well as situations characterized by appraisals of greater predictability, typically produce less stress and better outcomes. One reason for these differential effects may be the availability of and the types of coping strategies used to deal with the event. When individuals perceive that they can control the event, it may promote the use of more problem-focused techniques or greater acceptance, thereby alleviating much of the distress experienced. Additionally, greater predictability of the event allows individuals to prepare in the time before the event to deal effectively with the situation. Similarly, perceptions of available social support may serve to enhance the coping resources of individuals through offers of tangible aid or advice.

ACUTE AND CHRONIC STRESS

Not all exposures to stressors are equal and it can probably be assumed that more or worse exposures have more impact than fewer or less severe exposures. Stressor intensity and duration likely interact to produce a range of potential effects. The most common distinction between acute and chronic stress is based on the duration of the stressor. However, as already noted, there is inter- and intraindividual variability in stress responding even to the same stressor. Therefore, acute and chronic stress may best be conceptualized by examining the interactions among the duration of the event itself (acute or chronic), the duration of threat perception (acute or chronic), and the duration of psychological, physiological, or behavioral responses (acute or chronic; Baum, O'Keeffe, & Davidson, 1990).

A "perfect acute" stress situation would refer to a situation characterized by an acute stressor duration, short-lived threat perception, and an acute response, typical of most laboratory stress situations. A subject in a laboratory study of stress is normally exposed to a brief (5–30 minutes) stressor (or combination of stressors), views it as stressful for as long as it is present, and recovers rapidly after termination of the stressor. Chronic stress, however, is more complex. A "perfect chronic" situation would refer to a chronic event, chronic threat, and chronic responding. In reality, most stressful experiences consist of combinations of acute and chronic durations of the event, threat, and response, and this characterization may not be stable. For instance, following a

hurricane (an acute event), an individual may continue to experience perceived threat or harm and may exhibit chronic responding—such as elevations in norepinephrine (NE), epinephrine (EPI), cortisol, heart rate (HR), and blood pressure (BP)—and reductions in immune system functions. However, over time the individual may start to habituate to the chronic threat and show decreased stress responding (i.e., chronic threat with short-lived responding). The goal for stress reduction is for the individual to adapt to the stress situation and no longer perceive the chronic threat or respond to it. Unfortunately, not all individuals habituate or adapt to a stressor, and chronic stress persists or can even sensitize people to new stressors.

The alterations seen in the physiological, cognitive, and behavioral response systems are generally the same in both acute and chronic stress situations, but where acute stress occurs continuously, chronic stress does not appear to be a steady-state phenomenon. Rather, responding appears to be episodic, occurring repeatedly throughout the day as reminders or unwanted intrusions accost an individual. This appears to be the case whether the stressor is still present or long past. It is unlikely that an individual is conscious of a stressor 24 hours a day, 7 days a week, 365 days a year. Instead, it seems more likely that people experience good and bad days and good and bad moments within each day. Episodes of stress may be triggered by exposures to the event, reminders of the event, or anticipation of the event. Most models of stress fail to consider the impact of this repetitive activation of stress response systems, or the possibility that the experience of chronic stress may be best characterized as acute episodes of stress related to an overarching stressor.

The episodic nature of chronic stress is supported by evidence that although certain populations report higher levels of distress than comparison groups, there is considerable day-to-day and within-day variations among individuals within the group (Dougall, Baum, & Jenkins, 1998; Stone, Reed, & Neale, 1987). These variations average to consistent high levels over longer time frames. In addition to these daily fluctuations, the response systems themselves do not always covary. Each system has its own circadian or activity-based pattern of ups and downs, as well as different reactivity and recovery times (e.g., Mason, 1968; Nesse et al., 1985). For example, EPI and NE show immediate increases in response to an acute stressor, whereas cortisol responses are delayed and last much longer. Therefore, single assessments limit an individual's view of the stress process.

It is not hard to understand why an individual faced with daily stressors (e.g., hectic commutes to work or longtime care giving to a sick relative) experiences stress or excessive demand when dealing with them. Persistence of chronic stress responding after an event is long over is harder to explain and is an important question for stress researchers to tackle. It has been suggested that one important element in understanding chronic stress is the occurrence of stressor-related intrusive thoughts, especially in the absence of an ongoing stressor (Baum, L. Cohen, & Hall, 1993; Baum, Schooler, & Dougall, 1998; Craig, Heisler, & Baum, 1996). Plenty of evidence suggests that stressor-related in-

trusive thoughts are a common symptom following threatening events (e.g., Baider & De-Nour, 1997; Delahanty, Dougall, Craig, Jenkins, & Baum, 1997; Delahanty, Herberman, et al., 1997; Ironson et al., 1997). Intrusive thoughts are thought to be part of ongoing cognitive processing of the event (Creamer, Burgess, & Pattison, 1992; Greenberg, 1995; Horowitz, 1986). They help an individual work through the situation. Indeed, as individuals recover, they report fewer stressor-related intrusions (e.g., Delahanty, Dougall et al., 1997). However, intrusive thoughts tend to be unwanted, unbidden, and uncontrollable, which are characteristics common to many other types of stressors. In at least some cases, these characteristics of intrusive thoughts may make them more stressful and are related to greater chronic stress (e.g., Dougall, Craig, & Baum, 1999). Rather than being exclusively adaptive, these thoughts may serve as stressors in their own right, possibly sensitizing individuals to other reminiscent stimuli. Intrusions combined with other environmental event-related stimuli may serve to perpetuate chronic stress by eliciting the acute episodes described earlier.

