Immune responses to acute stress appear to be rapid and short lasting, occurring as early as 5 minutes after stressor onset (Herbert et al., 1994) and returning to baseline levels within 15 minutes, in the case of cell subset redistribution (Brosschot et al., 1992). Changes in functional measures have been shown to last longer, with reductions in lymphocyte proliferation remaining for at least 90 minutes after challenge (Weisse et al., 1990; Zakowski et al., 1992); elevations in NK cell activity may persist for at least 1 hour (Gerritsen et al., 1996). Studies that include both sexes demonstrate that immune responses to acute stress are similar among men and women (Herbert et al., 1994).

How the transient immune responses seen following discrete acute stress relate to those associated with chronic naturalistic stress is unknown. However, it is hypothesized that alternative physiological mechanisms may account for these differential effects (Herbert & S. Cohen, 1993). In the case of acute psychological stress, research findings suggest that immune responses are largely mediated by activation of the sympathetic nervous system. For example, it has been demonstrated that immune outcomes assessed after a laboratory stressor covary with the magnitude of sympathetic activation elicited under the same stimulus conditions (Landmann et al., 1984; Manuck et al., 1991; Zakowski et al., 1992). Pharmacological studies also indicate that the administration of physiological doses of sympathetic stimulants (e.g., exogenous catecholamines or isoproterenol) invokes functional modulations of cellular immunity that are similar to those seen during mental stress (Crary et al., 1983; van Tits et al., 1990). Finally, the speed of the immune reactions to acute stress makes it unlikely that other, slower responding hormones (e.g., cortisol) mediate these effects. Indeed, two studies have demonstrated immune changes in the absence of concomitant changes in cortisol levels (Manuck et al., 1991; Zakowski et al., 1992).

More direct evidence for sympathetic mediation derives from the observation that stress-related immune responses are blocked by adrenergic receptor inhibition (Bachen et al., 1995; Benschop et al., 1994). Indeed, it has been demonstrated that administration of an adrenergic inhibitor prevents stress-induced alterations in a variety of immune parameters, including proliferative responses to PHA and Con A, NK cell number and activity, and the ratio of T-helper to T-suppressor/cytotoxic cells (Bachen et al., 1995; Benschop et al., 1995).

The exact mechanism of sympathetic-immune mediation remains unclear. Recent evidence suggests that activation of the sympathetic nervous system may influence the immune system by both active and passive processes (Marsland et al., 1997). Under stress, an increase in arterial blood pressure driven by activation of the sympathetic nervous system causes fluid to filter out of circulation into extravascular spaces, leading to a passive increase in the concentration of all nondiffusible constituents of blood, including lymphocytes (C. Jern, Wadenvik, Mark, Hallgren, & S. Jern, 1989). It is

possible to mathematically correct changes in lymphocyte subtype numbers to determine the degree to which the passive concentration of blood constituents accounts for changes in circulating cell numbers. By using this arithmetic correction, it has been shown that increases in the concentration of circulating T-suppressor/cytotoxic and NK cells following acute stress are partly, but not wholly, attributable to hemoconcentration (Marsland et al., 1997). Interestingly, an active decrease in the circulating numbers of T-helper and B lymphocytes during stress was also revealed, but only when hemoconcentration was taken into account. This raises the possibility that there is a stress-induced decrease in these cell subtypes, which is frequently masked by a simultaneous reduction in plasma volume.

The observation that hemoconcentration only partly accounts for acute rises in T-suppressor/cytotoxic and NK cell numbers suggests that more active mechanisms of immune response must also be implicated (see Bachen et al., 1995, 1998, for further discussion). In this regard, it is thought that alterations in adhesion molecules on cell surfaces may enable these cell populations to be mobilized into circulation from the endothelium of blood vessels. Recent studies indicate that catecholamines prevent the adherence of human NK cells to endothelial tissue *in vitro* (Benshop, Oostveen, Heijen, & Ballieux, 1993). It has also been demonstrated that acute psychological stress alters the expression of surface adhesion molecules on lymphocytes (Mills & Dimsdale, 1996). Finally, changes in mitogen-stimulated lymphocyte proliferation may, in part, reflect sympathetically mediated impairments of IL-2 production by T-helper lymphocytes (Heilig, Irwin, Grewal, & Sercarz, 1993) and decreased antigen-presentation by macrophages (Heilig et al., 1993).

In contrast to the rapid, short-lived immune responses associated with acute stress, exposure to more chronic stressors leads to relatively stable shifts in the baseline levels of immune measures (Herbert & S. Cohen, 1993). Here, it is likely that more prolonged secretion of stress hormones induces more stable changes in neuroendocrine pathways, such as modification of receptor density and sensitivity (Chrousos & Gold, 1992; Herbert & S. Cohen, 1993). Alternatively, the more delayed release of other hormones (e.g., cortisol, ACTH, and B-endorphin) may account for differential effects. In this regard, Goodkin et al. (1996) reported that plasma cortisol levels correlated inversely with proliferative response to PHA. Similarly, Antoni and colleagues (1990) found that anxiety levels and intrusive thoughts were associated with higher plasma cortisol levels and lower proliferative responses to PHA among individuals who were awaiting the results of HIV testing. Mechanisms aside, there is recent evidence that immune responses to acute and chronic stress may be related, with individuals who report higher levels of life event stress and daily hassles mounting greater immunologic responses to acute stress (Brosschot et al., 1994; Pike et al., 1997).

Although it is now well established that acute and chronic stress are associated with both functional and enumerative aspects of immunity, an examination of response variability reveals that individuals differ substantially in the magnitude of

their immunologic reactivity to stress (Kiecolt-Glaser et al., 1992; Manuck et al., 1991; Naliboff et al., 1991), with many individuals exhibiting little or no response (Glaser, Kiecolt-Glaser, Stout et al., 1985; Manuck et al., 1991; Schleifer et al., 1983). It is suggested that these differences reflect variability among individuals in the magnitude of their sympathetic responsivity to stress, an aspect of individual difference that has been demonstrated to be relatively stable over time (Dimsdale, Young, Moore, & Struss, 1987). Recent findings provide initial evidence that interindividual variability of behaviorally evoked immune reactivity is also reproducible on retesting, and may therefore denote a stable dimension of individual differences (Marsland et al., 1995; Mills, Haeri, & Dimsdale, 1995). In these studies, the stability of cellular immune reactions to a laboratory stressor was assessed on two occasions, separated by a 2- or 6-week interval. Significant test-retest correlations were observed for the magnitude of change in proliferative response to PHA (but not Con A), numbers of T-suppressor/cytotoxic and NK cells, and the ratio of T-helper to T-suppressor/cytotoxic cells (r s ranged from .40-.60; Marsland et al., 1995; Mills et al., 1995). Similarly, another study has demonstrated that individuals who mount greater heart rate responses (an index of sympathetic arousal) to a speech task show greater increases in NK cell activity when exposed to a mental arithmetic task on a different day than do persons exhibiting low heart rate responses under the same stimulus conditions (Sgoutas-Emch et al., 1994). Taken together, these findings suggest that individuals vary consistently in the magnitude of their cellular immune reactivity to acute stress.

The existence of such dispositional characteristics makes it conceivable that exaggerated immune responsivity to behavioral challenge may be implicated in the pathogenesis of immune-related disease, such as host resistance to infection (S. Cohen & Manuck, 1995). One possibility is that individuals who show exaggerated immune responses to laboratory stressors exhibit similarly exaggerated reactions to everyday hassles (e.g., work demands and time pressures), rendering them more immunocompromised and hence more susceptible to infectious disease. To date, one published study has explored whether individual differences in immune reactivity moderate associations between psychological stress and infectious illness (Boyce et al., 1995). Boyce and colleagues found that children (age 3-5) showing the largest stress-induced increases in circulating numbers of B cells and in lymphocyte proliferation to PWM were at greatest risk for developing upper respiratory infections in response to a naturalistic stressor. However, interpretation of these effects is unclear because the interaction between immune reactivity and stress, as a predictor of infection, was attributable in large part to an unexpectedly lower incidence of disease for high reactive children not exposed to naturalistic stress (S. Cohen & Manuck, 1995). Moreover, previous studies involving adults have not found reliable increases in circulating B cell numbers or proliferative response to PWM following stress. Although intriguing, further replications of these findings are needed, not only with children, but using adult samples as well.

Marsland, S. Cohen, Rabin, and Manuck (in press) further explored whether individual differences in immune reactivity are germane to susceptibility to infectious disease. This study examined whether immune reactivity predicted antibody response to recombinant hepatitis B vaccination, an *in vivo* measure of host resistance to viral infection. For this purpose, 84 healthy graduate students who tested negative for prior exposure to hepatitis B virus were administered the standard series of three hepatitis B vaccinations. The first two vaccinations were given 6 weeks apart, with a follow-up booster dose administered 6 months following the first shot. Five months after the first dose, each subject completed a battery of stress measures and a blood sample was drawn to assess hepatitis B surface antibody levels. Four to 6 weeks following completion of the vaccination series, subjects returned to the laboratory to perform an acute laboratory stress protocol, measuring immunologic responses to an evaluative speech task. Findings demonstrated that, when compared with high antibody responders, subjects who mounted lower antibody responses to hepatitis B vaccination following the first two doses displayed greater stress-induced suppression of immune function, as measured by proliferative response to PHA, but not Con A or PWM. As such, this study lends some support to the hypothesis that individual differences in the magnitude of stress-induced suppression of immune function may have clinical significance, being related to an *in vivo* immune response relevant for protection against infection. Consistent with other studies measuring the impact of stress later in the antibody response (Jabaaij et al., 1993; Snyder et al., 1993; Stone et al., 1994), no association was found between stress and antibody response.

At present, the clinical significance of the observed differences in magnitude of antibody response among the high and low responders is unknown. This study was conducted using young, healthy participants and a vaccination protocol designed to produce maximal immunity to hepatitis B in greater than 90% of individuals. Hence, the majority of subjects show an antibody titer that is considered to be protective against hepatitis B infection by the end of the vaccination series. However, it is known that individuals who mount lower antibody responses to hepatitis B vaccination lose their protective status more quickly (Horowitz, Ershler, McKinney, & Battiola, 1988). Hence, subjects who showed greater immune reactivity following acute stress might be expected to have a decreased duration of immunity to hepatitis B than individuals who are less immunoreactive. It is also possible that individual differences in reactivity would have a greater impact on vaccination response among less healthy populations (e.g., elderly or very young persons) or those who already have compromised immune function (e.g., individuals with HIV or cancer).

In sum, some initial evidence is provided that individual differences in the magnitude of immune responses to acute laboratory challenge are related to an *in vivo* measure of immune competence. However, prospective studies employing measures of individual difference as predictors of disease outcome are required in order to show that individuals who show greater suppression of immune function following stress are more vulnerable to infectious disease.

CONCLUSIONS

In support of popular belief, there is now substantial evidence for the role of psychological stress in susceptibility to upper respiratory infectious disease (e.g., S. Cohen et al., 1991; Stone et al., 1992). One possible mediator of this relation is the modulation of immune function, thereby influencing host susceptibility to infectious pathogens. In this regard, it is well established that both major stressful experiences (e.g., bereavement or natural disasters) and more minor stressors (e.g., arguing with a spouse, acute laboratory challenge) are associated with changes in immune function. However, it remains unclear whether associations between psychological factors and infectious disease are attributable to stress-induced changes in immunity. Indeed, the clinical significance of relatively small immunologic alterations has not been established. Many associations between stress and health or between stress and the immune system may be attributable to concomitant changes in health behaviors. Recent studies conducted in laboratory settings, however, provide evidence that the sympathetic nervous system mediates some immunologic changes during acute challenge stress. It has also been demonstrated that individuals differ substantially in the magnitude of their immunologic responsiveness to stress, with recent evidence suggesting that these response tendencies may reflect stable attributes of individuals. Hence, it is conceivable that there is a meaningful distribution of differences in immunologic reactivity that may form a physiological basis for differences in susceptibility to infection.

Future research in psychoneuroimmunology needs to focus on whether the type or magnitude of stress-related immune modulation influences host resistance to disease, especially in light of the fact that immune responses of stressed persons generally fall within normal ranges (Rabin, S. Cohen, Ganguli, Lysle, & Cunnick, 1989). Indeed, it has been suggested that substantial fluctuations in immune function can be tolerated without producing increased susceptibility to disease (S. Cohen, 1988). The role of the immune system in susceptibility to infectious disease needs to be addressed with prospective studies, measuring psychosocial parameters and immune mediators relevant for the disease under study, controlling for health behavior, and documenting disease outcomes.

Nonpharmacological Treatment of Hypertension

Alvin P. Shapiro
University of Pittsburgh School of Medicine

The health benefit from lowering blood pressure in hypertensive patients has been a major clinical research accomplishment of the last four decades. In the late 1940s and 1950s, the efforts were primarily diagnostic and therapy was limited to reassurance, hope, and prayer. Pharmacological studies at that time were concerned with evaluating acute effects of potent drugs such as the ganglionic blocking agents and the veratrum alkaloids and their applications to therapy were limited because of their potent side effects. High blood pressure reduction, with such drastic measures as fever therapy and sympathectomy, were employed in some severe situations as well as nitrates, orally and parenterally. Clinics did follow hypertensive patients closely and were impressed by the variability of blood pressure and by the value of supportive therapy—mainly reassurance, hospitalization, and lifestyle changes—in reducing blood pressure and even occasionally reversing or delaying consequences of the disease. Reiser, Rosenbaum, and Ferris (1951), in fact, reported a small group of patients in whom malignant hypertension was ameliorated in this fashion, at least for a brief period of time. Nonpharmacological therapy was the order of the day, by default, because specific drugs to treat hypertension were not available. Indeed, it was preferable to speak of the drugs that began to emerge in the 1950s as “hypotensive” agents and not as “antihypertensive” drugs.

Pharmacological therapy of malignant hypertension did make progress in the 1950s with the advent of combinations of long acting ganglionic blocking agents, the vasodilator drug hydralazine, and the diuretics of the thiazide genre. With these agents, the malignant phase of the disease could be reverted to a more benign course, but their use in the more

modest forms of hypertension and in those with mild disease was inhibited by their disturbing side effects, which interfered in many ways with patient comfort and lifestyle. Orthostatic symptoms, difficulty in urination, constipation, headaches, impotence—both libidinous and erectile failure—were all very real problems in their use. And, although these could be tolerated in patients with the malignant and most severe phases of hypertension, it was difficult to justify their administration in the asymptomatic mild hypertensive. There was uncertainty as to whether life expectancy was shortened even in the individual with modest degrees of hypertension (i.e., diastolics of 100 to 115 mm Hg) and it was generally felt that with mild hypertension (i.e., diastolics of 90 to 105 mm Hg) who constituted about two thirds of the hypertensive population, the risk of death and even of significant morbidity was minimal. Accordingly, it was justifiable to view this approach with reassurance and supportive therapy, often accompanied by admonitions for weight control and a low salt diet as a method of management. These measures did result in significant lowering of blood pressure, as shown for example in studies from the 1951 group in Cincinnati (Reiser et al., 1951). Beyond the supportive therapy that was offered to patients, there were reports of significant lowering of blood pressure with more extensive psychotherapy, including psychoanalysis. These now historic events illustrate that the idea of treating hypertension with behavioral techniques is not a new concept, but rather one that physicians relied on before the advent of current pharmacological treatment.

Research has come full circle over the last 30 years. Pharmacological therapy first showed its value in the nonmalignant

nant hypertensive in the reports of Freis and his coworkers. Their classic study on a relatively small group of male veterans in the 1960s treated patients with reserpine, thiazides, and hydralazine. The patients were divided into three groups, depending on their blood pressure levels; levels were defined as severe, moderate, and mild. A definite diminution in deaths and morbidity primarily from cerebrovascular events was demonstrated in the first two of these groups—namely those with BPs of over 115 mm Hg and those with levels from 105 to 115 mm Hg—but it was still unclear whether an appreciable impact was made on the mild group (with BPs of 90 to 105 mm Hg; Veteran's Administration Cooperative Study Group on Antihypertensive Agents, 1967, 1970, 1972). It remained for the Hypertension Detection and Followup Program (HDFP), a study conducted in 14 centers throughout the United States, to establish the value of treatment in the mild group. The HDFP enlisted and studied a population of 10,000 patients, recruited directly by house-to-house surveys in selected census tracts who were treated and followed for a minimum of 5 years; it began in the early 1970s and was reported in 1979 (HDFP Cooperative Group, 1979a, 1979b). The design of the study was relatively simple: The patients were randomly divided into two groups, one of which received special care (SC) in clinics especially established for the purpose of goal oriented, intensive care. Patients were followed closely with medications added as necessary to achieve diastolic blood pressures of 90 mm Hg or at least 10 mm Hg below their baseline. The medication used was reserpine—and later propranolol-thiazides, hydralazine, methyl dopa, and guanethidine sulfate, added stepwise to achieve the aforementioned goal. The other group of patients were assigned to regular care (RC), meaning they were turned over to their regular source of treatment, usually from their community physicians, but were seen yearly by the investigators for evaluation and follow-up. The majority of the RC patients also received some therapy from their regular source, but it was not of the intensity or goal orientation of the SC group. Although it was not considered ethical or appropriate to have a placebo group, it was recognized that the RC group would have less intense treatment because, particularly for the mild hypertensives, this was the *Zeitgeist* during this period of time.

The results were impressive. The primary endpoint was overall mortality and there was a greater than 16% decrease in deaths in the SC group. This difference was most marked in the so-called mild hypertensive patients. In fact, the differences were less in the moderate and severe patients, a fact that was interpreted as meaning that the physicians caring for the RC patients were more convinced of the need for aggressive therapy in their more severe hypertensives than they were of the need for therapy in the milder forms of the disorder. The major cause of death prevented, as in the Freis study, was cerebrovascular event. Evidence for prevention of death from cardiac causes was much less convincing, in spite of the fact that hypertension is considered a significant risk factor in cardiac, particularly coronary atherosclerotic, disease. The meaning of this failure to demonstrate a decrease in coronary artery disease (CAD) mortality created a storm of controversy that remains to this day. It has been blamed on poor choice of

drugs (although at the time of this study only the ones used were pharmacologically available), electrolyte abnormalities, exaggeration of lipid risk factors, and the additional genetic/environmental/behavioral influences on atherosclerotic coronary artery disease, as contrasted to cerebrovascular disease. The difference is not due to drug factors, but to the fact that the connection between hypertension and CAD is not as direct as it is between cerebrovascular disease, particularly cerebral hemorrhage and hypertension.

These data, along with subsequent clinical trials, have firmly established that treatment of hypertension with present-day pharmacological agents has a significant impact on morbidity and mortality of the disease. Consequently, the development, evaluation, and marketing of drugs to treat hypertension has become a major industry whose goal is treatment for most all hypertensive subjects who number some 15% to 20% of the population. At the same time, however, the "pathopharmacology" of these drugs has posed a considerable problem and has led, as mentioned earlier, full circle to a reconsideration of nonpharmacological means of treatment, particularly in the milder degrees of hypertension. The problem of side effects of drugs is of course not insurmountable; in the aforementioned HDFP study, for example, although about a third of patients reported difficulties with one or another of the drugs they were receiving, only 9% had to be dropped from the program. The rest were successfully transferred to other drugs. Nevertheless, the problem has served as an impetus and a challenge to advocates of behavioral therapies and dietary and lifestyle change as alternative methods of treatment.

Under the heading of dietary changes in management, control of weight and reduction of sodium intake constitute the two major approaches. Calcium and potassium supplementation to the diet have had their advocates. Smoking cessation, alcohol restriction, and physical exercise have been scrutinized as lifestyle changes that can influence blood pressure. Avoidance of daily stress by change in occupation, environment, climatic extremes, spouse and associates, and so on all have had a long history of being offered as gratuitous advice to patients by friends, family, and indeed by physicians and other health care providers. Control of these factors requires knowledge of the social and cultural forces that influence them as well as the development of techniques to put them into effect, and in this respect behavioral manipulation, defined in a broad way, is essential. But the specific behavioral therapies which have been utilized to lower blood pressure have more direct psychological origins. They include psychotherapy, environmental modification, suggestion, placebo administration, relaxation, and biofeedback. The background, utilization, and outcomes are discussed for each of these. First, however, some discussion of the dietary and life changes is in order.

SODIUM INTAKE

Diet is strongly influenced by social and cultural factors and accordingly is affected by behavior. Most important to the consideration of hypertension is sodium intake. In fact, Denton (1965) argued that the salt-seeking behavior of humans has had

a major evolutionary impact. Some of the most potent adaptations in humans are directed at sodium control and the phylogenetic development of the renin-angiotensin system (RAS) primarily relates to sodium conservation. Salt is essential to human life, yet its intake can vary from as low as 1 mequiv/day to as high as 400 and perhaps 800 mequiv/day, while the person maintains normal health and function. Sodium intake has been considered a significant factor in the pathogenesis of hypertension for many years and this chapter does not cover this literature in any detail. However, some of the epidemiological data concerning the effects of sodium are pertinent to the social, cultural, and behavioral influences on hypertension, which are within the agenda here. Studies of various cultural groups have indicated that sodium intake in close, primitive societies correlates with differences in levels of blood pressure among such societies. Sodium intake in the most primitive tribes is quite low, as is the prevalence of hypertension within them. Cassel (1974) and Henry (1988) discussed the process of acculturation in terms of the stress that particular societies experience, but Page, Damon, and Moellering (1974) suggested that this process of acculturation is also associated with increased sodium intake, which plays an equally important role in their development of hypertension.

The sodium intake of civilized people (150–200 mequiv/day) can be considered high and “unnatural,” because primitive groups often subsist adequately even in hot climates with intakes of less than 40 mequiv/day. Older studies of the Yanamano Indians of South America have been particularly revealing in this regard; their sodium intake averages 5 mequiv/day and there is literally no hypertension among them and they do not show the blood pressure rise that occurs with aging. It is of interest, in view of what was said earlier about the evolutionary development of the RAS as a sodium conserving mechanism, that the Yanamanos maintain their low blood pressures in spite of peripheral renin activities (PRA) that are two to three times normal values (Oliver, Cohen, & Neal, 1975).

In regard to sodium conservation as an evolutionary development, an interesting theory has been put forward by Grim to possibly explain the higher prevalence of hypertension among Blacks in the United States (Wilson & Grim, 1991). He argued that Blacks from the interior of equatorial Africa had developed more potent sodium conservation mechanisms than those from coastal areas and they survived the rigors of the slave trade to a greater extent during the long sea voyages that brought them to this country. Deaths on the slave ships were massive and most were due to sodium-depleting causes (e.g., malnutrition, diarrhea, heat, fever, etc.). Thus the Blacks in the United States constitute the major descendants of this sodium conserving group, retaining sodium more avidly, having now a higher predilection to hypertension, and responding more dramatically to sodium restriction and diuretic therapy. Whether such a genetic selection could have taken place in the brief period of the past several hundred years is a matter of speculation, but it is an interesting hypothesis that is perhaps amenable to further investigation.

The evidence that a decrease in sodium intake in the diet will lower blood pressure in man derives mainly from the ef-

fectiveness of the diuretics and from the results of drastic sodium restriction with such regimens as the Kempner rice diets of years ago, in which sodium intake was decreased to approximately 10 mequiv/day. Direct evidence is less available concerning lesser degrees of sodium restriction, on the order of from 75 to 100 mequiv/day that could be achieved by avoidance of added salt and well-known high sodium foods, which can have a measurable effect on blood pressure in man. A study by Parijs, Joossens, Van der Linden, Verstreken, & Amery (1973) demonstrated that a reduction from the usual 200 mequiv/day to approximately 100 lowered blood pressure about 10/5 mm Hg and supplemented the effect of diuretics. Similarly, T. Morgan et al. (1978) demonstrated a diastolic decline averaging 7.3 mm Hg in a group of patients with a sodium intake reduction reflected in urinary sodium decrease from approximately 191 mequiv to only an average of 157 mequiv/day. There was a wide variation in the success in reducing sodium intake in Morgan's patients; those with values approaching 100 mequiv/day had the better blood pressure results. These results occurred and persisted over a 2-year period. A study of interest by Singer et al. (1995) relates to the additive effect of lowering sodium on the hypotensive effect of an ACE inhibitor. These investigators showed that modest reduction of sodium intake (from 206 mequiv/day to 109 mequiv/day) was equally effective as hydrochlorothiazide in improving blood pressure control.

Luft, Bloch, Weyman, Murray, and Weinberger (1978) derived the reverse data—namely, that in healthy people put on progressively high intakes of sodium starting at low levels and rising to as high as 800 mequiv/day—blood pressure will show a proportional rise. This certainly would be expected from animal data like those of Menely and Dahl, who showed this phenomenon in numerous experiments over the years (Menely & Ball, 1958; Dahl, 1961). Quite striking, however, in terms of Dahl's data on genetic differences in salt sensitive and resistant rats, studies of increased sodium intake reported by Kawasaki, Delea, Bartter, and H. Smith (1978) noted that mild hypertensive patients divided themselves into groups who were quite sensitive to salt intake and others who were considerably less sensitive.

What does all of this mean as a behavioral or cultural risk factor for hypertension? First, nobody really understands people's craving for excessive salt intake beyond their physiologic need and their ability to conserve it. It seems at least in part to be a learned habit. There is evidence that infants have little or no taste for salt, a fact that has finally persuaded some baby food manufacturers to remove sodium from baby food products because they primarily were adding it for the “tasting mothers” rather than the “consuming infants.” Avoidance of salt can be learned (or perhaps salt taste can be “unlearned”), as has been the experience in treating hypertensives; anecdotally, patients who observe this behavior for a significant period of time develop a sensitive sodium taste threshold and can taste salt in situations where others do not.

On the other hand, however, there seems to be some evidence that there is an increased salt avidity in hypertensives. The question “Do you salt your food before you taste it?” is said to be answered in the positive by hypertensive patients,

although there is no adequately controlled study of this phenomenon that includes normotensives. Interestingly, Langford, Watson, and Thomas, (1977) showed that patients put on diuretics can develop an increased salt intake if they are not closely watched in this regard. This is reminiscent of old observations that demonstrated that sodium-depleted rats (e.g., after adrenalectomy) preferentially will consume saline containing fluid when offered, rather than water alone.

These data suggest that man has developed a powerful tool to maintain the sodium content and concentration in his body at adequate levels for maintenance of life, and this has played a significant evolutionary role in development from marine to terrestrial animals. This mechanism may have evolved in man under certain environmental circumstances as per Grim's hypothesis. Because of cooking and preserving habits and other cultural influences on taste in modern society, people currently consume considerably more sodium than they need for their vital body functions and it is probable that this increase in sodium intake, at least in particularly prone individuals, plays a significant role in predisposition and perpetuation of hypertension.

Reduction of sodium intake to a more physiologic amount (e.g., 100 mequiv/day or about 4 to 5 grams of salt) would require major social and cultural behavioral changes. Until there is better information concerning variability of salt sensitivity, such a mass attempt at reeducation of the public, particularly in view of other dietary onslaughts on a hopeful but skeptical public, would be ill-advised. Freis (1976) suggested editorially that reduction of salt intake to low levels would "wipe out hypertension in several generations," but his statement at the most is a "provocative suggestion" rather than a pragmatic proposal. Nevertheless, the aforementioned decisions to remove sodium from baby food, and current labeling of food contents are encouraging examples of such cultural progress.

Although reduction of sodium intake is not easily achieved in normal persons, there is not enough data for its use in first step management of the hypertensive patient. Diminished intake becomes an important part of the nonpharmacological approach to the management of hypertension and is a behaviorally oriented therapy (Jacob, Wing, & A. P. Shapiro, 1987). In addition to being an important first step in the management of the hypertensive, it continues to apply when the patient is then put on a diuretic, because reduction of sodium intake does result in a lesser incidence of the development of hypokalemia from the diuretic.

WEIGHT MANAGEMENT

Obesity is a social and cultural phenomenon that has been clearly demonstrated to play a role in the predisposition and perpetuation of hypertension. It is not known why the prevalence of hypertension is greater in the obese individual, but much evidence has accumulated that weight reduction does reduce blood pressure. In fact, clinical experience finds it difficult to effectively lower blood pressure in the hypertensive patient who remains obese. Both epidemiological studies as well as clinical trials have established this relation, and many of these observations are cited and reviewed by Jacob et al.

(1987). One mechanism that has been suggested for this relation is that the obese person has performed an increased sodium intake, but several studies have controlled this factor and shown that weight loss without sodium reduction does lower blood pressure. Other studies have derived data indicating that drug therapy can be reduced and blood pressure control maintained with weight loss and some have provided data relating actual kilograms of weight loss to mm Hg of blood pressure decline achieved. Examples are the study by L. E. Ramsay, M. H. Ramsay, Hettiaracchi, Davies, and Winchester (1978) in which a fall of 2.5/1.5 mm Hg was noted with every kilogram of weight decline, and that by Stamler et al. (1980) on the Chicago Coronary Prevention Evaluation Program (CPEP) in which one kilogram of weight loss was associated with a 2.5/1.8 mm Hg decline. Such data give credence to the encouragement doctors often give patients that they will lower their blood pressure "one mm Hg for every pound they lose." In the CPEP study, the weight loss and blood pressure decline were maintained for the 5-year duration of the study in those patients who did not drop out of the program.

Most studies and treatments of obesity in the hypertensive patient have relied on nutrition-education interventions, involving the keeping of diaries of food intake along with review of these data and provision of caloric and nutritional advice. Behavioral strategies have been employed to a lesser extent, so that there is a need for their further study and application in the obese hypertensive.

Another aspect of the relation of obesity to hypertension is the so-called sleep-apnea syndrome. Unlike the usual "dipping" of blood pressure that occurs during sleep in most hypertensive patients, an undefined number of obese individuals suffer from periods of airway obstruction during sleep characterized by marked snoring, apnea, anoxia, and elevation of blood pressure. This syndrome has been associated with an increased incidence of strokes and coronary events in such individuals, although the exact prevalence of either the syndrome or its complications is not evident. Nevertheless, relief of the syndrome by weight loss as well as mechanical nighttime breathing aids and even airway surgery has been noted to improve hypertension and its control (Fletcher, 1995). This aspect of obesity and its relation to hypertension, cerebrovascular events, and heart disease requires further clinical application.

OTHER DIETARY INTERVENTIONS

An extensive literature exists of a variety of dietary interventions that have been advocated to treat and/or prevent hypertension. The most interest is in potassium intake, calcium intake, and vegetarianism. Reviews of these attempts and outcomes are available and no further discussion is offered here, except to mention them for the purpose of completeness. Suffice it to say from my own examination of the literature and clinical experience, I do not particularly use any of these modalities in treating my patients. In a recent report, Sachs et al. (1995) showed that no appreciable effects on blood pressure were noted in hypertensive patients treated with combinations of potassium, calcium, and magnesium.

PHYSICAL EXERCISE

Exercise has been advocated as a method of controlling blood pressure long before it was adopted in the behavioral field. The use of behavioral principles has moved it away from the coaches and fitness experts into the realm of nonpharmacological therapies. Cardiovascular fitness training is of particular pertinence to the management of hypertension. This literature has been reviewed recently (Jacob et al., 1987) and it has been noted that although aerobic exercise may result in modest reduction of blood pressure in most published studies, significant methodological limitations tend to minimize the value of the data. Thus, there is often an absence of no-treatment control groups and the lack of adequate documentation of intermediate variables such as maximal oxygen uptake as a measure of achieved fitness, and the possibility that weight loss is a compounding factor.

The persistence of an exercise effect has been studied by several investigators, who have found a tendency for the lowered levels to increase to baseline levels after discontinuation and a lack of relation to intensity of the exercise. Conflicting predictors of response have been noted, that is, low renin values predicted favorable results in one study and high catecholamines were predictive of diminished response in another. Most clinicians warn against the use of isometric exercise in hypertensive patients. Weight lifting, for instance, can cause sharp peaks in blood pressure that are considered potentially dangerous. Such exercise is ill-advised, for older individuals, although the effects in younger patients have not been impressive.

To summarize, the effects of exercise have not been evaluated with clinical trials methodology. It is likely, however, that small, at least transient, declines can be achieved with improved cardiovascular fitness achieved through aerobic exercise (and in our own patients we advocate this lifestyle addition). Most people are increasingly sedentary and when they become aware that they have an elevated blood pressure, their first reaction is often to "take it easy," thus further encouraging inactivity. Patients need to be made aware that exercise is not harmful to their blood pressure, cardiovascular fitness is improved, weight loss is helped, and the exercise need not be of an intense nature. Over the years, we have taken care of many adolescents and young people with modest elevations of blood pressure, who after secondary causes of their hypertension or significant congenital cardiac disease have been ruled out, have participated in strenuous sports activities (including football, basketball, running, skiing) without ill effects. To be sure, controlled clinical trials are sparse, and compliance over a long time, as with diet, is a problem in this lifetime disease, but it is a simple nonpharmacological change in lifestyle and it is strongly advocated in patient management, albeit not to the exclusion of pharmacological modalities as needed.

BEHAVIORAL THERAPIES

As mentioned earlier, behavioral methods of treatment have a long history that probably stems from the fact that observers

of blood pressure have always noted the variability and reactivity of the pressure under many circumstances—both spontaneously and seemingly induced by whatever is being done to the patient. Attempts to manipulate blood pressure behaviorally have been classified in six categories.

Psychotherapy

Traditional verbal psychotherapy as a method of treating hypertension arose from two concepts. First, because anxiety seemed to elevate blood pressure, its relief by psychotherapy should then lower it. This straightforward relation requires simple techniques, for example reassurance and supportive psychotherapy. Second, insofar as the hypertensive individual may not be able to handle aggressive and hostile impulses—as suggested by Alexander, Binger, and Dunbar, among others—psychodynamic analytics therapy might lead to resolution of these conflicts and hence lowering of blood pressure.

Historically, verbal reassurance has played an important role in the management of hypertension. In fact, current attempts at creating public and individual concern about hypertension contrast sharply to attitudes clinicians tried to develop in hypertensive patients before the development of current pharmacologic agents. Patients were reassured and discouraged from worrying about blood pressure levels, based on data that the actual level of blood pressure on any one occasion did not reflect the true status and severity of the ailment or correlate with symptoms; that blood pressure levels were variable and reactive to many stimuli; and that prognosis was often unpredictable and patients might function for many years without disability despite elevated blood pressures. Patients were not encouraged to take their own blood pressure, ask their physicians its level, or keep personal records of it. The development of a "manometer neurosis" was a matter of concern; reassurance and supportive psychotherapy often with a mild sedative, such as phenobarbital, were mainstays of treatment. Environmental manipulation—such as job change, rest periods, change of domicile, or domestic arrangements—was frequently recommended. Such treatment, which can be referred to as "a pill and a prayer," was in fact all that was available for the mild and moderate hypertensive, with such therapies as severe sodium restriction and sympathectomy considered as drastic and reserved for patients with severe and progressive disease as defined by end-organ damage rather than blood pressure levels per se.

Two specific studies, one of supportive psychotherapy, the other of analytic therapy, deserve comment in this historical context. The first of these is a study by Reiser et al. done by the Cincinnati group in the early 1950s (Reiser et al., 1951), before the "pharmacological explosion"; hence, this sample of 230 patients received no specific drug therapy. A supportive therapeutic relationship was maintained in 98 of these patients for a minimum of 2 years. Significantly improved blood pressure levels (falls of 20/10 to 40/20 mm Hg) occurred in from 22% to 58% of these patients, the degree of impact depending on which of three levels of intensity of supportive psychotherapy they received. Treatment

ranged from simple reassurance to superficial insight therapy and was administered by internists, albeit a group with special interest and training in psychosomatic illness. Of further note, from 17% to 40% showed improvement in physical findings, whereas 60% reported symptomatic improvement. Seventeen percent of the 98 patients died, with an average survival of 20 months, but the deaths related to the amount of target-organ damage with which they first presented, rather than to the levels of their blood pressure. Duration of these salutary effects on blood pressure and other findings was not established in this study. Even at the time, and certainly retrospectively, these outcomes were not impressive in terms of controlling the disease, but they do provide a background indicating that levels of blood pressure can decline and some improvement can ensue without specific therapy and thus they do speak to the natural history of hypertension.

A second, pertinent study was that by Moses, Daniels, and Nickerson (1956), which consisted of only 10 patients, but followed closely in psychoanalytic therapy for up to 6 years. Two of the patients discontinued therapy, but the other eight showed significant improvement with reduction of pressure to normal (in four with mild hypertension) and to a "borderline level" in two of the remaining four. One patient with an accelerated phase of his hypertension reverted to a benign state with the aid of potent drugs that became available during his course. Moses did not think that as a therapeutic modality, psychoanalysis had a role in the treatment of hypertension per se, being limited by its length, the age and intelligence of the patient, the severity of the psychiatric process, and the degree of reversibility of the somatic state. In the few patients who improved, major reconstructive changes in personality had to be achieved to accomplish the somatic results. There was never any advocacy or enthusiasm about further attempts to utilize psychoanalysis in the treatment of hypertension, but again Moses' work remains as an indication that blood pressure lowering of significance can occur during the course of hypertension, again without specific pharmacologic intervention.

The status of psychotherapy as a therapy for hypertension can thus be summarized from the data already described, and subsequent reviews as follows:

1. Declines in blood pressure of up to 20–40/10–30 mm Hg may be achieved and maintained over several years of continued therapy, although subject to "escape" with imposed stress.
2. Patients need to be seen regularly by an experienced therapist, but for supportive therapy it is appropriate and preferable that the therapist be the patient's internist or general physician. For psychoanalytic therapy, an analyst who is "comfortable" with somatic illness is necessary.
3. Supportive therapy is always indicated, especially when drugs are used, because it augments compliance. Any successful provider–patient relationship can offer this basic support.
4. Analytic therapy is highly selective, and the patient's suitability and psychiatric need independent of hyper-

tension determines its use. It is expensive and time consuming.

5. Psychotherapy as treatment clearly has not proceeded beyond a few brief uncontrolled clinical trials, but has a long history of anecdotal experience and pragmatic application.

Environmental Manipulation

Environmental manipulation and modification to lower blood pressure is based on the hypothesis that stressful stimuli arising in the patients' environment adversely affect their blood pressure. Considerable epidemiologic evidence that environment influences blood pressure levels is available. Urban populations generally have higher pressures than rural populations. Cultural change, adjustment to a new environment, socioeconomic status, and type of job all have been implicated as affecting blood pressure. Anecdotal examples of improvement with change of environment, job, or home can be provided by most clinicians, and such change is probably recommended to patients frequently without controlled follow-up. However, controlled studies in which change of environment as a therapy has been tested are not available. There are references in the Soviet literature to the use of rest therapy and job adaptation, but with little data (Simonson & Brozek, 1959).

Data are available concerning certain types of acute changes in environment. For instance, hospitalization generally has a predictable, although variable in degree, effect on blood pressure. In 33 hospitalized hypertensive patients receiving no specific pharmacologic therapy, a maximum fall of mean blood pressure of 25.4 ± 19.8 (standard deviation) mm Hg was reported, with this maximum occurring 10 ± 5 days after admission to the hospital (A. P. Shapiro, 1956). Moutsos, Sapira, Scheib, and A. P. Shapiro (1967) showed that the placebo effect in six hospitalized patients whose mean blood pressure fell an average of 20 mm Hg was largely the effect of withdrawal from environmental stress. This hospital effect might also relate to the extinction of a conditioned pressor response to blood pressure measurement.

The long-term consequences of hospitalization and other environmental changes are not known. Combining hospitalization with pharmacologic agents is additive and in accelerated hypertension can be an important therapeutic maneuver. Although most patients with benign hypertension can be managed as outpatients, hospitalization is justified when environmental stress causes progressive difficulty in blood pressure control. Hospitalization can have a "negative" effect when conflict between patient and physician or other hospital personnel develops or when problems at home or on the job are potentiated by the patient's hospitalization (A. P. Shapiro, 1959). Similarly, any environmental manipulation carries the risk of failing to reduce stress and hence could further exacerbate the blood pressure problem.

To summarize, with the exception of hospitalization, environmental manipulation as a therapy for hypertension primarily has the status of biobehavioral speculation based on epidemiologic data in animal models (Henry & Cassel, 1969).

PLACEBO AND SUGGESTION

The effects of placebos usually have been discussed in regard to their role in evaluating drug therapy. Placebo effects are not treatment modalities, but require understanding because they can confound the results achieved by specific therapies, both pharmacologic and nonpharmacologic. The placebo has been defined as any therapy for component of therapy that is used for its nonspecific psychologic and physiologic effect but has no specific pharmacologic impact on the condition being treated (A. K. Shapiro, 1968). Study of the placebo effect in hypertension has contributed to knowledge of the phenomenon, but especially it has related to the development of clinical pharmacology and new drug evaluation (Smith & Melmon, 1972).