Trauma and Chronic Stress

Intrusive thoughts are most prevalent following extreme stressors. However, they do occur following less severe events and even after benign and positive events that occur in everyday life (Berntsen, 1996). Although positive and neutral intrusions also occur, intrusive thoughts with negative valences are implicated in chronic stress and are probably one of the most salient hallmark symptoms of posttraumatic stress disorder (PTSD; American Psychiatric Association, 1994). Posttraumatic stress disorder is a special case of extreme stress responding following life threatening or extreme stressors. It has broad base effects across all domains of functioning, impairing an individual's ability to function normally. Victims experience the persistent recurrence of three categories of symptoms: reexperiencing or reliving the event, emotional numbing and avoidance of trauma-related stimuli, and heightened physiological arousal (APA, 1994). In addition to intrusive thoughts, victims experience other common symptoms such as recurrent and disruptive dreams, sleep disturbances, emotional withdrawal, anxiety, dissociation, aggressiveness, hyperarousal, and an exaggerated startle response (APA, 1994).

Posttraumatic stress disorder is also characterized by unusual physiological response profiles. When victims are reminded of the trauma, cardiovascular, respiratory, and negative emotional responses are typically more exaggerated compared with reactivity to unrelated stimuli. As in chronic stress situations, circulating levels of EPI, NE, and their metabolites are elevated (Kosten, Mason, Giller, Ostroff, & Harkness, 1987; Mason, Giller, Kosten, & Harkness, 1988; Mason, Giller, Kosten, Ostroff, & Podd, 1986; Yehuda, Southwick, Giller, Ma, & Mason, 1992). This chronic adrenergic activation is accompanied by down regulation of noradrenergic receptors, thereby helping to sustain the increased output (Lerer, Gur, Bleich, & Newman, 1994; Murburg, Ashleigh, Hommer, & Veith, 1994; Yatham,

Sacamano, & Kusumakar, 1996). In contrast, the alterations in the functioning of the HPA axis appear to result in suppressed release of glucocorticoids (i.e., cortisol in humans; Kosten et al., 1987; Yehuda, Boisoneau, Mason, & Giller, 1993; Yehuda et al., 1990). This dysregulation appears to be the result of a blunted pituitary adrenocorticotrophic hormone (ACTH) response to corticotropin releasing factor (CRF) from the hypothalamus (Yehuda, Giller, Levengood, Southwick, & Siever, 1995; Yehuda, Resnick, Kahana, & Giller, 1993). ACTH travels to the adrenal cortex where it stimulates release of cortisol. Because less ACTH is released, less cortisol is elicited. In addition to these alterations, there is an up regulation of glucocorticoid receptors on lymphocytes, probably due to the low circulating levels of glucocorticoids (Yehuda, Boisoneau, Lowy, & Giller, 1995; Yehuda, Lowy, Southwick, Shaffer, & Giller, 1991). The presence of large numbers of receptors may also regulate the transient hypersecretion of cortisol seen in PTSD patients in response to a novel stressor or acute symptomatology (Yehuda et al., 1990; Yehuda, Resnick, et al., 1993).

The experience of trauma is not limited by the physical presence of the precipitating event. Despite the often acute nature of traumatic events, responding may last for months or years. Additionally, time of onset is not limited to the time of exposure, and episodes of acute and chronic PTSD have been defined based on whether or not symptoms last less than or more than 3 months (APA, 1994). Although individual symptoms of PTSD predict subsequent diagnosis, not all of the symptoms need to be present for a diagnosis to occur. Additionally, many of these same symptoms are exaggerations of normal stress reactions to an overwhelming event and may in fact serve to promote adaptation to such a situation. This is consistent with the pervasive finding that a majority of trauma victims do not develop PTSD, but there are still a significant number of victims (approximately 25%) who are affected (Green, 1994).

These considerations suggest that it is important to identify factors in the environment or in the individual that affect whether or not an individual experiences symptoms of posttraumatic stress or ultimately develops PTSD. Several vulnerability factors have been identified, such as a genetic predisposition to heightened autonomic arousal and a history of psychopathology (e.g., Foy, Resnick, Sippelle, & Carroll, 1987; Goldberg, True, Eisen, & Henderson, 1990; True et al., 1993), as well as factors that influence normal stress responses such as gender, social class, social support, perceived control, and coping (for reviews see Gibbs, 1989; Green, 1994; Vitaliano, Maiuro, Bolton, & Armsden, 1987).

STRESS RESPONSES AND CONSEQUENCES

Emerging models of stress consider a range of responses and consequences of stress that bear on productivity, health, and well-being. Stress affects mood, behavior, and problem solving, changes individuals' motivation to achieve goals or engage in self-protective behavior, and appears to lessen restraints against harmful behaviors. Stress affects the whole body. The effects of stress on the SNS and the HPA axis were documented in the seminal work of Selye (1956/1984) and

Cannon (1914). These systems contribute to stimulation of others and exert direct and indirect effects on metabolism and arousal. Changes in these response systems are thought to account for some of the effects of stress on health, but are consistent with a mobilization of energy, and as such are inherently adaptive. Increases in heart rate and blood pressure, as well as increases in the release of neuroendocrines such as EPI, NE, ACTH, glucocorticoids, and prolactin prepare an individual to face a stressor and fight or to flee from the scene. Additionally, stress-related decreases in several markers of immune system functioning have been observed (for reviews see Herbert & S. Cohen, 1993; O'Leary, 1990). These changes could be adaptive, in that when an organism is injured in battle, the swelling, fever, and other characteristics of an immune response are delayed and therefore do not interfere with the actions of the organism. However, prolonged suppression of a variety of functions could open windows of heightened vulnerability to infection or progression of neoplastic disease.

In addition to physiological changes, stress can increase negative emotions such as depression, anxiety, anger, fear, and overall symptom reporting. Unwanted or uncontrollable thoughts and memories about a stressor may also be experienced (Baider & De-Nour, 1997; Delahanty, Dougall, et al., 1997; Delahanty, Herberman, et al., 1997; Ironson et al., 1997). These stressor-related intrusions are both a symptom of stress and a stressor in their own right. Painful event-related images and thoughts may elicit their own stress response and may help to perpetuate chronic stress responding by repeatedly exposing an individual to the stressor.

Stress also affects performance. Because attention is typically focused on dealing with stressors when they are present, people may have problems attending to more mundane tasks, such as balancing a checking account, monitoring computer screens, or assembling a product (for reviews see Baba et al., 1998; Cooper, 1988; Kompier & DiMartino, 1995; Krueger, 1989; McNally, 1997). Unfortunately, many of these tasks may be work or safety related (e.g., writing a report or driving an automobile) and could have severe consequences if done improperly. Further, exposure to even a brief laboratory stressor has been shown to induce transient performance deficits in tasks given during the stressor or after it (Glass & Singer, 1972). These negative aftereffects occur even though physiological and emotional responding has decreased and the individual appears to have adapted to the acute stressor. Other consequences of stress include deterioration of sleep quality and quantity, increases in aggressive behaviors, and changes in appetitive behaviors such as eating, drinking, and smoking (e.g., Conway, Vickers, Weid, & Rahe, 1981; Ganley, 1989; Grunberg & Baum, 1985; Mellman, 1997; Sadeh, 1996; Spaccarelli, Bowden, Coatsworth, & Kim, 1997). These wide-reaching effects of stress illustrate the importance of examining the effects of stress on the whole organism rather than focusing on one system such as the SNS, reports of depression, or alcohol use. Responses across all systems work in concert to help the individual adapt by either altering the situation or accommodating its effects. Whereas these biological, cognitive, and behavioral alterations may be

adaptive in the short-term, chronic activation of these response systems results in wear and tear on the organism and may make the organism more susceptible to negative mental and physical health outcomes.

Stress and Health

Stress can affect health as well as intervene at any point in the disease process: in disease etiology, progression, treatment, recovery, or recurrence. Stress exerts these effects in three basic ways: as direct physiological changes resulting from stress-related arousal (e.g., immunosuppression, damage to blood vessels), as cognitive and behavioral changes that convey physiological changes (e.g., intrusive thoughts, smoking, drug use), and as physiological, cognitive, and behavioral changes associated with an individual's illness that affect exposure or treatment (e.g., viral exposure, drug metabolism, treatment adherence, seeking medical help). As discussed later, stress has important implications for the onset, progression, and treatment of almost every known major disease.

Although often difficult to measure, stress appears to affect pathogenic processes that contribute to the onset of disease. One of the most salient mechanisms through which stress can promote disease is through chronic, sustained, and/or exaggerated responses, making them pathological. Prolonged feelings of depression or anxiety can interrupt normal functioning and result in the development of clinical disorders, whereas transient alterations in mood are considerably less harmful (e.g., Kendler et al., 1995; Terrazas, Gutierrez, & Lopez, 1987). Continued self-medication or use of licit or illicit drugs may lead to addiction, and eating disorders may develop from extreme alterations in eating behaviors (e.g., Grunberg & Baum, 1985; Meyer, 1997; Sharpe, Ryst, Hinshaw, & Steiner, 1997). Prolonged or often-repeated elevations in blood pressure may result in permanent changes contributing to hypertension and elevated circulating levels of stress hormones may contribute to atherosclerosis and heart disease (Markovitz & Matthews, 1991). Chronic immune system suppression appears to interfere with the ability to ward off pathogens making individuals more susceptible to infectious diseases such as colds, flu, and Human Immunodeficiency Virus (HIV) disease (for reviews see Dorian & Garfinkel, 1987; O'Leary, 1990). Stress also appears to affect tumor suppression and progression of cancer (e.g., Ben-Eliyahu, Yirmiya, Liebeskind, Taylor, & Gale, 1991; Bohus, Koolhaas, de Ruiter, & Heijnen, 1992; Stefanski & Ben-Eliyahu, 1996). Although exhaustive evaluations of the direct role of stress in disease etiology are hard to conduct, recent evidence from studies of controlled viral challenges and wound healing confirm the clinically relevant impact of stress on health and disease (e.g., Cohen et al., 1998; Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995; Marucha, Kiecolt-Glaser, & Favagehi, 1998; Stone et al., 1992).

Behavioral and cognitive deficits seen during stress can also affect disease by increasing an individual's chance of exposure to pathogenic agents. Individuals under stress are more likely to engage in high risk behaviors like unprotected

sex and intravenous drug use (Demas, Schoenbaum, Wills, Doll, & Klein, 1995; Harvey & Spigner, 1995; Hastings, Anderson, & Hemphill, 1997). These activities increase the likelihood that an individual will be exposed to an infectious disease or experience unplanned consequences such as pregnancy. As already discussed, decrements in performance can result in dismissal from work or injury and death as a result of inattention and lack of concentration while engaging in important activities, such as driving a car or operating machinery (for reviews see Baba et al., 1998; Cooper, 1988; Kompier & DiMartino, 1995; Krueger, 1989; McNally, 1997). Stress-related behaviors such as smoking, alcohol use, and sedentary lifestyles may also contribute to etiology of serious health problems (R. M. Kaplan, Sallis, & Patterson, 1993).