Placebo effects are variable and not always reproducible, the dose-response relations are difficult to identify, and the response is not a necessary consequence of the intent of the treatment. The mechanisms by which the physiologic effects occur are complex and diverse. However, that placebo effects are viewed as nonspecific is a consequence of current deficiencies in understanding the relations of the multiple factors involved. These factors fall within one of three general categories (Liberman, 1962, A. K. Shapiro, 1968, 1971): (a) patient variables—attitudes toward the physician, the treatment, and the illness; levels of anxiety and expectation, education, and past experience with illness; (b) physician variables—credibility, enthusiasm, authority, empathy, and sympathy; and (c) situational variables—location and form of treatment, interactions with staff and family, content and meaning of instructions and suggestions.

Several conclusions may be drawn from current analyses of the placebo effect. First, attempts to define an identifiable "placebo reactive" personality have generally failed (Beecher, 1959; A. K. Shapiro, 1971). Second, placebo effects can also adversely affect the clinical course of the patient because side effects, with both subjective and objective symptoms and signs, can be observed with placebo use (Beecher, 1959; A. P. Shapiro, 1956; A. P. Shapiro, Myers, Reiser, & Ferris, 1954; Uhlenhuth et al., 1959; Wolf, 1959). Third, deception is not essential to placebo action, except in the special case of "blind" drug trials. Fourth, the doctor (provider)-patient relationship is the agency of the placebo effect (Adler & Hammett, 1973).

Magnitude of Placebo and Suggestion Effects on Blood Pressure

Placebo factors include various psychological influences and manipulations that may be associated with systematic directional shifts in blood pressure (Alexander, 1939; Reiser et al., 1951; A. P. Shapiro, 1956; Wolf et al., 1955). Blood pressure changes in most studies are in the same range of magnitude as those described with behavioral procedures discussed elsewhere in this chapter (about 5–25 mm Hg, systolic or diastolic).

The salutary effect of a sustained therapeutic relation in the hypertensive patient has been mentioned earlier. The con-

verse effect, an adverse response to a negative change in the physician's attitudes and enthusiasm—which partially negated the effect of both the placebo and the antihypertensive drug under study (A. P. Shapiro et al., 1954), despite a double-blind experimental design—also has been described. Wolf and colleagues (1955) and Pickering (1968) likewise noted a potent role for the doctor-patient relationship as an adjunct or deterrent to pharmacotherapy.

Certain variables that cannot be easily separated from placebo effects are relevant to the procedures already described. The first appearance of a patient at treatment site often has a pressor effect, probably related to apprehension. Accommodation to the situation results in a relative decline in blood pressure, appearing to be improvement. The use of placebo as an "antihypertensive" medication may or may not result in lower blood pressure; this outcome depends on physician attitudes, severity of hypertension, and whether comparison is made with initial visits, nontreatment periods, or hospitalization (Freis, 1960; Jacob & A. P. Shapiro, 1994; Pickering, 1968; D. Shapiro, Schwartz, & Tursky, 1972; A. P. Shapiro & Teng, 1957).

An older, but classic, study of suggestion by Goldring and associates (1956) of 31 outpatients shows the effect of intensive reassurance combined with visual exposure to a dramatic but innocuous device, which subjects were informed was a "therapeutic electron gun." Blood pressures fell an average of 20/14 mm Hg; in eight of the patients diastolic blood pressure fell below 90 mm Hg, an average diastolic fall of 25 mm Hg. Although the effect lasted only several weeks and a precise experimental design was lacking, these data have special pertinence to biofeedback, relaxation, and psychotherapy studies. Similarly, numerous stimuli may result in acute blood pressure elevations in normotensive and hypertensive persons, for example, stressful interviews (Wolf et al., 1955), the amount of interpersonal interaction (Williams, Kimball, & Williard, 1972), forced perception of conflict (Sapira, Scheib, Moriarty, & A. P. Shapiro, 1971), psychodrama involving assertiveness or hostility (Kalis, Harris, & Sokolow, 1957), and frustrating or demanding verbal and mental tasks (Brod, Fencel, Hejl, & Jirka, 1959; A. P. Shapiro, 1961). Removal of the noxious stimulus in these situations results in a return of pressures to baseline that might be interpreted as resulting from a specific therapeutic intervention.

Suggestion as a therapeutic factor also has been shown in experiments involving direct verbal instruction to control blood pressure without biofeedback or meditation with appropriate directional changes of 15/10 mm Hg (Redmond, Gaylor, McDonald, & A. P. Shapiro, 1974; A. P. Shapiro, Redmond, McDonald, & Gaylor, 1975). In some studies of voluntary control of blood pressure, instruction appears crucial to responses (Brenner, 1974; Brenner & Kleinman, 1970; Redmond et al., 1974; D. Shapiro, Schwartz, & Tursky, 1972), and in most studies involving hypertensive persons, awareness of the task required (i.e., to lower blood pressure) occurs either explicitly or is surmised by the patient. Such awareness of therapeutic intent clearly influences the response to medications (Knowles & Lucas, 1960; Sternbach, 1964) and will facilitate voluntary control of other autonomic

responses (Bergman & Johnson, 1972; Blanchard et al., 1974) posing a further problem in evaluating the specificity of behavioral therapies.

Evaluation of Placebo Effects

Placebo influences produce a summation of social, attitudinal, and environmental factors that affect the blood pressure levels of hypertensive patients. Awareness of these factors has led to the design of elaborate control procedures for evaluating antihypertensive drugs, and such procedures are equally necessary for the rational assessment of nonpharmacologic therapies. Although the placebo effect is potent, it is not proposed as a planned therapeutic approach to the management of hypertension in the present era of pharmacological and nonpharmacological therapies, but its impact on the patient and on evaluation of therapy must be continually recognized. Similarly, suggestion per se will influence outcome, although it has little if any lasting value.

BIOFEEDBACK

As stated by Miller (1974), biofeedback is the "use of modern instrumentation to give better moment-to-moment information about a specific physiologic process that is under the control of the nervous system but not clearly or accurately perceived. In the terminology of 'servo systems,' such information has been called feedback. Such information about a biologic process is called biofeedback" (p. 684). With the aid of this information, it is possible to develop some control over a physiologic process.

Historically, responses innervated by the autonomic nervous system were considered "involuntary" and not modified by trial-and-error learning (also termed instrumental, or operant, conditioning). However, it is now documented that when animals or humans are provided with feedback for different physiologic processes and are given appropriate incentives for controlling the responses, they can learn to self-regulate functions such as heart rate, blood pressure, blood flow, skin temperature, sweat gland activity, and gastric and intestinal processes (Miller, 1969; D. Shapiro & Schwartz, 1972).

Neither the peripheral nor central mechanisms involved in the self-regulation of blood pressure are clearly known. Changes in muscle tension and respiration may be contributing factors, but they are not the sole mechanisms. Differential control of heart rate and blood pressure can be achieved depending on the specific type of biofeedback. For instance, in studies by Schwartz (Schwartz, 1974) and D. Shapiro and coworkers (D. Shapiro, Tursky, Gershon, & Stern, 1969; D. Shapiro, Tursky, & Schwartz, 1970a, 1970b), normotensive subjects learned to change either heart rate or systolic blood pressure, or both, simultaneously, and in either direction, with different kinds of biofeedback aimed at the patterns in which these different physiologic changes were recurring. Importantly, simultaneous changes in blood pressure and heart rate also may occur if subjects are given specific instructions to control these functions, and they will draw on various

cognitive and somatic strategies to produce more complex physiologic patterns. Because blood pressure is the outcome of the relation between cardiac output and peripheral resistance, then depending on the type of biofeedback and instructions used, changes in heart rate, stroke volume, and peripheral resistance may be differentially involved, with the exact details of each needing specification. In addition, biofeedback for other potentially relevant physiologic responses, such as muscle tension (electromyography), sweat gland activity (galvanic skin response), and skin temperature theoretically may aid in lowering blood pressure (Schwartz, 1973; D. Shapiro, Mainardi, & Surwit, 1976)

Biofeedback methods use diverse techniques. Most effective are constant pressure cuff systems with which binary (yes/no) feedback for increase or decrease of blood pressure at each beat can be given. The system is usually more reliable for systolic pressure than for diastolic pressure. More intermittent biofeedback procedures based on a standard cuff system obviously cannot be used to recognize rapid changes in blood pressure but may aid patients to self-monitor or regulate pressure both in the laboratory and at home. Ambulatory indirect monitors can be adapted for such use. Various types of "rewards" are used for lowering blood pressure or achieving objectives, but praise and support from family and therapist along with the patient's desire for self-regulation are major incentives in the process. The magnitude of blood pressure decline with biofeedback has been reviewed in numerous publications, and has not appreciably changed from what was described in a review of the then existing data (A. P. Shapiro, Schwartz, Ferguson, Redmond, & Weiss, 1977); it is usually modest and generally does not exceed approximately 20/10 mm Hg. How permanent such effects are and their value in the long-term for chronic hypertension is discussed in more detail in the next section.

RELAXATION THERAPY

Relaxation therapy is a form of stress management and has a long history. Practitioners of certain Eastern disciplines and religions, notably Zen and Yoga, for hundreds of years have reported the ability to control autonomically regulated functions. Consideration of biofeedback methods in the treatment of hypertension reawakened interest in these older methods of relaxation and led to a number of new and perhaps simpler techniques. As with biofeedback, the revision of traditional opinion that the autonomic nervous system is beyond conscious control encouraged this progress.

Relaxation methods, although differing in specifics and focus, seek to elicit calmness and a hypometabolic state. The response is associated with decreased sympathetic arousal and heightened activity in the supraoptic and preoptic areas of the anterior hypothalamus (Beary, Benson, & Klemchuk, 1974; Hess, 1957). This integrated state of lowered sympathetic activity might be expected to lower blood pressure, because essential hypertensive subjects show a reactive pressor response to stimuli and the sympathetic nervous system is the major mediator of this response (Abboud, 1976; Benson, 1975; Benson, Beary, & Carol, 1974).

Several specific relaxation methods have been proposed for the treatment of hypertension. Several publications (Schwartz et al., 1979; A. P. Shapiro et al., 1977) are summarized here:

1. Progressive relaxation (Jacobsonian): a technique directed at relaxation of major skeletal muscle groups.
2. Autogenic training: standard "autosuggestive" exercises for inducing altered physiologic and mental states.
3. Hypnotic relaxation: hypnosis and posthypnotic suggestion to induce physiologic and mental relaxation.
4. Zen meditation: methods of meditation involving passive concentration on respiration and a logical exercise (koans) to elicit the relaxation response.
5. Hatha yoga: relaxation is elicited through bodily postures and exercises (asanas), breath control (pranayana), and meditation (dhyana).
6. Transcendental meditation: a cognitive technique derived from Vedic practices in which individuals assume a comfortable position, breath peacefully, close the eyes, and repeat a "mantra" (a Sanskrit word for sound) as each breath is exhaled.
7. Relaxation response: a simplified and standardized meditative technique developed by Benson and co-workers based on transcendental meditation and Zen and specifically directed to relaxation, but tailored more to Western culture.

None of the previous methods were specifically devised for treatment of hypertension. All claim nonspecific benefits for lifestyle and "well-being," as well as their potential for hypotensive effects. The abbreviated descriptions fail to do justice to the emphasis and contextual variables that give each method its particular character. Benefits from each technique are enhanced by a trained clinician or teacher, who initiates and instructs the patient, gives encouragement and corrective feedback, and follows progress and compliance.

The magnitude of effects with relaxation and stress management techniques are modest and increasingly less impressive. Following the initial enthusiasm for their use, the effects have been shown to be relatively transient and not particularly evident outside of the laboratory, as for instance when ambulatory, day-long monitoring is performed. Effects on endpoints other than blood pressure have not been achieved, with the possible exception of studies by Patel (1975; Patel & North, 1975), who showed effects lasting up to 12 months associated with decrease in drug requirements and in a few patients a decline in morbidity, but her studies have not been repeated or confirmed by other investigators. An interesting observation by Stone and DeLeo (1976) did show some decline in plasma renin activity and components of the catecholamine system that were cited as evidence of decrease in adrenergic activity along with blood pressure, but whether cause or effect remains unanswered. Relaxation effects are also not easily distinguished from those due to sleep, particularly because some studies show EEG patterns of sleep during transcendental meditation, for instance. Recent studies by Chesney, Black, Swan, and Ward (1987) and Agras, Taylor, Kraemer, Southam, and Schneider (1987) have been discouraging in terms of the specificity of relaxation as a therapeutic mo-

dality in that they failed to show a long-term advantage of behavioral therapy over blood pressure monitoring in the research clinic. In both trials, there was a progressive decline in blood pressure in the control groups during monitoring in the clinic or work site. These studies emphasize the need to monitor for a period of time, before adding relaxation, a fact that has been well-known to the clinical pharmacologist evaluating drugs.

Concerns and doubts about the specificity of relaxation and other behavioral therapies have been summarized in a review questioning whether the effects of stress management really represent just regression to the mean and related factors (Jacob & A. P. Shapiro, 1994). As results of better designed studies have accumulated, the clinical effects appear less convincing. Larger blood pressure declines tend to be reported in studies that do not include adequate baseline assessments. Habituation to a new environment, as may occur in a subject attending a new clinic, treatment program, or provider plays a role in eliciting blood pressure decline as does the development of a therapeutic relationship with the physician or other provider. Differential effects in habituation between control and treatment groups may occur as related to waiting periods before therapy is started. Drop-out rates may differ; in some studies, drop-out rates are higher in the behavioral treatment patients than in controls or even in drug studies. Certainly, compliance is a major problem in behavioral studies, particularly when such treatments require home practice by the patient. Carryover effects into the environment are also questionable. In a study comparing drugs and relaxation with measurements done at different sites, the most favorable results were seen on blood pressure changes within a relaxation session; conversely, no relaxation effect was noted on automated ambulatory monitoring outside of the therapist's laboratory or in the hypertension clinic when seen by the patient's usual physician (Jacob et al., 1992).

These findings are consistent with the notion that relaxation produces a state opposite to that of "stress." In effect, whereas stress produces a transient pressor response, relaxation induces a transient depressor response. The situational specificity of the relaxation effect suggests that it is similar to the placebo response (Jacob et al., 1986). Gould et al., using intra-arterial ambulatory monitoring, observed that the placebo effect was limited to the clinic setting, while active drug effects were also observed in other environments (Gould, Mann, Davies, Altman, & Raferty, 1987). There does not seem to be any studies on relaxation therapy that have noted significant declines during ambulatory monitoring.

Self-quieting maneuvers may be acquired by subjects in any therapeutic study and are particularly pertinent in evaluating outcomes in behavioral studies. Thus patients may "learn" quickly to "sit still" when blood pressure is being measured and this ability may be different between treated and control groups.

SUMMARY OF OUTCOMES OF BEHAVIORAL THERAPIES

Over many years of clinical and research involvement with the management of hypertension much thought has been

given to the use of behavioral techniques, and most have been practiced at one time or another. In fact, as mentioned previously, such methods were all that were available in the "early days." Certain usages, such as reassurance and resistance to panic (both on the part of the patient as well as the doctor) when finding an unusually high pressure, have remained a part of the therapeutic armamentarium in the present era of specific and effective drug therapy. Our interests in biofeedback and relaxation treatments were primarily research-oriented and from our own work and from review of the contributions of many others, we have come to certain conclusions. Relaxation and biofeedback have provided further evidence of the reactivity and variability of blood pressure in the hypertensive patient. Just as stress studies have clearly delineated the pressor response as a feature of blood pressure control, which may cause detrimental consequences in the predisposition, precipitation, and perpetuation of hypertensive disease, the behavioral therapies have established the existence of a depressor response, which may in the short-term occasionally have ameliorative consequences, at least on blood pressure alone. As such, the lowering of blood pressure by relaxation is an epiphenomenon. It is the converse of the well-established pressor response, involving varied depressor mechanisms—autonomic nervous system, hormonal and local—of considerable interest in understanding blood pressure control, but of minimal clinical significance in the long-term management of hypertension. Similar conclusions regarding the effectiveness of cognitive behavioral therapies have been reached in a recent meta-analysis reported by Eisenberg et al. (1993). On the other hand, a report by Schneider et al. (1995) on a favorable short-term outcome from transcendental meditation and progressive muscle relaxation in a group of older African Americans is worthwhile to note and may have further application.

Cancer

Barbara L. Andersen
Deanna M. Golden-Kreutz
Ohio State University

Vicki DiLillo
University of Alabama, Birmingham

The human cost of cancer is staggering. Each year in the United States over 1.4 million individuals are diagnosed and another half million people—one person every 90 seconds—die of the disease (Parker, Tong, Bolden, & Wingo, 1997). Although much of the increase in cancer incidence and mortality over the years appears to be related to advances in early detection as well as the general aging of the population (age is a risk factor; Garfinkel, 1994), Cunningham (1997) noted cancer death rates may now be trending downward (i.e., drop of 1%–3%) in the United States.

Cancers vary in their prevalence and mortality. Tables 43.1 and 43.2 display data from the United States on the incidence and death rates by specific sites and genders. These data indicate, for example, that the most common diagnoses are breast cancer for women and prostate cancer for men, but that lung cancer is the number one killer for both sexes (Parker et al., 1997). There is, however, variability across countries. For example, age-adjusted death rates per 100,000 population across sites and gender from 1990 to 1993 ranged from a high of 385 in Hungary to a low of 139 in Albania; the rate for the United States was 276 (see Tables 43.3 and 43.4; Parker et al., 1997). In short, cancer is a significant medical problem that affects the health status of millions of people worldwide.

Research on the psychological, social, and behavioral aspects of oncology began in the early 1950s, however, the knowledge base has significantly expanded during the last 20 years. In particular, research has clarified relations between psychological responses (e.g., personality, mood, coping style, relationships), social factors (e.g., presence/absence of partner,

size of social network, level of social support), and behavioral variables (e.g., compliance with treatment, diet, exercise). Contemporary research incorporates these variables and biologic systems (e.g., immune and endocrine) to examine and test their effects on disease course (see F. I. Fawzy et al., 1993, for an example; see Andersen, Kiecolt-Glaser, & Glaser, 1994, for a discussion).

A brief overview of the biobehavioral aspects of cancer is provided. The chapter begins with a conceptual framework, the biobehavioral model of adjustment to the cancer stressor. Then, descriptive research findings are reviewed within a cancer-relevant time line—from symptom discovery to survivorship or recurrence and death. Aside from reviewing the relevant clinical and empirical data, specific psychological intervention studies are discussed that are designed to reduce stress and enhance coping and adjustment.

A BIOBEHAVIORAL MODEL OF CANCER STRESS AND DISEASE COURSE

The stability of many cancer mortality rates, particularly those with the highest incidence such as lung and breast, makes it imperative that new, innovative steps be taken to improve survival and enhance quality of life. Concurrently, it has become noteworthy to the medical community that psychological interventions result in significant improvements in quality of life (see Andersen, 1992, for a review). Further, both qualitative (e.g., Maier, Wakins, & Fleshner, 1994) and quantitative (e.g., Herbert & Cohen, 1993) summaries of the

TABLE 43.1
1997 Estimates of Cancer Incidence by Site and Gender for the 5 Leading Sites

Cancer Incidence			
Male (Total est. 785,800)		Female (Total est. 506,000)	
Site	Number(%)	Site	Number(%)
Prostate	334,500(43%)	Breast	180,200(30%)
Lung	98,300(13%)	Colon/Rectum	79,800(13%)
Colon/Rectum	48,100(8%)	Lung	50,900(11%)
Bladder	39,500(5%)	Uterus	34,900(6%)
Lymphoma	30,300(4%)	Ovary	26,800(4%)

Note: Adapted from Parker, Tong, Bolden, and Wingo (1997).

TABLE 43.2
1997 Estimates of Cancer Mortality by Site and Gender for the 5 Leading Sites

Cancer Mortality			
Male (Total est. 294,100)		Female (Total est. 265,900)	
Site	Number (%)	Site	Number (%)
Lung	94,400 (32%)	Lung	66,000 (25%)
Prostate	41,800 (14%)	Breast	43,900 (17%)
Colon/Rectum	27,000 (9%)	Colon/Rectum	27,900 (10%)
Pancreas	13,500 (5%)	Pancreas	14,600 (5%)
Lymphoma	12,400 (4%)	Ovary	14,200 (5%)

Note: Adapted from Parker, Tong, Bolden, and Wingo (1997).

TABLE 43.3
Age-Adjusted Death Rates in Adult Males Per 100,000 for Selected Countries and Disease Sites for 1990–1993

Country	All Sites	Colon/Rectum	Lung	Prostate	Stomach
United States	165.3 (27)	16.5	57.1	17.5	5.0
Hungary	258.7 (1)	38.0	81.6	15.8	23.4
Poland	204.2 (8)	15.4	71.3	9.9	21.6
Italy	189.2 (15)	15.3	57.0	11.6	16.9
New Zealand	170.6 (21)	26.4	42.6	19.0	9.0
Finland	149.9 (31)	12.4	46.1	18.3	11.5
Israel	116.9 (43)	15.3	25.7	9.2	8.7
Mexico	81.6 (48)	3.3	15.9	10.6	9.9

Albania	42.7 (48)	5.2	2.2	5.0	6.3

Note: Figures in parentheses are in order of rank based on data from 48 countries during the years 1990–1993. Adapted from Parker, Tong, Bolden, and Wingo (1997).

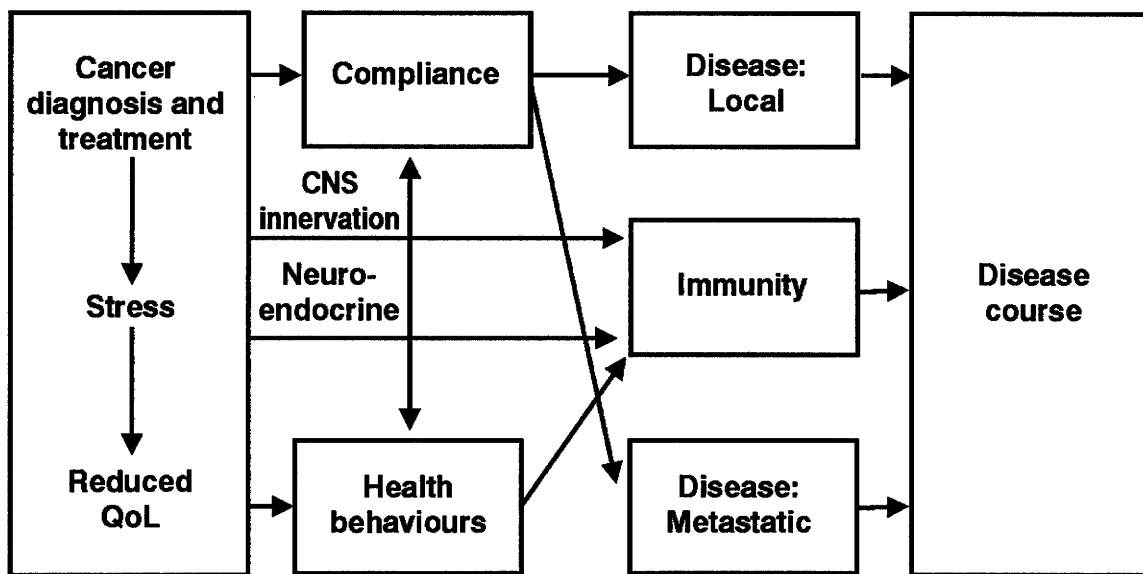

FIG. 43.1 Theoretical model. A biobehavioral model of the psychological, behavioral, and biologic pathways from cancer stressors to disease course (CNS = Central Nervous System). From Andersen, Kiecolt-Glaser, and Glaser (1994).

psychoneuroimmunology (PNI) literature conclude that psychological distress and stressors (i.e., negative life events, both acute and chronic) are reliably associated with changes—down regulation—in immunity. Thus, addressing the mental health needs of those with cancer will have important quality of life benefits, and the biologic or health consequences of psychological interventions are being tested as well. Figure 43.1 provides a representation of a model of the psychological and behavioral factors and biologic mechanisms by which disease or health outcomes might be influenced. The rationale and empirical support for this novel viewpoint are detailed in the following paragraphs.

Stress and Quality Of Life

The model first considers the occurrence of stress and lowered quality of life that come with diagnosis and treatment. These are objective, negative events, and whereas negative events do not always produce stress and lowered quality of life, data from many studies document severe, *acute stress* at diagnosis (e.g., Andersen, Anderson, & deProse, 1989a). It is also the case that lengthy cancer treatments and disruptions in major life areas occur, producing *chronic stress*. Emotional distress, in combination with the other life disruptions, can result in a stable, but lower, quality of life. Other permanent

sequelae, such as sexual problems and/or sterility, may impact intimate relationships and social support. Unemployment, underemployment, job discrimination, and difficulty in obtaining health insurance can also become chronic stressors.

Health Behaviors

Important adverse health behavior sequelae (see arrow from cancer stress and lowered quality of life to health behaviors in Fig. 43.1), an increase in negative behaviors and/or a decrease in positive ones, can occur. There are many circumstances that can result in negative health behaviors. Individuals who are depressed and/or anxious are more likely to self-medicate with alcohol and other drugs, and then alcohol abuse can potentiate distress. Distressed individuals often have appetite disturbances or dietary changes that are manifest by eating less often or eating meals of lower nutritional value. Although there are individual differences in behavioral changes of this type, women may be at greater risk. Distressed individuals may report sleep disturbances, such as early morning awakening, sleep onset insomnia, and middle night insomnia. Cigarette smoking and caffeine use, which often increase during periods of stress, can intensify the physiologic effects of psychosocial stress, such as increasing catecholamine release. Conversely, individuals who are stressed may not begin or abandon their previous positive health behaviors, such as engaging in regular physical activity.

The model suggests that health behaviors may, in turn, affect immunity (see arrow from health behaviors to immunity in Fig. 43.1). Problematic health behaviors can have direct as well as interactive effects on immunity. For example, substance abuse has direct effects on immunity, as well as indirect effects via alterations in nutrition, and poor nutrition is associated with a variety of immunological impairments. Conversely, there is growing evidence that positive health behaviors, such as physical activity, can have positive consequences for both the immune and endocrine systems, even among individuals with chronic diseases. In summary, these lines of data suggest that distressed individuals tend toward negative health behaviors that may potentiate their stress and, concurrently, exert down regulating immune effects. Furthermore, positive health behaviors, such as exercise, may have the converse effect.

The model suggests that health behaviors may be directly related to disease progression (see arrow from health behaviors to disease: metastatic in Fig. 43.1). Considering all the health behaviors already noted, the strongest case can be made for the importance of nutrition and diet in breast cancer. A variety of data links nutrition/dietary factors and risk for breast cancer, such as epidemiological data of varied cancer rates corresponding with population differences in body fat, animal models linking high fat diets and tumor growth, and correlations between rates of obesity and the increase of breast cancer incidence. More germane to the model are data suggesting that increased fat intake, obesity at diagnosis, and weight gain may be related to recurrence and survival. Alternatively, some suggest that fiber, rather than fat, is the critical dietary factor, in that fiber is postulated to modify serum estrogen levels by increased

fecal excretion of estrogens. Taken together, these data suggest that behavioral factors relevant to nutrition, fat/fiber balance, and energy expenditure (*vis-à-vis* weight gain) may be relevant to disease progression in breast cancer.

Compliance

The second behavioral factor noted in the model is treatment (non)compliance (see arrow from stress/quality of life to compliance in Fig. 43.1). Compliance problems cross a wide range of diseases, therapies, and individual patient characteristics. In cancer, some patients become discouraged and fail to complete treatment. A general implication of such behaviors is the invalidation of clinical trials, but a specific implication for individual patients is that their survival may be compromised if an inadequate dosage of therapy is received. That is, dosage reductions can compromise their survival when a lower intensity of cancer therapy results in differential (*i.e.*, lower) survival rates. The model presumes that a range of compliance behaviors may be relevant, as different treatments may produce different behavioral difficulties. The model suggests that poor compliance can affect either local or metastatic control of the disease or both, and the route selected depends on the treatment regimen as well as the characteristics of an individual's noncompliance.

The Interaction Of Health Behaviors And Compliance

The model specifies that the processes governing compliance and health behaviors may interact (see double-headed arrow between compliance and health behaviors in Fig. 43.1) or even be synergistic. That is, those who are compliant with treatment may expect better health outcomes and, thus, comply with diet, exercise, sleep, and so on or other behaviors indicative of "good health." It is also noteworthy that changes in health behaviors and/or compliance have been offered as post hoc explanations for the survival difference in the Spiegel, Bloom, Kraemer, and Gottheil (1989) report (discussed later).

Biological Pathways

Stress sets into motion important biological effects involving the autonomic, endocrine, and immune systems (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Stress may be routed to the immune system by the central nervous system (CNS) via activation of the sympathetic nervous system or through neuroendocrine-immune pathways (*i.e.*, the release of hormones; see Fig. 43.1). In the latter case, a variety of hormones released under stress have been implicated in immune modulation (*e.g.*, catecholamines, cortisol, prolactin, and growth hormone).

Without any stress pathway (effect) to immunity, there is evidence for the importance of the immune responses in host resistance against cancer progression, and hence the arrows going in both directions from immunity to local and metastatic disease. Experts in the immunology/cancer area (*e.g.*, Whiteside & Herberman, 1994) cite the following important findings

with regard to the specific importance of NK (natural killer) cell activity: (a) Patients with a variety of solid malignancies and large tumor burdens have diminished NK cell activity in the blood; (b) low NK cell activity in cancer patients is significantly associated with the development of distant metastases; and (c) in patients treated for metastatic disease, the survival time without metastasis correlates with NK cell activity.

In considering these mechanisms, a central issue is whether an immune response can be affected by stress, and if it can, whether or not the magnitude of the effect has any biologic significance. Both time-limited (acute), as well as chronic, stressors can produce immunologic changes in relatively healthy individuals. Some of the largest effects, usually found in NK cell assays, are found for lengthy stressors and/or those that have interpersonal components (Herbert & Cohen, 1993, for review). Many of the qualities of chronic stressors (continued emotional distress, disrupted life tasks—e.g., employment—and social relationships) are associated with decrements in quality of life reported by cancer patients.

This relation between stress and immunity has been tested by Andersen and colleagues (1998). Women ($N = 116$) diagnosed and surgically treated for Stage II (70%) or III (30%) invasive breast cancer were studied. Prior to beginning adjuvant therapy, all women completed a validated questionnaire assessing stress about the cancer experience (Impact of Event Scale) and provided a 60 cc blood sample. A panel of NK cell and T-cell assays were conducted: (a) NK cell lysis; (b) the response of NK cells to recombinant gamma interferon (rIFN-g) and recombinant interleukin-2 (rIL-2); (c) blastogenic response of peripheral blood leukocytes (PBLs) to phytohemagglutinin A (PHA) and concanavalin A (ConA) and the proliferative response of PBLs to a monoclonal antibody (MAb) to the T-cell receptor (T3). Multiple regression models were used to test the contribution of psychological stress in predicting immune function. All regression equations controlled for variables that might also be expected to exert short- or long-term effects on these responses, such as age, stage of disease, and length of time of surgical recovery, and ruled out other potentially confounding variables (e.g., nutritional status) that might also be influential. These controls reduced the plausibility of alternative, rival hypotheses for the findings. Significant effects were found and replicated between and within assays, including the following: stress significantly ($p < .05$) predicted NK cell lysis; stress significantly ($p < .01$) predicted the response of NK cells to rIFN-g, replicated across 4 effector:target dilution ratios; stress significantly predicted the response of PBLs to ConA ($p < .05$) and PHA ($p < .05$), and the proliferative response to the T3 MAb ($p < .05$). The cells from 62% of the sample did not respond to rIL-2, but stress was not a factor in predicting the response for the remainder of the sample (38%). The data show that the physiologic effects of stress inhibited a panel of cellular immune responses, including cancer-relevant NK cell cytotoxicity and T-cell responses.

Disease Course

Are there adverse health (illness) consequences of stress? There are few data on this important issue, and the majority

come from healthy (but stressed) adults. One of the more compelling studies is Cohen, Tyrrell, and Smith's (1991) experiment with healthy volunteers. Subjects were inoculated with either a cold virus or a placebo. Analyses revealed that rates of both respiratory infection and clinical colds increased in a dose-response manner with increases in psychological stress across five different strains of cold viruses. Data from the Kiecolt-Glaser/Glaser laboratories (Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995) show that Alzheimer's caregivers had slower healing of a wound (punch biopsy) than matched community controls. These relations remain to be studied with cancer patients, but this experimental data from stressed but otherwise healthy samples suggest the covariation of stress and selected health outcomes.

SPECIFIC PSYCHOLOGICAL, SOCIAL, AND BEHAVIORAL RESPONSES: FROM SYMPTOMS TO DISEASE OUTCOMES

Symptom Appearance

In view of the magnitude of the cancer problem and the potential for life threat, it is puzzling that some individuals delay in seeking medical treatment for symptoms, yet delay is a surprisingly common circumstance. Whether the time lag occurs when seeing a physician for symptoms, being diagnosed with a medical condition, or beginning treatment for the condition, all individuals, and even some physicians, can be "delayers."

One model of delay is that proposed by Andersen, Cacioppo, and Roberts (1995), in which delay is conceptualized as a series of stages, including appraisal, illness, behavioral, and scheduling delays. Each stage is governed by a distinct set of decisional and appraisal processes (see Fig. 43.2). Appraisal delay—delay surrounding interpretation of the importance and meaning of the symptoms—appears to be the most psychologically important and has been found, not surprisingly, to account for the bulk of the delay in seeking a cancer diagnosis. In a study of recently diagnosed women with cancer, the appraisal interval was approximately 80% of the total delay for women with gynecologic cancer, whereas for women with breast symptoms, a site with a narrower range of symptom diversity, the interval accounted for 60% of the delay (Andersen et al., 1995).

The finding of the appraisal period as being inordinately lengthy for cancer patients is consistent with the clinical presentation of this disease. First, the development of malignancy and the appearance of cancer symptoms are oftentimes protracted, and a complex and changing symptom picture can be typical, unlike the presentation of many other serious medical problems (e.g., myocardial infarction; see Matthews, Siegel, Kuller, Thompson, & Varat, 1983). Symptoms can also vary with the site and extent of the disease. For example, ovarian cancer has varied presentations—pelvic cramping, low back pain, pain or bleeding with intercourse, urinary frequency irregularities, among others. Moreover, as the disease progresses regionally or systemically, it can involve other bodily systems and the symptom picture can then change

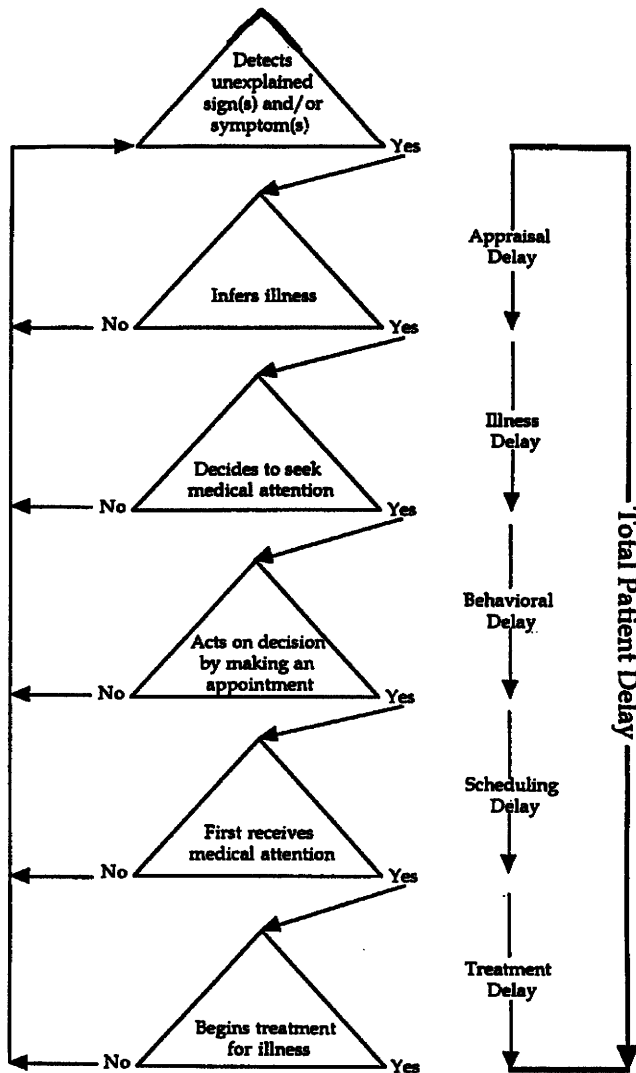

FIG. 43.2 Delay in seeking a cancer diagnosis: Delay stages and psychophysiological comparison processes. From Andersen, Cacioppo, and Roberts (1995).

from specific or localized complaints (e.g., vaginal discharge/bleeding) to diffuse ones (e.g., loss of appetite, nausea, "flu" symptoms). Finally, whereas cancer is a life threatening disease, it is a low probability one for many individuals. Thus, the appraisal process may lengthen as people think it unlikely that their symptoms would indicate a condition as serious as cancer.

Briefly considering the other stages, illness delay is defined as the number of days elapsing from the time individuals conclude they are ill to the day they decide to seek medical help. At this time individuals must decide, for example, whether to seek assistance from others (e.g., physician, others

with a similar condition) or to self-treat the illness. After this, the delay is spent in making two remaining decisions. One is the delay between the decision to seek medical attention and acting on this decision by making an appointment (e.g., behavioral delay). The other is the time that elapses between the person making an appointment and the first receipt of medical attention (e.g., scheduling delay). Economic factors such as affordability, social factors such as family influence, and cognitive factors such as the extent to which the decision to seek medical help is based on issue-relevant thinking, are more likely to modulate the delay time between a decision to seek and an action to receive medical care (behavioral delay). In contrast, both patient characteristics (such as the manner in which the person describes their concerns and symptoms) or medical environment characteristics (such as a physician's appointment backlog), which are not under an individual's control, may modulate the delay incurred when scheduling an appointment. Therefore, shortening delay to seeking a diagnosis once symptom/sign awareness has occurred (tertiary prevention) would improve survival as early detection is linked to improved survival rates for many sites (e.g., cervix, breast, colon, prostate).

Coping style is another factor that appears to be associated with a woman's perception of a breast mass as problematic. Styra, Sakinofsky, Mahoney, Colapinto, and Currie (1993) examined coping strategies employed by women attending a clinic for examination of an undiagnosed breast mass. Women were classified as "identifiers" or "nonidentifiers," based on their perception of the breast lump as problematic (i.e., women who perceived the mass as problematic were termed "identifiers," whereas those women who did not were "nonidentifiers"). Seventy-four percent of the women were classified as nonidentifiers. This group employed more than three times the number of avoidant coping mechanisms than did identifiers. Interestingly, time of delay to seeking definitive diagnosis of the mass was comparable for identifiers and nonidentifiers. Although this study did not examine the relationship between coping style and length of appraisal delay per se, it does raise the question of a potential association between the variables.

Diagnosis

Weisman and Worden (1976) noted that the diagnosis of cancer produces an "existential plight," meaning that the news brings shock, disbelief, and emotional turmoil. Today, it is known that individuals can even become alarmed at the time of medical screening, long before a cancer diagnosis is suggested (Wardle & Pope, 1992), and it may be the fear of the risk for disease that may deter individuals from involvement in screening and/or monitoring programs (Lerman et al., 1991, 1996).

Perhaps because of these natural, difficult reactions, decades ago there were concerns by the medical community about communicating a diagnosis of "cancer." Those times, however, are long since past in the United States as well as most Western countries. Patients, including children, are now told details of the disease and treatments. In addition to the moral, ethical, and legal reasons for such disclosure

(Woodard & Pamies, 1992), there are beneficial effects of coping successfully with extreme stressors (Taylor, 1983). Follow-up studies of childhood leukemia survivors, for example, have pointed toward more favorable long-term adjustment for children when they learn of their diagnosis early, whether directly, accidentally, or through their own efforts, in comparison to children who learn later (Slavin, O'Malley, Koocher, & Foster, 1982). Further, the manner in which the information is disclosed is important. For example, it has been suggested that a patient's tendency to cope with stress by seeking out or avoiding information influences satisfaction with medical communication, and an individual's information-seeking style should be considered when providing information about diagnosis and treatment (Steptoe, Sutcliffe, Allen, & Coombes, 1991). Additionally, physicians who communicate hope have, in turn, patients who are more hopeful and who report more favorable emotional adjustment (Sardell & Trierweiler, 1993).

Empirical reports have clarified the specific emotions—sadness (depression), fear (anxiety), and confusion—that can characterize this period. It is not surprising that depressive symptoms are the most common affective problem. In general, greater depressive symptomatology is more common for those patients in active treatment rather than those on follow-up, receiving palliative rather than curative treatment, with pain or other distressing symptoms rather than not, or those with a history of affective disorder, alcoholism, or other stressors (poor social support; e.g., Bukberg, Penman, & Holland, 1984; Holland, 1989; Pettingale, Burgess, & Greer, 1988). Whereas it has been estimated that approximately 50% of cancer patients meet the American Psychiatric Association's criteria for a formal psychiatric disorder, the clear majority of these diagnoses represent adjustment disorders (i.e., emotional and/or behavioral problems related to a known transient stressor—cancer; Derogatis et al., 1983; see Tope, Ahles, & Silberfarb, 1993, for a review). Specific clinical diagnoses for depression and anxiety are 13% and 4%, respectively (Derogatis et al., 1983).

One factor that has been found to moderate distress is dispositional optimism. A number of studies have documented beneficial effects of optimism on general psychological and physical well-being in a wide range of patient populations (for a review, see Scheier & Carver, 1992). With respect to cancer patients specifically, Carver and colleagues determined that optimism versus pessimism predicts adjustment to early stage breast cancer over several time points, with pessimists faring worse than their more optimistic counterparts in terms of subjective well-being, satisfaction with sex life, and occurrence of intrusive thoughts (Carver et al., 1994). They suggested that dispositional pessimism may serve as a marker of vulnerability to poor adjustment in the period of time surrounding treatment for early stage breast cancer.

Importantly, the clinical problem of diagnostic and treatment-related distress can be alleviated through psychological interventions (see Andersen, 1992, and Spiegel, 1996, for reviews). A comprehensive example of such an effort is the study by F. I. Fawzy and colleagues (1990a, 1990b). They attempted to reduce distress and enhance immune functioning in newly

diagnosed melanoma patients via a structured group support intervention that included health education, illness-related problem solving, relaxation training, and group support. The format was weekly group treatment for six sessions. Eighty patients with early stage melanoma participated and were randomized to intervention or control conditions. The posttreatment analyses indicated that the intervention subjects reported significantly more vigor, but there were no other emotional distress differences. By 6 months, emotional distress had improved for the intervention subjects with significantly lower depression, confusion, and fatigue, and higher vigor. Coping data indicated that the intervention subjects reported significantly more use of active behavioral strategies by treatment's end, a pattern that continued with the addition of active cognitive strategies by 6 months. Regarding the immunologic findings, at 6 months there was a significant difference in groups with better immunologic status for the intervention subjects. These data are impressive in that they suggest that improvements in psychological status and coping are associated with changes (up regulation) in immune responses.

Improvements such as these in mood and coping are all the more impressive because they are often achieved with brief, cost-effective interventions (e.g., 10 therapy hours with delivery in a group format; Andersen, 1992). Studies that have provided follow-up data also suggest some consolidation of intervention effects across time (upward of 6 months posttreatment), with lowered emotional distress, enhanced coping, and improved sexual functioning (e.g., Capone, Good, Westie, & Jacobson, 1980).

Treatment

A certain component of the emotional distress occurring at diagnosis is due to the anticipation of treatment. Primary cancer therapies are surgery and/or radiotherapy, with chemotherapy or hormonal therapy (e.g., tamoxifen) used as primary or adjuvant treatment. Bone marrow treatment, once reserved for metastatic disease is now being used in combination as a primary therapy not only for hematologic malignancies, but for solid tumors (e.g., breast, ovary) as well. Regardless of the protocol, however, all treatments are preceded or followed by physical examinations, tumor surveys, and/or laboratory studies. Thus, the diagnostic period can be prolonged, and the receipt of the therapy can represent multiple medical stressors for the individual.

As is discussed later, the data are consistent in their portrayal of more distress (particularly fear and anxiety), slower rates of emotional recovery, and, perhaps, higher rates of other behavioral difficulties (e.g., food aversions, continued fatigue and malaise) in cancer patients in comparison to individuals undergoing noncancer-related medical treatment. The emotional crisis that characterizes the diagnostic period lessens as time passes, and longitudinal studies find that as treatments end and recovery begins there is an emotional rebound (e.g., Andersen, Anderson, & deProse, 1989b; Bloom, 1987; Edgar, Rosberger, & Nowlis, 1992). This lowering of emotional distress over time is found even for pa-

tients undergoing radical treatment requiring major adjustments (e.g., radical neck dissection with laryngectomy; Manuel, Roth, Keefe, & Brantley, 1987).

There have been few investigations of cancer surgery or radiotherapy per se, but there are numerous descriptive and intervention studies of the reactions of healthy individuals undergoing surgery or other difficult medical procedures for benign conditions. In both literatures, the studies are consistent in their portrayal of high levels of self-reported preoperative or pretreatment anxiety predicting higher postoperative anxiety and longer recovery periods (e.g., decreased time out of bed, increased pain reports). What may distinguish cancer surgery patients are higher overall levels of distress and slower rates of emotional recovery (Gottesman & Lewis, 1982). The scenario for radiotherapy patients is similar. But as a course of radiotherapy can be lengthy (e.g., 4–6 weeks), heightened anxiety at the termination of treatment can also occur (e.g., Andersen & Tewfik, 1985). This unexpected increase in distress has been found clinically, and may be apt to occur at the completion of active treatment, when patients face being “on their own” and may experience heightened fears of recurrence.

Psychological and behavioral efforts to reduce patients’ treatment anxiety have been incorporated into patterns of routine care. Such efforts include procedural information (e.g., the way the surgery or radiotherapy is done), sensory information on the actual physical sensations of the surgery or preparatory events, behavioral coping instructions, cognitive coping interventions, relaxation, hypnosis, and emotion-focused interventions (e.g., Wallace, Priestman, Dunn, & Priestman, 1993). Such efforts produce benefits on a broad band of outcomes—ratings of negative affect and pain, amount of pain medication, length of stay, behavioral recovery, and physiological indices (Johnston & Vogeles, 1993).

Considerable research has been conducted on the psychological/behavioral aspects of coping with chemotherapy. Over a decade of research has revealed that many cancer patients will develop nausea and/or vomiting in response to cytotoxic treatments (Morrow & Hickok, 1993). However, antiemetic drug treatments have dramatically reduced the incidence of such problems. Behavioral treatments for these problems have included hypnosis, progressive muscle relaxation with guided imagery, systematic desensitization, cognitive distraction, and biofeedback. (e.g., Burish & Jenkins, 1992; Redd, 1993; Vasterling, Jenkins, Tope, & Burish, 1993). Effective preventive care, with or without behavioral strategies, can reduce the likelihood of classically conditioned anticipatory reactions (i.e., nausea and vomiting becoming associated with previously neutral events such as going to the hospital, sitting in the waiting room).

Bone Marrow Transplantation (BMT)

Over the past two decades, BMT has evolved from an experimental procedure performed only when conventional therapies have failed (e.g., recurrent breast cancer) to a therapy tested as a first line therapy in clinical trials (Baker, Curbow,

& Wingard, 1991). Initially used only for those with lymphohematopoietic malignancies or disorders characterized by bone marrow failure (e.g., leukemia, Hodgkin’s disease, and non-Hodgkin’s lymphoma; Wingard, Curbow, Baker, & Piantadosi, 1991), BMT is now being tested with a variety of solid tumors for which the risk of recurrence is high (e.g., neuroblastomas, germ cell tumors, and cancers of the breast and ovary). The rapid acceptance and expanded use of this toxic modality is no less than dramatic, particularly as an adjuvant treatment for breast cancer patients.

BMT is a complex and potentially fatal treatment. The target of the treatment, the bone marrow, is destroyed with high dose chemotherapy, with or without subsequent whole body irradiation. The bone marrow to be transplanted comes from either a donor (allogenic BMT) or from the patients themselves (autologous BMT) after it has been removed and treated. Although allogenic BMT has a role, its expansion is limited by the need for a suitable donor and the subsequent risk of graft versus host disease for the patient. In the case of autologous BMT, a variety of ex vivo procedures are used to destroy the malignant cells in the patient’s marrow prior to reinfusion, including treatment with cytotoxic drugs, exposure to monoclonal antibodies that will attack tumor associated antigens, or harvesting and introducing stem cells (cells from peripheral blood).

Patients (and their families) are faced with a number of stressors: a life threatening illness, location of a suitable donor (for allogeneic transplants; Alby, 1991; Patenaude, 1990), a toxic treatment, and common but potentially fatal side effects (e.g., liver failure). There are also many acute side effects (e.g., hair loss, mouth and gastrointestinal mucositis, infertility, skin breakdown, infection, pneumonia). Hospitalization can be prolonged (e.g., 3–6 weeks) and it is generally spent in isolation (Alby, 1991; Baker et al., 1991; Winer & Sutton, 1994). Of course, in the end, the treatment can fail and the disease can persist or rapidly recur (Patenaude, 1990; Winer & Sutton, 1994). The many difficulties—toxicity, uncertainty, illness and isolation, dependency, constant need for care, financial strain—all communicate to patients that they have little or no control and can result in loneliness, anxiety, and/or depression (Alby, 1991; Altmaier, Gingrich, & Fyfe, 1991). In attempting to cope, patients may be demanding or, conversely, withdrawn (H. N. Brown & Kelly, 1976; Patenaude, 1990). Psychological efforts have focused on providing support to patients, their families, and staff, maximizing control for patients (e.g., making choices about the hospital environment whenever possible; Patenaude, 1990). For example, BMT rooms are often equipped with televisions/radios and free weights or stationary bicycles so that patients might exercise to feel stronger and less fatigued. Additionally, patients are encouraged to bring personal items from home (e.g., pictures, photographs) to decorate their rooms. Finally, as might be expected, increased medical complications, age, distance from home, and poorer pretransplant psychosocial adjustment are variables associated with the need for more intensive psychological consultation (Futterman, Wellisch, Bond, & Carr, 1991).

Treatment Morbidity

Although there are many disease/treatment-related complications, behavioral efforts have focused on three specific ones. First, a primary side effect of cancer treatment is fatigue (Pickard-Holley, 1991), which is the most commonly reported symptom of people that have been diagnosed with and treated for cancer, especially those receiving radio- and/or chemotherapy (Nail & King, 1987; Smets, Garssen, Schuster-Uitterhoeve, & deHaes, 1993). Fatigue and associated symptoms (feeling tired, a lack of energy, sleepy, confused) have been related to other cancer morbidities (e.g., decreased quality of life) and poor treatment compliance (e.g., stopping treatments). Despite being a common experience for patients, few studies have been conducted to delineate the underlying mechanisms and correlates of fatigue (see Smets et al., 1993, and Winningham et al., 1994, for reviews). Irvine, Vincent, Bubela, Thompson, and Graydon (1991), for example, noted that research has not demonstrated consistent relations among fatigue, sleeplessness, psychological distress (e.g., negative mood/depression) and a possible biological correlate (e.g., anemia). However, it appears that fatigue does reduce overall daily functioning. It is important for patients and researchers to document fatigue as distinct from depression, and that fatigue is an expected side effect of treatment rather than a sign of disease.

Psychological and behavioral interventions for fatigue have focused on alleviating or increasing tolerance to fatigue through preparatory information on side effects and activity/rest cycle recommendations (e.g., naps in the afternoon; Nail & King, 1987; Smets et al., 1993), as well as other activity (e.g. exercise; Winningham, 1991), coping efforts (e.g., planning and scheduling activities, decreasing nonessential activities, relying on others for assistance as needed; Rhodes, Watson, & Hanson, 1988), and interventions aimed at improving/maintaining nutritional status (Kalman & Villani, 1997).

Second, appetite and weight changes (either loss or gain) can represent different problems for patients based on their diagnosis and treatments. Appetite and weight loss are significant clinical problems for those cancer patients susceptible to tumor-induced metabolism or taste changes, having tumor-related obstructions (often diagnosed as primary cachexia/anorexia), or receiving gastrointestinal-toxic chemotherapy or abdominal radiotherapy (secondary cachexia/anorexia). Importantly, malnutrition is associated with increased morbidity and mortality (Knox, 1991). Food aversions learned in connection with chemotherapy may affect up to 50% of the aforementioned patients. These conditioned aversions are rapidly acquired (usually after 1 to 3 treatments) and maintained after long delays (e.g., 48 hours between food intake and aversive drug-induced reactions such as nausea; Jacobson & Schwartz, 1993). Whereas food aversions may not involve appetite or weight loss per se, patients may unknowingly develop aversions to their favorite foods and this can in turn affect their daily routine and perceived quality of life (Jacobson & Schwartz, 1993; Knox, 1991).

Researchers have recently begun to investigate morbidity related to weight gain in breast cancer patients. The mecha-

nisms of such weight gain have yet to be clearly elucidated (Demark-Wahnefried, Rimer, & Winer, 1997), but it appears that this phenomenon may be more pronounced in women receiving hormonal therapy and/or chemotherapy, than in women receiving surgery or surgery plus radiation (Demark, Winer, & Rimer, 1993). It is clear that treatment-related weight gain is subjectively distressing to many breast cancer patients, and may result in decreased quality of life (Knobf, Mullen, Xistris, & Moritz, 1983; Prozanto et al., 1990). Furthermore, it has been suggested that weight gain during therapy for breast cancer may be associated with increased recurrence and decreased survival (Camoriano et al., 1990, Chlebowski et al., 1991; Cruz, Muss, Brockschmidt, & Evans, 1990; Donegan, Hartz, & Rimm, 1978). Given the potential psychosocial and physical morbidities associated with weight gain in breast cancer patients, it seems relevant to more clearly elucidate the mechanisms behind, and consequences of, this common occurrence.

Third, much of the current literature regarding compliance has focused on early detection/screening practices of patients, especially in regards to breast (i.e., mammography utilization), prostate, skin, and colorectal cancers. However, compliance with treatment remains important, as the expectation and/or experience of unpleasant side effects (such as those described here) can diminish a patient's quality of life. Furthermore, such side effects can at times be so discouraging or annoying that a patient may be reluctant to continue treatment or even want to prematurely terminate (Morrow & Hickok, 1993; Richardson, Marks, & Levine, 1988). When patients are noncompliant, the dosage of treatment may be reduced, which can in turn lower the cure rate. Noncompliance with treatment has been related to increased emotional distress (e.g., Gilbar & De-Nour, 1989; Richardson et al., 1988), increased hostility and guilt (Ayres et al., 1994) severity of treatment side effects (e.g., nausea and vomiting; Lewis, Linet, & Abeloff, 1983; Richardson et al., 1988), lower income (Lebovits et al., 1990), and being an adolescent patient (Tebbi, 1993). Even when patients are responsible for self-administration of therapy, such as taking their chemotherapy at home in order to reduce the number of hospital visits, their noncompliance may continue. One report of multidrug therapy with adults with hematologic malignancies indicated that self-reports (vs. sera reports) overestimated compliance by a factor of two (Richardson et al., 1987). In short, noncompliance is a behavioral problem that can directly impact the effectiveness of cancer therapy.

Psychological interventions to improve patient compliance have focused on a variety of techniques, including appointment reminders, clearly written and specific treatment communications (Anderson & Kirk, 1982), home visits, and medication-taking shaping interventions (Richardson et al., 1987). Additionally, hospital-based interventions such as offering a tour of the oncology clinic, videotape presentations about the therapy, discussion/question sessions, and take-home information (Burish, Snyder, & Jenkins, 1991; Nail & King, 1987; Rainey, 1985) have been employed as well. Burish et al. (1991) and others (e.g., Nail & King, 1987; Rainey, 1985) suggested that preparatory information can improve coping with treatment.

Importantly, psychological interventions can reduce distress during and immediately following cancer treatments. The findings from two illustrative studies are presented. Cain, Kohorn, Quinlan, Latimer, and Schwartz (1986), for example, compared individual and group therapy formats with 72 women with gynecologic cancer. The intervention was comprised of eight components, including discussion of the causes of cancer at diagnosis, impact of the treatment(s) on body image and sexuality, relaxation training, emphasis on good dietary and exercise patterns, communication difficulties with medical staff and friends/family, and setting goals for the future to cope with uncertainty and fears of recurrence. Posttreatment analyses indicated all groups improved with time, however anxiety was significantly lower for the individual therapy subjects only. Gains for the intervention subjects were more impressive with the 6-month follow-up data when there were no differences between the intervention formats, but both groups reported less depression and anxiety and better psychosocial adjustment than the no treatment control group. Thus, the brief intervention, delivered either in an individual or group format, appeared to be immediately effective, with gains enhanced during the early recovery months.

Edgar et al. (1992) provided a psychosocial intervention to 205 patients who were randomized into two groups: One group received the intervention soon after entering the study and the other group after a wait of 4 months. The majority ($n = 159$) of patients had been diagnosed with breast, colon, lung, uterine, or head and neck cancers. The intervention (comprised of 5 1-hour sessions) focused on coping skills and included problem solving, goal setting, cognitive reappraisal, relaxation training, and at 4-month intervals, workshops on health care information and available resources. Whereas coping improved over the year for all patients, the later intervention group experienced lower levels of distress sooner than the group who had received the intervention earlier. Edgar et al. (1992) suggested that the delay in intervention may have been beneficial because it afforded patients the time to reduce feelings of being overwhelmed and they were, therefore, more ready to participate in the intervention. These and related data (e.g., Forester, Kornfield, & Fleiss, 1985; see Andersen, 1992, for a review) attest to the significant distress that occurs when patients are in the midst of coping with diagnosis and treatment. Importantly, impressive gains can be achieved by the end of the intervention and often these positive gains are stronger with follow-up.

Recovery and Long-Term Survival

The most important cancer endpoints have been treatment response rates, length of disease-free interval, and survival. Yet, as the prognosis for some sites has improved, there has been increased attention to quality of life, particularly for long-term survivors of cancer. The term *survivor* typically refers to individuals surviving at least 5 years, as the probability of late recurrence declines significantly after that time for most sites. As individuals recover and resume their life patterns, there may be residual emotional distress, with some difficulties requiring continued coping. Each of these

circumstances is discussed, and examples are provided of both emotional and physical challenges that may confront the cancer survivor.

An investigation by Dunkel-Schetter, Feinstein, Taylor, and Falke (1992) sheds light on the strategies cancer patients use as they recover and resume their life activities. They studied coping patterns of 603 cancer patients. Patient diagnoses included breast cancer, gastrointestinal, circulatory or lymph, gynecological, and respiratory cancers. The timing of the assessment ranged from initial diagnosis to more than 5 years posttreatment. Five coping patterns were identified: seeking or using social support, focusing on positive aspects, distancing, cognitive escape-avoidance (e.g., fantasizing or wishful thinking with fatalistic thoughts of poor outcomes), and behavioral escape-avoidance (e.g., social withdrawal, drug use). All patients used multiple coping strategies, but distancing was the most common. Unique patterns were also found for subgroups. For example, individuals who viewed cancer as more stressful tended to use less adaptive strategies, such as cognitive and behavioral escape-avoidance, whereas patients reporting less distress relied on more adaptive strategies, such as seeking or using social support, focusing on the positive, and distancing themselves from the cancer experience. Data such as these might be considered when tailoring psychological interventions to patient subgroups (e.g., identifying patients likely to use drugs/alcohol to cope).

Lingering emotional distress from the "trauma" of a cancer diagnosis, treatment, and more generally life threat is similar to the distress experienced by individuals who have experienced other traumatic events (e.g., natural disasters, physical assault; Alter et al., 1996). In fact, the residual distress from the diagnosis and treatment of a life threatening illness/disorder (e.g., cardiac arrest, burns, cancer) is now included as one of the circumstances that may precipitate Posttraumatic Stress Disorder (PTSD), a disorder characterized by intrusive thoughts, avoidant behavior, and hyperarousal surrounding the traumatic event (*DSM-IV*, American Psychiatric Association, 1994). Much of the existing PTSD research has been conducted with pediatric cancer patients and their parents (e.g., Butler, Rizzi, & Handwerker, 1996; Kazak et al., 1997; Stuber, Christakis, Houskamp, & Kazak, 1996). However, it is known that adults undergoing BMT for acute leukemia (Lesko, Ostroff, Mumma, Mashberg, & Holland, 1992) and survivors of Hodgkin's disease (Cella & Tross, 1986) report higher levels of PTSD symptoms than healthy controls. Although it is unlikely that such a diagnosis would be made for the "average" cancer patient, Cordova and colleagues (1995) documented PTSD rates in a breast cancer sample ranging from 5% to 10%, and suggested that this may be comparable, if not an underestimate, to other cancer survivor populations. Risk factors for cancer-related PTSD may include undergoing the most difficult of treatment regimens (e.g., BMT), having treatments with life altering and/or disfiguring effects (e.g., limb amputations, pelvic exenteration, laryngectomies), having a history of anxiety disorder and/or being exposed to previous traumatic events, and reporting a lower quality of life (e.g., Green, 1990; Irvine, B. Brown, Crooks, Roberts, & Browne, 1991).

Second, some cancer survivors may need to cope with the expected but nevertheless troubling sequelae, which may be a consequence of the disease or treatment and be permanent. For example, coping with altered cognitive and physical abilities (e.g., changes in memory and attention due to chemotherapy/radiation or loss of natural speech following laryngectomy); and/or changes in organ functions (e.g., infertility) may require adjustment that demands new behaviors or emotions. Others may have to cope with losses (e.g., a sexual relationship that does not include intercourse). Third, late side effects of cancer treatment, for example, a bowel dysfunction that is traced to pelvic radiotherapy, can occur and change health status as well as impact mood and coping.

Despite these possibilities, longitudinal data indicate that if the disease is controlled, by 1 year posttreatment the severe distress of diagnosis will have dissipated and emotions will have stabilized. The first longitudinal studies conducted in the United Kingdom for breast cancer patients indicated that by 12 (Maguire et al., 1978) and 24 months (Morris, Greer, & White, 1977), approximately 20% of the patients had problems with moderate to severe depression in comparison to 8% of benign disease comparison subjects. However, more recent controlled longitudinal studies of breast (Bloom, 1987; Vinokur, Threatt, Caplan, & Zimmerman, 1989), gynecologic (Andersen et al., 1989b), and Hodgkin's disease and non-Hodgkin's lymphoma (Devlen, Maguire, Phillips, Crowther, & Chambers, 1987) patients conducted in the United States and other countries (e.g., the Netherlands; de Haes, van Oostrom, & Welvaart, 1986) have indicated no differences between the levels of emotional distress of individuals with cancer and either benign disease or healthy comparison subjects. The consistency of findings is important because it represents replications across site and, to some degree, treatment toxicity. Thus, the remaining discussion is prefaced by noting that global adjustment problems do not occur for the majority of cancer survivors; a more likely scenario is the occurrence of specific problem areas.

An exception to this positive trajectory may be the circumstances of BMT survivors, who generally experience a somewhat slower recovery (Syrajala, Chapko, Vitaliano, Cummings, & Sullivan, 1993). Comparison of BMT survivors and other cancer patients on maintenance chemotherapy indicated that psychological functioning was satisfactory for both groups when assessed 3 to 4 years postdiagnosis (Altmaier et al., 1991). However, when BMT patients were assessed sooner (2–4 years posttreatment), they reported poorer physical functioning, greater impaired personal functioning (e.g., need for self-care assistance), and more sexual difficulties than individuals on maintenance chemotherapy (Altmaier et al., 1991). Also, data do suggest a risk of neuropsychological impairment from BMT procedures. Andrykowski (1992) found impairments in memory and higher cognitive processing, which may be a sequelae of BMT per se, or due to cancer treatments prior to BMT (e.g., cranial radiation, intrathecal chemotherapy). The many difficult aspects of BMT already noted (e.g., intensive chemotherapy, possible whole body irradiation, long recovery time, isolation) may also contribute to this slowed and more

problematic recovery (see Winer & Sutton, 1994; or Andrykowski, 1994, for a review).

One life area that undergoes disruption for cancer survivors is sexuality. All cancer patients with solid tumors (approximately 85% of adult patients) and many treated for hematologic malignancies are vulnerable to sexual dysfunction. Across sites, estimates range from 10% (e.g., breast cancer patients treated with lumpectomy), 70% to 90% (e.g., women with vulva cancer treated with modified radical vulvectomy), to 100% (e.g., men with prostate cancer treated with radical prostatectomy), with the distribution skewed toward greater levels of disruption; among the hematologic malignancies, estimates are in the range of 20% (Andersen & Lamb, 1995). Although it is clear that the sexual problems are psychologically distressing, disease and treatment sequelae are the primary reasons for the sexual problems (e.g., nerve dissection during prostatectomy, gynecologic complications with long-term adjuvant tamoxifen therapy for breast cancer, Wolf & Jordan, 1992; female androgen deficiency syndrome from cytotoxic agents and/or bilateral salpingo-oophorectomies, Kaplan & Owett, 1993). Consistent with this etiology, longitudinal studies indicate that if sexual problems develop, they do so as soon as intercourse resumes, and if untreated, they are unlikely to resolve (see Andersen & Elliott, 1994, for a discussion).

Even with disease and cancer treatments producing significant disruption, there also appear to be important individual differences in the magnitude of the difficulty. Moreover, a specific aspect—sexual self schema (self-concept)—appears to predict specific risk for sexual morbidity. Sexual self schema is a cognitive view about sexual aspects of oneself; it is derived from past experience, manifest in current experience, and it guides the processing of sexually relevant social information (Andersen & Cyranowski, 1994). For women, the concept includes two positive aspects (an inclination to experience romantic/passionate emotions and a behavioral openness to sexual experiences and/or relationships) and a negative aspect (embarrassment and/or conservatism), which appears to deter sexual expression. For men, there are three positive aspects; an inclination to experience romantic/passionate emotions, a view of the self as aggressive and powerful, and an open-minded, liberal attitude (Andersen, Cyranowski, & Espindle, 1999). Individual differences can play a powerful role in predicting sexual behaviors and responses (Andersen & Cyranowski, 1995). Cognitive representations of sexuality represent a novel and important aspect, and tests of their predictive utility for sexual morbidity are confirmatory. For example, the role of sexual schema in predicting risk for sexual morbidity following gynecologic cancer was tested by Andersen, Woods, and Copeland (1997). It was hypothesized that women with a negative sexual self-concept, in contrast to women with a positive sexual self-concept, would be at greatest risk for sexual difficulty. Negative sexual schema women would be expected to have more difficulties because they are, in general, less romantic/passionate in their emotions, less open to sexual experiences, and more likely to have negative feelings about their sexuality. The researchers assessed 62 women who were cur-

rently disease free but who received treatment from 6 months to 5 years previously for Stage I–II disease. Comparison subjects included 68 women seeking routine gynecologic care. Analysis of the quality of life data replicated earlier prospective longitudinal findings (Andersen et al., 1989a). That is, there were no differences between the groups in the areas of mental health (emotional distress, depression) or social functioning, and, in contrast, the cancer survivors reported lower levels of sexual behavior, sexual responsiveness, and global evaluations. Sexual self schema accounted for a significant and large portion of the variance (26%) in the prediction of current sexual responsiveness (e.g., desire, excitement, orgasm, and resolution), as well as significant variance in the prediction of sexual behavior. Thus, sexual self schema appears to be an important individual difference variable in the prediction of sexual morbidity.

Despite the emotional distress and, for some, accompanying sexual disruption that couples experience, data from the controlled longitudinal studies previously discussed indicate that the majority of marriages remain intact and satisfactory. These data are consistent with early prospective studies showing that, when health problems arise for newly married couples, they are not among those problems precipitant to divorce (Bentler & Newcomb, 1978). However, multicenter studies have indicated that young survivors of childhood cancers are significantly less likely to marry, and once married they may be at greater risk for subfertility (Byrne et al., 1985; Teeter, G. E. Holmes, F. F. Holmes, & Baker, 1987).

Still, families are not immune to the cancer experience (see Baider, Cooper, & De-Nour, 1996, for a review), and the kin's distress may approach that of the patient's (Cassileth et al., 1985). Family strain appears to be affected by illness variables (e.g., prognosis, stage/duration of illness, caregiving demands, patient's distress), family variables (e.g., age and gender of family members, socioeconomic status, other family stressors), and relational variables (e.g., quality of marriage, marital communication, family stage, and social support; see Sales, Schulz, & Biegel, 1992, for a review). Those couples in which the wife/mother has cancer and young children are still in the home may be at heightened risk for relationship difficulties (Vess, Moreland, & Schwebel, 1985). In addition, Ell, Nishimoto, Mantell, and Hamovitch (1988) found that those kin who were functioning poorly (e.g., less adequate emotional support from close others, and greater stress unrelated to cancer) when the patient was diagnosed or who lost personal and social resources during the patient's treatment and recovery also, not surprisingly, functioned poorly at follow-up. In sum, a subset of partners and family members appear to be at psychosocial risk. For a review of strategies that have been used to assist spouses of cancer patients cope with stress over the illness course, see Northouse and Peters-Golden (1993).

There have been few interventions targeted for cancer survivors per se, but one such study was that by C. F. Telch and M. J. Telch (1986). They compared the effectiveness of coping skills instruction versus supportive therapy for a heterogeneous sample of cancer patients with "clear evidence of psychological distress." Both interventions were offered in a

group format. The emotional distress data indicated that the coping skills group improved significantly across all measures, the support group improved on the anxiety and depression only, but the no treatment control worsened and reported significantly more mood distress, indicating differential effectiveness for cognitive behavioral/coping interventions.

Recurrence and Death

Cancer recurrence is devastating; the magnitude of distress is even greater than that found with the initial diagnosis (Mahon, Cella, & Donovan, 1990; Thompson, Andersen, & DePetrillo, 1992), and studies contrasting cancer patients showing no evidence of disease with those receiving palliative treatment (e.g., Cassileth et al., 1985) have reported the greatest distress for those with disseminated disease (Bloom, 1987). In fact, cancer recurrence has been conceptualized as a "traumatic event" with the potential to induce stress response symptoms such as intrusive thoughts, behavior aimed at avoiding cancer-related stimuli, and hyperarousal (Cella, Mahon, & Donovan, 1990). Patients recently told of their cancer recurrence reported being less hopeful, more discouraged, having increased thoughts of death and dying, as well as feelings of guilt/regret about their previous treatment decisions. In one study (Mahon et al., 1990), 45% of the patients indicated that they perceived their recurrence as "punishment," and so difficult decisions (e.g., beginning a regimen that offers little chance for cure and also has toxic side effects vs. no treatment) are made in a context of extreme emotional distress and perhaps physical debilitation from symptoms (e.g., shortness of breath with lung disease, pain from bone metastases). Yet, important emotional gains can be achieved during terminal stages (M. W. Linn, B. S. Linn, & Harris, 1982) and children and adolescents, as well as adults, can make independent decisions about the continuation of therapy when death is imminent (Nitschke et al., 1982).

Psychological interventions offered to terminal patients appear to have the effect of enhancing their quality of life. Spiegel and colleagues (Spiegel, Bloom, & Yalom, 1981; Spiegel & Bloom, 1983), for example, studied a group support intervention that included discussion of death and dying, family problems, communication problems with physicians, and living fully with terminal breast cancer. A random half of the intervention subjects were also offered self-hypnosis for pain problems (Spiegel & Bloom, 1983), which was incorporated into the support group format. Eighty-six women, 50 intervention and 36 no treatment control, participated. Analyses indicated that the intervention group reported significantly fewer phobic responses and lower anxiety, fatigue, and confusion and higher vigor than the controls. These differences were evident at all assessments, but the magnitude increased from 4 to 12 months. Women receiving hypnosis within the group support intervention reported no change in their pain sensations during the year, whereas pain sensations significantly increased for the other women in group support who did not receive hypnosis. The most startling data from this project was reported in a survival analysis: Controlling for initial disease stage, days of radiotherapy, or use of andro-

gen or steroid treatments, the analysis indicated a survival time difference (18 months longer) favoring the intervention participants.

Finally, there are two frequent complications of disseminated disease: delirium and pain. Delirium is the second most commonly diagnosed psychiatric disorder in cancer patients and is characterized by acute perceptual and behavioral disturbances such as impairment of attention, orientation, and memory (Tope et al., 1993). Massie, Holland, and Glass (1983) found that approximately 75% of patients with metastatic cancer meet criteria for delirium as compared to 8% of all cancer patients. Delirium in cancer patients can be caused by a number of factors, including treatment side effects (e.g., type/dosage of chemotherapy), medications (e.g., narcotics), disease progression (e.g., brain metastases), and other treatment and/or disease-related complications (e.g., metabolic and endocrine disorders; see Tope et al., 1993, for a review). Whereas delirium is a reversible brain disorder, it is often misunderstood and underdiagnosed by medical personnel, with symptoms often being attributed to depression and anxiety (Levine, Silberfarb, & Lipowski, 1978).

Although it might be one of the first symptoms of cancer or be present when disease is localized, pain is more common and less controllable for those with metastatic disease (Ahles, Ruckdeschel, & Blanchard, 1984). Eighty percent of patients with recurrent cancer report moderate to severe pain, as compared to 40% of earlier stage patients (see Ashburn & Lipman, 1993, for a review). The major cause of cancer pain, accounting for roughly 70% of the cases, is due to direct tumor involvement (e.g., nearby metastatic bone disease, nerve compression), and the remainder is usually due to medical therapy (e.g., postoperative pain, radiation-induced pain). Thus, the pain experienced by cancer patients can be any combination of acute malignant pain, chronic malignant pain, and/or chronic nonmalignant pain (Ashburn & Lipman, 1993).

With this variable presentation, it is important that a pain assessment be completed before and during treatment for pain control (Ashburn & Lipman, 1993; Coyle, Adlehardt, Foley, & Portenoy, 1990). Besides pain-specific qualities and diagnostic/treatment considerations, other factors are also important in assessing the patient's experience of pain. For instance, pain is associated with depression, anxiety, and delirium (Massie & Holland, 1992), and may increase suicidal ideation (Coyle et al., 1990). If pain worsens or is difficult to control, then quality of life deteriorates and emotional distress increases (Massie & Holland, 1992), physical mobility may decline (Ashburn & Lipman, 1993), and social interactions may suffer (Strang & Qvarner, 1990). It is striking that inadequately controlled pain has been cited as a primary reason for requests of physician-assisted suicide among cancer patients (Foley, 1991, 1995; Seale & Addington-Hall, 1994).

The most difficult circumstance of pain control is when chronic pain accompanies disease progression. Treatment combinations of antitumor therapy, anesthetic blocks, and behavioral approaches are considered. When palliative therapy is of little use and/or brings further debilitation, psychological interventions may provide support and pain control and, sec-

ondarily, treat pain sequelae (e.g., sleep disturbances, reduced appetite, irritability).

CONCLUSIONS

Significant progress has been made in understanding the psychological, social, and behavioral aspects of cancer. More is known about the psychological processes and reactions to the diagnosis and treatment of cancer than is known about any other chronic illness. Breast cancer patients (see Glanz & Lerman, 1992, for a review), have been well studied, but other disease sites, men, and children are becoming more commonly studied. Future research will test the generalizability of these descriptive data and formulate general principles of adjustment to illness. While providing estimates of the magnitude of quality of life problems, these data can be used for models that predict which patients might be at greatest risk for adjustment difficulties (see Andersen, 1996, for a discussion). The latter is an important step toward designing interventions tailored to the difficulties and circumstances of cancer patients. The mental health community emphasizes the need to reduce stress and prevent deteriorations in quality of life for those with cancer. The importance of such efforts is underscored by three contextual factors. First, the stability of many cancer mortality rates (particularly those with the highest incidence such as lung and breast) makes it imperative that new, innovative treatments be developed to improve survival rates. Second, research has demonstrated that psychological interventions result in significant improvements in quality of life (see Andersen, 1992, for a review). Third, both qualitative (Maier et al., 1994) and quantitative (Herbert & Cohen, 1993) summaries of the psychoneuroimmunology (PNI) literature conclude that psychological distress and stressors (e.g., negative life events, both acute and chronic) are reliably associated with changes—down regulation—in immunity. Thus, addressing the mental health needs of those with cancer will have important quality of life benefits and the possibility is raised of positive biologic (or health) consequences as well. Finally, the biobehavioral model offered here provides a theoretical framework for examining questions of the interaction of psychological, behavioral, and biological variables in disease course.

Subjective Risk and Health Protective Behavior: Cancer Screening and Cancer Prevention

Leona S. Aiken
Mary A. Gerend
Arizona State University

Kristina M. Jackson
University of Missouri

This chapter explores the role of perceived risk in health protective behavior. Cancer serves as the context of the presentation; the discussion employs the literature on cancer screening and prevention to highlight theory and findings on the perception of risk in relation to health behavior. The origins of perceived risk, its role in health behavior models, and the linkages between perceived risk and behavior are explored. In models of health behavior, perceived risk for disease is the motivational engine for health protective action. This chapter is intended to serve two purposes: to provide both a broad picture of the literature on risk perception in health psychology and to characterize research on perceived risk for cancer as a putative determinant of cancer screening and preventive behavior.

CHAPTER OVERVIEW

The chapter first addresses the role of perceived susceptibility in models of health behavior. It then turns to perceived risk as a construct, its measurement, its observed relation to objective risk for cancer, and its determinants. It next explores the relation of perceived susceptibility and cancer distress to cancer screening and cancer preventive behavior. Here it considers not only the susceptibility–behavior link, but also explores other variables that may moderate or even mitigate the impact of perceived susceptibility on specific cancer pro-

ductive behaviors. The chapter then considers interventions to increase screening and preventive behavior that involve the perceived susceptibility construct. The emphasis is on the use of mediational analysis to assess the direct and indirect impact of perceived susceptibility on screening and preventive behavior. Finally, it explores a number of issues that arise in consideration of how perceived susceptibility impacts health protective behavior.

CANCER PREVALENCE

Cancer is a feared disease of high prevalence. By age 59, over 8% of men and 9% of women will have developed an invasive cancer; from birth to death, these percentages rise to 47% of men and 38% of women (Landis, Murray, Bolden, & Wingo, 1998). Cancer is the second leading cause of death (23% of all deaths) behind heart disease (32%) among adults in the United States. In all, 1.23 million new cases of cancer and over 564,800 cancer deaths are expected in the United States in 1998 (Landis et al., 1998).

SCREENING AND PREVENTIVE RECOMMENDATIONS

The public is inundated with information about cancer and with recommendations for cancer screening and prevention.

As of 1998, the American Cancer Society recommended extensive cancer screening (American Cancer Society, 1998). Screening recommendations include an annual mammogram for women age 40 and older; colon and rectal screening with fecal occult blood test (FOBT) annually, plus flexible sigmoidoscopy every 5 years for men and women over age 50; annual prostate-specific antigen (PSA) blood test and digital rectal examination (DRE) for men age 50 and older; annual pelvic examinations for all women age 18 and older, with annual Pap tests until at least three negative Pap tests have been achieved, and then less frequent Pap tests; and endometrial screening for women at high risk for uterine cancer (American Cancer Society, 1998). Regular self-examinations are also recommended, including skin self-examination (American Academy of Dermatology, 1994; National Cancer Institute, 1995), breast self-examination (BSE) for all women beginning at age 20 (American Cancer Society, 1998), and testicular self-examination for men (National Cancer Institute, 1992). (See also the screening recommendations of the U.S. Preventive Services Task Force, 1996.) Beyond screening are recommendations for cancer prevention through lifestyle modification, including skin protection (American Cancer Society, 1997b) and diet (American Cancer Society, 1996).

SCREENING UTILIZATION IN THE UNITED STATES

According to the National Health Interview Surveys of 1987, 1992, and 1994, a population-based national survey of 40,000 households (American Cancer Society, 1997a; National Center for Health Statistics, 1996), the percentage of women age 50 and over who have had a mammogram in the past 2 years rose from 25% to 56% between 1987 and 1994. These rates were similar for Black and Hispanic women (56% and 50%, respectively, in 1994, up from 19% and 18%, respectively, in 1987), although rates lagged for low income women (38% in 1994) and those with less than a high school education (42%). Rates for Pap test utilization (within the past 3 years) achieved 77% in 1994 (74% for Hispanic women), again lagging behind for low education women (62%). As of 1992, about a third of the population had had one of three colorectal screening tests, DRE within the past year, FOBT within the past 2 years, or a sigmoidoscopy at least once.

OPENLY AIRED CANCER DEBATES

Epidemiological findings make the news, and the public hears a relentless array, often contradictory, of associations between behaviors and cancer (Taubes, 1995). Medical debates about the efficacy of screening for mortality reduction are publicly aired (Aiken, Jackson, & Lapin, 1998). The debate on the efficacy of mammography screening for women under age 50 raged in the public media for most of this decade (Aiken et al., 1998). Prostate screening currently is occasioning considerable debate, along the lines of the previous mammography debate (Albertsen, 1996; E. S. Wolfe & W. W. Wolfe, 1997). Increasingly, laypersons are asked by their physicians to decide whether

they wish to be screened, with the argument that patient choice must be preserved (Woolf & Lawrence, 1997). Issues concerning appropriate screening are aired against a backdrop of economic constraints posed by the health care industry.

CLASSES OF CANCER PROTECTIVE BEHAVIORS

For the exploration of perceived risk and behavior, cancer protective behaviors must be divided into two broad categories—screening for early detection versus prevention. Screening behaviors may further be divided into those that are medically based (e.g., mammography) versus those that involve self-examination (e.g., BSE). This distinction is important because the barriers to screening are expected to be very different for the two categories. These barriers may interact with or obscure the role of perceived risk. A similar argument can be made for specific preventive behaviors. Although the discussion draws on literature on a variety of cancers, medically based screening is exemplified with mammography, self-screening with BSE, and preventive behavior with skin protection.