Disease progression and treatment are also affected by stress. New feelings of depression or anxiety may interfere with treatment of preexisting disorders and can increase the likelihood of acute disease events such as heart attacks (e.g., Frasure-Smith, Lesperance, & Talajic, 1995; Kamarck & Jennings, 1991; Tennant, 1985). Individuals in treatment for psychiatric disorders (e.g., schizophrenia, depression, substance use, or eating disorders) may relapse and experience a return of their symptoms or return to their abusive behaviors (e.g., Belsher & Costello, 1988; Brewer, Catalano, Haggerty, Gainey, & Fleming, 1998; S. A. Brown, Vik, Patterson, Grant, & Schuckit, 1995; Shiffman et al., 1996; Tennant, 1985). Physiological changes may also interfere with the metabolism of prescription drugs (Katzung, 1992; Zorzet, Perissin, Rapozzi, & Giraldo, 1998), and behavioral and cognitive stress effects may impair treatment, reducing the likelihood that patients comply with instructions, prescriptions, and recommendations given by their medical teams (e.g., Brickman & Yount, 1996; Mehta, Moore, & Graham, 1997). Additionally, transient stressors, especially those producing strong emotions such as depression, anxiety, or outward expressions of anger, can promote platelet aggregation, contributing to the underlying cardiovascular disease state, or can trigger acute cardiac events such as myocardial infarction and sudden cardiac death (e.g., Frasure-Smith et al., 1995; Mendes de Leon, 1992; Wenneberg et al., 1997).

Stress can also retard the speed of recovery, make adjustment to diseases and injuries harder, and increase the rates of disease recurrence. Patients who report more stress have a harder time recovering from and adjusting to illnesses or injuries than individuals who report less stress (e.g., Grassi & Rosti, 1996; Kiecolt-Glaser, Stephens, Lipetz, Speicher, & Glaser, 1995; Marucha et al., 1998; Mullins, Chaney, Pace, & Hartman, 1997). Additionally, stress management interventions given prior to surgery or other medical procedures have improved healing and rehabilitation afterward (e.g., Enqvist & Fischer, 1997; Ross & Berger, 1996). Stress may also make patients in remission more vulnerable to recurrence of their disease; among people with latent viruses (e.g., HSV, EBV), stress has been linked to reactivation of the viruses and disease symptoms (e.g., Jenkins & Baum, 1995; Kiecolt-Glaser, Fisher et al., 1987; Kiecolt-Glaser, Glaser et al., 1987; Kiecolt-Glaser et al., 1988). Stress has also been linked with recurrence of cancer, which is possibly

a result of its immunosuppressive effects (Baltrusch, Stangel, & Titze, 1991).

Most of these health effects are linked with episodes of long-term or chronic stress. However, acute stressors may also affect health by making an individual more vulnerable during a time of exposure to an infectious agent or by triggering acute events such as heart attacks (as discussed earlier). The difference between acute and chronic stress is not always clearly defined, and most of the models already discussed fail to make a distinction between the two. Closer examination of the meaning and implications of short- and long-term stress needs to be addressed before examining the relation between stress and disease more closely.

STRESS AND DISEASE

Although stress affects everyday functioning and well-being, its more profound consequences are manifest as influences on disease processes. Whereas the effects of stress on the immune system are one putative mechanism for explaining the relation between stress and disease, other stress response systems affect disease processes as well. Further, these effects are apparent at several levels and stages of ill health. By examining the effects of stress on some major diseases, the importance of stress in the disease process as well as the integration of whole body responses are highlighted.

In addition to the effects of stress on the onset, management, and recovery from disease, there is evidence to suggest that people with chronic diseases experience more stress, that is, that these illnesses (or aspects of their management) can cause stress. Patients tend to report more social problems and psychological symptoms than people in the general population and more psychiatric morbidity has been associated with poorer disease management (e.g., Dougall et al., 1998; Irvine, B. Brown, Crooks, Roberts, & Browne, 1991; Mayou, Peveler, Davies, Mann, & Fairburn, 1991; Mullins et al., 1997). This bidirectional relation between stress and disease has lead researchers to propose that in some cases a vicious cycle develops, in which chronic diseases predispose individuals to psychiatric symptoms and social problems that then impair self-care and result in poor disease management. Disease flare-ups, recurrence, or increases in symptoms then further exacerbate psychiatric symptoms and social problems (e.g., Mayou et al., 1991).

Stress and Immune-Mediated Disease

One of the most salient mechanisms through which stress can make an individual more vulnerable to disease is the link between stress and immune functioning. Both acute and chronic stress have been linked with decreases in immune system activity (for reviews see Herbert & S. Cohen, 1993; O'Leary, 1990). These instances of immunosuppression could render the body less able to fight off pathogens or recover from injuries. Researchers have documented consistent decreases in the ability of lymphocytes to proliferate when challenged with a known pathogen (Bachen et al., 1992; Delahanty et al., 1996; Kiecolt-Glaser, Fisher, et al., 1987; Zakowski, L. Cohen, Hall,

Wollman, & Baum, 1994). These decreases in lymphocyte functioning are seen in both acute and chronic stress situations.