PERCEIVED RISK IN MODELS OF HEALTH BEHAVIOR

This section is devoted to an overview of the role of perceived risk in models of health protective behavior. Health psychology is rich in models of the putative determinants of health protective behavior. At the core of essentially all these models is the concept of *perceived risk*—the extent to which individuals believe that they are subject to a health threat (Becker, 1990; Gerrard, Gibbons, & Bushman, 1996; Kowalewski, Henson, & Longshore, 1997; van der Pligt, 1998; Weinstein, 1993).

Health psychology draws on a theoretically based literature in risk perception and its determinants (Kahneman & Tversky, 1973; Kasperson et al., 1988; Slovic, 1987; Tversky & Kahneman, 1974). Formal models of risk (Kasperson et al., 1988) postulate that risk is a joint function of the probability of occurrence of a negative event, and the magnitude of its consequences; risk is the product of these factors.

Literature applying perceptions of risk to health behavior is less precise. The term *perceived risk*, as well as the terms *perceived susceptibility* and *perceived vulnerability* are used interchangeably for measures of the subjective likelihood of contracting a disease, absent any consideration of severity. Consistent with application in health, the terms *perceived risk*, *perceived susceptibility*, and *perceived vulnerability* are used here to refer to subjective estimates of the likelihood of personally contracting a disease, and not the combination of likelihood and consequences. *Perceived severity* is used here to refer to perceptions of disease consequences independent of likelihood.

According to Weinstein (1993), models of health behavior assume that the motivation for health protective behavior stems from anticipation of some negative health outcome coupled with hope of avoiding the outcome. Anticipation of a negative outcome involves foremost the perception that one is

personally susceptible to some disease; for strong health motivation to be achieved, this perception must be coupled with the anticipation that the disease consequences are severe (Weinstein, 1993).

Our particular interest in this chapter is the linkage of perceived susceptibility to health protective behavior. A theoretical context for this linkage is provided by consideration of the way in which perceived susceptibility is used in models of health protective behavior. Three widely applicable models of health behavior, the health belief model (HBM; Becker & Maiman, 1975; Rosenstock, 1966; 1974a, 1974b, 1990), protection motivation theory (PMT; Prentice-Dunn & Rogers, 1986; Rogers, 1975, 1983), and the precaution adoption process model (PAPM; Weinstein, 1988) employ the perceived susceptibility construct as a driving force in health protective behavior. Perceived risk appears as well in the transtheoretical model of change (TTM; Prochaska, DiClemente, & Norcross, 1992), and the recently proposed cognitive-social health information processing (C-SHIP) model (S. M. Miller, Shoda, & Hurley, 1996). Perceived risk is also implicit in the theory of reasoned action (TRA; Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975) and its extension, the theory of planned behavior (Ajzen, 1991), as well as subjective expected utility theory (Ronis, 1992; Weinstein, 1993), as they are applied to health behavior.

Although perceived susceptibility is consistently cast as the motivating engine for health protective behavior, the specific role of perceived susceptibility and assumptions about how it combines with other constructs vary in informative ways across models. A brief characterization of the role of the perceived susceptibility construct in several well-established models of health behavior and the newer C-SHIP model is provided. A characterization of the complete health models is beyond the scope of this chapter; Conner and Norman (1996); Glanz, Lewis, and Rimer (1990); Weinstein (1993); and Weinstein, Rothman, and Sutton (1998) provided explanations of these and other models; Conner and Norman (1996) provided extensive reviews of literature employing these models as well. Curry and Emmons (1994) provided a thorough summary of applications of the HBM, TRA, and the TTM to breast cancer screening.

Perceived Susceptibility as Motivator: Health Belief Model

The health belief model (HBM) traces its origins to problems encountered in the U.S. Public Health Service nearly half a century ago—problems of failures of *asymptomatic* individuals to undergo screening tests or to engage in preventive health behaviors (Rosenstock, 1966, 1974a; 1990). Ironically, the health belief model is still being applied to the same issues, which are abundant in the area of cancer prevention and early detection. The HBM states that individuals will undertake a health action to the extent that they believe themselves to be susceptible to a health threat (*perceived susceptibility*), believe that the consequences of the disease are serious (*perceived severity or seriousness*), believe that the

proposed health action will offer protection against the health threat (*perceived benefits*), and believe that barriers to performing the health action can be overcome (*perceived barriers*). Finally, individuals must receive some trigger, or cue, in order to act (*cue to action*). Interestingly, in current interventions to increase cancer screening, a reminder letter (a cue to action) is a common component (e.g., Bastani, Marcus, Maxwell, Das, & Yan, 1994). Physicians' recommendations for screening have been conceptualized as a cue to action as well (Fox, Siu, & Stein, 1994).

Perceived susceptibility is, in a sense, the centerpiece of the HBM. There are two aspects to perceived susceptibility: the individuals' belief that contracting a disease is a realistic possibility for themselves, and the individuals' belief that they may have the disease in the complete absence of symptoms (Rosenstock, 1990). Failure to utilize cancer screening tests may be attributed to a lack of belief that pathology can exist in the absence of symptoms (Rosenstock, 1990). Perceived susceptibility and perceived severity combine to form perceived threat, a determinant of the likelihood of adopting a health action; this combination closely reflects the formal definition of risk (Kasperson et al., 1988) provided earlier. The HBM is silent on the nature of the combinatorial rules for the constructs; in most applications of the health belief model, simple additive effects of the constructs have been explored. The interplay of perceived threat with perceived benefits is important for cancer screening, in that high risk individuals, although they perceive heightened vulnerability, may avoid seeking screening if they believe that cancer treatment cannot save them (e.g., Lerman & M. D. Schwartz, 1993, for breast cancer; M. D. Schwartz, Lerman, Daly, et al., 1995, for ovarian cancer). Ronis (1992) suggested a combinatorial rule for HBM constructs in which perceived susceptibility and severity are necessary precursors to the perception of benefits of health action, a characterization on which we draw in our later discussion of interventions.

The health belief model has made sustained contributions as a heuristic for the study of psychosocial correlates of preventive health behavior. (See reviews by Harrison, Mullen, & Green, 1992; Janz & Becker, 1984; and Sheeran & Abraham, 1996.) Typically, the perceived barriers construct has been the strongest correlate of lack of protective behavior, whereas perceived susceptibility has typically exhibited low to moderate positive correlations with protective behavior.

Whereas perceived susceptibility is expected to combine with perceived severity to motivate health protective behavior, perceived severity by itself rarely correlates with preventive behavior or screening behavior (Janz & Becker, 1984; Harrison et al., 1992). This is certainly true for cancer research: Perceived severity has failed to show predictive utility and has not been amenable to change via intervention, as cancer apparently is seen as uniformly serious (Champion, 1994; Curry & Emmons, 1994; Rimer, 1990; but see Ronis & Harel, 1989, for an exception). Researchers often forgo the measurement of perceived severity in characterizing the HBM for cancer-related behavior (e.g., Hyman, Baker, Ephraim, Moadel, & Philip, 1994; Vernon, Myers, & Tilley, 1997). Thus, perceived susceptibility by itself, rather than the combination of suscepti-

bility and severity, is de facto characterized as the motivating force for cancer protective behavior.

Fear Arousing Communication, Perceived Susceptibility, and Behavior: Protection Motivation Theory

Perceived susceptibility also plays a central role as a motivator of health protective behavior in PMT, a model that arose from consideration of the impact of fear arousing communication on the adoption of health protective behavior (Beck & Frankel, 1981; Rogers, 1975). As in the HBM, perceptions of susceptibility and severity that resulted from fear communications were expected to combine with perceptions of the existence of an effective health protective behavior to arouse *protection motivation*, which in turn led to intentions to adopt the protective health behavior (Rogers, 1975). In the revised form of PMT (Rogers, 1983; Prentice-Dunn & Rogers, 1986), a special motivating role for perceived susceptibility coupled with perceived severity was provided, that of lowering the probability of a maladaptive response (e.g., delay in seeking treatment for suspected cancer symptoms, persistence in behaviors that put one at increased cancer risk). Rippetoe and Rogers (1987) applied PMT to an experimental investigation of breast self-examination.

How Perceptions of Susceptibility Accrue: The Precaution Adoption Process Model

Models of health behavior assume that in order for perceived susceptibility to act as a motivational force, perceptions of susceptibility must be personal (i.e., individuals must feel that they, themselves, are vulnerable). Weinstein (1988) proposed the precaution adoption process (PAPM) as a stage model of the adoption of health behavior. In general, stage models (Weinstein et al., 1998) characterize individuals as falling into a series of ordered categories with regard to adoption of a health behavior. In PAPM, these stages move from lack of awareness of the health issue (Stage 1) through health behavior maintenance (Stage 7). Consistent with this stage structure, beliefs about perceived susceptibility are assumed to develop in a series of cumulative stages. First, individuals are assumed to become aware of a health hazard (awareness), then to believe in the likelihood of the hazard for others (general susceptibility), and finally to acknowledge their own personal vulnerability (personal susceptibility). Personal susceptibility is assumed to be critical in the decision to take precautionary action (Weinstein et al., 1998). Assessment of discrepancies between general susceptibility versus personal susceptibility has uncovered optimistic biases (Weinstein, 1980) about people's vulnerability; these biases are discussed later. The PAPM has been applied to home testing for radon gas, which is an environmental cancer threat (Weinstein & Sandman, 1992).

The Growth of Perceived Susceptibility and the Process of Adopting Health Behaviors: Transtheoretical Model of Change

The TTM, as the PAPM, is a stage model of health behavior adoption (Prochaska et al., 1992). Progress through the first

two stages is hypothesized to be driven by the growth of awareness of perceived susceptibility from *precontemplation*, during which the individual has no sense of vulnerability to a health threat, to *contemplation*, in which there is an awareness of one's own vulnerability to a health threat but no commitment to health action. Although the transtheoretical model was initially applied to smoking cessation as a cancer preventive action, the model has now been applied to cancer screening as well. For example, Lipkus, Rimer, and Strigo (1996), Rakowski et al. (1992), and Siegler, Feaganes, and Rimer (1995) applied this model to mammography screening.

Cognitive-Social Health Information Processing

The C-SHIP model (S. M. Miller et al., 1996) is a comprehensive model of the genesis and maintenance of health-protective behavior, initially expounded in the context of the complex sustained behavior of breast self-examination (BSE). The model considers five classes of determinants of health behavior that incorporate both cognitions and affect. Among these, two classes address issues of perceived susceptibility: *health-relevant encodings*, including health risks and vulnerabilities, plus attentional strategies for gathering versus avoiding health relevant information; and *health beliefs and expectancies*, including how vulnerabilities, such as genetic predisposition, impact subjective likelihood of disease development. The model specifies how information about objective risk and resultant perceptions of susceptibility interact with emotions associated with receiving health information, with health goals, and with self-regulation in producing health behaviors. That the model addresses the interplay of emotion with cognitions about people's vulnerability is important for an understanding of cancer screening behavior among high risk individuals; this issue is discussed later.

Perceived Susceptibility as a Predisposing Factor in Complex Hybrid Models of Health Behavior Adoption

Within this decade, a number of authors have proposed extensive integrative frameworks of the putative determinants of health protective behavior, which have been employed in the design of interventions to increase health behavior. Four such frameworks are summarized in Curry and Emmons (1994). Each framework specifies a complex causal chain of variables that ultimately leads to health behavior. Most important for our consideration is the fact that perceived susceptibility is included as a predisposing factor for health behavior adoption early in the causal chain, a factor that may facilitate overcoming barriers to the health protective behavior (McBride, Curry, Taplin, Anderman, & Grothaus, 1993) and lead to receptiveness to health promotion interventions (the PRECEDE-PROCEED model of Green & Kreuter, 1991).

Summary: Perceived Susceptibility as a Predisposing Factor for Health Behavior Adoption

Not surprisingly, models of health behavior have matured and increased in complexity. Early models have been augmented with new variables, for example, the addition of self-efficacy for health behavior to both the HBM (Rosenstock, Strecher, & Becker, 1988) and PMT (Rogers, 1983). New stage models have viewed health behavior adoption as dynamic, in part driven by perceived susceptibility. The interplay of susceptibility cognitions with emotion has been elucidated. Hybrid models have incorporated a complex network of environmental and medical system variables along with individual cognitions, including perceived susceptibility. The evolution of these models has clarified the role of perceived susceptibility as a potentially powerful predisposing factor at the outset of the process of adoption of health behaviors, a factor that motivates this process of adoption. Drawing on this evolution of health behavior models, we conceptualize perceived susceptibility to disease as a *distal construct in a mediational chain* of constructs that eventuates in protective health behavior.

PERCEIVED SUSCEPTIBILITY: MEASUREMENT AND DETERMINANTS

This section first considers approaches to the measurement of perceived susceptibility. It then reviews comparisons of objective risk for cancer with subjective risk, raising the question of whether individuals overestimate or underestimate their cancer risk relative to objective risk. Finally, it explores the putative determinants of perceived susceptibility, drawing on both a broad literature on determinants of risk, and a cancer-specific literature.

Measurement of Perceived Susceptibility

Alternative approaches to the measurement of perceived susceptibility lead to varying pictures of personal perceptions of risk for developing cancer. Two broad classes of measures are *absolute measures*, in which personal ratings are made without reference to any outside group, and *comparative measures*, in which personal perceived susceptibility is compared to susceptibility in some normative group (Weinstein & Klein, 1996).

Absolute Measures

Rating Scales. Among absolute measures, typical rating scales ask individuals for Likert scale judgments of their likelihood of developing cancer—for example, “What do you think are the chances that you personally will get breast cancer someday” (5-point scale; Bastani, Marcus, & Hollatz-Brown, 1991). These are the most commonly used measures of perceived susceptibility, employed both in studies of the psychosocial correlates of health protective behavior and in evaluations of interventions.

Numerical Estimates. Numerical estimates of the chance of contracting cancer are also taken as absolute indicators of perceived susceptibility—for example, “Risk of developing breast cancer in the next 10 years” (< 1%, 1–5%, 6–10%, 11–20% or > 20%; Dolan, Lee, & McDermott, 1997). Perceived risk has also been measured with rate judgments—for example, “the number of women out of 1000 whom you think would develop breast cancer in the next 10 years” (Black, Nease, & Tosteson, 1995; see also L. M. Schwartz, Woloshin, Black, & Welch, 1997). Such measures have enjoyed relatively limited application, most often in studies comparing perceived to objective risk.

Comparative Risk

Direct comparative risk is measured with some form of the following question: “What do you believe are your chances of getting (disease) compared to other (men/women) your own age?”, with typical responses of “a lot lower, somewhat lower, about the same, somewhat higher, and a lot higher.” This measure has been applied to cancer in general (Kreuter & Strecher, 1995); lung cancer, skin cancer, and cancer in general (Weinstein, 1987); breast cancer (e.g., Aiken, Fenaughty, West, Johnson, & Lockett, 1995); and colorectal cancer (e.g., Blalock, DeVellis, Afifi, & Sandler, 1990). **Indirect comparative risk** is assessed by having individuals rate the perceived likelihood of developing the disease for themselves and for others on separate scales; the difference between these two ratings reflects comparative risk (Weinstein & Klein, 1996).

Measure of comparative risk are sometimes used in combination with absolute rating scales in the formation of multi-item susceptibility measures. However, the two most common applications of comparative risk items have been in research on optimistic bias (e.g., Weinstein, 1980) and in studies of individual attributions of risk (e.g., Aiken et al., 1995). Direct comparative risk items provide risk estimates only in relation to others; thus, the specification of the comparison group is critical. An individual who felt quite vulnerable to a disease, when measured on an absolute rating scale, might nonetheless feel less at risk than more unfortunate others (Klein & Weinstein, 1997), yielding a comparative rating of relatively low comparative risk.

Perceived Susceptibility Versus Cancer Worry and Cancer Distress

Perceived susceptibility has been distinguished from more emotional aspects of vulnerability in studies of cancer-related health behaviors, consistent with the C-SHIP model. Items such as “Thinking about breast cancer makes me feel upset and frightened” (McCaul, Schroeder, & Reid, 1996) have been used to characterize cancer *worry*, as distinct from perceived susceptibility. Sjöberg (1998) argued that worry versus perceived risk reflect emotional versus cognitive reactions to threat, respectively. The two variables are weakly correlated (e.g., $r = .20$; McCaul et al., 1996) and form independent factors in the measurement of predictors of colorectal cancer screening adherence (Vernon et al., 1997). In addition

to worry, fear of cancer and cancer treatment (Berman & Wandersman, 1992; Salazar & de Moor, 1995), cancer anxiety (Gram & Slenker, 1992), and morbid concern about breast cancer (Irwig et al., 1991) also have been included in research. A growing literature on breast and ovarian cancer screening among high risk women (e.g., Audrain et al., 1998; M. D. Schwartz, Taylor, et al., 1999) has employed such measures of cancer-specific distress.

Perceived Vulnerability to Cancer and Objective Risk

Comparisons of Objective and Subjective Risk

A number of approaches have been taken to the comparison of objective with subjective risk for cancer. Objective risk measures are of two types. First are rates of risk in the *population* (e.g., the percent of women in the population ever contracting breast cancer). Second are risk estimates derived for specific *individuals*, based on their particular status on known risk factors; derivation of these latter estimates employs epidemiological models of risk. Subjective measures are numerical estimates of risk, or rating scale measures of absolute or comparative risk.

Population Estimates. When determined from actual versus estimated population rates, community samples overestimate their probability of developing and dying of cancer (e.g., Helzlsouer, Ford, Hayward, Midzenski, & Perry, 1994, for cancer in general; Ward, Hughes, Hirst, & Winchester, 1997, for prostate cancer).

Epidemiological Estimates and Individual Assessments. Individuals' risk estimates based on epidemiological models have been compared with their own subjective numerical risk estimates. The Gail model (Gail et al., 1989), a five-factor epidemiological model of breast cancer risk among Caucasian women, predicts risk for breast cancer among women who obtain annual mammograms. Risk factors include number of first-degree relatives (mother or sisters) with breast cancer, age at menarche, age at first live birth, number of previous biopsies and chronological age. Using this model, Black et al. (1995) and Dolan et al. (1997) found that women grossly overestimate their chances of developing breast cancer, for example, by a factor of 20 in women under age 50 (Black et al., 1995). Subjective and objective estimates correlate moderately (for example, $r = .46$ for breast cancer in a sample of women under age 50; Siegler et al., 1995).

Those at heightened cancer risk due to their being first-degree relatives (FDRs) of individuals with cancer also overestimate their personal risk. More than 60% of FDRs greatly overestimated their lifetime risk of breast cancer as compared to Gail estimates (Lerman et al., 1995). Among FDRs, specific Gail model risk components were found to be unrelated to numerical ratings (0%–100%) of the chance of getting breast cancer someday (Daly et al., 1996).

Comparative Risk Ratings Versus Epidemiological Estimates. A number of investigations have compared an epidemiological estimate of risk with a direct measure of comparative risk. Such studies provide a very different picture of the relation of objective to subjective risk, depending on the disease. Individuals are optimistic (i.e., underestimate their risk) for heart attack within the next 10 years (Avis, Smith, & McKinlay, 1989; Kreuter & Strecher, 1995), but overestimate their risk of cancer in this time frame, with almost half of individuals showing pessimistic bias (Kreuter & Strecher, 1995).

Comparative Risk and Unrealistic Optimism

While people overestimate their absolute risk of contracting cancer, studies of comparative risk suggest that individuals exhibit *unrealistic optimism* or *optimistic bias* (Weinstein, 1980, 1987; Weinstein & Klein, 1996); that is, they believe they are less likely to contract specific cancers than are others their own age. This bias has been demonstrated for breast cancer (Aiken et al., 1995), skin cancer (A. J. Miller, Ashton, McHoskey, & Gimbel, 1990), and colorectal cancer (Blalock et al., 1990; Lipkus, Rimer, Lyna, et al., 1996), as well as brain cancer, leukemia, and lung cancer (Lek & Bishop, 1995). In contrast, comparative judgments of "cancer in general" do not yield optimistic bias (Weinstein, 1980, 1984), even when "cancer in general" and specific cancers are rated by the same sample (Weinstein, 1982, 1987). FDRs of women with breast cancer accurately estimate their comparative risk as high when asked to compare their risk to women without a family history of breast cancer (Audrain et al., 1995; Lerman, Kash, & Stefanek, 1994). However, when asked to compare their risk to others their own age, with family history unspecified, a substantial portion of FDRs incorrectly rate their risk as lower than average (Aiken et al., 1995; Blalock et al., 1990).

Whereas much effort has been made to untangle the sources of optimistic bias and risk perceptions in general, the behavioral implications of the optimistic bias for protective behavior are unclear (van der Pligt, 1998; Weinstein & Klein, 1996), and have not been addressed in the context of cancer. Van der Pligt (1996) argued that comparative risk appraisal may not be a determinant of health behavior and does not contribute to the prediction of health behavior beyond perceived vulnerability.

Determinants of Perceived Risk for Cancer

Two literatures inform the question of the determinants of perceived risk for cancer. The first, cancer-specific literature examines individuals' rationales for their ratings of their own risk of cancer relative to others their own age, following a methodology first employed by Weinstein (1984). The second is a broader literature on the determinants of risk.

Determinants of Comparative Risk for Cancer

Weinstein (1984) coded the reasons generated by individuals for their comparative risk judgments into five categories:

actions and behavior patterns, heredity, physiology or physical attributes, environment, and psychological attributes. For cancer in general, breast cancer (Aiken et al., 1995; Lipkus, Rimer, & Strigo, 1996; Salazar, 1994), and colorectal cancer (Blalock et al., 1990; Lipkus, Rimer, Lyna, et al., 1996), personal lifestyle-related actions were seen as decreasing risk (e.g., proper diet, exercise). For lung cancer, personal actions (smoking) were seen as increasing risk (Lek & Bishop, 1995). Across cancers, attributions for heredity were that the absence of disease in the family reduced risk below average. In contrast, women who believed their risk to be above average for breast cancer mentioned heredity most often as the determining factor (Aiken et al., 1995; McCaul & O'Donnell, 1998; Savage & Clarke, 1996). Of interest is that FDRs of colorectal cancer patients rarely mentioned heredity as increasing their risk, even after they had been informed they were at increased risk due to their sibling's cancer (Blalock et al., 1990). These results taken together suggest that individuals believe they have some control over whether they get cancer through their own actions. However, there is lack of understanding of the role of heredity in cancer. Absence of family history is viewed as highly protective, even though most cancers are not associated with family history. At the same time, a family history of cancer may not lead to perceptions of increased risk.

General Determinants of Perceived Risk

Van der Pligt (1996, 1998) summarized an extensive literature on the determinants of perceived risk. Classes of determinants include cognitive heuristics, disease characteristics, personal motivations, and personality and information-processing strategies (Gerend, 1998). (See Fischhoff, Bostrom, & Quadrel, 1993, for a discussion of risk perception and communication.)

Cognitive Heuristics. Individuals rely on cognitive heuristics in estimating uncertain events (Kahneman & Tversky, 1973; Tversky & Kahneman, 1973, 1974), and these heuristics may underlie inaccurate perceptions of risk in the health domain. The *availability heuristic* (Tversky & Kahneman, 1973) indicates that individuals base frequency estimates on the salience of the event in question, or the ease with which the event comes to mind. Personal experience with other individuals who have cancer (Wardle, 1995), coupled with the extensive media coverage of cancer, may contribute to the observed overestimates of cancer risk (Slovic, Fischhoff, & Lichtenstein, 1979; van der Pligt, 1998). The *representativeness heuristic* (Kahneman & Tversky, 1973) indicates that individuals base likelihood estimates for a hypothetical event (e.g., a personal diagnosis of breast cancer) on their similarity to events with comparable characteristics (e.g., the individual's similarity to others diagnosed with breast cancer).

Characteristics of the Health Threat. Bias in perceptions of comparative risk has been hypothesized to depend on disease characteristics (Weinstein, 1984, 1987; Weinstein

& Klein, 1996). Harris (1996) and Weinstein (1987) provided support for a direct relation between the perceived controllability or preventability of a disease and optimistic bias concerning risk; that is, the more controllable or preventable a disease was perceived to be, the greater the optimistic bias. Evidence of a relation of optimistic bias with disease heritability is lacking (Weinstein, 1982). The "absent/exempt" principle (e.g., "If I haven't gotten the disease by now, I won't get it"; Weinstein, 1987) is associated with lower perceived risk with increasing age (e.g., Aiken, West, Woodward, & Reno, 1994, for breast cancer), although cancer incidence increases with age.

Maintenance of Self-Esteem. Optimistic biases for perceived personal risk have in part been attributed to a motivation to protect oneself from feelings of distress or anxiety about future negative events (e.g., Perloff, 1983). This protection may accrue from downward social comparisons, that is, comparisons of one's own risk with the risk of others who are actually more vulnerable (Klein, 1996; Klein & Weinstein, 1997; Perloff & Fetzer, 1986).

Personality Characteristics and Modes of Information Processing. A variety of personality dimensions have been associated with perceived risk. Among them are monitoring blunting (M. D. Schwartz, Lerman, S. Miller, Daly, & Masny, 1995), psychological defense (Dziokonski & Weber, 1977; Paulhus, Fridhandler, & Hayes, 1997), anxiety (MacLeod, Williams, & Berekian, 1991), and neuroticism (Darvill & Johnson, 1991). This may explain linkages noted between personality factors and breast screening behavior (Siegler et al., 1995) reviewed by Siegler and Costa (1994).

PERCEIVED SUSCEPTIBILITY AND CANCER RELATED BEHAVIOR

This section considers the relations of perceived susceptibility to both screening for early detection of cancer and cancer preventive behavior. A critical issue for health psychology is the implication of perceptions of susceptibility for protective behavior. As we have already indicated, we conceptualize perceived susceptibility to disease as a distal construct in a mediational chain of constructs that eventuates in health behavior. Relations of perceived susceptibility to behavior are likely to be complex, to be mediated, moderated, or nullified by other determinants of the particular behavior in question, determinants that are explored in the discussion of perceived susceptibility and protective behavior. Given space limitations, this chapter does not provide a comprehensive review, but it does reference and summarize existing reviews and highlight important themes (see Royak-Schaler, Stanton, & Danoff-Burg, 1997, for related work).

Perceived Susceptibility, Distress, and Screening

Accuracy of Self-Report of Screening Behavior

Studies of screening behavior often rely on self-report of screening. Several reports suggest approximately 95% accu-

racy for self-reports of having had a mammogram when compared to clinic records (Aiken, West, Woodward, Reno, & Reynolds, 1994; Degnan et al., 1992; Etzi, Lane, & Grimson, 1994; King, Rimer, Trock, Balshem, & Engstrom, 1990; Rimer et al., 1992). Correct recollection of whether a mammogram occurred within the past year or 2 years appears somewhat lower (73% accuracy; Degnan et al., 1992). Self-report accuracy is lower for screening tests that occur during the course of physician examination, for example, 61% verification of Pap smears against laboratory records (Bowman, Sanson-Fisher, & Redman, 1997), and very low verification rates for digital rectal examination (DRE) and fecal occult blood test (FOBT) against medical charts (Lipkus, Rimer, Lyna et al., 1996). Finally, self-reports of breast self-examination (BSE) may overestimate actual performance (Alagna, Morokoff, Bevet, & Reddy, 1987).

Perceived Susceptibility and Mammography Screening

McCaul, Branstetter, Schroeder, and Glasgow (1996) provided an extensive meta-analysis of the relation between breast cancer risk and mammography screening. The weighted average correlation between family history and screening was $r = .27$, with only one article reporting a nonsignificant negative correlation. For perceived vulnerability and screening, the average weighted correlation was a somewhat lower, $r = .16$, with a stronger relationship evidenced in cross-sectional ($r = .19$) than in prospective designs ($r = .10$). Higher screening likelihood was noted among women who had breast problems, $r = .30$. Worry about breast cancer was positively associated with screening, $r = .14$. The positive relation of perceived susceptibility to screening has been confirmed in more recent studies (Cole, Bryant, McDermott, Sorrell, & Flynn, 1997; Lauver, Nabholz, Scott, & Tak, 1997; Lipkus, Rimer, & Strigo, 1996). Perceived susceptibility is not a proxy for family history, and predicts screening compliance above and beyond family history (Aiken, West, Woodward, & Reno, 1994).

As we have argued, the relation of perceived susceptibility to screening has been found to be moderated by other psychosocial variables. Aiken, West, Woodward, and Reno (1994) found that susceptibility related to compliance with mammography screening only when perceived barriers to screening were low; under high perceived barriers, no such relation was observed.

Medical System and Demographic Determinants of Screening. A growing literature in the public health domain provides documentation of medical system determinants of the use of medically based cancer screening tests. The impact of health care coverage (e.g., Potosky, Breen, Graubard, & Parsons, 1998) and, moreover, continuity of care, (e.g., O'Malley, Mandelblatt, Gold, Cagney, & Kerner, 1997), have been documented. This literature further reflects the impact of demographic variables on screening utilization, among them race (e.g., Frazier, Jiles, & Mayberry, 1996; Paskett, Rushing, D'Agostino, & Tatum, 1997; Pearlman,

Rakowski, Ehrich, & Clark, 1996), acculturation among minority women (Kaplan et al., 1996), and age (Caplan & Haynes, 1996; M. E. Costanza, 1992) in interaction with race (Fox & Roetzheim, 1994). These variables set limits on the impact of psychosocial variables on screening utilization.

Perceived Susceptibility and Breast Self-Examination (BSE)

Evaluation of the relation of perceived vulnerability to BSE performance takes into account not only the frequency of BSE performance relative to the recommended monthly schedule (American Cancer Society, 1998), but also the adequacy of BSE performance (see review by Zapka & Mamon, 1986). S. M. Miller et al. (1996), Savage and Clarke (1996), and Aiken et al. (1995) all pointed out the mixture of positive and null results for the relation of perceived vulnerability to BSE frequency. When relations of vulnerability to BSE frequency are found, they are modest, ranging from .14 to .25 (S. M. Miller et al., 1996). The balanced mix of positive and null results yields a lower average correlation across studies. Interestingly, perceived susceptibility relates to thoroughness and accuracy of BSE performance (Fletcher, Morgan, O'Malley, Earp, & Degnan, 1989; Wyper, 1990). However, across studies, the perceived barriers construct (including such factors as large breast size, difficulty of performing BSE, lack of expertise in BSE; Salazar, 1994) dominates as the strongest predictor of BSE frequency within the HBM framework, with correlations approaching $-.5$ (Wyper, 1990). Strong barriers may override perceptions of susceptibility in influencing performance versus nonperformance of BSE.

Self-Efficacy and Screening. As would be expected for a self-screening behavior, self-efficacy or self-confidence in the ability to adequately perform BSE is correlated strongly with BSE frequency (e.g., Alagna et al., 1987; Champion, 1991; Rutledge & Davis, 1988; Sortet & Banks, 1997; see reviews by S. M. Miller et al., 1996, and Salazar, 1994). This relation has been found both retrospectively and prospectively. Similarly, the importance of self-efficacy has also been demonstrated for testicular self-examination (Brubaker & Wickersham, 1990).

Fear, Worry, Cancer Distress, and Screening Behavior

In both the general population and in FDRs of individuals with cancer, fear of cancer, worry about cancer, and cancer distress have been associated with both insufficient and excessive screening, thus providing a plethora of conflicting results across studies.

General Population. McCaul and colleagues (McCaul, Reid, Rathge, & Martinson, 1996; McCaul, Schroeder, & Reid, 1996) found a positive relation of breast cancer worry to mammography screening in the general population, as did Ward et al. (1997) for prostate cancer. However,

in an inner-city population, an inverted U-shaped relation was observed: Moderate worry about breast cancer was associated with greater attendance at a first mammography screening than was either extreme (Sutton, Bickler, Sancho-Aldridge, & Saidi, 1994). The same inverted U-shaped relation was observed between BSE frequency and breast cancer worries (Lerman et al., 1991). Among older low income Mexican American women, fear of and fatalism about cancer were associated with lower Pap smear rates (Suarez, Roche, Nichols, & Simpson, 1997). Worry appears to serve as a barrier to mammography among African American women (Friedman et al., 1995). Again in a sample with a substantial inner-city component, Bastani et al. (1994) reported a strong negative association between fear of finding breast cancer and screening. This brief sampling of articles suggests possible demographic differences in the relation of emotional aspects of cancer threat on screening, with cancer worry adversely affecting screening among inner-city, low income, and minority individuals; these findings, however, are not universal.

High Risk Individuals. A conflicting pattern of results is also observed for high risk individuals, FDRs of individuals with cancer. Ovarian cancer worries among FDRs have been positively associated with screening (M. D. Schwartz, Lerman, Daly, et al., 1995). In contrast, high breast cancer distress (i.e., extreme worry, intrusive thoughts about breast cancer) among FDRs is associated with reduced screening (Lerman et al., 1993; see also Kash, Holland, Halper, & D. G. Miller, 1992; Lerman et al., 1994), although the opposite has also been found (Stefanek & Wilcox, 1991). Interestingly, distress has been associated with either excessive or insufficient BSE (Epstein et al., 1997; Lerman et al., 1994). Cancer distress among FDRs of women with breast and ovarian cancer is associated with high perceived risk of cancer and low perceived control over cancer development (Audrain et al., in press).

Conflicting Findings and the Elusive Inverted U-Shaped Function

In the now classic fear communication literature, Janis and Feshbach (1953) argued that fear served as a positive motivator for protective behavior up to some critical level of fear. Above that critical fear level, avoidance of the threat was expected to replace protective behavior, yielding an inverted U-shaped relation between level of fear and behavior.

Resolving Conflicting Findings. Lerman and M. D. Schwartz (1993) used the notion of an inverted U-shaped relation to highlight an important issue in resolving conflicting literature on the relations of worry and distress to cancer screening—the range and level of distress represented among participants in any individual study. If it is assumed for a moment that an inverted U-shaped relation of distress to screening exists, then all relations (positive, inverted U, negative, or no relation) are possible as segments of the distress continuum are sampled. The resolution of conflicting study out-

comes may lie in the segment of the distress continuum represented in any study. The McCaul, Reid, et al. (1996) meta-analysis showed only monotonic increasing relations of both susceptibility and cancer worry to behavior. However, the meta-analysis did not include articles in which avoidance of screening by FDRs of breast cancer victims was associated with high cancer distress, discussed further later (e.g., Kash et al., 1992; Lerman et al., 1994). In samples from the general population—samples such as those of McCaul, Reid, et al. (1996)—it is possible that there are insufficient very high distress cases for a curvilinear relation to be manifested and/or detected statistically.

Distress Versus Perceived Susceptibility. Support for the inverted U-shaped relation is found when emotional distress and not the more cognitive assessment of perceived susceptibility serves as the predictor of cancer screening behavior. Perhaps the inverted U-shaped relation of risk to behavior has been sought in the wrong variable, that is, in perceived susceptibility rather than cancer distress. (See Hailey, 1991, for consideration of an inverted U-shaped relation of distress to screening among FDRs of women with breast cancer.)

Modifying Perceived Susceptibility and Cancer Distress Through Training

High Risk Women. As already described, FDRs of women with cancer typically exhibit excessive perceived risk and associated high cancer distress, apparently leading to failure to follow screening recommendations (i.e., either excessive or insufficient screening) and even to requests for prophylactic surgery (Lerman et al., 1995). Interventions to reduce perceived susceptibility among FDRs have sometimes been successful (Alexander, Ross, Sumner, Nease, & Littenberg, 1995). However, women with high cancer distress benefit less from such susceptibility focused interventions, suggesting that both cancer distress and inaccurate perceptions of risk must be simultaneously addressed (Lerman et al., 1995). Reductions in cancer distress have been achieved through individual counseling (Lerman et al., 1996; Schwartz, Lerman, et al., 1998). An important issue is whether clarifying that perceived risk is overestimated will lead to underutilization of mammography screening (M. D. Schwartz, Rimer, Daly, Sands, & Lerman, 1998).

General Population. The extent to which subjective risk estimates can be made more accurate through intervention has also been explored in the general population (Weinstein & Klein, 1995), where perceived risk typically exceeds objective risk. Kreuter and Strecher (1995) reported increased accuracy in perceived risk (i.e., decreased perceived risk) for cancer in the general population following an educational intervention. Lipkus, Biradavolu, Fenn, Keller, and Rimer (1998) explored strategies for increasing accuracy of risk perceptions for cancer.

Repeated Screening

An important question is whether screening behaviors are sustained over time among asymptomatic women. Ronis, Yates, and Kirscht (1989) argued that the factors that lead to initiation of a behavior do not sustain the behavior, and that habits, rather than attitudinal variables, determine repeated behavior. Similar arguments were made by S. M. Miller et al. (1996) in the context of BSE performance.

Correlations of perceived susceptibility with repeated mammography screening are not reliably observed, with positive associations noted by Lerman, Rimer, Trock, Balschem, and Engstrom (1990) and Fenaughty, Aiken, and West (1993), but no association noted by Marshall (1994), Cockburn, Schofield, White, Hill, and Russell (1997), and Orton et al. (1991). Anxiety about mammography appears to be negatively related to repeated screening (Lerman et al., 1990).

Medical System and Demographic Determinants of Repeated Screening. A host of demographic and medical system variables relate to repeated screening, just as with mammography compliance taken at any single point in time. Younger age, physician recommendation, having had regular clinical breast examinations by a physician, and family breast cancer history are positively associated with repeated mammography screening (Hitchcock, Steckevecz, & Thompson, 1995; Lerman et al., 1990; Zapka, Stoddard, Maul, & Costanza, 1991). Failure of asymptomatic women to return for a second mammogram at a regular interval is associated with negative experiences with the initial mammogram, among them pain, embarrassment, and unpleasant interaction with clinic staff (Marshall, 1994; Orton et al., 1991). Again, it appears that many variables operate on repeated screening that weaken the potential impact of perceptions of susceptibility.

Sequelae of Abnormal Screening Tests and Discovery of Symptoms

Two related literatures highlight the reciprocal nature between screening and perceived vulnerability and cancer distress. The first literature, which addresses the impact of abnormal screening tests on psychological functioning, was reviewed by Paskett and Rimer (1995). This literature shows clear negative psychological effects of abnormal Pap smear and mammography test results, including heightened cancer distress, with varying levels of follow-up screening (from 20% to 95% across studies). The second literature, on delay in seeking treatment following the self-identification of a possible cancer symptom (e.g., a breast lump), was reviewed by Facione (1993). This literature characterizes the myriad fears engendered by discovery of cancer symptoms and their association with delay in seeking treatment.

Preventive Behavior: Sun Protection

Although the focus is primarily on screening, this section touches on cancer prevention, with a consideration of per-

ceived vulnerability as a correlate of sun protection. The incidence of deadly melanoma has risen 4% per year since 1973. Skin protection through limiting sun exposure and sunscreen use is recommended (American Cancer Society, 1998). (However, there is now significant controversy as to the efficacy of sunscreen for protection against melanoma; Facelmann & Wu, 1998).

Sun protection against skin cancer poses four related issues. First, because intensive sun exposure between age 10 and 24 is associated with melanoma development (Holman et al., 1986), adolescents must adopt sun protection. Second, sun exposure early in life is associated with much later development of skin cancer, thus raising the issue for health psychology of how to induce behavior change against *distal* risk. Third, normative influences play heavily in tanning: A suntan is perceived as healthy (e.g., Hill et al., 1992; Mermelstein & Riesenber, 1992) and attractive (A. J. Miller et al., 1990). Fourth, parents must play an active role in their children's skin protection (Rodrigue, 1996).

Objective risk based on skin type (Fitzpatrick, 1988) is associated with perceived susceptibility to skin cancer (Clarke, Williams, & Arthey, 1997; Jackson, 1997; Webb, Friedman, Luce, Weinberg, & Cooper, 1996). Arthey and Clarke (1995) provided a review of the psychological literature on suntanning and sun protection. Positive associations between perceived susceptibility and sun protection have been noted among high school students (Mermelstein & Riesenber, 1992; Wichstrom, 1994), university students (Cody & Lee, 1990), the general U.S. population (Hall, May, Lew, Koh, & Nadel, 1997), and parents protecting their children (Lescano & Rodrigue, 1997), but such relations are not uniformly observed. In fact, a negative relation has been found between sun protection and perceived risk among individuals with chronically high sun exposure (Carmel, Shani, & Rosenberg, 1996). Elevated perceptions of susceptibility in this case appear to result from past high risk behavior. A similar relation has been observed in the HIV/AIDS literature; those who have engaged in high risk sexual behavior subsequently report high perceived vulnerability to HIV/AIDS (Gerrard et al., 1996). Manipulations of perceived susceptibility in interventions have resulted in increased intentions for sun protection (e.g., Cody & Lee, 1990; Mahler, Fitzpatrick, Parker, & Lapin, 1997).