Researchers have also examined alterations in the functioning of immune cells involved in faster acting natural immunity. Natural killer (NK) cells are large granular lymphocytes that act quickly to destroy viral and cancer cells (Moretta, Ciccone, Mingari, Biassoni, & Moretta, 1994), but are affected differently by acute and chronic stress. Decreases in the number and capacity of NK cells to lyse tumor cells *in vitro* have been observed in populations exposed to chronic stress (e.g., Esterling, Kiecolt-Glaser, Bodnar, & Glaser, 1994; Ironson et al., 1997). However, alterations in NK cell activity in response to acute stress are more dynamic. Initially there appears to be an increase in NK cell activity, followed by a rebound decrease and then recovery to baseline (Delahanty et al., 1996; Schedlowski et al., 1993). Additionally, stress can interfere with seroconversion following Hepatitis B vaccination, decreasing the amount of protection normally afforded (Glaser et al., 1992).

These immune system alterations appear to be related to SNS activation (i.e., increases in heart rate, blood pressure, and catecholamines). Greater SNS activation has been associated with larger alterations in immune functioning (for reviews see Cacioppo, 1994; Esquifino & Cardinali, 1994). Changes in immune system parameters, such as numbers of lymphocytes and their ability to proliferate or lyse other cells, have been correlated with changes in cardiovascular arousal (specifically, changes in blood pressure and heart rate) and plasma catecholamine levels (L. Cohen, Delahanty, Schmitz, Jenkins, & Baum, 1993; Delahanty et al., 1996; Schedlowski et al., 1993; Zakowski et al., 1994). Additionally, adrenergic blockade before challenge has been shown to ameliorate immune system changes to a laboratory stressor (Bachen et al., 1995), and cardiovascular reactivity to a stressful task has been used to examine differences in stress-related immune responses (Caggiula et al., 1995; Herbert et al., 1994; Manuck, S. Cohen, Rabin, Muldoon, & Bachen, 1991; Zakowski, McAllister, Deal, & Baum, 1992). Measured as changes in blood pressure and heart rate associated with a stressor, people who exhibit higher reactivity to a laboratory challenge also exhibit larger immune changes. Psychological variables such as control, predictability, social support, and availability of a behavioral response have also been shown to mediate immune system alterations associated with stress. In general, uncontrollable or unpredictable stressors or situations affording little social support produce greater immunosuppression (e.g., Baron, Cutrona, Hicklin, Russell, & Lubaroff, 1990; Kennedy, Kiecolt-Glaser, & Glaser, 1988; Sieber, Rodin, Larson, Ortega, & Cummings, 1992; Wiedefeld et al., 1990; Zakowski, 1995).

Infectious Illness. Infectious illness refers to diseases caused by pathogens (e.g., virus, bacteria) that is communicable between two or more individuals. Primary defenses against these illnesses are immune system activity that seeks to control and destroy infectious agents. Because stress is associated with periods of lowered immune activity, it should also be associated with less resistance to infectious illnesses. Research in

both controlled and natural settings provides support for the contention that stress is associated with vulnerability to infectious illness (for reviews see Biondi & Zannino, 1997; S. Cohen & Williamson, 1991; Kiecolt-Glaser & Glaser, 1995; McEwen & Stellar, 1993). In natural environments, increases in stress often precede the onset of illnesses (Kasl, Evans, & Niederman, 1979; Rahe, 1972; Stone et al., 1987). Additionally, physiological reactivity moderates the effects of stress on illness, with high reactors developing more respiratory infections than low reactors (Boyce et al., 1995). Reactivations of latent viral infections such as herpes simplex virus (HSV) and Epstein-Barr virus (EBV) also appear more likely when individuals are experiencing ongoing stress (Kiecolt-Glaser, Fisher et al., 1987; Kiecolt-Glaser, Glaser et al., 1987; Kiecolt-Glaser et al., 1988).

In addition to these correlational studies, recent advances in measurement procedures have made it possible to conduct studies in controlled environments, confirming that individuals with high levels of life stress are more likely to become infected and display symptoms when exposed to cold viruses (S. Cohen et al., 1998; Stone et al., 1992). In these studies, healthy participants are typically exposed to known amounts of a cold virus and then quarantined in a hotel room for 5 or more days. There are two major disease outcomes that are examined. One outcome is the rate of viral infection, typically ranging from 69% to 100% of the sample exposed to the virus, and the other is the actual incidence of cold symptoms, ranging from 19% to 71% of the sample (S. Cohen et al., 1998; S. Cohen, Tyrrell, & Smith, 1991; Stone et al., 1992). Although individuals cannot have cold symptoms without being infected, they can be infected without showing signs of a cold. Rates of both viral infection and cold symptoms increase in a dose-response fashion with the amount of life stress the participants report (S. Cohen et al., 1991, 1998; Stone et al., 1992). More severe and chronic stressors tend to have a greater impact on disease development than less severe or acute stressors (S. Cohen et al., 1998).

Cancer. The relations among stress, immunity, and cancer appear to be more complex than those underlying the pathophysiology of infectious diseases. In part, this is due to the chronic nature of cancer and the more acute time frames of most infections. In addition, immune activity has an unknown role in controlling initial mutations or in the process from benign to malignant neoplastic growth and a suspected but underexplored role in resistance to tumor growth and metastatic spread. There is better general evidence that stress is associated with cancer progression and may be linked to survival as well as general susceptibility, risk, and quality of life. Again, problems related to the chronic nature of cancer development and treatment have made studies of stress and cancer incidence difficult, and research on disease course, recurrence, survival, and so on share similar problems.