Normative Influences. Normative influences (Pratt & Borland, 1994; Wichstrom, 1994), particularly for appearance (A. J. Miller et al., 1990), have shown reliable relations with sun tanning versus sun protective behavior, particularly among adolescents. Self-presentation (impression management) may well lead to health risks (Leary, Tchividjian, & Kraxberger, 1994); suntanning exemplifies this phenomenon. Recent interventions (e.g., Jones & Leary, 1994; Prentice-Dunn, Jones, & Floyd, 1997) also highlight the impact of appearance concerns. These powerful normative influences, which are much less often considered in relation to screening behaviors such as mammography (but see Montano & Taplin, 1991), highlight the unique forces, in addition to perceived vulnerability, that influence particular cancer-specific behaviors.

INTERVENTIONS TO INCREASE SCREENING

This section addresses interventions to increase cancer screening, and, more specifically, attempts to link manipulations of perceived susceptibility to increased screening. Experimental interventions provide the vehicle for untangling the causal impact of putative determinants such as perceived vulnerability on cancer protective behavior. The use of mediational analysis to assess the extent of direct and indirect impact of manipulations of perceived susceptibility on screening outcomes is also highlighted. Comprehensive summaries of interventions to increase cancer screening have been provided by Rimer (1994) for mammography screening and by Snell and Buck (1996) for breast, cervical, and colorectal cancer.

From the perspective of health psychology, theory-based interventions that employ models such as the HBM to design program components are most of interest, because they permit the linking of changes in constructs in the model (e.g., perceived susceptibility) to changes in screening behaviors. A number of mammography screening interventions have included components designed to increase perceived vulnerability to breast cancer (Aiken, West, Woodward, Reno, & Reynolds, 1994; Champion, 1994; Curry, Taplin, Anderman, Barlow, & McBride, 1993; Rimer et al., 1992; Skinner, Strecher, & Hospers, 1994; Zapka et al., 1993). In some studies, the perceived susceptibility component was only one small part of a large complex intervention, and no attempt was made to establish a direct linkage from this component to behavioral outcomes (Champion, 1994; Rimer et al., 1992; Zapka et al., 1993). In contrast, Curry et al. (1993) showed that providing tailored personal objective risk information to FDRs of breast cancer victims increased screening; Skinner et al. (1994) showed a similar impact of tailored messages in a community sample.

Mediational Analysis of Intervention Impacts

Aiken, West, Woodward, Reno, and Reynolds (1994) implemented an HBM-based mammography intervention, with individual program components that targeted each of the four HBM constructs: perceived susceptibility, severity, benefits, and barriers. *Mediational analysis*, a statistical procedure that establishes linkages among chains of variables, was used to test the linkages from an intervention through intermediate *mediators* (the HBM components) to mammography compliance (West & Aiken, 1997). This mediational analysis is presented here because of our strong conviction (West & Aiken, 1997) that mediational analysis provides important insights into the way in which theoretical constructs influence behavior. To date, mediational analysis has been used productively in both mental health and substance abuse research, as well as in several areas of basic psychological research.

Requirements for Mediational Analysis. In order to test the theory of an intervention through mediational analysis, the following are required: a specified theoretical model

on which the program will be built, a measurement instrument that provides distinct measures of each construct in the model that will serve as a mediator, a translation of each construct of the model into a distinct component of the intervention, assessment of postintervention levels on each of the constructs targeted in the model in an experimental versus control group (with adequate statistical control of pretest levels), and measurement of the outcome. West and Aiken (1997) summarized the conditions that must be met in order to demonstrate that a putative mediator (here, perceived susceptibility) produced change in the outcome (here, mammography screening), as specified by Judd and Kenny (1981), Baron and Kenny (1986), and MacKinnon (1994).

The Mediational Role of Susceptibility in Intervention

In the intervention, the HBM was amended by assessing intentions for screening at immediate posttest as well as actual compliance 3 months following the intervention. Mediational paths were established from perceived susceptibility and perceived benefits to intentions, as was a strong link from intentions to subsequent screening. The role of perceived susceptibility in the causal chain from intervention through compliance is of interest here. The model of the impact of HBM constructs on outcomes is illustrated in Fig. 44.1. It differs from typical characterizations of the HBM in that the four HBM constructs are not treated as coequal predictors of outcome. Rather, following Ronis (1992), a model was specified in which perceived susceptibility and perceived severity were antecedents of perceived benefits, under the assumption that a woman would not perceive the benefits of mammography screening unless she felt threatened (perceived susceptibility plus severity) by breast cancer. Again following Ronis (1992), it was specified that the effect of perceived susceptibility on outcome would be mediated through perceived benefits, that is, that the effect of susceptibility would be an *indirect effect* through benefits, in the following causal sequence:

Intervention → Susceptibility → Benefits → Intentions.

This mediational chain was confirmed. In addition, a *direct path* from susceptibility to intentions was confirmed, that is,

Intervention → Susceptibility → Intentions.

The size of the indirect effect of susceptibility, over and above the direct effect, was substantial.

The full details of the mediational analysis, including explorations of possible roles for perceived susceptibility, are provided in West and Aiken (1997). What is critical here is a conception of perceived susceptibility at the outset of a causal chain that flows through other constructs. Examining only the direct effects of susceptibility on intentions or behavior may obscure the role of perceived susceptibility in the behavioral compliance process, potentially leading to underestimates of the total effect of perceived susceptibility on behavior.

Some research on screening and preventive behavior omits considerations of perceived susceptibility and examines variables that are conceptually downstream of perceived suscepti-

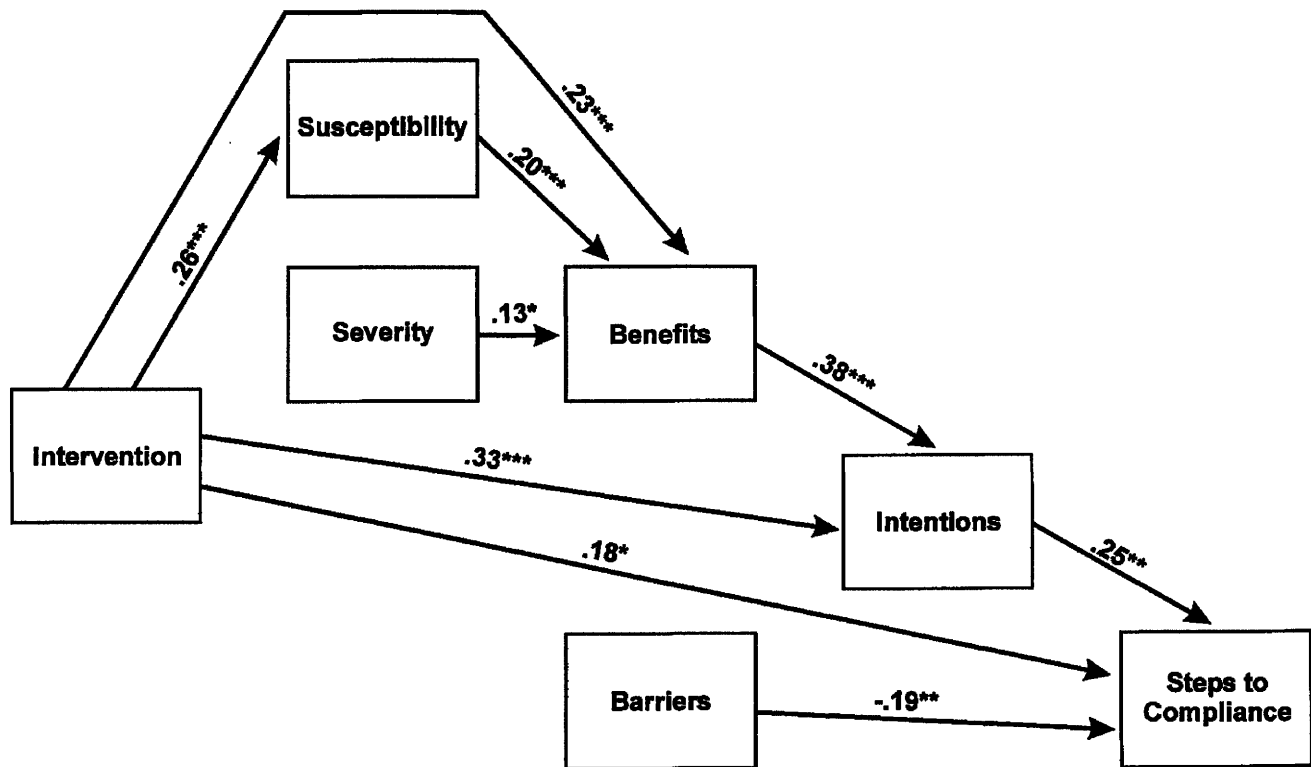

FIG. 44.1. Mediation analysis of the impact of a health belief model (HBM) based intervention on compliance with mammography screening recommendations. The indirect mediational path from intervention to perceived susceptibility through perceived benefits to intentions for screening illustrates how perceived susceptibility serves as an apparent precursor to benefits in the HBM. For paths, * $p < .05$, ** $p < .01$, *** $p < .001$. From "Increasing Screening Mammography in Asymptomatic Women: Evaluation of a Second-Generation, Theory-Based Program" by L. S. Aiken, S. G. West, C. K. Woodward, R. R. Reno, and K. D. Reynolds, 1994, *Health Psychology*, 13, p. 534. Copyright © 1994 by the American Psychological Association. Reprinted with permission.

bility in the causal chain from perceived susceptibility to behavior. For example, Rakowski (Rakowski et al., 1992, 1997; Rakowski, Fulton, & Feldman, 1993) focused on the impact of *decisional balance*, or the balance between perceived pros and cons of mammography on screening uptake. Such a focus on downstream variables (here analogous to benefits of and barriers to screening) does not diminish the role of perceived susceptibility earlier in the causal process.

ISSUES IN CHARACTERIZING THE ROLE OF PERCEIVED VULNERABILITY IN CANCER-RELATED BEHAVIOR

A number of issues have arisen in the course of this consideration of the impact of perceived vulnerability on cancer protective behavior. These have included the impact of perceived vulnerability versus cancer fear, worry, and distress on screening behavior; the existence of an inverted U-shaped relation between cancer distress and protective behavior; the difference in determinants of medically based versus self-im-

plemented screening; and the place of perceived vulnerability in mediational chains of putative determinants of cancer-related behavior.

To these issues the following are added: the level of numeracy in the lay public, defined as "facility with basic probability and numerical concepts" (L. M. Schwartz et al., 1997), and the ability of lay individuals to understand and produce risk estimates; public understanding of screening tests and the impact of confusion between early detection and prevention; the difference in relation of perceived vulnerability to screening versus preventive health action over time; the impact of the complementary relation among screening behaviors (e.g., BSE versus mammography) on the observed link between vulnerability and screening; the role of conditional versus unconditional threat in accounting for cancer-related behavior; the impact of message framing on the link from risk to behavior; the existence of moderators of the relation of perceived vulnerability to cancer related behavior, including demographics, level of risk, personality, and barriers to behavior; and the need for experimental intervention as well as

psychosocial research, coupled with mediational analysis, to understand the role of individual constructs in cancer protective behavior.

Numeracy

One critical issue that has only very recently been broached in the context of cancer screening is the *numeracy* of the lay public, a parallel in the quantitative domain to literacy. Although individuals' numerical estimates of perceived risk for cancer are interpreted as meaningfully reflecting perceived vulnerability, the competency of the lay public in understanding and using probability estimates or rates has not been considered. More numerate women exhibit smaller overestimates of the probability of developing and dying of breast cancer, as well as of the absolute mortality risk reduction attributable to mammography (Black et al., 1995), and are better able to apprehend information about mortality reduction attributable to mammography (L. M. Schwartz et al., 1997). Consideration of numeracy is critical in risk-related research (Fischhoff et al., 1993), as well as in medical settings, where individuals are asked to make their own medical decisions with regard to screening and treatment based on probability and rate information (L.M. Schwartz et al., 1997).

Humans as Intuitive Statisticians. Over three decades ago, a literature developed in applications of Bayesian decision theory in psychology (Edwards, Lindman, & Savage, 1963), which examined the ways in which individuals estimate the probability of events and revise their probability estimates based on new information. Two principles emerged that may help to explain biases in the lay public's understanding of risk for cancer. First, people appeared to overestimate low probabilities and underestimate high probabilities (Mueller & Edmonds, 1967; see also Lichtenstein, Slovic, Fischhoff, Layman, & Combs, 1978). This may partially explain the overestimates of rates of specific cancers, which are low percentage wise, on a cancer by cancer basis (American Cancer Society, 1998). Second, people are conservative in revising their estimates of probabilities in the face of new information (Phillips & Edwards, 1966), which may partially account for failures of training to eradicate biases in perceived risk.

Public Understanding of Screening Tests, and Detection Versus Prevention

The public historically has exhibited a lack of understanding of screening tests for asymptomatic individuals. Both Rimer, Keintz, Kessler, Engstrom, and Rosan (1989) and Zapka, Stoddard, M. D. Costanza, and Greene (1989) reported that women believed mammograms were unnecessary in the absence of breast symptoms (see review by Vernon, Laville, & Jackson, 1990). Recall that in the original HBM formulation, perceived vulnerability in the absence of symptoms was seen as requisite for health behavior (Rosenstock, 1990). Public belief that screening tests are unnecessary for asymptomatic individuals persists (Cockburn, Redman, Hill, & Henry, 1995).

Aiken et al. (1995) and Barnard and Nicholson (1997) also found confusion between screening for cancer detection versus cancer prevention. Cancer detection aims at finding existing cancers in an early, treatable state, whereas prevention aims to avoid cancer development. Women, failing to distinguish early detection from prevention, mistakenly attributed their lower perceived personal risk for contracting breast cancer to the fact that they receive regular mammograms. From an intervention perspective, correcting this misconception ironically may result in decreased screening rates. Even with these misconceptions, there is apparently understanding of and acceptance of the fact that screening tests may result in both false negative and false positive outcomes (Aiken et al., 1998; Cockburn et al., 1995).

Temporal Factors in the Perceived Risk–Behavior Linkage

For both prevention and detection, the cross-sectional relation of perceived risk to behavior changes in complex ways as health innovations diffuse over time (Weinstein & Nicolich, 1993). When a health protective behavior is first introduced, those who perceive themselves at the highest risk for the health threat may self-select the behavior, occasioning a strong positive correlation between perceived risk and behavior. If the behavior is screening, then perceived vulnerability to the occurrence of the disease should not diminish as the behavior is adopted, because screening is not, of course, preventive. In fact, perceived severity may diminish if people come to believe in the benefits of early detection for cancer survival. However, as a screening innovation is adopted broadly by the medical profession and increasing numbers of individuals are screened, the pool of screened individuals will contain individuals at lower perceived risk, thus diluting the correlation of perceived risk and screening. For preventive behavior, the initial self-selection of high risk individuals may again result in substantial positive correlations between perceived risk and behavior. However, should the disease risk be mitigated or substantially lessened by the preventive behavior, then, in time, a negative correlation may be observed between perceived risk and behavior—those who reliably engage in the behavior may correctly perceive themselves to be at lower risk. (See Aiken et al., 1995, for a consideration of temporal factors in perceived and objective risk as related to mammography screening, and Gerrard et al., 1996, for a critical discussion of these relations in the HIV/AIDS context.)

Complementary Screening Tests

Multiple screening tests for the same cancer (e.g., BSE and mammography) may be considered by some individuals to be complementary (i.e., a woman might opt for regular BSE and forego mammography). If so, this would weaken the relation of psychosocial variables to each behavior taken separately. BSE frequency and mammography compliance appear to be uncorrelated (Aiken et al., 1995). Perceived vulnerability might better predict a breast screening index crediting either mammography or BSE, but this possibility has not been explored empirically. Similar arguments can be made for FOBT, sigmoidoscopy, and DRE for colorectal cancer, and PSA and DRE for prostate screening.

Conditional Health Threat

Perceptions of susceptibility to cancer or its severity are in part governed by beliefs about personal actions that mitigate or increase cancer risk. Ronis (1992) characterized *conditional health threat* as the perception of threat under some behavior specification, that is, if the individual were to take a specific protective health action versus to take no health action (see also Rogers, 1983). Ronis (1992) and van der Pligt (1998) argued that the measurement of conditional health threat would provide better understanding of protective health behavior because such conditional measures untangle the influence of current protective behavior on perceived vulnerability. Weinstein and Nicolich (1993) theorized that the discrepancy in level of perceived risk associated with participation versus nonparticipation in a health protective behavior reflected perceived effectiveness of the health precaution.

It is proposed that the components of conditional health threat—that is, conditional susceptibility versus conditional severity—will have differential associations with preventive versus screening behavior. For preventive behavior, high perceived susceptibility given inaction coupled with high perceived benefits of the health action is expected to produce preventive behavior, with a subsequent reduction in perceived susceptibility. For screening, the matter is different because susceptibility is not reduced by screening; rather, the argument for screening is that consequences (severity) of cancer will be reduced with early detection, so that the appropriate conditional characterizations of perceived severity are “severity if treated early” versus “severity if treated late” (Ronis & Harel, 1989). Ronis and Harel (1989) applied this dual conception of perceived severity to BSE performance and showed a link of these severity measures, but not conditional susceptibility, to BSE, yielding new insight into the potential role of perceived severity in screening. Jackson (1997) applied conditional perceived susceptibility and severity to skin cancer preventive behaviors and found the opposite effect—that conditional measures of perceived susceptibility, but not severity, predicted skin protection. Measures of conditional threat may provide help to clarify the links of perceived susceptibility and severity to cancer protective behaviors.

Message Framing, the Understanding of Risk, and Health Protective Behavior

The impact of perceptions of risk on decisions concerning health behavior is strongly affected by the manner in which risks are framed. As specified in prospect theory (Kahneman & Tversky, 1979), individuals respond differently to information presented as gains (e.g., the number of breast cancer deaths averted by regular mammography screening) versus as losses (e.g., the number of breast cancer deaths associated with failures to be screened). Thus considerations of perceived risk in relation to cancer-related behavior must take into account message framing as a moderator of the perceived risk–behavior link. Rothman and Salovey (1997) provided an extensive review of the impact of message framing on health behavior. Meyerowitz and Chaiken (1987), Rothman,

Salovey, Antone, Keough, and Martin (1993), and Banks et al. (1995) provided examples of the impact of message framing on BSE, skin protection, and mammography utilization, respectively.

Moderators of the Role of Perceived Susceptibility

Variables like demographics, personality, and barriers to health action may moderate (change) the relation of perceived vulnerability to protective health behavior. High perceived barriers nullified the effect of susceptibility on mammography compliance (Aiken, West, Woodward, & Reno, 1994). Conscientiousness as a personality trait moderated the relation of cancer distress to mammography screening among FDRs of breast cancer victims (Schwartz, Taylor, et al., 1999). Moderation of the perceived susceptibility–behavior link by demographic, medical system, personality, and other psychosocial variables should be explored.

Mediational Chains and Experimental Intervention Research

Our conception of perceived susceptibility is that it stands at the outset of a causal chain that flows through other constructs to health behavior. Consideration of mediational chains from perceived susceptibility through other variables to behavior is critical for advancing an understanding of the way health behaviors accrue. To reiterate, examination of both the direct effect and the indirect effects of susceptibility through other variables on behavior is required to estimate accurately the total effect of perceived susceptibility on health protective behavior.

The understanding of whether, how, and to what extent individual variables such as perceived susceptibility operate in determining health protective behavior is best advanced through the evaluation of model-based interventions, with research structured so that mediational analysis of the effects of putative determinants of behavior can be accomplished (West & Aiken, 1997). A distinguishing feature of psychology as a discipline is the strength in theory and experimentation. Thus, health psychologists may entertain a special role in health behavior research, providing careful theory testing in controlled settings, and the refinement of models of health behavior on a strong empirical base.

Stress and Breast Cancer

Douglas L. Delahanty

Andrew Baum
University of Pittsburgh Cancer Institute

A major theme in research on health and behavior has been the impact of stress on the pathophysiology of disease and development of systemic dysfunction. Stress appears to be a major factor in the etiology of cardiovascular disease, AIDS, and several other chronic and/or life threatening illnesses. For disease states produced by years of slowly developing pathogenic conditions, this means identifying stressors and processes experienced over very long periods of time. This daunting task has made conclusions about stress and disease in humans tentative, and this literature requires cautious reading and interpretation. Nevertheless, research has produced suggestive evidence of the role of stress in a wide array of disease processes, including cancer. A growing area of investigation concerns stress as an etiological factor in breast cancer.

Each year, more than 184,000 American women are diagnosed with breast cancer, and 45,000 die from the disease (Parker, Tong, Bolden, & Wingo, 1996). Breast cancer is the most common cancer among women and is second only to lung cancer in mortality rates (Henderson, 1995). As with many cancers, until recently, relatively little was known about its etiology and progression. Researchers now know that some breast cancer is attributable to heritable genetic polymorphisms, some appears to be associated with lifetime estrogen exposure, and some to other major known risk factors (e.g., weight, age). There is also considerable variability of disease course among patients (Henderson, 1995) and the reasons for this variability are not well understood. Researchers have increasingly turned to psychological or behavioral variables to explain cases in which response to treatment and/or treatment outcomes vary (Andersen, 1994; Fox, 1983; Jensen, 1991).

Studies of the effects of stress on the development and promotion of breast cancer have produced variable results, with some researchers noting an association between stress and cancer outcomes (C. L. Cooper, R. Cooper, & Faragher, 1989; Funch & Marshall, 1983; Ramirez et al., 1989). Other investigations have not found associations between stress and disease outcomes (Cassileth, Lusk, D. S. Miller, Brown, & C. Miller, 1985; Greer & Morris, 1975; T. J. Priestman, S. G. Priestman, & Bradshaw, 1985). This chapter reviews the findings and limitations of studies examining the link between stress and breast cancer, concentrating on the extent to which stress and psychological factors contribute to the etiology and progression of breast cancer in women. Mechanisms through which stress may influence breast cancer are also discussed. This discussion does not review the larger literatures on stress and coping; these issues have been discussed elsewhere in this volume (see chap. 17).

THE EFFECTS OF STRESS ON BREAST CANCER

The term *cancer* refers to a heterogeneous group of more than 100 specific types of cancer that are characterized by dysregulated and rapid cell growth and the potential for invasive or metastatic growth. Types of cancer vary considerably with regard to risk factors, etiology, disease course, and treatment. Depending on the site of the original tumor, its size, or whether it has metastasized, different cancers follow different courses and some appear to be related to stress. Some cancers are extremely aggressive, follow a very predictable disease

course, and appear to progress inexorably as a function of biological factors (Levy & Wise, 1987). Others, including breast cancer, follow more variable disease courses, appear to be less exclusively affected by tumor biology, and appear to be affected by other factors. Investigators and clinicians have argued that the unexplained variance in the course of breast cancer may be due to psychosocial factors, and the impact of factors like stress on disease course has been examined at virtually every stage of breast cancer. The popular press has focused primarily on studies finding positive relations between psychosocial variables and breast cancer, and many popular books and magazine articles have instructed cancer patients that they can overcome cancer with their thoughts or by reducing distress (LeShan, 1977; Siegel, 1986). Methodological limitations alone suggest caution in interpreting such bold claims, and consequences of such lessons are also evident. If cancer patients believe they caused their cancer themselves or that they can prevent it from progressing, they may blame themselves, becoming depressed and less responsive to treatment and exacerbating their disease (Sapolsky, 1994). Scientific evidence of a direct link between psychological factors and cancer onset and progression lags far behind these popular assertions (Fox, 1983; Levenson & Bemis, 1991).

Available data are drawn from several sources, most notably animal studies of experimentally applied stress on tumor growth or rejection and from correlational studies of human cancer patients and naturalistic stressors. As might be expected, evidence of an association between stress and cancer is more dramatic in animal studies than in human investigations.

Animal Research

Animal models allow for highly controlled studies under laboratory conditions and have provided important information about the relations between stress and cancer (e.g., Justice, 1985; Riley, Fitzmaurice, & Spackman, 1981; Sklar & Anisman, 1980). Interestingly, this research has produced findings suggesting both exacerbation and inhibition of tumor growth and metastasis as a function of stress (Ben-Eliyahu, Yirmiya, Liebeskind, Taylor, & Gale, 1991; Newberry, Frankie, Beatty, Maloney, & Gilchrist, 1972). This highlights the complex nature of the stress-cancer relation, and has led to the examination of differences in methodology among studies to explain the different findings. Several factors appear to determine outcomes in these studies, most notably the timing of tumor initiation and the organism being studied.

Type of Cancer and Timing of Tumor Induction.

In animals, viral tumors and mammary tumor viruses appear to be more responsive to stress than nonviral, chemically induced tumors such as chemically induced mammary tumors (Justice, 1985). The reverse appears to be true in humans; nonviral tumors have been more affected by stress, whereas viral tumors tend to follow a fairly nonmodifiable course (Levy & Wise, 1987). In animals, viral tumors also appear to be more immunoresponsive than nonviral tumors, and the stress-induced enhancement of these tumors might be due to stress-induced immunomodulation (Justice, 1985).

The timing of tumor induction and stress exposure appears to be very important in interpreting these studies (Justice, 1985; Riley, 1981). Stress applied after introduction of tumors appears to decrease immune defenses and enhance tumor growth, but stress experienced before induction has the opposite effect. Forced swimming decreased NK activity against mammary tumors in Fischer 344 rats in an in vitro assay and led to significantly more lung metastases in stressed animals (Ben-eliyahu et al., 1991). In another study, rotation stress administered 4 to 6 days after tumor implantation resulted in immunosuppression and rapid tumor growth, and was associated with higher mortality than when stress was administered 3 days before implantation (Riley, 1981). Administering stress before implantation resulted in immunoenhancement and suppression of tumor growth.

This finding can be explained if the importance of adaptation and rebound of bodily systems following resolution or termination of a stressor is considered. For example, Monjan and Collector (1977) found that stress-induced immunosuppression is often followed by a rebound increase in number or efficacy of cells after the stressor has been terminated or adaptation is achieved. This would result in a transient increase in immune function prior to settling back to "baseline" levels. For animals who were stressed after implantation, tumor growth may have been enhanced by suppression of host defenses by stress experienced while tumors were growing. For animals who experienced stress first, tumors may have been implanted into a rebounding, enhanced host defense.

Species, Strain, and Previous Experience. Findings in the animal literature also differ across species and across different strains of the same species (Sklar & Anisman, 1980). For example, stress differentially affects neurochemical and hormonal levels in different strains of mice and rats, and this can have opposite effects on disease progression (Ray & Barrett, 1975; Wahlsten, 1978). In addition, social conditions (housing) and previous stress history have been shown to play a role in determining the effects of stress on cancer progression (Sklar & Anisman, 1980). Group-housed mice have smaller stress-induced catecholamine changes than do mice raised in isolation (Blanc et al., 1980; B. L. Welch & A. S. Welch, 1970), and mice raised in isolation develop mammary tumors earlier than do group-reared mice (Henry, Stephens, & Watson, 1975).

Prior stress exposure can also affect subsequent stressful experiences. Anisman and Sklar (1979) exposed mice to a set of 60 shocks that resulted in a depletion of hypothalamic norepinephrine (NE; Anisman & Sklar, 1979). Subsequent exposure to 10 shocks resulted in no NE depletion in mice not previously exposed to shock, but a large depletion in those that were previously exposed, suggesting that previous stress exposure may sensitize an animal to subsequent stressful experiences. Early life stress experience has also been found to affect later ability to resist tumor development (Seligman & Visintainer, 1985). At 27 days old, rats were exposed to either escapable shock, inescapable shock, or no shock. The escapable and inescapable shock groups were yoked so that the ani-

imals received the same amount of shock. When the rats were 90 days old, they were injected with sarcoma tumor cells and were reassigned to the three conditions in such a way that nine groups of every combination of early and later stress experience were formed. Results indicated that early escapable shock experience was associated with better tumor rejection in both adult shock conditions. Exposure to early inescapable shock was associated with poorer rejection of tumors in both the escapable and inescapable adult conditions. These studies suggest, despite equivocal data, that stress affects the growth of tumors. They also highlight the importance of control and adaptation as determinants of stress and cancer progression. Further, this research suggests the possibility of sensitization of stress-related responses and raises questions about the conditions necessary for more protective habituation of responses to occur. In addition, animal research has clearly identified the immune system as a potential mechanism underlying stress-related cancer progression (Sikora & James, 1991).

Animal research has been useful in many ways, permitting accelerated views of cancer etiology, experimental manipulation of tumor induction, and facilitating identification of potential mechanisms of stress-related influences on cancer etiology. However, findings in the animal literature often apply to only one strain of animal, and generalization of these findings to a more heterogeneous population may be inappropriate (Redd & Jacobsen, 1988). In addition, the level of carcinogen to which the animals are exposed, or the dose with which they are injected, is typically much higher than humans would experience (Redd & Jacobsen, 1988). As noted, viral tumors appear more sensitive to psychological factors in animals, but human cancers that are the most modifiable by psychological influences are more often nonviral (Levy & Wise, 1987). Finally, it may be unwarranted to assume that using injected or induced tumors parallels "spontaneous" breast cancer in humans (Levy, 1985). However, the animal literature suggests there is a link between stress and tumor growth/rejection, and that psychological variables can affect disease course. The next section examines the relation between stress and cancer in humans.

Stress and Breast Cancer in Humans

The broad physiological, behavioral, cognitive, and emotional changes associated with stress could affect breast cancer at several different levels. First, stress may have direct effects on immune defenses and on the tumor itself that may enhance tumor growth or metastases. Stress can also increase drug, alcohol, or tobacco use, result in poorer diets, poorer sleep, and less exercise, and inhibit screening, prevention, and early detection. These behaviors may have further effects on immunity (Friedman, Klein, & Specter, 1991; Grunberg & Baum, 1985; Irwin, Smith, & Gillin, 1992; MacGregor, 1986). Stress may also decrease the likelihood of a woman engaging in breast self-examination or having regular mammograms, which may lead to a delay in seeking treatment and a worse prognosis if subsequent diagnosis is first made at a later stage of disease. Lerman and colleagues (1993) found that people who are experiencing stress are less likely to adhere to

their doctor's suggestions, prescriptions, or orders. However, evidence linking stress directly to the onset of cancer is weak and methodological problems suggest caution when interpreting the findings of studies examining the effects of stress on breast cancer onset.

Retrospective studies of stress and the onset of breast cancer have also produced variable results, with some studies reporting that stress is associated with initial appearance of disease (Becker, 1979; Forsen, 1991), some finding that stress protects against cancer onset (T. J. Priestman et al., 1985), and some finding no relation between stress and cancer diagnosis (Schonfield, 1975; Snell & Graham, 1971). Obvious mismatches between the time frame inherent in cancer development and the periods that can be monitored for stress are responsible for some of these mixed results, particularly in retrospective studies. There are limits to accurate recall of stress or stressors and most studies limit measurement to periods within a few years of diagnosis. Other studies have examined women during their postoperative disease-free interval following surgery for breast cancer (Barracough et al., 1992; Ramirez et al., 1989) and have also produced mixed results. Although these studies evaluate stress effects on disease progression, they are relevant because they examine recurrence following a disease-free interval. Ramirez et al. (1989) found that severely threatening life events and difficulties were significantly associated with the first recurrence of breast cancer (relative risk = 5.67). However, in a similar study, the opposite was found (Barracough et al., 1992). After adjusting for age and axillary lymph node involvement, the relative risk of recurrence associated with severe life events during the year before surgery was .43, suggesting that psychosocial stress did not contribute to the relapse of breast cancer.

Retrospective studies of stressful life events and breast cancer development have been criticized for a number of reasons. C. L. Cooper, R. D. Cooper, and Faragher (1986a) discussed several limitations of these studies, including the small numbers of participants and lack of or improper control groups that are often found in these studies. Other than limits on recall, however, the most serious limitation of these studies is the fact that the participants knew their diagnosis prior to participating in the research. Knowledge of disease status could influence the way patients recall past stressful experiences. Those individuals experiencing stress because they have just been diagnosed with a life threatening disease may be more likely to report or recall life stress prior to diagnosis than women not experiencing the stress of diagnosis.

To correct for influences due to patients knowing their diagnoses prior to participation in studies, investigators have used limited prospective designs in which participants were interviewed prior to learning their diagnoses. These studies revealed that, although the number of stressful life events reported was comparable among patients diagnosed with breast cancer and those with benign lesions or healthy breasts, perceived severity of stressful events differed among the groups (C. L. Cooper, R.F.D. Cooper, & Faragher, 1986b, 1989; C. L. Cooper & Faragher, 1993; Edwards et al., 1990; Geyer, 1993; Muslin, Gyrfas, & Pieper, 1969). In general, more severe events were reported by women subsequently diagnosed

with breast cancer than by women in control groups (C. L. Cooper et al., 1986b, 1989). Coping may be important in this observed association. A higher proportion of women diagnosed with breast cancer reported suppressing emotions (especially anger) than those with benign disease (Greer & Morris, 1975; Wirsching, Stierlin, Hoffmann, Weber, & Wirsching, 1982). Some of these studies have not found such effects (e.g., Schonfield, 1975). However, eliminating retrospective recall after diagnosis appears to have produced stronger evidence of a stress-cancer link.

Although results of life events research in breast cancer onset are sometimes inconsistent, many studies have reported positive relations between stressful experiences and subsequent breast cancer diagnosis. However, these studies must be interpreted cautiously, even when retrospective biases have been avoided. Brown (1981) argued that respondent-based measures of recent life events are largely inaccurate and subject to bias, and investigator-based interviews should be used in life event research. Perhaps more damaging to the previous findings are timing issues involved in the onset of breast cancer. Breast cancer is a relatively slow developing disease (Henderson, 1995). From the time cancerous cells appear, it may take 10 years before a tumor is detectable. Recent life event studies typically ask about life events occurring between 2 and 5 years preceding diagnosis. This suggests that researchers are not measuring stressful events that occur prior to cancer onset, but instead are measuring events that occur prior to diagnosis that may be associated with the progression of disease (i.e., the speed and extent of tumor growth). These problems have led many investigators to conclude there is no demonstrable relation between stress and the onset of breast cancer (Hilakivi-Clarke, Rowland, Clarke, & Lippman, 1993; A. B. Jensen, 1991; Levenson & Bemis, 1991).

Stress and Breast Cancer Progression

Although the evidence for a relation between stressful experiences and onset of breast cancer is weak, research examining the effects of stress on the progression of breast cancer is more promising. In part this is because of the uncertainty about the events causing and characterizing initial development of tumors. Initiation of disease is characterized by a series of mutagenic events in which cell mechanics are altered and restraints against uncontrolled growth are eliminated. Progression, on the other hand, refers to the development and course of the disease. Research on the onset of breast cancer suffers from the difficulty of not knowing exactly when onset occurs, and promotion and development of disease before discovery are similarly diffuse. However, consideration of progression of disease after detection and diagnosis bears the benefit of a clearer time frame. The stage of breast cancer can be determined at diagnosis and progression is readily measured. Abundant anecdotal evidence suggests that psychological factors can impact breast cancer progression. For instance, two patients can present with identical tumor types, identical stage at diagnosis, and identical treatment histories and still have vastly different disease outcomes. It is thought that some of this variance in outcome may be due to psychosocial factors such as stress.

Stressors Experienced by Breast Cancer Patients.

There are many stressors that face women diagnosed with breast cancer, including the fear of possible death, the stress of informing family members, and the stress associated with being informed that their life is going to drastically change. Disruption, social stigmatization, side effects of treatment, and other stressors more specific to the disease and treatment are also pertinent. These stressors occur in the context of a disrupted family and other ongoing sources of stress. The majority of studies that are discussed here examine responses to the stress of screening and diagnosis. However, treatment can also be extremely stressful. The initial choice between a full mastectomy versus breast conservation surgery can be a difficult decision, and women choosing breast conservation surgery have been found to have more short-term psychological symptoms than those choosing a mastectomy (Levy et al., 1992). Anticipation of surgery as well as surgery itself can be extremely stressful, and it has been shown to decrease NK cell activity for as long as 24 hours postsurgery, just when physicians would want NK activity to be at its highest (Massie & Holland, 1991; Pollock, Lotzova, & Stanford, 1991). Further, the toxic side effects of chemotherapy can be so aversive that some patients believe they are worse than the cancer itself. An extensive literature has examined the effects of these diagnostic and treatment stressors on breast cancer progression, and has implicated a number of factors as moderators of the relation between stress and cancer progression.

Moderators of Stress and Breast Cancer Progression.

In addition to being the primary risk factor for breast cancer, age has also been examined as a potential moderator of the relation between stress and cancer progression. Younger and older women may respond differently to a diagnosis of breast cancer. Younger patients perceive breast cancer to be a greater threat to their lives than older patients, and younger patients are rated as being in marginally poorer mental health following diagnosis (Funch & Marshall, 1983; Vinokur, Threatt, Vinokur-Kaplan, & Satariano, 1990). In addition, an interaction between disease severity and age has been found, indicating that younger patients with later stage disease experienced more deterioration of mental health and well-being in the first year postdiagnosis than did similarly impaired older women (Vinokur et al., 1990). Although older age was associated with use of more medications and greater limitation in activity, it was also associated with better mental health and well-being (Vinokur, Threatt, Caplan, & Zimmerman, 1989). Age also interacted with severity of disease such that younger patients with more severe disease had significantly greater difficulty adjusting to their illness than equally ill older women.

Personality and coping style also appear to moderate the relation between stress and cancer. The Type C personality has been proposed to describe a set of personality characteristics commonly seen in individuals diagnosed with malignant melanoma (Temoshok & Fox, 1984). Subsequently, Type C or the cancer prone personality was extended to refer to behaviors and characteristics common to victims of all cancers (Temoshok, 1987). Type C individuals express the opposite personality style of Type A individuals studied in research on

cardiovascular disease (e.g., Glass, 1977). Type C individuals are cooperative, unassertive, patient, compliant, and likely to suppress their emotions. Although Type C individuals make very good patients, these characteristics have been consistently linked to poorer outcome in breast cancer patients (M. R. Jensen, 1987; Temoshok, 1987).

M. R. Jensen (1987) examined 52 women with a history of breast cancer and 34 healthy controls to determine what percentage of the variance in cancer progression could be accounted for by psychological variables. All patients were aware of their diagnoses when they filled out a variety of questionnaires designed to measure coping and personality variables, and rate of neoplastic growth and spread over an average of 2 years was examined. After controlling for disease stage at diagnosis, age, total length of disease course, and blood chemistry, neoplastic spread was found to be positively associated with a repressive personality style, suppression of emotion, helplessness-hopelessness, chronic stress, and comforting daydreaming. These psychological variables alone accounted for 44% of the variance in outcomes (higher levels were associated with greater neoplastic spread), whereas medical variables alone accounted for only 23% of the variance in disease progression.

Hostility appears to affect progression of breast cancer by itself, although results are mixed as to the direction of the relation. Two studies have found that patients who report lower levels of hostility have shorter survival times than those who report higher levels of hostility (Derogatis, Abelloff, & Melisaratos, 1979; Stavrayk et al., 1968). Short-term survivors reported higher levels of positive mood, and treating oncologists perceived short-term survivors as being better adjusted to their illnesses. On the other hand, long-term survivors reported higher levels of hostility, as well as higher anxiety, alienation, dysphoric mood, and overall symptomatology, suggesting again that individuals who did not suppress emotions had longer overall and disease-free survival times. Long-term survivors also reported significantly more negative attitudes toward their physicians, again suggesting that "good" patients (i.e., more compliant, quiet, noncomplaining patients) may have faster cancer progression (Derogatis et al., 1979). In contrast, a study of 133 recently diagnosed breast cancer patients found that low anger was a significant predictor of survival 4 years later (Hislop, Waxler, Coldman, Elwood, & Kan, 1987), and Stanton and Snider (1993) found that cancer and benign diagnosis patients did not differ in mood, coping, or appraisal.

Optimism has been examined as an intervening variable in stress-cancer research as well. Having an optimistic outlook has been associated with less distress (Carver et al., 1993). Researchers met with patients 1 day before surgery, 10 days after surgery, and at 3-, 6-, and 12-month follow-ups. Optimistic outlook was inversely related to distress at each time point. In addition, use of acceptance (accepting the reality of the situation) before surgery predicted less postsurgical distress. The use of humor at the 3-month follow-up also predicted less distress at the 6-month follow-up, and denial and disengagement 3 months after surgery predicted higher levels of distress at the 6-month follow-up. However, no indices of disease state or

progression were measured, so the effects of coping style on progression of breast cancer were not observed. Extrapolating from studies examining personality variables and progression, it might be predicted that optimism and humor would be associated with less distress and poorer prognosis.

In a series of studies, Greer, Morris, and Pettingale prospectively followed early stage breast cancer patients and measured outcomes in 5-year intervals. Five-year recurrence-free survival was significantly more common in patients who had responded to their diagnoses with denial and a "fighting spirit" versus those who responded with stoic acceptance or feelings of helplessness/hopelessness (Greer, Morris, & Pettingale, 1979). Denial, in this study, referred to a pattern of response in which patients rejected or minimized any evidence of their disease and the seriousness of their disease. Fighting spirit, on the other hand, referred to those who planned to do everything possible to conquer or beat their cancer. Therefore, fighting spirit is similar to the more active, hostile responses reported as leading to better prognoses in the previously mentioned studies. Ten and 15-year follow-up revealed that initial psychological response to diagnosis continued to predict outcome as long as 15 years postdiagnosis (Greer, Morris, Pettingale, & Haybittle, 1990; Pettingale, Morris, Greer, & Haybittle, 1985). It is important to note that this study has been criticized for not controlling for stage of disease, and the results should be interpreted with caution. However, analyses that controlled for this revealed that psychological responses to diagnosis were not related to clinical stage (Greer, 1991).

In a replication of these studies, Dean and Surtees (1989) found that after controlling for age, tumor size, histological node status, treatment, marital status, and menopausal status, women who responded with this kind of denial were significantly more likely to be recurrence-free at follow-up relative to those employing other coping strategies. However, there were no differences in outcome between those responding with a fighting spirit and those responding with stoic acceptance or helplessness-hopelessness. In addition, women who were diagnosed with a psychiatric illness prior to surgery were significantly less likely to have a recurrence at follow-up. This finding is similar to those of Derogatis et al. (1979) and Jensen (1987), who found that women reporting more anxiety and negative mood had a better prognosis.

Not all studies examining personality variables have found a relation between personal predispositions and breast cancer progression (Buddeberg et al., 1991; Cassileth et al., 1985; Jamison, Burish, & Wallston, 1987). Many of these negative studies examined samples composed entirely or predominantly of patients with advanced cancer. A possible explanation for the differences in results may be that personality variables influence earlier stages of breast cancer, but once the disease has progressed past a certain stage, the influences of personality may recede or be overwhelmed by other factors.

As these data suggest, one of the most controversial issues in breast cancer patients is the use of denial in coping with diagnosis. Studies examining the use of denial report contradictory results, with some studies finding that denial is

associated with lower levels of distress and better prognosis (e.g., Dean & Surtees, 1989; Greer et al., 1979; Watson, Greer, Blake, & Shrapnell, 1984) and others finding that use of denial predicts higher distress and poorer outcome (e.g., Carver et al., 1993; C. L. Cooper & Faragher, 1993). However, studies that find a relation between denial and lower stress or better prognosis typically assess denial prior to or immediately following knowledge of disease state (Watson et al., 1984). For example, recently diagnosed breast cancer patients who denied the seriousness of their diagnoses reported significantly less mood disturbance during the time between diagnosis and surgery than did women who did not use denial (Dean & Surtees, 1989; Greer et al., 1979). In addition, the use of denial was not associated with length of delay in seeking treatment (Watson et al., 1984). However, studies examining the use of denial at later times following diagnosis tend to report negative effects of denial (Carver et al., 1993). Overall, it appears that initial use of denial, after screening but prior to diagnosis, may lead to decreased distress and better prognosis in breast cancer patients. However, later use of denial may be a poor coping strategy that could lead to faster disease progression.

Social support and perceived social support have also received attention as potential moderators of the relation between stress and breast cancer progression. Funch and Marshall (1983) found that marital status and number of friends and relatives were not related to survival, but organizational involvement was, indicating that women who reported being involved in more organizations had significantly longer survival. A series of studies found that social support was a factor in the effects of stress on cancer-related immune activity (Levy, Herberman, Lippman, & d'Angelo, 1987; Levy, Herberman, Maluish, Schlien, & Lippman, 1985; Levy et al., 1990). Levels of social support predicted natural killer (NK) cell activity and NK measures were linked to indices of progression (Levy et al., 1987). Other studies have found that NK cell activity has been associated with longer disease-free survival time (Pross & Lotzova, 1993). Coping through seeking social support has also been associated with more positive mood after diagnosis (Stanton & Snider, 1993), and breast cancer patients who engage in expressive activities (involving social interaction) and extroversion have significantly longer survival and disease-free survival times than women who do not report these activities (Hislop et al., 1987). Some researchers have not found evidence of social support affecting breast cancer (Edwards et al., 1990; Roberts, Cox, Shannon, & Wells, 1994). However, the majority of studies have found that social support is associated with higher levels of cancer-related immune indices and better prognosis (e.g., Helgeson & Cohen, 1996).

Summary and Conclusions. Overall, the evidence for a relation between stress and progression of breast cancer is suggestive but far from definitive. Literature reviews have concluded that cancer progression, rather than onset, may be influenced by psychosocial factors (Levenson & Bemis, 1991), and Fox (1983) suggested that if psychosocial factors have any influence on cancer it is prognostic rather than etiologic. The

variables that seem most likely to influence the effects of stress on progression include the use of denial, social support, and personality characteristics consistent with the Type C personality. Initial use of denial seems to predict less subsequent distress and better prognosis, whereas patients with higher levels of social support tend to have better outcomes. In addition, those who are "good patients" (those individuals who are cooperative, unassertive, patient, and compliant) tend to have worse prognoses, whereas the "bad patients" (those who are hostile, anxious, uncooperative, and impatient) have longer disease-free and overall survival times.

THE EFFECTS OF STRESS REDUCTION

One of the best ways to study stress and cancer progression is to reduce stress in some patients and look at differences in disease and treatment outcomes later on. Psychosocial interventions have produced dramatic differences in subsequent mortality in late stage metastatic breast cancer patients (Spiegel, Bloom, Kraemer, & Gottheil, 1989). In this key study, patients attending weekly supportive group therapy meetings lived an average of 36.6 months following onset of the intervention and control patients who received routine oncological care averaged 18.9 months. Although confounding variables were controlled for in analyses, it is important to note that, despite randomization, participants in the intervention group were marginally different from controls in initial stage of disease. In addition, the intervention group received more radiation treatment than controls.

Fawzy and colleagues examined cancer patients with malignant melanoma. Although participants were not breast cancer patients, this study is important here because it examined the immune system as a potential mechanism through which interventions may influence subsequent morbidity and mortality. Following a 6-week group intervention consisting of health education, stress management, enhancement of problem-solving skills, and psychological support, the intervention group reported higher vigor and greater use of active-behavioral coping than controls (Fawzy, Cousins, et al., 1990). At a 6-month follow-up, the intervention participants continued to report higher vigor as well as significantly lower depression, fatigue, confusion, and mood disturbance than controls (F. I. Fawzy et al., 1993). In addition, intervention subjects continued to use more active coping strategies than controls.

Patients were also examined for differences in immunological measures (F. I. Fawzy, Kemeny, et al., 1990). Immediately following the intervention, no immune differences were found between the groups. However, at the 6-month follow-up, the intervention group had significantly increased percentages of NK cells and significantly higher interferon alpha-stimulated NK cell activity relative to controls. Changes in immune parameters were correlated with changes in reported mood; the larger the decrease in self-reported depression and anxiety, the larger the increase in NK cell cytotoxicity. In a 6-year follow-up, intervention patients were more likely to have survived than were controls (F. I. Fawzy et al., 1993).

A number of other studies have examined the efficacy of stress-reducing psychosocial interventions in treating adult victims of a variety of cancers (for reviews see Andersen, 1992; Meyer & Mark, 1995). Gruber, Hall, Hersh, and Dubois (1988) administered guided imagery, relaxation training, and biofeedback to cancer patients monthly over a 1-year period. Patients were instructed to practice these techniques twice daily, and immune levels and activity were measured at each monthly session. Results showed that levels, lymphocyte proliferation to Con A and PHA, NK activity, erythrocyte-rosette formation, IL-2 production, and levels of IgG and IgM were enhanced by the intervention relative to baseline (Gruber et al., 1988, 1993).

The large number of studies examining stress reducing interventions in treating cancer patients is reflected in a number of review articles and meta-analyses that have evaluated the effectiveness of various interventions (Andersen, 1992; Helgeson & Cohen, 1996; Meyer & Mark, 1995; Posluszny, Hyman, & Baum, 1998; Sims, 1987). Although results have been mixed, relaxation training appears to be an effective component of interventions to the extent to which patients comply with practicing at home (Sims, 1987). Building social support, self-esteem, and other psychosocial moderators interventions have been effective in increasing quality of life in victims of a variety of cancers in varying stages of disease (Andersen, 1992; Helgeson & Cohen, 1996; Helgeson, Cohen, Schultz, & Yasko, 1999). Further, a recent meta-analysis of randomized psychosocial interventions in adult cancer patients found moderate effect sizes (ranging from .19-.28) of the intervention on emotional and functional adjustment as well as disease-related symptoms (Meyer & Mark, 1995).

MEDIATING EFFECTS OF THE IMMUNE SYSTEM

The possible role of stress-induced immunosuppression on the etiology and progression of breast cancer has been mentioned several times in this chapter. There is some promising evidence that stress may act through the immune system to affect breast cancer progression (Baltrusch, Stangel, & Titze, 1991; Levy & Wise, 1987; Sikora & James, 1991). However, very few studies have examined distress, immune activity, and disease course together, so the role of immune activity in the stress and breast cancer relation is often inferred from what is known about the relation between stress and immune activity and studies of immune activity in cancer patients.

Stress-related changes in T- and NK cell numbers and activity have been widely reported (Bachen et al., 1992; Goodkin et al., 1996; Manuck, Cohen, Rabin, Muldoon, & Bachen, 1991; Sieber et al., 1992; Zakowski, McAllister, Deal, & Baum, 1992). In addition, studies comparing women with breast cancer to healthy women find that women with breast cancer typically have lower levels of these immune measures (Keller, Joachim, Pearse, & Siletti, 1976; Nemoto et al., 1974). Lower levels of immune activity have been associated with decreased survival times and shorter time to recurrence (Akimoto et al., 1986; Hacene et al., 1986; Ownby et al., 1983; Pross & Lotzova, 1993). Recently, cancer-related dis-

stress in breast cancer patients was found to predict lower NK activity and lower T-cell response to mitogenic challenge (Andersen et al., 1998).

Levy and her colleagues (1985) were among the first to systematically assess immune system activity or a factor in studies of stress and breast cancer. They found that patients who had low levels of NK activity were rated as more well-adjusted to their disease than patients with higher NK activity. In addition, patients with high NK activity had significantly fewer positive nodes than those with low NK activity. These results parallel those of studies examining personality effects on progression; "good" patients tended to fare worse than "bad" patients. However, immune measures were taken following surgery so it is impossible to determine whether having more positive axillary nodes led to decreased NK activity or whether decreased NK activity led to more positive nodes. In a 3-month follow-up, NK activity remained significantly lower in those patients with positive nodes as compared to those with negative nodes (Levy et al., 1987).

CONCLUSIONS AND FUTURE DIRECTIONS

The literature on the effects of stress on breast cancer development is typical of literatures on other complicated real-world issues. Inconsistencies in the findings of these studies are often attributable to confounding variables that are difficult to control and to small or nonrepresentative samples. Control groups and time frames for measurement are often less than ideal or optimal. There have been few prospective studies examining baseline biopsychosocial measures prior to diagnosis and following participants through subsequent diagnosis of breast cancer, measuring progression, recurrence, and mortality. A prospective study of this nature would involve a substantial investment of time and money and it may be more realistic to study high risk populations beginning before patients know their diagnoses. Most studies compare women diagnosed with cancer to those diagnosed with benign disease. However, the presence of a breast lump may influence or alter the way in which a women may recall life events or answer other questionnaires, suggesting that a healthy control group also should be examined. Confounding variables need to be controlled when possible, and those that cannot should be measured to allow their influence to be corrected statistically. Perhaps most importantly, stage of disease needs to be controlled, because stress may influence breast cancer progression differently at different stages of disease.

Despite the volume of research on stress and breast cancer, a number of questions remain unanswered. The effects of stress on progression of breast cancer need to be clarified. It appears that stress can affect progression, because patients who report higher levels of distress exhibit earlier recurrence and shorter survival than those reporting lower levels of distress. However, research has also indicated that patients who complain the most, and who appear least well-adjusted to their disease, have the best prognoses. As suppression of emotion is characteristic of patients with poorer prognoses, it is difficult to interpret whether individuals reporting low levels of distress are suppressing their emotions or are actually

not experiencing distress. For this reason it is important to take multiple measures of stress (self-report, other-report, and physiological), as well as measures of personality and coping behaviors, to determine if patients are prone to suppressing emotions. The role of the immune system and specific immune indices in mediating the effects of stress on breast cancer progression also needs to be examined in greater detail. Although the link between stress and immune changes has been shown repeatedly, the link between stress-related immune activity and disease has not been consistently found, and mediational analyses are needed to determine if stress does affect breast cancer progression through its influence on immune cells.

Finally, although initial findings appear very promising, the efficacy of stress-reducing interventions is still untested and the understanding of mechanisms indulging their effects is still poor. Replication of studies finding less recurrence and lower mortality in patients undergoing interventions and verification of theoretically predicted moderators are necessary before endorsing these interventions. It is unknown what type of patient is most likely to benefit from interventions, whether the effectiveness of these interventions differs depending on patient's stage of disease, and what qualities of the interventions are most beneficial (i.e., content, frequency, and/or length of intervention). However, they provide a plausible and attractive mechanism explaining some of the effects of stress on cancer. Future intervention studies need to address these questions to determine the most effective and economical way to treat breast cancer patients.

Behavioral Intervention in Comprehensive Cancer Care

William H. Redd

Ruttenberg Cancer Center, Mount Sinai Medical Center

Paul Jacobsen

Moffitt Cancer Center & Research Institute

Cancer and its treatment adversely affect almost every aspect of a person's life. Indeed, there are few things more dreaded than being diagnosed with cancer. Although severe psychiatric reactions are relatively infrequent among cancer patients, significant adjustment problems and disorders are common. Indeed, over one-half of those treated for the disease experience fear, pain, insomnia, and related anxiety disorders (Derogatis, Morrow, & Fetting, 1983). A major advance in efforts to reduce such cancer-related distress has been the application of behavioral principles.

In this chapter, we discuss the application of behavioral principles in the design of psychosocial interventions with adult and pediatric cancer patients. The chapter is presented in four distinct sections. The first section reviews basic principles of behavioral intervention in the context of cancer treatment. The aim of that overview is to lay the foundation for the discussion of specific interventions. The second and third sections examine behavioral intervention with adults and children, respectively. It is important to note that the foci of clinical research with each of these two groups are quite different, each reflecting the problems that are encountered most frequently. Intervention research with adult patients has focused on symptom control and psychological adjustment, whereas the pediatric work has been broader. That work has examined methods to reduce pain and distress as well as issues surrounding treatment compliance and parents' impact on children's adjustment. These differences are reflected in

the specific organization used in the adult and pediatric sections. The final section of the chapter considers future directions for clinical research.

OVERVIEW

The cognitive-behavioral perspective is based on the postulate that patient reactions to cancer and its treatment are a function of the context (i.e., social setting) under which the individual is diagnosed and treated, the social contingencies that operate, as well as his/her prior history and his/her individual strengths and weaknesses. Cognitive factors (e.g., beliefs, attitudes, and expectations) are also seen as playing a role (Turk, Meichenbaum, & Genest, 1983). Each of these factors is considered in the design and implementation of psychosocial interventions. The aim of such cognitive-behavioral intervention (the term that is most frequently used to identify this approach to clinical care) is to identify and then modify those factors (i.e., social contingencies, thoughts, feelings, and behaviors) that contribute to the development and maintenance of symptom. As the name implies, the cognitive-behavioral perspective incorporates both behavioral and cognitive approaches to psychosocial change. Reflecting its behavioral origins, the cognitive-behavioral perspective uses techniques for behavior change derived from the principles of operant conditioning (Skinner, 1953) and respondent conditioning (Pavlov, 1927).

To maximize therapeutic effectiveness, cognitive-behavioral interventions often combine several cognitive and behavioral change techniques into a "package." Standardized multi-component intervention packages have been developed for a range of purposes including the management of stress reactions (Meichenbaum, 1985) and chronic pain (Turk, Meichenbaum, & Genest, 1983) and the treatment of anxiety disorders (Barlow & Cerny, 1988). When the patient is a child, parents are often included in the intervention as coaches. In such pediatric interventions, parents typically function as change agents as they play a role in both the development and maintenance of the child's symptom behavior.

The contribution of cognitive-behavioral approaches to comprehensive care in adults and children is increasingly well recognized by various professional groups. A recent survey of cancer center health care providers revealed that cognitive-behavioral interventions were among the most widely offered psychosocial services (Coluzzi, Grant, Doroshov, Rhiner, Ferrell, & Rivera, 1995). This widespread use of such intervention strategies can be attributed to several factors. First, and perhaps most important, cognitive-behavioral interventions have been shown to be effective in reducing emotional distress and controlling physical symptoms in cancer patients (Meyer & Mark, 1995). Second, the interventions can usually be administered in a brief period of time and thus are well suited for use in oncology where rapid control of aversive symptoms may be necessary. Third, the interventions can be easily tailored to deal with the unique symptom control problems and quality of life issues that cancer patients experience. Fourth, the interventions are readily accepted by patients because of the emphasis that is placed on increasing the patient's sense of personal control and self-efficacy. Cognitive-behavioral intervention strategies place great importance on the normalization of patient adjustment.

INTERVENTION WITH ADULTS

We focus on three areas in oncology where cognitive-behavioral interventions have had a major impact on care of adult cancer patients. They are relief of pain, control of aversive reactions to chemotherapy administration, and enhancement of emotional well-being. Summaries of controlled randomized trials of the effectiveness of cognitive-behavioral intervention with adults are provided in Tables 46.1, 46.2, and 46.3.

Pain

Relaxation training is often recommended, either alone or as an adjunct to pharmacotherapy, in the management of cancer pain (Cobb, 1984). Despite considerable anecdotal evidence of the efficacy of relaxation training for cancer-related pain (Ahles, 1987; Millard, 1993), an extensive literature search uncovered only one study that used a controlled randomized design to directly examine the effectiveness of this technique (Sloman, Brown, Aldana, & Chee, 1994; see Table 46.1). In this study, researchers examined the effects of an intervention that combined progressive muscle relaxation with "mental imagery" on patients' reports of pain and their use of analgesic medications.

Hospitalized patients with cancer pain were randomly assigned to a no intervention condition or to conditions in which relaxation training was provided either by audiotape or by a nurse. Compared to the control group, patients who received either audio taped instruction or live instruction reported significantly less pain and used fewer non-opioid analgesics. Although this study requires replication, it provides preliminary evidence of the effectiveness of relaxation training in alleviating cancer-related pain.

As with relaxation training, there is considerable anecdotal evidence in support of the use of hypnosis to relieve cancer-related pain (Hilgard, 1975; Margolis, 1985). However, evidence based on randomized studies is extremely limited. Spiegel and colleagues (1989) conducted one of the few controlled investigations of the efficacy of hypnosis in relieving cancer-related pain. In this study, women with metastatic breast cancer were randomly assigned to a no intervention condition or to group therapy. Patients assigned to the group therapy condition were then nonrandomly assigned to groups that either did or did not include instruction in hypnosis for pain control. Results indicated that, compared to patients in the control condition, patients who received group therapy reported less severe pain and less suffering over a one-year period. Additional analyses indicated that patients who received group therapy and hypnosis experienced less pain than patients who received group therapy alone. Although these findings support the use of hypnosis for relief of pain related to metastatic disease, they require replication for at least two reasons. First, the assignment to self-hypnosis in this study was not based on random assignment. Second, since many subjects died before the one year follow-up, the outcome analyses required extensive use of statistical corrections for missing data. Future studies could best deal with this issue by examining the efficacy of hypnosis over shorter time intervals.

Multicomponent cognitive-behavioral interventions have repeatedly been demonstrated to be effective in the treatment of chronic nonmalignant pain (Keefe, Dunsmore, & Burnett, 1992). Turk and Rennert (1981) were among the first to describe a multicomponent cognitive-behavioral intervention specifically designed to relieve cancer-related pain. Their approach involved education about the contribution of beliefs, attitudes, and emotions to the experience of pain as well as training in the use of both behavioral and cognitive techniques (e.g., relaxation, imagery, attention diversion, problem solving) for coping with pain. Clinical reports suggest that multicomponent cognitive-behavioral interventions are effective against cancer-related pain (Fishman & Loscalzo, 1987; Loscalzo & Jacobsen, 1990). However, the first controlled study to evaluate this approach yielded equivocal results. In this study (Syrjala, Cummings, & Donaldson, 1992), patients receiving chemotherapy before bone marrow transplantation were randomized to one of four conditions: (1) cognitive-behavioral coping skills training; (2) hypnosis training; (3) attentional control; or (4) no treatment control. Of principal interest was the impact of the interventions on the severity of chemotherapy-induced oral mucositis pain. Results indicated that patients who underwent hypnosis training, but not cognitive-behavioral training, experienced less pain than controls.

The authors of this study caution, however, that the numerous components included in the two cognitive-behavioral training sessions (relaxation training, cognitive restructuring, development of coping self-statements, and psychoeducation about symptoms and side effects) may have exceeded what patients could learn in such a short time. In a subsequent study (Syrjala, Donaldson, Davis, Kippes, & Carr, 1995), the same investigators tested a refined version of the cognitive-behavioral intervention in which the number of skills taught was reduced. Once again, patients receiving chemotherapy before bone marrow transplantation were randomized to one of four conditions: (1) cognitive-behavioral coping skills training; (2) relaxation training only; (3) nonspecific therapist support; or (4) no treatment control. Results of this subsequent study confirmed predictions that patients who received the cognitive-behavioral intervention or relaxation training alone would report less pain than patients in the other two groups. It should be noted, however, that an expected additive benefit of cognitive-behavioral skills training beyond relaxation training alone was not observed.

Aversion Reactions to Chemotherapy

The use of cognitive-behavioral interventions with chemotherapy patients initially focused on the clinical problem of anticipatory nausea and vomiting (ANV). In the early 1980s, a series of clinical reports described patients who had previously received emetogenic chemotherapy and who became nauseated and/or vomited in anticipation of subsequent treatments (Redd & Andresen, 1981; Nesse, Carli, Curtis, & Kleinman, 1980). In addition to describing this phenomenon, the authors of these clinical reports hypothesized that anticipatory reactions in chemotherapy patients were examples of classically conditioned responses. Similar to conditioned vomiting responses that could be experimentally induced in laboratory animals (Skinner, 1953), cancer patients appeared to develop ANV when previously neutral stimuli (e.g., the sights, sounds, and smells of the treatment environment) acquired nausea/emesis eliciting properties due to repeated association with chemotherapy administration and its aversive aftereffects. Based on this respondent conditioning conceptualization, several researchers investigated the efficacy of cognitive-behavioral interventions for controlling ANV. Three interventions were found to be effective in the first round of controlled clinical trials: hypnosis (Redd, Andresen, & Minagawa, 1982), progressive muscle relaxation training combined with guided imagery (Burish & Lyles, 1981; Lyles et al., 1982) and systematic desensitization (Morrow & Morrell, 1982; see Table 46.2). In the study of hypnosis, changes in anticipatory vomiting were shown to correspond in the expected direction with the introduction, withdrawal, and reintroduction of hypnosis-induced relaxation. In the studies of relaxation training and systematic desensitization, patients with ANV who were randomly assigned to the cognitive-behavioral intervention subsequently experienced less anticipatory nausea and/or vomiting than patients randomly assigned to either no treatment or attention control conditions.

In the studies cited, the cognitive-behavioral interventions were delivered to chemotherapy patients by specially trained mental health professionals. At least one study has investigated whether the potential availability of these interventions could be increased by training oncology personnel in the use of cognitive-behavioral techniques. In this study (Morrow, Asbury, Hammon, Dobkin, Caruso, & Pandya, 1992), patients with ANV were randomly assigned to receive no treatment or to receive systematic desensitization from either a clinical psychologist, an oncologist, or an oncology nurse trained in the technique. Results indicated that patients in each intervention condition experienced significant declines in anticipatory nausea relative to patients who received no treatment. Moreover, there were no differences in the magnitude of the therapeutic effects based on whether the intervention was delivered by a psychologist, a physician, or a nurse.

The means by which relaxation training and systematic desensitization reduce ANV have been the subject of considerable debate (Carey & Burish, 1988; Jacobsen & Redd, 1988). Speculation among researchers (Carey & Burish, 1988; Jacobsen & Redd, 1988) has centered around two possible mechanisms of action: physiological relaxation and cognitive distraction. The relaxing effects of these interventions may serve to inhibit the muscular contractions in the gastrointestinal tract involved in nausea and vomiting. Alternatively, the cognitive demands of these interventions could serve to direct attention away from sensations of nausea or from stimuli that have acquired nausea-eliciting properties. To isolate the possible role of distraction in ANV control, one study (Vasterling, Jenkins, Tope, & Burish, 1993) evaluated an intervention that has both distraction and relaxation components (progressive muscle relaxation training) as well as an intervention that has a distraction component but no relaxation component (video game playing). Compared to a no treatment control condition, patients in both intervention conditions experienced significantly less anticipatory nausea. Moreover, the two interventions did not differ in their effectiveness. Thus, results suggest that control of ANV can be achieved by distraction alone.

Other research has examined whether cognitive-behavioral interventions conducted before the start of chemotherapy are effective in preventing or postponing development of ANV. Two studies that examined this issue (Burish, Carey, Krozely, & Greco, 1987; Lerman et al., 1990) yielded mixed results. In both studies, patients scheduled to begin chemotherapy were randomly assigned to receive either progressive muscle relaxation and guided imagery or no intervention before the start of treatment. One study (Burish, Carey, Krozely, & Greco, 1987) found that by the fourth infusion (i.e., after several "conditioning trials") patients in the no intervention condition were experiencing significantly more anticipatory nausea and anticipatory anxiety than patients in the intervention condition. The same study also found that patients in the intervention condition experienced significantly less nausea, vomiting, and anxiety after chemotherapy than patients in the no intervention condition. The other study (Lerman et al., 1990) found no significant group differences in anticipatory nausea when it was assessed at the third infusion. However,

patients in the intervention condition did experience significantly less nausea after chemotherapy than patients in the no intervention condition.

Although findings regarding ANV prevention are inconclusive, both studies suggest that cognitive-behavioral interventions conducted before the start of chemotherapy may have other beneficial effects. Specifically, these interventions may serve to limit posttreatment nausea and vomiting and reduce treatment-related emotional distress. In one of the few controlled studies designed specifically to address this issue (Burish, Snyder, & Jenkins, 1991), patients about to begin chemotherapy were randomly assigned to one of four intervention conditions: relaxation training, coping preparation, relaxation training and coping preparation, or no treatment. Relaxation training consisted of instruction in progressive muscle relaxation immediately before the first infusion. Coping preparation consisted of four components: (1) a tour of the oncology clinic that provided patients with procedural information as well as concrete sensory information regarding chemotherapy administration; (2) a videotape presentation of a patient modeling successful coping with chemotherapy treatment; (3) a discussion and question and answer session that offered patients an opportunity to express feelings and concerns and to receive suggestions on how to cope with treatment and its side effects; and (4) a booklet that patients could use to review previously presented information. This 90-minute intervention was conducted on a day prior to the first chemotherapy administration. Findings indicated that the coping preparation yielded a number of beneficial effects. Compared to patients in the no treatment condition, patients who received coping preparation reported less anticipatory nausea, posttreatment vomiting, and depression. Moreover, among patients working outside the home, those who underwent the coping preparation reported less interference associated with cancer and its treatment on their ability to work. The benefits of relaxation training were less extensive, and the addition of relaxation training to coping preparation did not yield additional benefits. Findings from this study suggest that brief training in coping skills before the start of treatment may be an effective means of improving quality of life during chemotherapy.

Emotional Well-Being

The use of multi-component cognitive-behavioral interventions to improve well-being in cancer patients has been the subject of considerable attention in recent years. This interest can be attributed, in part, to evidence suggesting that psychosocial interventions designed to improve emotional and physical well-being in cancer patients may also improve survival (F. I. Fawzy, N. W. Fawzy, & Kemeny, 1990; Spiegel, Bloom, Kraemer, & Gottheil, 1989). Interest in this area has also been stimulated by the increased recognition of the importance of quality of life (a construct that includes both emotional and physical well-being) as an endpoint in cancer treatment (Cella, 1993; Osoba, 1994). Although there is considerable enthusiasm for the use of cognitive-behavioral

interventions to improve emotional well-being, a review of the literature indicates that only a handful of studies have evaluated these interventions using controlled randomized designs (see Table 46.3).

Worden and Weisman were among the first to develop and evaluate cognitive-behavioral interventions to reduce distress and improve well-being in cancer patients. In a landmark study (Worden & Weisman, 1984), these investigators evaluated two interventions designed to promote coping and adaptation among newly diagnosed patients. Both interventions focused on the development of problem-solving skills. In the first approach, the therapist focused on the specific problems the patient was currently facing. In the second approach, the therapist focused more on the development of general problem-solving skills and discussed the solution of common problems faced by cancer patients. The second approach also included training in progressive muscle relaxation. Participants in the study were newly diagnosed cancer patients who were identified as being at high risk for psychological distress using well-defined criteria. These individuals were randomized to one of the two intervention conditions and their responses were compared to those of a nonrandomized control group. Results indicated that patients in both intervention groups experienced less psychological distress at follow-up than controls. Despite its methodological limitations (i.e., the lack of a nonrandomized control group), this study has had an enormous impact on the field of psychosocial oncology. Elements of this intervention have been incorporated into several other multi-component interventions that have been clinically validated and are described later.

Building on the work of Worden and Weisman (1984), Heinrich and Schag (1985) evaluated a stress and activity management program designed for cancer patients and their spouses. In multi-couple groups, participants were taught specific problem solving skills, received training in relaxation and information about coping with cancer and its treatment, and were encouraged to engage in physical exercise and to increase positively valued activities. The responses of couples randomized to this program were compared with those of couples randomized to standard care. Contrary to predictions, patients who received stress and activity management training did not demonstrate better psychosocial adjustment or activity levels than patients who received standard care.

Other studies that have evaluated similar cognitive-behavioral interventions have obtained different results. Telch and Telch (1986) examined the impact on quality of life of a group-administered program of coping skills training. The program consisted of five modules that covered: (1) relaxation and stress management; (2) communication and assertion; (3) problem solving and constructive thinking; (4) feelings management; and (5) pleasant activity planning. The effects of this intervention were tested by randomly assigning cancer patients to receive group coping skills instruction, supportive group therapy, or no treatment. Results indicated that, immediately following the 6-week intervention, patients who underwent coping skills training were less emotionally distressed and reported fewer problems than patients in the other two conditions.

Table 46.3
 Summary of Controlled Randomized Studies of Cognitive-Behavioral Interventions to Improve Emotional Well-Being

STUDY	PARTICIPANTS		INTERVENTION							OUTCOMES			
	Diagnosis	Females/ Males	Control groups (n)	Experimental groups (n)	Format	# length of sessions	Info	Coping/ Problem Solving	Relax	Activity Planning	Coping	Emotional Well Being	Func- tioning
Heinrich & Schag (1985)	Mixed	?	No tx (25)	#1 (26)	Group Group	6 sessions, 2 hours	x	x	x	x		0	
Telch & Telch (1986)	Mixed	F=27 M=14	No tx (14)	#1 (13) #2 (14)	Group Group	6 sessions, 90 mins 6 sessions, 90 mins		x	x	x	+	+	+
Fawzy et al. (1990)	Melanoma	F=35 M=31	No tx (28)	#1 (38)	Group	6 sessions, 90 mins	x	x	x		+	+	
Greer et al. (1992)	Mixed	F=32 M=124	No tx (84)	#1 (72)	Indiv	6 sessions, 1 hour		x	x	x		+

x = Component included in intervention
 + = Significant improvement relative to controls
 0 = Nonsignificant improvement relative to controls

A study by Fawzy and colleagues (1990) has provided additional evidence that cognitive-behavioral interventions are effective in promoting adaptive coping and reducing emotional distress. In this study, patients with early stage melanoma were randomly assigned to a no treatment control condition or to a group administered program that included: health education, problem-solving skills training modeled after the work of Worden and Weisman (1984), stress management training, and psychological support. At a 6-month follow-up, the intervention group was found to be experiencing less emotional distress and to be using more active coping methods than the control group.

Greer and colleagues (1992) tested an individually administered cognitive-behavioral intervention designed to improve emotional well-being. The intervention, referred to as "adjuvant psychological therapy," has multiple components including coping skills training, cognitive restructuring, and progressive muscle relaxation training. In a controlled outcome study designed to evaluate the effectiveness of this intervention, cancer patients who met specific criteria for psychological morbidity were randomized to receive either adjuvant psychological therapy or no treatment. At a 4-month follow-up, patients who had received the cognitive-behavioral intervention were found to be experiencing less emotional distress than patients who received no treatment. These effects remained evident at a 12-month follow-up (Moorey et al., 1994).

At least one study has directly compared individual versus group administered forms of cognitive-behavioral interventions to promote emotional well-being. In this study (Cain, Kohorn, Quinlan, Latimer, & Schwartz, 1986), women with gynecologic cancer were randomized to either individual or group forms of "thematic counseling" or no treatment. Both the individual and group interventions included the following components: psychoeducation about cancer and its treatment, relaxation training, development of problem-solving skills, and discussion of diet and exercise. Data collected at a 6-month follow-up indicated that women who received thematic counseling either as individuals or in groups were less emotionally distressed and had made a better adjustment to their illness than women in the control group. Women who received thematic counseling also report better sexual functioning and greater participation in leisure activities. Thus, there does not appear to be any difference in efficacy associated with the format (i.e., group vs. individual) of cognitive-behavioral intervention.

INTERVENTION WITH CHILDREN

The importance of behavioral intervention in pediatric oncology is appreciated by most pediatric oncologists and nurse specialists. Clear evidence of this recognition is the recommendation made by the World Health Organization Consensus Conference for childhood cancer. That group endorsed behavioral procedures as the treatment of choice for pain associated with invasive medical procedures (Zeltzer et al., 1990). Interest in behavioral intervention has grown steadily as medical treatment regimes for children have become more

aggressive and thereby more painful for the patient. Behavioral research in pediatric oncology has focused on the application of specific behavioral procedures to increase treatment compliance and reduce child suffering.

Intervention With Specific Adjustment/Psychosocial Problems

Problems that have been studied include: distress during invasive diagnostic and treatment procedures, treatment side effects, and social and academic reintegration. Under each problem we discuss how specific behavioral procedures have been applied, and results from clinical trials of their efficacy.

Bone marrow aspiration and lumbar puncture are used in both the diagnosis and treatment of patients. Bone marrow aspiration is a diagnostic procedure in which a needle is inserted into a bone, usually in the lower back, in order to extract marrow. This procedure is used to diagnose leukemia and other cancers, to determine if the cancer has metastasized, and to evaluate chemotherapy effectiveness (Gambino, 1989). It is extremely painful and often requires physical restraint of the child to complete the procedure if inadequate local anesthesia or sedation are used. Lumbar puncture involves the insertion of a needle into the spinal canal and the removal of spinal fluid. It is used to diagnose infections, brain hemorrhage, tumors, or other obstructions (Gambino, 1989). Like bone marrow aspiration, many children become anxious and uncooperative during lumbar puncture.

Unfortunately, in many cases both of these procedures must be administered repeatedly, creating for some children, near phobic reactions. Depending on the child's age and cognitive understanding of the procedure, bone marrow aspiration sometimes resembles torture to the child (Katz, Kellerman, & Siegel, 1980). Because of the anxiety and pain caused by such invasive treatments and many children's limited understanding of why treatment is necessary, young patients often become noncompliant and actively resist these procedures. Indeed, from 38% to 84% do not cope well during bone marrow aspiration and lumbar puncture (Ellis & Spanos, 1994).

Pharmacological interventions can reduce pain and anxiety during bone marrow aspiration and lumbar puncture, but many clinicians try to limit their use due to feared long-term neurological side effects. In addition, some children report that sedation makes them feel out of control (Ellis & Spanos, 1994), further supporting the use of behavioral interventions in lieu of, or in addition to pharmacological intervention.

Although hypnosis has been used for over a century, most of the research regarding its effectiveness is anecdotal or based on case reports (Carey & Burish, 1988; Ellis & Spanos, 1994; Manne & Andersen, 1991; Rape & Bush, 1994; Zeltzer & LeBaron, 1986). Despite imprecision in definitions, a general lack of standardized interventions, and few controlled studies, hypnosis has been found to be effective in alleviating distress associated with a number of cancer treatment procedures. (Systematic studies of behavioral interventions with pediatric oncology patients undergoing bone marrow aspiration and lumbar puncture are reviewed in Table 46.4).

In a pioneering study, Hilgard and LeBaron (1984) found that hypnosis reduced distress during bone marrow aspiration in a group of 6- to 19-year-old patients. After one hypnosis treatment session, patients experienced a 30% reduction in self-reported pain. Treatment effects were found to vary by patients' level of hypnotizability, with more hypnotizable patients experiencing greater reductions in pain and anxiety.

In a more methodologically rigorous, randomized controlled study, Kuttner, Bowman, and Teasdale (1988) investigated the relative efficacy of imaginative involvement/hypnosis as compared to both distraction and standard care. Participants were 3- to 10-year-old children identified by medical staff as having difficulty tolerating bone marrow aspirations. After one intervention session, imaginative involvement/hypnosis was determined to be better (in terms of reduction in distress) than standard care.

Multimodal Strategies With Bone Marrow Aspiration and Lumbar Puncture

Jay and her colleagues have developed a comprehensive intervention package that employs a range of techniques to reduce the pain and suffering of pediatric oncology patients during medical procedures (Jay, Elliott, Katz, & Siegel, 1987; Jay, Elliott, Ozolins, Olson, & Pruitt, 1985; Jay, Elliott, Woody, & Siegel, 1991). Their intervention package includes various strategies such as breathing exercises, reinforcement in the form of a trophy (a prize) for lying still and doing the breathing exercises, emotive imagery, behavioral rehearsal, and modeling. Although there have been other multimodal intervention packages for reducing distress associated with lumbar puncture (e.g., Chen, Zeltzer, Craske, & Katz, 1999; McGrath & de Veber, 1986), the intervention developed by Jay and colleagues has been the most thoroughly evaluated. In a series of studies, Jay and colleagues found their intervention to be effective in reducing procedural stress for children with cancer and their parents (Jay & Elliott, 1990; Jay, Elliott, Katz, & Siegel, 1987; Jay, Elliott, Woody, & Siegel, 1991).

Medical procedures are not only potentially distressing for the children who experience them, but may also cause distress for the parents who watch their children undergo these invasive procedures. Because some parents become distressed when their children undergo medical procedures and parents influence the distress experienced by their children (Jay, Ozolins, Elliott, & Caldwell, 1983), Jay and Elliot (1990) designed and evaluated the efficacy of a multimodal intervention for parents. Parents were assigned to either accompany their child as he or she received one of two child-focused interventions or received stress inoculation training themselves. The stress inoculation program employed by Jay and Elliot (1990) included three components: modeling and education; positive self-statements; and relaxation training combined with suggestions for coping. As compared to parents in the child focused conditions, parents in the stress inoculation group reported lower state and trait anxiety and higher positive self-statements.

The work of Jay and her colleagues indicated that a multimodal intervention is effective in reducing children's

distress during bone marrow aspiration and lumbar puncture (Jay, Elliott, Katz, & Siegel, 1987; Jay, Elliott, Ozolins, Olson, & Pruitt, 1985; Jay, Elliott, Woody, & Siegel, 1991). In addition, their multimodal intervention was found to be more effective than a pharmacological intervention or an attention control condition in reduction of children's behavioral distress and pain during bone marrow aspiration (Jay, Elliott, Katz, & Siegel, 1987). Adding a pharmacological treatment to the psychological intervention did not enhance the effect of the psychological intervention in reducing children's bone marrow aspiration and lumbar puncture distress (Jay, Elliott, Woody, & Siegel, 1991). Finally, an intervention for parents based on a stress inoculation training model was found to reduce parents' distress associated with their child's medical procedure (Jay & Elliott, 1990). It is important to point out that these studies did not address which aspects of the multimodal intervention package were most effective nor which components were effective for which children. The question, "Which intervention, and for whom?", needs to be addressed.

Venipuncture is frequently used for diagnostic blood tests, transfusions, bone marrow aspiration, lumbar puncture, and chemotherapy. Up to 77% of children find venipuncture distressing (Jacobsen et al., 1990). Children's apprehension concerning venipuncture can lead to muscle rigidity, making the procedure more difficult (and painful) to perform. The recent development of a local anesthetic, EMLA, may make the entire procedure less painful, thereby diminishing the need for behavioral intervention with venipuncture. However, until EMLA is more widely assessed in randomized clinical trials with children, behavioral interventions remain an important treatment option for distress associated with venipuncture. (Systematic studies of behavioral interventions with pediatric oncology patients undergoing venipuncture are reviewed in Table 46.4).