These problems have often left the literature linking stress and cancer weak and open to alternative explanations. Inconsistent findings are also an issue, with studies reporting significant and nonsignificant association of depression and cancer (e.g., Hahn & Petitti, 1988; G. A. Kaplan & Reynolds,

1988; Shekelle et al., 1981; Zonderman, Costa, & McCrae, 1989) and few relations between bereavement or other major stressors and the development of cancer (e.g., Jones & Goldblatt, 1986; Keehn, Goldberg, & Beebe, 1974). Significant loss in a 6-year prodromal period predicted breast cancer in one study (Forsen, 1991), but overall there is little evidence of direct stress effects in the development of cancer (e.g., Fox, 1978, 1983). Again, problems of timing and tracking of disease-related events makes this research difficult and uncontrolled. Tumors develop over years or decades and grow irregularly. Further, several different mutagenic events are needed to produce malignancy, suggesting several points at which stress could affect initial development. Mechanisms such as cellular DNA repair have been proposed and some studies have linked stress to poorer DNA repair capabilities (e.g., Kiecolt-Glaser et al., 1985), but in general there is no evidence of stress-related repair suppression as a component of cancer onset.

There is better evidence of stress-related modulation of cancer course and some of immune system involvement, focusing principally on NK cell numbers and activity. Retrospective studies of life stress and cancer have suggested that stressful events are associated with shorter survival, fatigue, distress, and recurrence of breast cancer (Funch & Marshall, 1983; Ramirez et al., 1989). Some investigators have not found evidence of life stress associations with cancer course (Ell, Nishimoto, Mediansky, Mantell, & Hamovitch, 1992; Greer, Morris, & Pettingale, 1979; Hislop, Waxler, Coldman, Elwood, & Kan, 1987; Jamison, Burish, & Wallston, 1987). Studies have not consistently studied the impact of cancer-related stress on disease course, nor has systematic consideration of stressor timing issues, coping, or social assets been characteristic of this work. However, coping, social support, and other stress mediators are associated with length of survival among cancer patients (Dean & Surtees, 1989; Goodwin, Hunt, Key, & Samet, 1987; Greer et al., 1979; Hislop et al., 1987; Levy et al., 1990; Neale, Tilley, & Vernon, 1986).

Stress has considerable influence on the number and activity of NK cells, presumably through stimulation and inhibition associated with neuroendocrine activity during stress (e.g., Kiecolt-Glaser & Glaser, 1992; O'Leary, 1990; Schedlowski et al., 1993; Schneiderman & Baum, 1992). Further studies have found that stress, social support, and fatigue or depression are related to NK activity in cancer patients and differences in NK activity appear to be related to prognostic risk (Levy, Herberman, Lippman, & D'Angelo, 1987; Levy, Herberman, Lippman, D'Angelo, & Lee, 1991; Levy, Herberman, Maluish, Schlien, & Lippman, 1985). Aparicio-Pages, Verspaget, Pena, Jansen, and Lamers (1991) found evidence of NK activity predicting disease course in GI cancer, but only among patients who exhibited NK activity in normal ranges.

Perhaps the best evidence for stress effects on cancer course are results of stress-reducing psychological interventions for cancer patients. These interventions appear to have the capacity to extend survival and bolster immune system activity. These issues are dealt with in greater detail elsewhere in this Handbook (see chap. 46, this volume). It is sufficient to

conclude here that the evidence that stress affects cancer course is suggestive and encouraging but far from definitive or complete.

Stress and Heart Disease

Stress can be implicated throughout the natural history of coronary heart disease (CHD), in its formation, progression, and in triggering a cardiac event. Stress affects CHD mainly through its influences on behavioral factors and activation of the autonomic nervous system (ANS; Kamarck & Jennings, 1991). In particular, stress activates the SNS resulting in increases in epinephrine and norepinephrine that lead to increased beta and alpha receptor activity (Kamarck & Jennings, 1991; Markovitz & Matthews, 1991). Briefly, beta activation increases heart rate and heart contractility, therefore increasing cardiac output and blood pressure (Guyton, 1991). Alpha activation causes vasoconstriction of the arteries and veins and causes increases in total peripheral resistance and venous return, both of which increase blood pressure (Guyton, 1991). All of these physiological events may contribute to CHD. For example, with an increase in blood flow, shear stress on the arteries is increased causing cells in the blood to be damaged and plaque to form and/or rupture (Traub & Berk, 1998). This, along with sharp increases in epinephrine, stimulates platelet activation and the sequelae that follow (Markovitz & Matthews, 1991; Wenneberg et al., 1997). Activation of the parasympathetic nervous system (PNS) can have opposite effects on the heart and blood vessels, and extensive PNS activation can also lead to cardiac events (Lane, Adcock, & Burnett, 1992; Podrid, 1984).

Stress can contribute to atherosclerosis and other underlying CHD processes by increasing heart rate and decreasing diastolic and washout periods in recirculation zones leading to increased contact of the blood constituents and vessel walls (Markovitz & Matthews, 1991; Traub & Berk, 1998). Platelet aggregation, along with coronary vasoconstriction and plaque rupture, can lead to other priming processes such as thrombosis, ischemia, and acute myocardial infarction. As discussed earlier, stress and its related emotional indices (e.g., hostility) increase platelet aggregation through induction of the ANS (Kamarck & Jennings, 1991; Markovitz & Matthews, 1991; Wenneberg et al., 1997).