Building on the work of Dahlquist and colleagues (1985), Manne and colleagues (Manne et al., 1990; Manne, Bakeman, Jacobsen, Gorfinkle, & Redd, 1994) have obtained strong support for the efficacy of behavioral interventions in reducing distress associated with venipuncture. Their three session intervention package involves both the child and the parent and includes a combination of distraction, paced breathing, and reinforcement for the children, and instructions in behavioral coaching for the parents. During venipuncture, the child is distracted by using a party blower while the parent coaches. The parent counts out loud to pace the child's breathing into the blower and encourages the child to use it. Positive reinforcement consists of the child "winning" stickers for holding their hand still while the venipuncture is performed and for using the party blower. In randomized controlled studies, Manne and her colleagues have found that these behavioral interventions effectively reduce distress during venipuncture (1990, 1994). Particularly important for clinicians is that they demonstrated that this cost effective (e.g., use of a party blower and parent coaching) intervention reduced both children's and parents' distress. There are, however, several remaining questions, including which behavioral strategy is most ef-

Table 46.4
Behavioral Interventions for Pediatric Oncology Patients

Medical Procedure/Authors	Sample	Research Design	Intervention	Variables	Major Results/Significant Findings
BMA Hilgard & LeBaron (1982)	N=24, 6-19 years old "chiefly forms of leukemia"; 24 had 1 intervention session, 19 had 2 or more	Baseline- posttest	Hypnosis (e.g., imaginative involvement through story telling)	Self-reported Pain (scale of 0-10 or FACES). Observer-rated Pain & Anx (scale of 0-10). Hypnotizability (Stanford Hypnotic Clinical Scale for Children; SHCSC).	1. After 1 session reduction in: self-report pain, observer rated pain, and observer rated anxiety. 2. High hypnotizability associated w/greater decreases in pain & anxiety. 3. Additive effects of session 2 not sig. 4. Overall, the higher initial distress (pain and anxiety), the greater the likelihood of patients to participate in the intervention.
BMA & LP Zeltzer & LeBaron (1982)	N=33, 6-17 years old; 28 L, 3 NHL, 2 Neural Tumors	Repeated -Measures Factorial	Hypnosis (e.g., imagery, fantasy & deep breathing) vs. Nonhypnotic behavioral techniques (e.g., distraction & deep breathing)	Self-reported Pain & Anx (scale of 1-5). Observer-rated Pain & Anx (scale of 1-5).	1. BMA pain decreased in both groups, greater reductions in hypnosis group. 2. BMA anxiety reduced in hypnosis group. 3. LP pain decreased in hypnosis group. 4. LP anxiety reduced in both groups.
BMA & LP & Chemotherapy Injection Kellerman et al. (1983)	N=16, mean age 14.0 years, SD+ 1.6, 8 ALL, 3 AML, 2 HD & Ewing's sarcoma, 1 NHL, 1 Neurobl, 1 Osteogenic sarcoma	Baseline-posttest	Hypnosis (e.g., fantasy and relaxation)	Self-reported Anx & Discomfort (scale of 1-5). Trait Anx (State-Trait Anxiety Inventory; STAI). Self-Esteem (Rosenberg Self-Esteem Scale; RSES). Health Locus of Control (HLOC) . Illness Impact (II).	1. Reductions in anxiety & discomfort. 2. Reduction in Trait Anx.
BMA Katz et al. (1987)	N=36, 6-12 years old; 36 ALL	Repeated-measur es factorial	Hypnosis (e.g., imagery, muscle relaxation, suggestion for mastery, and reentering hypnosis) vs. Nondirected Play	Observer-rated Procedural Distress (Procedural Behavioral Rating Scale-revised; PBRs-r). Nurses rating of child's Anx (scale 1-5). Self-reported Fear (FACES 1-7) & Pain (scale 0-100). Therapist rating of rapport & responsiveness to hypnosis (scale 1-5).	1. Self-rated pain & fear decreased after intervention in both groups. 2. Children who were rated as responding to the hypnosis training tended to report less fear and pain during procedure.
BMA Kuttner et al. (1988)	N=48, 3-10 years old; 48 had ALL or AML. 48 had 1 intervention session, 30 had 2nd session	Repeated-measur es factorial	Hypnosis /Imaginative Involvement (e.g., imagery & direct suggestions for analgesia) vs. Distraction (e.g., younger children instructed in bubble blowing and older children in deep breathing) vs. Standard Medical Practice (control group)	Observer-rated Procedural Distress (PBRs-r). Observer- rated Anx (1-5). Observer rated Pain (1-5). Self-reported Pain & Anx (FACES 1-5).	1. At 1st intervention session, younger children (3-6 years old), who received hypnosis treatment had lower observer rated distress as compared to the other 2 groups. 2. For older children (7-10 years old) both interventions resulted in less observer rated pain and anxiety vs. the control group. 3. At 2nd intervention session, all 3 groups showed reductions in distress, pain, and anxiety, and medical staff were observed using distraction with the control group.

<p>BMA & LP Wall & Womack (1989)</p>	<p>N=20, 5-18 years old; no information on cancer diagnosis</p>	<p>Repeated-measures factorial</p>	<p>Hypnosis (e.g. imagery & relaxation) & Procedural Information vs. Active Cognitive Strategy (e.g. distraction techniques) & Procedural Information</p>	<p>Self-reported Anticipatory Anx, Procedural Anx, & Procedural Pain (scale 1-20). State Anx (STAI). McGill Pain Questionnaire (MPQ; for 12+ year old patients). Hypnotizability (SHCSC). Level of imaginative involvement (scale 1-4). Observer-rated Procedural Pain and Anx (scale 1-20). Heart rate. Peripheral temp. (in finger).</p>	<p>1. Reductions in self-reported and observer rated pain in both groups. 2. Observer rated anxiety decreased in both groups.</p>
<p>LP McGrath & deVeber (1986)</p>	<p>N=14, 3-11 years old; AML or ALL</p>	<p>Baseline-posttest</p>	<p>Information, distraction, "hypnotic-like" suggestions for analgesia, imagery, relaxation, and modification of children's expectations of fear, anxiety, or pain.</p>	<p>Parent & Nurses rated Anx (not at all anxious to extremely anxious), Pain (no pain to intense pain), Behavioral Distress (e.g., crying), & Relaxed Behaviors (e.g., playing, remaining calm). Self-reported pain, and strength and unpleasantness of pain (FACES). Children were interviewed extensively about the procedure (e.g., about their perceived ability to control their pain & about their pain coping strategies).</p>	<p>1. Reductions in anxiety, pain, and distress behaviors. 2. Reductions in anxiety and pain at three-month, and six month follow ups.</p>

Reductions in observer rated distress, self-report of pain, and pulse rates in the behavior therapy condition as compared to the attention control condition. 2. Reductions represent 18% less behavioral distress, and 25% less self-reported pain in the behavioral treatment as compared to the attention control condition. 3. Reductions in diastolic blood pressure in the Valium condition as compared to the attention control condition.</p>

Medical Procedure /Authors	Sample	Research Design	Intervention	Variables	Major Results/Significant Findings
BMA&LP Jay & Elliott (1990)	N =72 parents of L or Lymph patients 3-12 years old	Repeated-measures factorial	Stress Inoculation (e.g., filmed modeling & education, self-statement training, muscle relaxation & imagery) vs. Child focused intervention (accompanying child in a multimodal condition or multimodal & Valium condition)	Observer-rated Parent Behavior (Parent Behavior Scale; PBS). State & Trait Anx (STAI). Pulse Rate. Blood Pressure. Self-reported Anx & Coping Difficulty. Self-statements (Self-Statement Inventory for Medical Procedures; SSIMP).	1. Lower state & trait anxiety, & higher positive self-statement scores were found for parents in the stress inoculation condition as compared to parents in the child-focused condition.
BMA&LP Jay et al. (1991)	N=83, 3.5-12 years old; 83 L or Lymph	Repeated-measures factorial	Multimodal, see Jay et al.(Jay, S.M., Elliott, C.H., Ozolins, M., Olson, R.A., & Pruitt, S.D. 1985) vs. Multimodal & Valium	Observer-rated behavioral distress (OSBD). Self-rated Pain and Fear (FACES 1-5). Pulse Rate.	1. Reductions in behavioral distress, pain ratings, and heart rate found for both groups. 2. Although not sig., reduction in behavioral distress was greater in the multimodal intervention vs. multimodal and Valium.
VP Dahlquist et al. (1985)	N=3, 11-13 years old; 3 Lymph or Osteosarcoma	Baseline-posttest	Multimodal (e.g., muscle relaxation, positive coping statements & positive reinforcement)	Observer-rated behavioral distress (OSBD). Parent-rated Child's Distress. Medical personnel-rated Child's Distress. Self-reported Distress (Scale 1-7).	1. 46% - 68% reduction in observer rated distress. 2. 9% - 22% reduction in medical personnel rated distress. 3. 0% - 67 % reduction in self-rated distress.
VP Manne et al. (1990)	N=23, 3-9 years old; 1 Neurobl, 13 L, 5 Embryonic rhabdomyosarcoma 1 Wilm's tumor, 1 Congenital immune disorder, 1 Eosinophiloma	Repeated-measures factorial	Multimodal involves both the child and the parent (e.g. distraction, paced breathing, and reinforcement for the child, and instruction in behavioral coaching for the parents) vs. Attention control	Observer-rated Procedural Distress (modified PBRs). Self-reported Pain & Fear (FACES). Parents' self-report of their Anx and their child's Pain. Nurses report of Needle Insertion Difficulty, his/her Own Distress, and the Child's Distress (5 point scales).	1. Decreased observed child's distress, parents' rating of child's pain, and parents' own anxiety only in the intervention group. 2. Intervention was associated with reductions of physical restraint.
VP Manne et al. (1994)	N=35, 3-8 years old; 19 AL, 5 Neurobl, 2 Wilm's tumor, 2 Glioma, 2 Kostman's syndrome, 1 Embryonic Rhabdomyosarcoma, 1 HD, 2 Wiscott Aldrich syndrome, 1 Hepatoblastoma	Repeated-measures factorial	Multimodal, see Manne et al.(Manne, S.L., Redd, W.H., Jacobsen, P.B., Gorfinkle K, Schorr O, & Rapkin B. 1990) & IV Nurses Coaching of parents to coach the child vs. Multimodal without Nurses Coaching	Observer-rated Child's Distress (e.g., pain or fear, procedure noncompliance), Child's Coping (e.g., non-procedure-related activity), and Parents' Coping (scale developed by authors based in part on CAMPTIS). Child's Use of Intervention Procedure. Parents' Coaching Behaviors and Parents' Praise. Nurses Coaching of Parent, Coaching of Child, and Praise.	1. Most parents and children used the intervention, and intervention use was associated with less child crying. 2. Specific directions by parents predicted the child's use of the intervention more strongly than global encouragement. 3. Nurses in the no coach condition were instructed to not coach parents, but parents in the no nurse coaching condition were coached by the nurses. 4. Nurses in both conditions were instructed not to coach children directly, but most did. 5. Children who were older and less distressed during procedure preparation were more likely to accept the intervention.

Medical Procedure /Authors	Sample	Research Design	Intervention	Variables	Major Results/Significant Findings
Chemotherapy Zeltzer, Kellerman, Ellenberg, & Dash (1983)	N=8 (3 additional participants rejected hypnosis & 1 participant didn't display chemotherapy-related symptoms), 10-20 years old; 4 HD, 2 ANLL, 1 Neurobl, 1 Ependymoma 1 Astrocytoma, 1 Ovarian carcinoma, 1 Brain stem astrocytoma, & 1 Osteogenic sarcoma	Baseline-posttest	Hypnosis (e.g., symptom specific suggestions during imagery for "notice the cool, clean air and taste the snow", and posthypnotic suggestions for relaxation and reentering a hypnotic state)	Self-reported frequency, duration, and intensity of emesis episode (scale 1-10). Trait Anx (STAI). Self-esteem (RSES). Health Locus of Control (HLOC).Illness Impact (II). Observer-rated (parents & nurses) frequency, duration, and intensity of emesis episode (scale 1-10).	1. Reductions in self-reported frequency on emesis ranging from 19%-100%. 2. Duration of emesis was reduced in six of the eight participants. 3. Reductions in trait Anx 6 months post-intervention. 4. Four of the five participants who had taken an antiemetic (chlorpromazine) discontinued its use.
Chemotherapy Zeltzer, LeBaron & Zeltzer (1984)	N=19, 6-17 years old; 11 L, 3 Lymph, 5 Bone Tumors	Repeated-Measures Factorial	Hypnosis (e.g., imagery, and posthypnotic suggestion to have a good appetite) vs. Supportive Counseling (e.g. distraction, deep breathing, and instruction to avoid thinking about his/her symptoms)	Self-reported Nausea, Vomiting, and extent of Bother caused by these symptoms (scale of 0-10). Parent-rated Child's Nausea, Vomiting, and Bother (scale 0-10). Hypnotizability (SHCSC).	1. Reductions in nausea, vomiting, and bother in both groups. No differences between intervention groups. 2. Hypnotizability was not related to symptom reduction in the hypnosis group.
Chemotherapy LeBaron & Zeltzer (1984)	N= 8, 10-17 years old; 5 L, 1 Lymph, 2 Bone tumors	Baseline-posttest	Hypnosis, Distraction (e.g., playing games), Relaxation, Reassurance & Information	Self-reported Nausea, Vomiting, and extent of Bother and Disruption of Activities caused by these symptoms (scale of 0-10). Parent-rated Child's Nausea, Vomiting, Bother, and Disruption of Actives (scale 0-10).	1. Reductions in nausea, vomiting, bother, and disruption of activities.
Chemotherapy Cotanch et al. (1985)	N=12, 10-18 years old; 8 Sarcomas, 1 Testicular Seminoma, 1 Neurobl, 2 ALL	Repeated-Measures Factorial	Hypnosis (e.g., imagery, fantasy, suggestions for safety, feeling thirst) vs. Standard Procedure Control Group (e.g., comfort, deep breathing, and distraction)	Self-reported Nausea & Vomiting (e.g., severity 0-100). Nurse-rated Nausea & Vomiting (e.g., duration, amount of vomiting). Psychophysical Scaling of Child's Severity & Intensity of Nausea (adapted Pain Perception Profile, PPP). Oral Intake.	1. Reduction in frequency, amount, severity and duration of vomiting in the hypnosis group. 2. Children in the hypnosis group reported being "less bothered" by chemotherapy. 3. Children in the hypnosis group tended (p = .071) to have greater oral intake 24 hours post-infusion.

Medical Procedure /Authors	Sample	Research Design	Intervention	Variables	Major Results/Significant Findings
Chemotherapy Kolko & Rickard-Figueroa (1985)	N=3, 11-17 years old; 3 ALL	Combined Multiple- baseline & ABAB withdrawal	Distraction (i.e. played video games)	Self-reported Anticipatory Distress (24 hr. Symptom. Checklist e.g., bit nails, insomnia). Self-reported & Observer-rated distress due to side-effects (e.g., distress, scale 0-4 due to dizziness, nausea). State Anx (STAI). Observer-rated distress (modified PBRs).	1. Reductions in anticipatory symptoms and state anxiety with video game use. The effect was replicated on the withdrawal and reintroduction of video game use. 2. Reductions in observer-rated distress with video game use. The effect was replicated on the withdrawal and reintroduction of video game use. 3. The introduction and withdrawal of video games produced changes (reductions and exacerbations) in postchemotherapy side effects.
Chemotherapy Redd et al (1987)	Study 1: N=26, 9-20 years old; 7L, 6 Lymph, 11 Sarcoma, 1 Teratoma, 1 Brain Tumor Study 2: N=15 of initial 26, 9-18 years old; 6 L, 4 Lymph, 1 Brain Tumor, 4 Sarcoma	Study 1: Repeated- Measures Factorial Study 2: Combined ABAB withdrawal & Repeated Measures	Distraction (played video games) vs. Control (no attempts to limit or change children's behavior)	Study 1: Self-reported Nausea (no nausea to nausea as bad as it could be). Observer - rated Nausea-related Behaviors. Study 2: Self-reported Nausea (same format as Study 1). Self-reported Anx (no anxiety to anxiety as bad as it could be). Pulse Rate. Blood Pressure.	Study 1: 1. Reductions in nausea for the intervention group. 69% of the children who played video games reported a sizable decrease in nausea vs. 23% of the children in the control group reported a similar decrease. Study 2: 1. The introduction and withdrawal of the opportunity to play video games produced changes (reduction and exacerbation, respectively) in nausea. 2. In one instance (of nine comparisons) a physiological measure changed significantly, video game playing was associated with an increase in physiological arousal (i.e. increase in systolic blood pressure). 3. Contrast groups (based on the use of antimetics) indicated that the group receiving antimetics reported greater changes in nausea with the withdrawal and introduction of video games.
Chemotherapy Zeltzer et al. (1991)	N=54, 5-17 years old; 20 L, 34 Solid Tumor	Repeated- measures factorial	Hypnosis (e.g., fantasy, suggestions for feeling good, security, feeling hungry and wanting to socialize) vs. Active Cognitive Distraction /Relaxation (e.g. counting dots on a father's tie, deep breathing), vs. Equal amount of therapist attention (control group)	Self-reported Anticipatory Nausea & Vomiting (yes or no). Self-reported and Parent-reported Postchemotherapy Side-Effects (e.g., severity in terms of duration of nausea and vomiting on a scale from 0 - 10). Distress (indicated by how much chemotherapy bothered the child. Functional Disfunction (e.g., days of disruption of school and social activities).	1. Shorter duration of nausea in both intervention groups vs. the control group. 2. Shorter duration of vomiting in the hypnosis vs. control group. 3. In general, side-effects for the hypnosis group improved over time, for the active cognitive distraction/relaxation group side-effects improved slightly or stayed the same, and for the control group they got worse. 4. Functional disfunction (e.g., in school, social, eating and sleeping) was determined by emetic potential of chemotherapy and total symptom score was predicted by emetic potential and prophyllactic antimetics.

<p>Chemotherapy Jacknow et al. (1994)</p>	<p>N=20, 6-18 years old; 5 L, 8 HL, 7 Solid Tumors</p>	<p>Repeated-measures factorial</p>	<p>Hypnosis (e.g., imaginative involvement, suggestions for feeling safe and well, for turning off the vomiting-control center in the brain) & p.r.n. antiemetics vs. Equal amount of therapist attention & Standard Antiemetic Regimen (control group)</p>	<p>Self-reported Nausea (five faces), Vomiting (frequency scale 0-9). Practice of Hypnosis (for the intervention group). Antiemetic Medication Use (from medical records).</p>	<p>1. The hypnosis group used less p.r.n. medication. 2. At 1 to 2 months postdiagnosis, the hypnosis group experienced less anticipatory nausea, but no significant differences were found at 4-6 months postdiagnosis.</p>
<p>Social Reintegration Varni, Katz, Colegrove & Dolgin (1993)</p>	<p>N=64, 5-13 years old; 36 ALL, 7 HD, 2 NHL, 3 Wilim's tumor, 3 Neurobl, 4 Rhabdomyo-sarcoma, 1 Osteogenic sarcoma, 1 Ewing's sarcoma, 2 Brain tumor, 5 Other</p>	<p>Repeated-measures factorial</p>	<p>Multimodal Behavioral (e.g., modeling and cue-controlled relaxation) & Standard Intervention vs. Standard Intervention</p>	<p>Self-reported depression (CDI), anxiety (STAIC), general self-esteem (SPPC), and perceived social support (SSSC). Parent-reported behavioral and emotional problems and social competence (CBCL).</p>	<p>1. Nine months post-intervention the Behavioral Intervention group displayed fewer behavioral problems, experienced increased school competence, and reported greater social and emotional support from classmates and teachers compared to pre-intervention. No such differences were found in the Standard Intervention group.</p>

Adapted from DuHamel, K. N., Vickberg, S.M.J., & Redd, W. H. (1998). Behavioral interventions pediatric oncology. In J. Holland, W. Breitbart, P. Jacobsen, M. Lederberg, M. Loscalzo, M. J. Massie, & R. McCorkle (Eds.), *Handbook of psycho-oncology: Psychological care of the patient with cancer* (pp. 161-172). New York: Oxford.

fective for reducing venipuncture distress, an intervention package such as that developed by Manne and colleagues or an intervention such as those used with bone marrow aspiration and lumbar puncture, which also included hypnosis.

Treatment side effects can be severe with pediatric patients. In addition to pain and anxiety associated with medical procedures, patients often have problems related to treatment side effects. Aggressive treatments using multimodal therapy such as surgery, radiation, and chemotherapy can lead to a variety of aversive side effects. With several chemotherapeutic agents and radiation, patients often experience fatigue, diarrhea, hair loss, and post-treatment nausea. The most common side effects associated with cancer chemotherapy are nausea, vomiting, and dysphoria. After repeated chemotherapy treatments some patients develop anticipatory nausea, that is, they become nauseated in anticipation of treatment. Like the conditioned reflex of Pavlov's dogs (Pavlov, 1927), the patient's nausea in response to conditioned stimuli, such as the site of the clinic, can be as intense as unconditioned responses elicited by actual treatment (Redd, Andresen, & Minagawa, 1982). Although the prevalence of nausea and vomiting reported in the literature varies, up to 71.2% of children receiving chemotherapy have been reported to have nausea during chemotherapy, and up to 76% of children have been reported to have anticipatory nausea (Dolgin, Katz, McGinty, & Siegel, 1985; Hockenberry-Eaton & Benner, 1990; Jacknow, Tschann, Link, & Boyce, 1994; Zeltzer, Dolgin, LeBaron, & LeBaron, 1991). In addition, up to 43% of children have been reported to have anticipatory vomiting (Zeltzer, Dolgin, S. LeBaron, & C. LeBaron, 1991). Although antiemetic medications have had some success in treating nausea and vomiting during chemotherapy, they are not effective for anticipatory symptoms. Further, antiemetic use can result in multiple side effects such as headache and extrapyramidal reactions (Jacknow, Tschann, Link, & Boyce, 1994). In young children, severe nausea and vomiting can also lead to dehydration, electrolyte imbalance, and weight loss (Hockenberry-Eaton & Benner, 1990). Compounding the issues surrounding side effects and quality of life, some patients' treatment can be so aversive that they become noncompliant with treatment regimes, leading to increased morbidity and mortality (Burish, Carey, Krozely, & Greco, 1987).

Hypnosis and/or distraction for control of nausea and vomiting has received considerable clinical and research attention. Most of the studies have focused on adult cancer patients. Behavioral methods studied with children have been generally limited to hypnosis and/or distraction and most involve a single participant, not comparisons of intervention groups (Carey & Burish, 1988). (Systematic studies of behavioral interventions for treatment side effects with pediatric oncology patients are reviewed in Table 46.3).

In a group of 10- to 17-year-old patients, LeBaron and Zeltzer (1984) assessed the efficacy of a behavioral intervention for reducing nausea and vomiting during chemotherapy. The behavioral intervention package included directing the child's attention away from thoughts about the chemotherapy by playing games, focusing on a object in the room, telling stories, and using muscle relaxation. Reassurance and information were also

provided. The results indicated that after the intervention, there were reductions in children's disruption of activities, nausea, vomiting, and the difficulties these symptoms caused. However, the lack of a control group makes the benefits of the behavioral strategies over nonspecific factors, such as reassurance or simply the passage of time, difficult to evaluate. Despite this study limitation, this classic study provided preliminary results suggesting that a behavioral intervention package was effective in reducing treatment side effects.

Cognitive/attentional distraction through video game playing to control anticipatory nausea in a group of 9- to 20-year-old cancer patients was assessed in two studies conducted by Redd and colleagues (Redd et al., 1987). In both studies there was a marked (up to 69%) reduction in nausea. In a subsequent study Zeltzer et al. (1991) investigated the relative efficacy of a hypnosis intervention as compared to a nonhypnotic distraction/relaxation intervention, and a standard control group in children 5 to 17 years of age. Their results suggested that hypnosis was superior to the nonhypnotic distraction/relaxation intervention in reducing chemotherapy side effects.

A recent study by Jacknow and colleagues (1994) evaluated the efficacy of hypnosis to control nausea and antiemetics in a group of 6- to 18-year-old newly diagnosed cancer patients. Not only did the children in the hypnosis group experience less anticipatory nausea than those in the standard care comparison group, they also used less antiemetic medication that was prescribed to be taken as they felt it was needed. The results also indicated the need to maintain active patient intervention throughout the child's treatment course. Beneficial effects were observed at 1 and 2 month post hypnotic intervention, but not at 6 months.

It is difficult to draw clear conclusions regarding the relative efficacy of hypnosis versus distraction in the control of chemotherapy side effects in children. The problem is that the procedures (i.e., counting the dots on their father's tie and completing arithmetic problems) used by Zeltzer and colleagues (1991) may be far less effective for distracting children than the video games procedures used by Redd and colleagues (1987). Further research is needed to define the parameters of hypnosis, cognitive/attention distraction, and relaxation training in the control of treatment side effects.

Post-treatment adjustment has received increased attention during the last five years. Indeed, in addition to coping with the distress associated with medical procedures and treatment side effects, children with cancer must confront other challenges, such as re-entering the school environment after diagnosis. Returning to school and resuming normal interactions with peers is an important process for the child who has been diagnosed with cancer. Based on the notion that an early return to school can "normalize" the child's life in the midst of coping with cancer, thus promoting optimal rehabilitation, several authors have recommended re-entry into the school environment as soon as possible for pediatric cancer patients (Deasy-Spinetta & Spinetta, 1980; Katz, Dolgin, & Varni, 1990; Lansky, Cairns, & Zwartjes, 1983). In addition to normalizing life and encouraging rehabilitation, a prompt return to school can provide opportunities for social support (from peers and teachers)

and exposure to socialization processes typically experienced by school-aged children. Such access to social support and socialization experiences may be crucial for proper adjustment. Indeed, positive peer relationships and perceived social support are associated with several positive corollaries, such as increased stress resistance, improved academic achievement, decreased levels of behavioral problems, and pro-social behaviors in general (Green, Forehand, Beck, & Vosk, 1980; Varni, Katz, Colegrove, & Dolgin, 1993).

Clinical researchers have only recently begun to explore the use of multimodal interventions to promote post-treatment adjustment. Varni and his colleagues (1993) assessed the relative efficacy of a social skills training intervention as compared to a standard school reintegration program with 5 to 13 year old children with cancer. Both groups received the Standard Intervention, which included: (1) education for patients, parents, school and medical staff emphasizing the importance of an early return to school; (2) school conferences and classroom presentations intended to demystify the cancer experience for both teachers and classmates; and (3) regular follow-ups with patients, parents, teachers, classmates, and medical staff. The Behavioral Intervention Group also received the multimodal social skills training (e.g., modeling and cue-controlled relaxation), while the Standard Care Intervention Group spent equal time in individual play interaction with the research assistant. Results indicate that nine months after completing the intervention, pediatric cancer patients in the Behavioral Intervention condition experienced fewer behavioral problems and increased school competence (as reported by their parents). In addition, these children reported experiencing greater emotional and social support from their classmates and teachers after completing the multimodal intervention. Children receiving standard care did not experience these positive changes. Results of this initial study are quite important as they indicate that behavioral techniques are useful tools for teaching social skills and that the acquisition of such skills has a positive effect on pediatric adjustment.

FUTURE DIRECTIONS

The clinical research reviewed in this chapter clearly indicates the utility of behavioral interventions to reduce the pain and suffering of cancer patients. Hypnosis, distraction, and multimodal interventions have been found to effectively reduce distress associated with medical procedures, and hypnosis and distraction were found to reduce treatment side effects. In addition, a multimodal behavioral intervention has been effectively used to improve adjustment and overall quality of life.

It is always difficult to predict future advances in clinical research. However, there are a number of important new trends. The first is the shift towards greater sophistication in research methodology. For example, the earlier studies generally lacked appropriate comparison groups, making the effect of the specific intervention as compared to nonspecific factors or time difficult to assess. More recent studies have included standard care comparison groups, in addition to two treatment groups, making examination of the mechanisms underlying treatment

effectiveness possible (e.g., comparing distraction through hypnosis with distraction through focusing on objects in the room). Second, there has been increased interest in training family members and other health care providers to provide behavioral interventions in the hope of adding to the benefits of interventions provided by trained professionals. Third, behavioral interventions are also being applied to new areas outside of symptom management, for example, to facilitate school reintegration. In addition, there is recent work involving the application of both behavioral interventions and cognitive remediation for neuropsychological (attention difficulties) deficits (Butler, 1996).

There also are new problem areas currently being identified that may benefit from application of behavioral interventions, such as other medical procedures (e.g., bone marrow transplant; BMT), cancer related fatigue, and symptoms of posttraumatic stress disorder (PTSD), such as night terrors. There has been research documenting that BMT is a stressful experience for oncology patients and their families, and that BMT may be associated with PTSD (Lee, Cohen, Stuber, & Nader, 1994; Smith, Redd, DuHamel, Vickberg, & Ricketts, 1999; Stuber, Nader, Yasuda, Pynoos, & Cohen, 1991). In addition, PTSD and fatigue have been documented in adult cancer survivors (Alter et al., 1996; Piper, 1996), and behavioral interventions are being used to help adults cope with these difficulties (Piper, 1994; Shalev, Bonne, & Eth, 1996). Cancer survivors with PTSD symptoms and/or fatigue, may also benefit from behavioral intervention to reduce these difficulties; this is an area for future research.

One of the main thrusts of future work may well be the application of behavioral theory and research to prevent adjustment problems. For example, how can chemotherapy be given so as to reduce the development of aversive side effects, such as food aversions? We do not mean to suggest that behavioral interventions are a panacea for all the challenges faced by oncology patients. Nor are we suggesting that behavioral interventions be used exclusively, but rather as adjunctive treatments to other biological and psychosocial interventions. Indeed, there are limits to the application of behavioral principles, such as challenges to family adaptation. As noted by Ostroff and Steinglass (1996), there are challenges experienced by most families of children with cancer, such as the family's need to change and adjust to the different stages of the child's illness (e.g., from illness-focus during acute phase to post-treatment readjustment). These areas of potential difficulty faced by families of cancer patients are outside the realm of behavioral interventions and may be more effectively treated by family therapy interventions designed specifically to address them (Ostroff & Steinglass, 1996). In addition, there are many factors (i.e., cultural influences) that may contribute to the patient's and their families adjustment, or lack thereof, which are also outside the realm of behavioral principles.

Given the limits in theory and application, it is clear that behavioral researchers and clinicians have made a significant contribution to our understanding of patients' responses to cancer diagnosis, treatment, and rehabilitation, and to the design of effective methods for reducing pediatric patients' dis-

tress. The strength of the work that has been conducted leads one to expect important advances in the future.

Frontiers in the Behavioral Epidemiology of HIV/STDs

Joseph A. Catania

Diane Binson

M. Margaret Dolcini

Judith Tedlie Moskowitz

Ariane van der Straten

University of California, San Francisco

This chapter discusses the field of HIV/STD behavioral epidemiology with a special emphasis on heterosexual adults.¹ We have limited our review of the extensive HIV-behavioral epidemiological literature to include an in-depth examination of the following topic areas considered pivotal to understanding the spread of HIV/STDs. The topic areas, including sexual mixing and networks, mapping risk behavior, and the conceptualization of the several dimensions related to sexual relationships, parallel the following general aims (listed later) of the field (Catania & Binson, 1992; Catania et al., 1993; Dolcini, Coates, Catania, Kegeles, & Hauck, 1995): (a) prevention behaviors and beliefs (mapping studies), and assessment of how these change over time; (b) identification of social vectors related to the spread and prevention of HIV/STDs (e.g., how people within a particular social stratum sexually interact with other social strata); and (c) development of explanatory models for understanding onset, maintenance, and change in the patterns of behavior related to HIV/STD transmission. In short, the primary goals of behavioral epidemiology are to predict po-

tential routes of future disease spread, target population segments for prevention, and generate an understanding of the causes of safe and unsafe behaviors.

Prior work on the first two aims includes research on the geography of disease spread (e.g., Golub, Gorr, & Gould, 1993; Wallace, 1991, 1994), studies on the risk behaviors of travelers (e.g., Choi, Catania, Coates, Hyung, & Hearst, 1992), research on sexual networks (e.g., Service & Blower, 1995), and at the population level, investigations of the size and characteristics of at risk populations with respect to HIV testing, condom use, and risk practices (e.g., Catania, Binson, et al., 1995; Catania, Stone, Binson, & Dolcini, 1995).

There have been a number of national and urban surveys on aspects of the behavioral epidemiology of HIV infection for representative samples of adults (e.g., Catania, Coates, & Kegeles, 1994; Catania, Coates, Kegeles, Ekstrand, et al., 1989; Catania et al., 1993; Choi, Catania, & Dolcini, 1994; Dolcini et al., 1993; Grinstead, Faigles, Binson, & Eversley, 1993; Hingson et al., 1989; Kanouse et al., 1991; Keeter & Bradford, 1988; Kost & Forrest, 1992; Laumann, Gagnon, Michael, & Michaels, 1994; Leigh, Temple, & Trocki, 1993; Marín, Gomez, & Hearst, 1993; Peterson, Catania, Dolcini, & Faigles, 1993; Sabogal, Pierce, Pollack,

¹To better understand how HIV may spread, the sociobehavioral pathways that other STDs follow must also be recognized. Therefore, it is of primary importance to consider other STDs when investigating the routes of HIV infection.

Faigeles, & Catania, 1993; Tanfer, Grady, Klepinger, & Billy, 1993). Prior surveys have sampled young and middle-aged adults, but recent work has explored the behavioral epidemiology of HIV disease among late middle-aged and elderly individuals who, since 1984, have annually comprised some 10% of the AIDS cases (Stall & Catania, 1994). Regardless of the age groups studied, the bulk of this prior work has been on mapping the distribution of risk behavior and prevention practices and examining their antecedents. Few studies have focused on issues of sexual networks and sexual mixing. Mapping and sexual mixing are two of the three central topics of this chapter.

The third section discusses the varied theoretical perspectives that guide the research that specifically examines the antecedents of risk behavior, behavior change, and maintenance of healthy sexual practice. Despite the apparent diversity of theoretical models concerning risky sexual behavior, they are, in fact, remarkably similar in terms of their focus on the assessment of the individual rather than the sexual relationship or dyad. In order to explore this critical gap in HIV behavioral-epidemiological research, the discussion is centered on the relational aspects of sexual risk behavior, and previously unpublished data on sexual roles, sexual communication, power structures, and relationship cohesion are presented.

In brief, the chapter provides an overview of the epidemiology of HIV and other STDs among heterosexual adults, discusses the topic of sexual mixing, and presents recent

research findings in this area. The second section is devoted to the presentation of recent findings on mapping HIV-related risk behaviors and prevention practices among heterosexual adults. The last section discusses a proposed model of sexual relationships, and provides data relevant to this model.

SEXUAL MIXING

Epidemiology of HIV (and Other STDs)

Intravenous drug users and gay and bisexual men continue to be the groups most affected by HIV disease (Centers for Disease Control, 1994), and there is recent evidence that the prevention gains evidenced in the 1980s among gay cohorts of that time have not translated to the younger gay cohorts (D. H. Osmond et al., 1994). It is also important to recognize that new infections among heterosexuals are growing. For some time, heterosexual spread through sexual routes appeared to be chiefly due to sexual contact with partners in other high risk groups (bisexual, IDU, transfusion recipients). However, since 1992, the number of AIDS cases that have been attributed to heterosexual contact with a heterosexual partner not considered to be at high risk have increased to either match or even surpass the number of heterosexuals infected by high risk partners (see Fig. 47.1).

The following demographic breakdown describes heterosexual groups that currently appear to be at the greatest risk for HIV/STD infection. In general, African American and Latin

FIG. 47.1. Heterosexual contact (IDU, non-IDU, Blood, Pattern II) AIDS cases 1989-1994, ages 13 and older. Source of data: Centers for Disease Control.

women show the highest rates of new HIV/STD infections (Centers for Disease Control, 1994). However, both the AIDS data and recent behavior surveys now indicate that young adults are the largest and probably highest risk group. Young adults are in a developmental stage associated with extensive dating. Consequently, they are more likely to engage in increased sexual activity with a wider range of partners than at any other point in their adult life cycle (Binson, Dolcini, Pollock, & Catania, 1993; Dolcini et al., 1993; Siegel et al., 1992).

Other STDs that are cofactors for HIV, and are serious problems in their own right, are highly prevalent among heterosexuals. Siegel et al. (1992) reported biological data for a probability sample of White, African American, and Hispanic unmarried heterosexuals from age 20 to 44 indicating that, among women, 35% of Whites, 39% of Hispanics, and 55% of African Americans were positive for genital herpes; for men, the estimates are 26%, 20%, and 32%, respectively. The rate of Chlamydia infection has (per 100,000) doubled from 1987 to 1991 (from 91.4 to 197.5) (Webster, Greenspan, Nakashima, & Johnson, 1993), and has been found across a wide spectrum of populations (including Whites, African Americans, urban and rural populations, and low and high education groups; Ferris & Litaker, 1993; A. H. Herold et al., 1993; Holmes et al., 1993; Leka, Patrick, & Benenson, 1990). These alarming statistics make us keenly aware that there are large and active pathways for HIV to travel throughout segments of the heterosexual population.

Sexual Mixing

The degree to which HIV will spread along the biological pathways created by other STDs will depend on the extent of sexual mixing (in addition to relevant biological factors). Sexual mixing, which has been found to have a central influence on HIV/STD transmission rates (Anderson, 1991; Garnett & Anderson, 1993), is defined as the extent to which people engage in sexual activities with sexual partners from other sexual networks (dissortative mixing), and the extent to which they interact sexually with partners from their own network (assortative mixing; Gupta, Anderson, & May, 1989). Sexual networks are keys to understanding sexual mixing (Laumann et al., 1994).

The basic idea of a sexual network is quite simple. If, for example, Person A is having sex with Person C, and Person B is having sex with Person A, then Persons A, B, and C are all members of the same sexual network. STDs are spread, according to current perspectives, when members of a "core group" transmit infection to other network members. A core group is defined as one that, by virtue of its behavior, is disproportionately responsible for the spread of an STD in a given community (e.g., Aral & Holmes, 1984; Garnett & Anderson, 1993; Potterat, 1992). For instance, commercial sex workers in some communities might be conceptualized as a core group.

However, an emphasis on core groups as a key concept is problematic for the following reasons. First, the concept of a core group places a few vaguely defined social groups at the center of HIV/STD spread. Although this approach may have had utility when dealing with STDs that are concentrated in

distinct geographic or social clusterings of the population, it does not provide much guidance for understanding the social pathways that lead to STD/HIV spread across diverse social segments. The core group concept is particularly limited when dealing with highly prevalent STDs with a wide geographic and social distribution (e.g., HSV-2 and Chlamydia; H. Miller, personal communication, 1995; N. Padian, personal communication, 1995). With a highly prevalent STD, a large number of sexual networks may contribute to disease spread in relation to the degree of infection in each network and the extent of sexual mixing within and between networks. Thus, rather than simply specifying core groups, it is possible to go a step further within network theory and specify a range of network contributions to disease spread.

A modification to the core group concept is proposed that assumes the degree of infection often varies across sexual networks. In other words, some networks would have a high prevalence of an STD(s), others moderate levels, whereas others may have no STDs whatsoever. STD spread within a network may produce local or "small" epidemics, but community, regional, or national spread will depend in large part on the extent to which other networks become infected, and the amount of contact that takes place between networks. In conceptualizing the network population that mixes across sexual networks, the term "heavy mixer" (disassortative mixers) has been proposed to describe people who sexually mix across multiple networks, "light mixers" who only rarely stray outside their own network, and "nonmixers" who stay completely within their own network.

Heavy mixers, as a group, may have a high prevalence of STDs, but they do not necessarily have to originate from the same sexual network or social segment. Thus, some heavy mixers may reside, for the most part, in networks with a low prevalence of STDs but through their diverse extra network contacts, they may subsequently contract an STD. That is, people who have multiple sexual partners from multiple networks are more likely to encounter a network with a high STD prevalence, to become infected, and to transport an STD back to their current "home" network (i.e., the network they interact with most frequently). In general, heavy mixers form an important link in the spread of HIV and other STDs from infected networks to non- or less infected sexual networks. For prevention purposes, it would be useful to identify the social psychological characteristics of networks with a high prevalence of STDs and of heavy mixers; these data could then be used to more effectively target particular networks and heavy mixers.

Sexual Patterns

Very few studies have been conducted that provide a broad perspective on sexual networks and mixing patterns. The research examining sexual networks has generally been based on tracing studies, which are subject to substantial bias. In the case of tracing studies, investigators begin with an infected sample from a public health STD clinic, and then attempt to trace the sexual contacts of the infected individuals, their partners, and sometimes the partners of the partners (Garnett & Anderson,

1993; Klondahl et al., 1994; Ramstedt, Giesecke, Forssman, & Granath, 1991; Woodhouse et al., 1994). Garnett and Anderson (1993) noted that the primary difficulty with tracing studies is that they contain self-selection biases related to the geographic service areas of public STD clinics, and the following additional biases: underreporting of STDs by private physicians, and the fact that those seeking care at public clinics or private practices are a nonrandom subsample of those who are infected (e.g., infected people may not seek treatment because they are asymptomatic or because the symptoms abate). Therefore, tracing studies do not provide a representative picture of sexual networks or patterns of mixing in the general population. To adequately describe segments of the population that mix across different social strata, a representative sample of the community, under investigation for HIV/STD spread, is mandatory.