Psychological stress is also associated with transient changes in coronary circulation and metabolism along with the other coronary changes discussed earlier. Stress may reduce oxygen delivery to the heart and thereby lower the threshold for myocardial ischemia or may trigger acute arrhythmic events through activation of the ANS, making myocardial infarction more likely (e.g., Frasure-Smith et al., 1995; Jiang et al., 1996; Kaufmann et al., 1998; Natelson & Chang, 1993; Podrid, 1984; Saini & Verrier, 1989). Recent evidence has also suggested that mental stress-induced ischemic episodes are good indicators of 5-year rates of cardiac events (Jiang et al., 1996). Additionally, stress-induced silent ischemia (ischemia without angina) occurs much more frequently than is detectable by some clinical measures (see

Kop, Gottdiener, & Krantz, chap. 41, in this volume). There is also evidence that acute stress events, such as public speaking and anger provoking situations, can disrupt cardiac electrical potential and lead to arrhythmias and possibly to myocardial infarction (Mendes de Leon, 1992; Natelson & Chang, 1993; Saini & Verrier, 1989). These arrhythmic disturbances may also be linked to an individual's prevailing psychological state. For example, increased incidences of arrhythmias are associated with anxiety and depressive disorders, Type A/competitiveness, and postinfarction distress (Cameron, 1996; Frasure-Smith et al., 1995; Moser & Dracup, 1996; Rosenman, 1996; Tennant, 1987).

Stress and Diabetes

Just about every neuroendocrine system responds to stress. Hormonal control is essential for individuals with endocrine disorders, and if this control is upset by stress, the hormonal balance is lost and disease symptoms worsen. In addition to direct effects of stress on hormonal levels, stress affects many of the risk factors associated with disease onset and flare-ups, such as diet, licit and illicit drug intake, and compliance with treatment regimens.

One of the most common neuroendocrine disorders is diabetes mellitus, affecting approximately 6%, or 1 in 17, of the U.S. population (American Diabetes Association, 1997). There are two primary types of diabetes mellitus, insulin-dependent or Type I and insulin independent or Type II. Both disorders are the result of high blood glucose levels and are characterized by symptoms such as blurred vision, unexplained fatigue, and increases in thirst and urination. A primary fuel for all body cells, circulating glucose enters cells to be used through the action of another hormone called insulin. In Type I diabetes, the immune system attacks the insulin-producing cells in the pancreas slowing insulin production and decreasing the amount of glucose that can be used by cells (Bosi & Sarugeri, 1998; Schranz & Lernmark, 1998). The onset of Type I diabetes usually occurs before age 40 (more than 50% develop Type I before age 20) and is more common among Whites than other racial groups (ADA, 1997).

In contrast, Type II diabetes typically occurs later in life, with 11% of the U.S. population between age 65 and 74 having the disease (ADA, 1997). Additionally, Mexican Americans, Puerto Rican Americans, African Americans, and Native Americans have higher incidence rates than Cuban Americans and Whites. Type II diabetes develops gradually over time as the cells in the body become resistant to the effects of insulin, thereby decreasing the amount of glucose that can enter the cells to be used. Although both Type I and Type II diabetes are more prevalent when there is a family history of the disease and appear to have genetic links (Bosi & Sarugeri, 1998; Krolewski, Fogarty, & Warram, 1998; Schranz & Lernmark, 1998), Type II diabetes is also associated with several other behavioral and physiological risk factors. The most common Type II risk factors, are older age, ethnicity, being overweight, being a smoker, having high blood pressure, having high levels of fat in the blood, and being a woman who had gestational diabetes (Bloomgarden,

1998; Danne, Kordonouri, Enders, Hovener, & Weber, 1998; Ryan, 1998; Sanchez-Thorin, 1998).

Stress does not directly cause diabetes, but it may make individuals more susceptible to diabetes onset (ADA, 1997; Ionescu-Tirgoviste, Simion, Mariana, Dan, & Iulian, 1987). For example, part of the stress response is oriented toward liberation of large quantities of glucose for cells to use for energy. In Type I diabetes, stress may overwhelm the pancreas' ability to produce insulin and, as a result, unmask the diabetes sooner than the onset would normally occur. Similarly, in Type II diabetes, stress hormones interfere with insulin use in an already compromised system resulting in earlier detection of diabetic symptoms. Furthermore, stress plays a role in the risk factors associated with diabetes onset (e.g., obesity and high blood pressure) and can impact treatment by interfering with glycemic control (K. S. Aikens, J. E. Aikens, Wallander, & Hunt, 1997; J. E. Aikens, Kiolbasa, & Sobel, 1997; Murphy, Thompson, & Morris, 1997). Stress-related behaviors (e.g., eating, alcohol use, cigarette smoking, inactivity, and forgetting to take medications) can impair self-care and result in abnormal glucose levels.

Stress can also have direct effects on symptoms and disease management. As mentioned earlier, stress increases blood glucose levels. In Type I diabetes, the body does not produce enough insulin to handle the high blood glucose levels and in Type II diabetes, the body cells are resistant to insulin so blood glucose levels remain high. Therefore, high blood glucose levels associated with stress cannot be properly handled by the body (Surwit & Williams, 1996). Untreated high glucose levels are dangerous and can lead to ketoacidosis and diabetic coma (Guyton, 1991).

Stress and Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a debilitating chronic disease that afflicts 70,000 people a year in the United States (Janeway & Travers, 1994). Most cases are a result of a T-cell (CD4) mediated autoimmunity that results in joint inflammation and destruction (Janeway & Travers, 1994). Some cases also involve the production of autoantibodies called rheumatoid factor. As with other chronic diseases, people with RA experience many limitations and disease-related stressors. The most frequent stressors patients report are taking care of their disease, their lack of control over the disease, and the resultant fatigue, pain, and functional impairment (Katz, 1998; Melanson & Downe-Wamboldt, 1995).

In addition to the inherent stressfulness of RA, disease activity and symptoms are exacerbated by the occurrence of daily stressors (Affleck et al., 1997; Zautra et al., 1997, 1998). Similar to the stress and disease relations observed in diabetes and other chronic diseases, a cyclic pattern can develop in which RA leads to increases in stress which in turn exacerbates RA symptoms. However, the relation between stress and disease activity is not clear-cut. The type of stressful event as well as important psychosocial factors, such as spousal support, can alter the relation between stress and RA (Zautra et al., 1998). Minor types of stressors appear to affect RA disease activity and symptoms differently than major life

events such as the death of a loved one. Although daily stress has been linked to exacerbation of RA, major life events have actually been associated with decreases in disease activity (Potter & Zautra, 1997). This finding is supported by differences in immunological responses in RA patients to minor and major stressors. Some have suggested that acute, minor stressors are generally associated with increases in immune system activity, whereas major stressors are generally associated with decreases in the same immune parameters (Huysen & Parker, 1998; Zautra et al., 1989). As already mentioned, T-cells, especially CD4 cells, and autoantibodies from B-cells are responsible for the joint inflammation and destruction seen in RA. Therefore, increases in the activity of these cells in response to minor stress should be associated with increases in disease activity. Likewise, the decreases in immune system activity following major stressors should be associated with less disease activity (Huysen & Parker, 1998; Potter & Zautra, 1997).

These differential effects appear to be mediated by the release of catecholamines and cortisol (Huysen & Parker, 1998). Rheumatoid arthritis is typically characterized by decreases in HPA axis activity (i.e., cortisol) and increases in SNS activity (i.e., epinephrine and norepinephrine). Each of these systems have opposing effects on RA management and symptoms. Cortisol has important anti-inflammatory actions that decrease RA activity by reducing the chemical activators of the inflammation process and by suppressing the immune system (Guyton, 1991). Consequently, corticosteroids are often prescribed to RA patients to help manage their symptoms. In contrast, SNS activation has been associated with changes in immune activity and RA symptoms (Huysen & Parker, 1998). Additionally, RA patients have heightened SNS reactivity to minor stressors (Zautra et al., 1998). Although both catecholamine and cortisol levels increase in response to stress, it has been proposed that the heightened SNS reactivity to minor stressors counteracts any anti-inflammatory effects of HPA axis activation and cortisol release and results in exacerbations of RA activity and symptoms (Huysen & Parker, 1998). In contrast, RA patients who report major life events may experience dramatic increases in HPA axis activation and cortisol release, which in turn may result in decreases in disease activity (Huysen & Parker, 1998; McFarlane & Brooks, 1990).

Although stress can have a profound impact on the etiology and course of RA, there is a subset of RA patients who appear to be immune to its effects. In these patients genetic and etiological influences appear to be more influential in determining RA symptoms (Rimon & Laakso, 1985). Two subgroups of RA patients have been identified based on whether or not RA patients are seropositive for the autoantibody rheumatoid factor. In patients who are seronegative, the occurrence of negative life events are associated not only with increases in disease activity but also with the onset of the disease. In contrast, in people who are seropositive, no such relations exist (Stewart, Knight, Palmer, & Highton, 1994), suggesting that vulnerability to stress is linked to the physiology of the disease process.

CONCLUSIONS

Stress is a critical crosscutting process that is basic to research, theory, and application in health psychology. It represents modifiable variance in the etiology of disease, affects nearly every behavior that contributes to good or bad health outcomes, and has direct effects on all or most bodily systems and can thereby contribute to developing health problems as well. Stress is basic to the commerce between organisms and their environments, motivating them to take action against stressors or to insulate themselves from stress effects. It also produces nonspecific catabolic arousal, driven primarily by neural-endocrine regulatory loops that supports adaptive capabilities such as fight or flight. More specific aspect of stress responding, tied more closely to the stressful situation and its interaction with the organism's resources and abilities, are reflected in emotional responding and coping as well as in cognitive appraisal processes and memory.

Most people are able to adapt to stressful situations and even in the most extreme cases, it would be expected that most people would be able to cope effectively and move on to new challenges. The multiple changes that occur during stress facilitate adaptation. However, there are negative effects of stress that have been observed, including aspects of the pathophysiology of cardiovascular disorders, infectious illnesses (including HIV disease and hepatitis), cancer, diabetes, and autoimmune diseases like rheumatoid arthritis. These effects appear most often when stress responses are extremely intense or abnormally prolonged. They can also become manifest when resources and coping are not able to immediately overcome or displace stressful conditions. Uncontrollable stress appears to be more difficult to resist than controllable and predictable periods of threat or demand.

Quantification of contributions of stress to disease etiology and personal susceptibility to major health problems has been a slow project, but has been increasingly successful in measuring harmful and beneficial effects of stress. Similarly, the ability to intervene and modify lifestyle, coping, social resources, and appraisals of major chronic illnesses, stressors, and associated conditions has continued to improve. Research during the next 10 years should continue framing the extent and limits of stress effects on health and disease and designing ways to minimize unnecessary risk.

What Are the Health Effects of Disclosure?

Joshua M. Smyth
North Dakota State University

James W. Pennebaker
University of Texas

Across history and cultures, people seek to disclose their personal experiences. Confession constitutes an important aspect of healing rituals in a variety of cultures. Indeed, self-disclosure is integral to the majority of psychotherapeutic orientations. Cross-cultural studies indicate that people everywhere are inclined to share their emotions with others and even the darkest secrets—once told to one person in confidence—spread quickly to others (Rimé, 1995). Such social sharing is thought to be part of the process by which people avoid the negative consequences of stressful life events. Metaphorical language for disclosure suggests that emotions are harbored in the body until disclosed. Individuals “get things off their chest” or “get it out of their system” when disclosing. They “blow off steam.” Others may worry if friends are “bottling up” their emotions.