Although, the mate selection research may provide some guides to the study of sexual networks, this literature has generally limited its attention to the selection of marital or primary sexual partners (e.g., see reviews by Buss, 1988; Buss & Schmitt, 1993; Feingold, 1992; Perper, 1989). Patterns of selection may be different for primary and secondary partners (e.g., Buss & Schmitt, 1993). Empirical data supporting this position found that the social class of infected respondents was predictive of choice of primary partner, but not of secondary partners (Ramstedt et al., 1991). Although the mate selection literature does not provide an exhaustive guide to the types of patterns that might be expected among people with multiple sexual partners, this work does provide a starting point. Investigators of friendship networks and mate selection have defined networks in terms of social characteristics (e.g., race, age, social class, education), geographic location (e.g., a city, neighborhood, a public bar), and value systems (Laumann et al., 1994; Verbrugge, 1977; Yamaguchi, 1990), and have generally found that people form primary relationships and friendships with similar others (i.e., homophily).

An investigation of sexual networks examined age and ethnic mixing by analyzing data gathered from unmarried heterosexuals who participated in the AMEN survey (AIDS in Multiethnic Neighborhoods survey; a household probability survey in San Francisco; Catania, Binson, & Stone, 1996). A mixing typology (nonmixers, light mixers, heavy mixers) was derived, the validity of this typology with respect to biological indices of genital herpes was examined, and social and psychological characteristics of people evidencing sexual mixing across different age and racial/ethnic groups were identified. Heavy mixing was defined as engaging in sex with two or more partners outside one's own social stratum in the past year. Age mixing (i.e., engaging in sex with people outside your own age group) may be a particularly important element in STD transmission. For an STD to be maintained in the population it must be propagated from older generations to each new generation entering the sociosexual phase of life (typically beginning during adolescence and reaching a zenith in the 20s). In a closed social system (i.e., no STDs entering from outside the system), the STDs unique to the older group will die out with the eventual deaths of the group mem-

bers, as long as none of the members engaged in sex with younger cohorts.

Race and ethnicity are also important network-mixing features because they provide barriers to forming relationships. Different racial and ethnic groups may be separated by geography, language, social class, social customs, and prejudice. When racial/ethnic barriers are strong, it would be expected that sexual mixing and, to some degree, particular STDs would be well contained. However, as these barriers break down and more sexual mixing occurs, it could then be assumed that there would be a greater increase in the transmission of STDs across racial/ethnic lines. What is particularly unclear, however, is the extent to which members of different racial/ethnic groups mix with other ethnic/racial groups.

It was found that heavy age and ethnic mixers were significantly more likely than light/nonmixers to evidence genital herpes, even after controlling for numbers of sexual partners, race, age, gender, education, neighborhood of residence. Thus, mixing accounts for variation in STD prevalence above that accounted for by the usual set of STD risk factors. In addition, ethnic and age mixing reflect different mixing patterns (i.e., heavy age mixers are not redundant with heavy ethnic mixers). In general, light and heavy mixers tended to be similar with respect to condom use, attitudes toward condoms, perceived risk for HIV, and in misconceptions concerning routes of HIV transmission. Thus, heavy mixers are not cognizant, or at least not concerned, about their greater risk for HIV/STDs. Also, people having a history of IDU and incarceration were more likely to be heavy age mixers, but not heavy ethnic mixers. Thus, heavy age and ethnic mixing comprise individuals from the same types of high risk social groups. With regard to age mixing, the IDU-jail findings have important targeting and epidemiological implications. IDUs and incarcerated people are easier to target because they often come into contact with social institutions (corrections officers, the police, methadone treatment centers). Epidemiologically, both populations tend to have high levels of HIV and other STDs, and therefore are major conduits for the spread of these diseases to other social strata.

Originally, it was hypothesized that male heavy mixers would be more likely than female heavy mixers to be represented among those with a history of incarceration or drug use, but the study was unable to find any gender differences with respect to age mixing. Significant variation in ethnic mixing was exclusively related to the group of individuals who endorsed the "other" ethnic category (i.e., comprised of Asians, Pacific Islanders, American Indians, and others). Hispanics and African Americans relative to Whites (reference group) did not contribute significantly to this pool of heavy mixers. Apparently, members of the "other" ethnic groups have greater social license to interact sexually with partners from Hispanic, White, or African American groups, whereas the latter three groups seem less willing to engage in interracial sex. Lastly, mixing patterns did not yield substantial variations by gender. These latter results seem somewhat atypical when compared to other urban centers throughout the United States, and may reflect sexual mixing norms unique to San Francisco.

Mixing By City Size and Demographic Group

A recent survey has examined sexual network and mixing issues in a national probability sample of heterosexual adults from age 18 to 49 (Laumann et al., 1994). This data set has been analyzed using our mixing typology to focus on race (restricted to White, African American, Hispanic), which is the most reliably reported variable compared to other common demographics (e.g., partner's income, education, religion). Because the spread of HIV/STDs beyond current high risk groups may be primarily driven by people who have unprotected sex with multiple sexual partners, the analysis was constrained to people with two or more sexual partners. Numerous studies have indicated that having even two partners in the past year will increase the odds of contracting STDs. Furthermore, the bulk of HIV/STD risk factors (e.g., unprotected sex with multiple sexual partners) and AIDS/STD cases occur among young adults, minority populations, and in major urban areas.

The prevalence of heavy (race) mixing among respondents with multiple sexual partners in the past year was highest for the largest urban centers (18%), and decreased with city size (medium cities (12%), suburbs of medium cities (9%), and small cities/rural areas (10%). The 18% figure for all large size cities is somewhat lower than that observed in San Francisco. The relatively high number of unmarried people with multiple sexual partners (25%) from San Francisco reflects perhaps a greater diversity in racial groups or an acceptance of cross-race dating that would be more typical of a liberal urban setting such as San Francisco.

With regard to gender, race, and age group, the national data indicate that for respondents with multiple sexual partners, women are more likely than men to be heavy mixers (14% vs. 11%, $p < .05$)² that Hispanic males (59% vs. 17% African Americans, 5% Whites, $p < .05$), and females (33% vs. 4% African Americans, 15% Whites, $p < .05$) are more likely than other males or females to be heavy mixers, with African American males and White females reporting moderate levels of heavy mixing. These patterns vary somewhat by age group. Young adult (age 18–29) Hispanic males and females report the most heavy mixing (79% and 36%, respectively), with moderate levels reported by African American males and White females (23% and 20%, respectively). The overall pattern is similar for those in their 30s, with missing cells making other age comparisons by race and gender impractical. However, the overall age pattern reveals a decline of heavy mixing related to an increase in age across gender (e.g., 19%, 10%, and 10%, respectively, for female respondents age 18–29, 30–39, 40–49, $p < .05$; and 12%, 11%, and 8%, respectively, for male respondents age 18–29, 30–39, 40–49, $p < .05$). In both gender groups, there were insufficient numbers to compute figures for those from age 50 to 59. Apparently, norms for age-appropriate partners influence the age mixing patterns of both men and women.

In brief, an analysis of the Laumann et al. national data in conjunction with the AMEN study's San Francisco data indicated that people in large urban centers evidence the greatest degree of sexual mixing. This observation may vary somewhat

for different age, gender, and race groups. The mixing data indicate some interesting patterns with regard to race and gender that need to be further explored, but the present data suggest that the cross-racial spread of HIV/STDs may be propagated across social groups to a larger extent by Hispanic males and White females, particularly in large urban settings. This does not preclude spread within racial groups. For instance, among African Americans there may be considerable within-group transmission of STDs and HIV, and indeed prevalence levels of AIDS and STDs have been found to be relatively high among young adult African Americans. Lastly, although the heavy mixers analyses defines mixing as "out group" sexual contacts based on demographic characteristics, in fact, some of these "out group" sexual contacts may reside exclusively within one's own network. It is not possible to separate assortative from disassortative mixing; a full network tracing study would ultimately be needed to accomplish this task.

MAPPING AT RISK POPULATIONS OVER TIME

Although it is important to study the social and behavioral dynamics of sexual networks and mixing, it is also important to describe the various segments of the heterosexual population that are at risk for HIV, estimate the size of these populations, and investigate the population dynamics of at risk groups. One issue that has not been extensively investigated, is how rapidly people move into or out of the at risk population over time. The relevance of this turnover may depend on the following factors: the degree of infectivity and susceptibility to infection associated with a particular pathogen, size of the sexual networks, degree of mixing, number of contacts, and type of sexual contacts. If an infectious agent is highly contagious (e.g., an STD with a high probability of transmission on any given sexual encounter) and the population of at risk people is turning over rapidly, then many people might be expected to become infected over a very short period of time. Similarly, a pathogen with a low rate of transmission that enters a population with a low turnover rate (i.e., at risk people stay at risk for long periods of time) may also lead, over a longer time span, to a widely spread disease. Some STDs have low rates of partner-partner transmission, particularly for penis-in-vagina sexual activity.³ In order to more fully understand the ways these infections may spread, more must be known about the disbursement of sexual net-

³Although some reports have obtained low HIV infectivity rates for vaginal intercourse, there is considerable variability in rates both within and across studies (de Vincenzi, 1994; Haverkos & Battjes, 1992; Jacquez, Koopman, Simon, & Longini, 1994; Padian, Shiboski, & Jewell, 1991; Phillips & Johnson, 1992). Heterosexual transmission of HIV has occurred after only a few sexual contacts and has failed to occur after hundreds of contacts (Auerbach, Wypijewska, & Brodie, 1994) and per contact female-to-male infectivity rates across studies have ranged from .0001 to .06 (Jacquez et al., 1994). Recent work sheds light on these anomalies in indicating that infectivity may vary with stage of HIV disease progression (Jacquez et al., 1994). Infectivity is high following initial infection, reduces dramatically during the asymptomatic period, and then rebounds during the symptomatic stage. Thus, average infectivity rates may not be meaningful.

²All statistical tests are based on chi-square analyses.

works across different sociogeographic areas (e.g., neighborhoods, urban centers, inter-city).

Recent Mapping Data: National AIDS Behavioral Survey

Although ideally it would be useful to conduct mapping studies in conjunction with information obtained on sexual networks, at the present time such data are not available. Thus, mapping work has proceeded on the more general level, and has largely consisted of examining large population segments and variations in prevention practices, along with risk factors in various subsegments. In recent attempts to map changes in HIV/STD-relevant risk factors, condom use, and HIV antibody testing for a national probability sample of heterosexual adults, no appreciable reduction was found, over an approximate 1-year span, in the prevalence of HIV-related sexual risk factors nationally or in major urban centers (Catania et al., 1995). However, this seemingly stable population is actually very dynamic in that the annual turnover rate is approximately 38% for the segment of the high risk population that has multiple sexual partners. Thus, over a 1-year period, 38% of the at risk population moves to a no risk status, whereas another 38% of previously no risk people acquire some level of risk for HIV or other STDs. Movement into and out of the "at risk pool" may be facilitated by a host of factors, including such things as changes in marital/relationship status, partner availability, illness, and concerns about HIV/STDs. Although the process of partnering through legal marriage or cohabitation insures some degree of risk reduction, this reduction may at times be illusory. It has actually been found that heterosexuals with a history of risk factors for HIV seldom obtain testing prior to cohabiting or marriage, and do not regularly use condoms following establishment of the relationship (Catania, Coates, & Kegeles, 1996). Further, married people reporting extramarital sexual partners are typically the least likely to use condoms or obtain HIV testing (Choi et al., 1994).

CURRENT MODELS OF HIV/STD PREVENTION PRACTICES

The third major topic area in behavioral epidemiology concerns research on the antecedents of risk behaviors, and behavior change and maintenance. An enormous amount of research focusing on the antecedents of HIV-related risk behaviors and prevention practices has been conducted on a wide variety of populations. Guiding this work in the sexual area are a number of models and theoretical formulations, including Cognitive Social Learning Theory (Bandura, 1986), Script Theory (Gagnon, 1990; Miller, Bettencourt, DeBro, & Hoffman, 1993), Self-efficacy models (Mahoney, Thombs, & Ford, 1995), Theory of Reasoned Action (Terry, Gallois, & McCamish, 1993), Health Belief Model (Mahoney et al., 1995), Perceived Risk models (Weinstein, 1989), Protection Motivation Theory (e.g., Black, Stanton, Whitehead, & Galbraith, 1993), Stage Models (Bowen & Trotter, 1995; Boyer & Kegeles, 1991; Breakwell, Millward & Fife-Schaw, 1994; Catania, Coates, Kegeles, et al., 1989; Catania, Coates, & Kegeles, 1996; Catania, Kegeles, & Coates,

1990; J. D. Fisher, W. A. Fisher, Williams, & Malloy, 1994; Grimley, Prochaska, Velicer, & Prochaska, 1995; Grimley, Riley, Bellis, & Prochaska, 1993; Kowalewski, Longshore, & Anglin, 1994; Malow, Corrigan, Cunningham, West, & Pena, 1993; Prochaska, Redding, Harlow, Rossi, & Velicer, 1994), Interpersonal Communication Models (Cupach & Metts, 1991; Edgar, Hammond, & Freimuth, 1989; Freimuth, Hammond, Edgar, McDonald, & Fink, 1992), and a synthesis of these models/theories with concepts from developmental psychology (Boyer & Kegeles, 1991; Catania, Coates, Kegeles, et al., 1989; Catania et al., 1990; Catania, Coates, & Kegeles, 1994), diffusion theory (Rogers, 1982), social network theory (Dolcini et al., 1995), gender-related social role models (Amaro, 1995), social support and help-seeking models (Boyer & Kegeles, 1991; Breakwell et al., 1994; Catania, Coates, Kegeles, et al., 1989; Catania et al., 1990; Catania, Coates, & Kegeles, 1996; Kowalewski et al., 1994; Malow et al., 1993), and stress and coping models (Folkman, Chesney, Pollack, & Phillips, 1992).

In the tradition of American psychology and sociology, there is considerable emphasis placed on the effects of cognitions and social norms related to AIDS-relevant sexual behaviors. Some perspectives focus on a small select set of beliefs, norms, and behaviors (e.g., TRA, HBM, SEM), and are concerned with the individual. This focus on individuals may be more appropriate for understanding the health risks associated with solitary activities like cigarette smoking and alcohol consumption rather than interpersonal sexual behavior. In addition, many models do not address behavior change processes and, in fact, some cases incorrectly describe sexual behavior change as an instantaneous, all-or-none phenomenon. However, a number of models or theories of sexual health either explicitly (e.g., stage models; Boyer & Kegeles, 1991; Catania, Coates, Kegeles, et al., 1989; Catania et al., 1990; Catania, Coates, & Kegeles, 1996; Prochaska et al., 1994) or implicitly⁴ include consideration of change processes in the form of stages that divide the process into meaningful units. Stage models of change are heuristic in value and have a long history of utility in developmental psychology and sociology. Change processes are important to consider at both the individual and dyadic levels, because changes in sexual behavior typically require two people, with possibly different expectations and beliefs, to cooperate in making these changes. These stages may be investigated individually (e.g., Breakwell et al., 1994) or as multistage models (e.g., Catania, Coates, & Kegeles, 1996). Stage models are most useful when there is a normative or modal pattern of change (e.g., Catania et al., 1990; Freimuth et al., 1992) that, in turn, aids in delineating individuals or couples who deviate from this pattern.

In an effort to overcome the limitations of any single model or theory attempting to understand sexual behavior, a number of models have been based on heuristic amalgamations derived from a combination of existing theoretical perspectives. For instance, the AIDS Risk Reduction Model combines aspects of

⁴For example, although cognitive social learning theory does not explicitly make use of stage concepts, it can be implied from assertions, such as Bandura's (1994) comment, that commitment to behavior change almost uniformly precedes adoption of the behavior.

perceived risk models, attribution theory, self-efficacy models, cost-benefit analysis, social support and help seeking models, interpersonal negotiation models, and developmentally based stage theory to aid in understanding the process of behavior change in the sexual context (Catania, Binson, & Stone, 1996; Catania, Coates, Kegeles, et al., 1989; Catania et al., 1990, 1991; Catania, Coates, Golden, et al., 1994; Catania, Coates, & Kegeles, 1994). The unique aspect of this model is its movement from an initial consideration of the individual to consideration of the sexual dyad, all set within the broader social psychological context of support networks and reference group norms. Other approaches to understanding sexual health are being developed (J. D. Fisher et al., 1994), but the utility of these models over prior models remains to be demonstrated. Some models contain conceptual gaps. For instance, the Transtheoretical Model (Grimley et al., 1993; 1995; Prochaska et al., 1994) hypothesizes that the change process begins with problem recognition, but neglects to mention the causal attributions that may dictate the type of preventive behavior individuals may choose (e.g., believing one is at risk for HIV due to mosquito bites might lead to purchasing mosquito repellent rather than condoms). Furthermore, the Transtheoretical Model emphasizes interpersonal control issues, but is somewhat vague on other interpersonal issues that are relevant in the sexual context, such as interpersonal negotiation skills and coping with a partner's rejection (Boyer & Kegeles, 1991; Catania, Coates, & Kegeles, 1994; J. D. Fisher et al., 1994; Freimuth et al., 1992; Miller et al., 1993).

Sexual Relationships

To some extent, however, conceptual limitations at the interpersonal level plague most models of sexual health, although some models examine interpersonal skills (Boyer & Kegeles, 1991; Breakwell et al., 1994; Catania, Coates, Kegeles, et al., 1989; Catania et al., 1990; Catania, Coates, & Kegeles, 1996; J. D. Fisher et al., 1994; Freimuth et al., 1992; Malow et al., 1993; Miller et al., 1993). Prior work has demonstrated the importance of interpersonal situations by showing that condom use varies for people with risk factors for HIV/STDs, depending on the type of relationship (casual or committed; for review see Catania, Coates, & Kegeles, 1996; Dolcini et al., 1993), and by showing that the antecedents of condom use related to these two types of relationships vary as well (Catania, Coates, & Kegeles, 1994). Understanding the interpersonal factors in HIV/STD risk behaviors and prevention practices is crucial. Models that do not include interpersonal components are at best incomplete, and may lead to prevention programs that cannot be expected to have a strong impact. In the area of adolescent AIDS prevention programs, for instance, programs based solely on cognitive models have been typically ineffective, as compared to approaches that also emphasize interpersonal skills and problem solving (J. Fisher & W. Fisher, 1992; Kirby, Barth, Leland, & Fetro, 1991).

Despite recent work that includes consideration of the sexual dyad, and a small corpus of theories that highlight the importance of interpersonal dynamics (e.g., Cognitive Social Learning Theory, Script Theory), it is difficult to make pre-

dictions regarding specific sexual situations. For instance, it is not possible to derive from the existing models or theories a set of hypotheses that would predict the consistently observed differences in condom use with secondary versus primary sexual partners, nor would these models predict that people who have extramarital sexual activity are highly unlikely to use condoms with their extramarital partners (Catania et al., 1993; Catania, Coates, & Kegeles, 1994; Choi et al., 1994). Whereas the current models are conceptually elegant, and offer post hoc explanations, they may fall short in predicting behavior in real-life relationships.

This is not to say that the literature has completely ignored social considerations. However, in terms of interpersonal factors, the major focus of the empirical literature, to date, has been on interactive elements of sexual relationships (e.g., the effects of sexual communication, negotiation, and assertiveness skills on prevention practices; Catania, Coates, & Kegeles, 1994). These studies have produced only a very limited understanding of the way interpersonal variables may change across sexual situations, and have not provided much information on their antecedents and expression within different social groups.

Despite the paucity of work on sexual relationships, there is, however, a rich body of literature in the area of family and marital relationships that may be useful to understanding sexual relationships and health (Boss, Doherty, LaRossa, Schumm, & Steinmetz, 1993). The model proposed is based on six major "relational" elements of import in understanding how relationships function, adapt, and reach decisions. These elements include relationship roles, interactive processes, conflict issues, relationship cohesion and flexibility, and emotional factors. Each of these elements has a pivotal role in various models or theories of close interpersonal relationships, and are supported by data from studies of marital relationships and families.

A Relational Model

Although in marital relationships relationship roles often involve issues concerning expectations for husbands and wives (Rodgers & White, 1993), the use of the concept of relationship roles is restricted here to that of sexual roles. The concept of a sexual role has application to a broad set of relationships, including first-time sexual encounters, casual sexual relationships, as well as relationships at varying stages of greater interpersonal commitment and involvement, (e.g., steady dating, engaged, married). Thus, the concept of sexual roles should reflect the varied and changing roles that men and women occupy in their sexual relationship(s) over time. Sexual roles are generally defined then as norm-governed expectations that men and women have regarding appropriate behavior in a given sexual encounter. To a large extent these roles are expected to be gender specific, reflecting gender role differences with respect to sexual conduct, and to be patterned by normative scripts for appropriate sequences of sexual activity (e.g., kissing and petting precede coitus, men initiate increasing levels of sexual intimacy). However, sexual roles alone do not a relationship make, and couples often have to negotiate varia-

tions in sexual practices, condom use, and actively problem solve sexual difficulties that arise. Interactive processes, which are key to marital theories (Fitzpatrick & Ritchie, 1993), are also proposed to be a central element governing the interaction between sexual partners. These processes may include modes of communication (verbal, nonverbal), listening skills, content issues (e.g., substantive vs. affective communication) and qualitative dimensions that reflect, for instance, assertiveness, combativeness, and gentleness.

Sexual roles and interactive processes are important for guiding sexual behavior across a wide variety of sexual relationships (from one-time contacts to ongoing relationships), but there are a number of other potential socioemotional dimensions that effect intimate relationships, and are important to the decisions people may make about their sexual practices and, consequently, their sexual health. Because people may enter into a sexual relationship with different expectations and motives, there is often, but not universally, an element of conflict between partners. For instance, one person may feel things are moving too quickly toward intercourse, or one partner may want to use condoms whereas the other will not. Conflict theories have had a long history in the study of marital and family relationships (Farrington & Chertok, 1993), and this work can be applied to the study of sexual relationships. In particular, issues of power are central to most social conflict theories, and are often considered to be important elements in sexual relationships (Amaro, 1995). Sexual relationships, however, should not be characterized solely as power struggles. They also involve other strong emotional components (e.g., lust, physical attraction, and love) that may influence the decisions couples make about sexual health practices. For instance, some people may forgo condoms because they were so attracted to a new partner that they did not want to "turn them off" by suggesting they might have a disease.

Intimate relationships also can be characterized in terms of their degree of cohesiveness and flexibility (Doherty & Baptiste, 1993). The degree of commitment that partners have to each other and the boundaries they place on their sexual relationship define the degree of cohesion in the sexual relationship. For example, a sexual relationship may be characterized at one extreme in terms of mutual monogamy and at the other extreme in terms of mutual nonmonogamy; the boundaries of the sexual relationship will determine the degree of extra-relationship sex that partners may engage in. Cohesiveness may be virtually absent in the one-time casual sexual encounter as compared to the marital dyad where the presumption of fidelity is often adhered to. Lastly, flexibility is important to sexual relationships. If sexual partners are highly flexible in their approach to their sexual relationship, then they are able to modify their sexual roles, introduce innovations into the relationship (e.g., condom use), and adapt to the changing demands on that relationship. Flexibility in relationships will enable partners to more easily achieve a healthy and enjoyable sex life.

The six elements of the sexual relationship described previously are hypothesized as a set of factors that will directly impact sexual health risks in a given relationship.⁵ However, these six elements do not exist in isolation from other social,

environmental, situational, and developmental contexts. For instance, Amaro (1995) noted the importance of considering social or cultural contexts related to ethnicity/race in considering gender differences in sexuality. Situational contexts also must be considered, and may for example involve variations in mood and drug use across sexual encounters. People and relationships have histories that form a developmental context for considering the sexual relationship. Developmental contexts may include personality differences or similarities brought by partners into the sexual encounter that reflect differences in developmental histories (e.g., differences in sexual guilt, personal sexual history). Developmental context may also include changes in the relationship (e.g., changes in trust, commitment, nurturance, mutuality, and meaning), and the interplay between individual and relationship change (e.g., changes in self-concept that influence a person's assertiveness in the relationship). Sexual relationships also occur in different social environmental contexts that may be more or less supportive of healthy sexual practices. For example, the world of the intravenous drug user or the crack addict would provide another contextual element to consider within the rubric of external forces that influence the six key elements of the sexual relationship outlined earlier.

A number of investigators have noted the lack of research on various elements in the model already outlined (e.g., gender differences; Amaro, 1995). Further, the significance of power differentials and role-related behavior patterns in sexual relationships (i.e., scripts) has received attention on a theoretical level, but has not been actively researched (Abraham & Sheeran, 1994; Amaro, 1995). Relationship cohesion issues have not been extended to considerations of sexual relationships and sexual health. Lastly, sexual communication has been studied (Catania, McDermott, & Pollack, 1984), but variations in communication skills across social groups have not been adequately described. The antecedents of good sexual communication skills are still unknown.

The next sections concern aspects of four of the model elements described earlier. Based on data from the National AIDS Behavioral Survey (Catania, Coates, Stall, et al., 1992; Catania et al., 1995), Judith Moskowitz examined gender differences in perceptions of sexual self-regulation and sexual resistance in the developmental context formed by changes in the sexual relationship over time. Ariane van der Straten discusses the importance of sexual communication, and presents data from Wave 2 of the National AIDS Behavioral Survey (Catania, Coates, Stall, et al., 1992; Catania et al., 1995) on the distribution of health protective sexual communication skills (HPSC) across social strata, and examines preliminary evidence on the antecedents of HPSC. Diane Binson, based on qualitative studies of heterosexual men and women, discusses issues of power in sexual relationships. Lastly, M. Margaret Dolcini explores personal and interpersonal differences between relationships that differ in their emphasis on sexual fidelity.

⁵This description of the model is not intended to explicate the full range of relations among this set of relational variables.

Sexual Roles: Gender Differences and Developmental Context

For heterosexuals, traditional sexual roles and scripts provide sexual partners with a simple set of behavioral expectations that govern what men and women are "supposed" to do in their sexual encounters. Not surprisingly, many investigators believe that gender differences in sexual attitudes, beliefs, and behaviors touch at the very heart of heterosexual interactions (for review see Amaro, 1995). There are well-documented gender differences in sexual beliefs, attitudes, and behaviors that rival or exceed the magnitude of gender differences in verbal ability, mathematics performance, and aggressive behavior (Oliver & Hyde, 1993). Men tend to have more liberal sexual attitudes, an earlier age of first sexual intercourse, and more extensive sexual experience than women (E. S. Herold & Mewhinney, 1993; Kim, Marmor, Dubin, & Wolfe, 1993; Laumann et al., 1994; Leitenberg, Detzer, & Srebnik, 1993; Oliver & Hyde, 1993; Trocki, 1992). Gender differences in sexual beliefs and behavior have important implications for sexual health. For instance, if a man and a woman in a sexual dyad have vastly different attitudes toward condom use, the likelihood of the partners coming to some agreement on safer sexual behavior is probably low. Therefore, the study of gender differences in sexual behaviors is extremely important in determining whether individuals in a dyad will engage in safe sexual behavior.

Although other investigators have pointed out the importance of gender differences in sexual relationships and considered how sociocultural context interacts with gender issues (Amaro, 1995), prior models have not entertained the possibility that developmental factors may influence the extent to which gender roles and stereotypes may affect sexual encounters. Relationships evolve and change with time, and the effects of such changes have been postulated to account for the striking differences observed in condom use with secondary relationships when compared with primary relationships (Catania, Coates, & Kegeles, 1994). Developmental considerations may help to explain the fluctuation in the impact that gender differences have on the sexual relationship over time. Based on prior work (Deaux & Major, 1987), it is proposed that gender differences are of most concern in the early stages of relationships, because there has been less time to learn about the intrinsic qualities of one's sexual partner. The tendency would be to view the person in terms of stereotypic beliefs. As information about that person increases with subsequent interactions, these stereotypic beliefs may be expected to break down. Thus, in sexual relationships, the operation of gender stereotypes may be expected to peak early in the sexual relationship, but to wane over the course of time (Holland, Ramazanoglu, Scott, Sharpe, & Thompson, 1991).

Gender Differences: National AIDS Behavioral Survey Findings

The possibility that gender differences are dependent on the developmental context of the relationship was examined.

Specifically, the study looked at the possibility that the strength of sexual beliefs and behaviors as a function of gender is dependent on the length of time the respondent has been in the relationship. The present analyses are based on data from the second wave of the NABS (Catania, Coates, Stall, et al., 1992; Catania et al., 1995). Two variables were examined within relationships of different length. The two variables reflect elements of the sexual relationship that might be expected to have significant gender-stereotypic components early in relationships but that may change over time. Following traditional sexual scripts and/or gender stereotypes, men are expected to be more likely than women to initiate sexual activity, and to be successful in regulating the sexual relationship to obtain desired outcomes. Women, in this traditional script, are more passive about initiating sex, and less assertive in getting what they want when they do have sex. These expected gender differences were examined in respondents with primary sexual relationships of varying length. Although cross-sectional data are not ideal for studying intrarelationship change, they do provide a means for modeling developmental changes in that the information obtained on interrelationship gender differences most likely reflects an underlying normative pattern of intrarelationship change. Thus, the magnitude of the gender differences in four groups of respondents was compared: respondents who had been with their partners for a year or less, respondents who had been with their partner for 2 to 5 years, those who had been with their partners for 6 to 10 years, and respondents with partners for 11 years or more.

Initiating Sex. Respondents were asked if "When you have sex you are usually the one who makes the first move? (agree-disagree scale)." It was hypothesized that men would be more likely to agree with this statement than women and the gender difference would be especially large in relationships of shorter duration. Based on an analysis of variance model, it was found that of respondents with a primary sexual partner ($N = 3,057$), there were significant gender difference in initiation ($p = .001$) with males being more likely to report initiation. However, the extent of the gender difference did not change as a function of length of relationship. Thus, gender-related role differences in expectations for initiation apparently do not change as a result of an increase in partner contact.

Sexual Self-Regulation. The sexual self-regulation scale was used to assess respondents' perceptions of their ability to regulate the sexual encounter so as to achieve positive outcomes (Catania et al., 1984). As noted previously, traditional gender stereotypes would dictate that women would be reluctant to achieve sexual satisfaction through assertive means (i.e., it is the male's responsibility to satisfy his partner). This stereotype may be operating at its peak early on in a relationship, but as the relationship matures, and the female partner becomes more comfortable with and knowledgeable about her male partner, she may become more assertive in meeting her sexual needs. The data partially support this hypothesis. An analysis of variance confirms the predicted interaction between gender and length of

current relationship on sexual self-regulation. However, although women in short duration relationships (< 1 year) had lower self-regulation scores than their male counterparts ($N = 666$), this difference was not significant. Nevertheless, gender differences were apparent for respondents in relationships of longer duration. For respondents who had been with their partners from 2 to 5 years ($N = 846$), women were significantly higher than men on sexual self-regulation. At 6 to 10 years ($N = 652$), women were still higher, although the difference did not reach statistical significance. At 11 years or more ($N = 820$), women were again significantly higher than men on sexual self-regulation. The pattern of means for male and female respondents within each length of relationship group is illustrated in Fig. 47.2, and suggest that women's perceptions of their ability to regulate the sexual relationship increased with relationship length.

These analyses are preliminary, but they do suggest that some role-related gender differences are not influenced by developmental context and others apparently are affected. Thus, some sexual role-related behaviors, such as initiating the sexual encounter, may be resistant or slow to change. Understanding which role-related behaviors are difficult to change is important to efforts aimed at motivating couples to achieve healthy sexual practices. The ability to regulate the sexual relationship may be of particular import to efforts to use condoms. As research has demonstrated, some women may be at a disadvantage in this regard, especially early on in

a new sexual relationship. The data have not yet been examined with respect to race and age, but it might be expected that some minority women and older women may have more difficulty with being sexually assertive (M. T. Fullilove, R. E. Fullilove, Haynes, K. & Gross, 1990; Marín, Tschann, Gomez, & Kegeles, 1993; M. W. Osmond et al., 1993; Sabogal, Perez-Stable, Otero-Sabogal, & Hiatt, 1995).

In order to further pursue the idea that gender differences in sexual attitudes, behaviors, and safer sex strategies are modified by relationship development, longitudinal designs must be used in order to study couples throughout all phases of their relationships (e.g., Blumstein & Schwartz, 1983; Howard, Blumstein, & Schwartz, 1986; Peplau, Rubin, & Hill, 1977).

Some have argued that psychologists should discontinue the study of gender differences on the grounds that gender studies perpetuate differences between the genders, along with sex discrimination (Baumeister, 1988; McHugh, Koeske, & Frieze, 1986). However, gender differences in the sexual behavior of individuals involved in a sexual encounter play a fundamental role in the manifestation of safer sexual behaviors, and for this reason alone they cannot be ignored. Without the continued study of the gender differences, and the ways in which these differences are expressed within various contexts, a vital source of information would be missed that could be extremely beneficial in designing more effective sexual risk interventions.

FIG. 47.2. Sexual self-regulation. *Difference is statistically significant.

Sexual Communication and Sexual Health

Interactive processes are extremely important for understanding sexual relationships. By virtue of the cooperative and interpersonal nature of most sexual activities, communication is an integral component of sex. In interpersonal relationships, the quality of the communication and the quality of the relationship are closely linked. Good sexual communication skills are important both for sexual and relationship satisfaction (Cupach & Metts, 1991; Snyder & Berg, 1983; Zimmer, 1983).

Although all aspects of interpersonal communication (e.g. process, style, and content) are likely to influence sexual behavior, this discussion is limited to the topic of communication content, specifically related to new relationships. The content of sexual communications is likely to be somewhat different for new versus committed relationships, thus it is important to consider the developmental context of the sexual communication process (Cupach & Metts, 1991; Galligan & Terry, 1993; Wight, 1992; Wingood, Hunter-Gamble, & DiClemente, 1993). Individuals in a new relationship may have little knowledge of their partner's sexual history and views on safer sex precisely when need for discussion and negotiation of sexual issues is at its zenith (Metts & Fitzpatrick, 1992). Thus, new relationships represent both a critical time for safer sex communication, and a "window of opportunity" for developing interventions aimed at changing behavior. However, discussions regarding sexual matters are not easy to conduct. In new or developing relationships, where there is a great deal of uncertainty about commitment and expectations, concerns about self-presentation, partner selection, and the relationship may take precedence over longer term health concerns. Furthermore, many heterosexuals do not discuss condoms with their partner if another contraceptive method is used, because they associate condoms primarily with birth control (Edgar, Freimuth, Hammond, McDonald, & Fink, 1992; Gold, Karmiloff-Smith, Skinner, & Morton, 1992). The use of sexual communication for health purposes is further complicated because indirectness and ambiguity are strategically used in sexual encounters both for erotic purpose and to avoid rejection (Adelman, 1992b; Cupach & Metts, 1991). In addition, sexual communication is sometimes coded and nonverbal, and explicit discussion about safer sex may be an open acknowledgment of sexual intentions, which may seem contrary to normative sexual scripts. Nevertheless, many people do communicate about sexual health matters early in their relationships (Catania, Coates, & Kegeles, 1994; see Table 47.1).

Health Related Sexual Communication

We have used the term *health protective sexual communication* (HPSC) to describe communication content that pertains to HIV, STDs, and birth control. HPSC is an important interpersonal element in HIV prevention. Prior work provides strong evidence for the link between HPSC and safer sexual practices (Catania, Coates, & Kegeles, 1994), and reciprocally, a lack of communication has been associated with unprotected sex and other negative outcomes such as unintended pregnancies (Campbell & Barnlund, 1977; Edgar

et al., 1992; Gold et al., 1992). It was previously found that people with high levels of HPSC are nearly four times more likely to use condoms than those at moderate to low levels (Catania, Coates, & Kegeles, 1994). Furthermore, the relation between HPSC and condom use holds across diverse populations even after controlling for psychosocial and behavioral factors in multivariate models (Catania, Coates, Greenblatt, et al., 1989; Catania, Coates, Kegeles, et al., 1992; Catania, Coates, Golden, et al., 1994; Centers for Disease Control, 1990; Choi, Wermuth, & Sorensen, 1990; DiClemente, 1991; Edgar et al., 1992; Freimuth et al., 1992; Mays & Cochran, 1993). Lastly, interventions that improve interpersonal communication have beneficial effects on condom use (Kelly et al., 1994; Wenger, Linn, Epstein, & Shapiro, 1991).

HPSC may facilitate safer sex practice in a number of ways. First, HPSC may facilitate the translation of shared intentions into action (e.g., mutual intention to use condoms). Second, HPSC may act as a reminder of HIV and influence the saliency of safer sex concerns over other sexual desires. Third, HPSC may have a persuasive function, for example, by changing the mind of an unmotivated person. Whereas cooperation may be obtained in order to please the partner, or out of fear of punishment, HPSC may in fact reduce uncertainties regarding safe sex behavior, and increase social support by allowing an expression of support, perhaps even encouragement, for safer sex. Finally, HPSC may reinforce subjective norms about condom use, which in turn facilitates the enactment of the behavior.

Correlates of Health Protective Sexual Communication

Despite robust findings linking HPSC and safer sex behavior, little is known about the antecedents of HPSC in the context of new relationships (Basen-Engquist, 1992; Catania, Coates, & Kegeles, 1994; Cupach & Metts, 1991; Edgar et al., 1992; Galligan & Terry, 1993). Preliminary findings are presented on an analysis of demographic and psychosocial correlates of HPSC from a national sample of heterosexuals who, in the past year, had sex with a new (for that year) person.⁶

A number of potential antecedents of HPSC were examined. Of primary importance are variables in the sexual domain. These include perceived sexual self-regulation with regard to the sexual dyad as a whole, and to sexual health matters such as use of condoms, sexual assertiveness skills, and comfort with the possibility of displeasing the partner. These are central elements in negotiating safer sex. Indeed, changing sexual behavior is an interpersonal process that requires confident and assertive people to regulate their sexual interactions, to cope with the embarrassment over discussing sexual matters, as well as overcoming concerns about potential negative consequences of such discussions (Bandura, 1994; Basen-Engquist, 1992; Edgar, 1992; Edgar et al., 1992; Freimuth et al., 1992; Galligan & Terry, 1993). Gender was examined as a proxy for relationship-related role variables,

⁶A summary of the psychosocial measures can be obtained from the first author.

and the following contextual variables were assessed. These include situational (alcohol and drug use during sex), socio-cultural (race, education), and developmental context variables (marital status, age, risk expectancies/labeling, sexual guilt, commitment to use condoms, testing and prevention histories; note that commitment and risk expectancies are viewed here as outcomes of individual developmental histories concerning past risk practices, experiences with STDs, and sex-related health scares).

The hypothesized correlates of HPSC were examined in a multivariate model (final $R^2 = .31$; data not shown).⁷ The results indicate that respondents with higher HPSC scores were more likely to have greater sexual self-regulation skills (ΔR^2 at entry = .015, $p < .001$; final $\beta = .083$) and condom regulation skills (ΔR^2 at entry = .138, $p < .001$; final b: ability to use a condom = .133, ability to have condom available = .154; persuasive ability = $-.002$), to be more able to resist unwanted sexual advances (ΔR^2 at entry = .04, $p < .001$; final $\beta = .119$), but were not more or less likely to be concerned about issues of social impression management with regard to voicing desires to use condoms with a new partner.

In terms of developmental contextual variables, higher HPSC scores were associated with a history of being tested for HIV (ΔR^2 at entry = .007, $p < .05$; final $\beta = .08$). Success and failure with HIV-preventive experience may then shape motivations to communicate about such matters (e.g., experience with preventive behaviors may increase self-confidence in one's ability to communicate about safer sex matters to new sexual partners). The multivariate analyses did not show significant differences in HPSC by marital status⁸ (see Table 47.1). Age, however, did correlate with HPSC (see Table 47.1; ΔR^2 at entry = .007, $p < .05$; final β : ages 18–29 = .169, 30–39 = .109), with younger respondents from age 18 to 29 being more likely to report HPSC. This may reflect historical differences in comfort with discussing sexual matters or age differences in perceptions of the need to discuss such matters (e.g., greater concern by the young regarding STDs, HIV). Sexual guilt, commitment to use condoms, and perceived HIV risk were also unrelated to HPSC. However, perceived STD risk was significant (ΔR^2 at entry = .005, $p < .05$; final $\beta = -.079$). The STD-related perceived risk findings are counterintuitive, and may reflect the causal problems associated with concurrent assessments of perceived risk and sexual communication. Thus, people who have communicated about condoms are more likely to have used them, and therefore perceive themselves to be at low risk (Weinstein & Nicolich, 1993). Perceived susceptibility to HIV was not associated with HPSC, indicating that in this population STDs may be

perceived as a bigger threat than HIV, or alternatively, that people feel they have little control over their ability to protect themselves against AIDS. Researchers are continuing to explore possible mediating factors (e.g., gender, ethnicity) with regard to the developmental contextual correlates of HPSC.

In terms of situational variables, respondents who reported having used alcohol before sex were less likely to have communicated with their partner (ΔR^2 at entry = .007, $p < .01$; final $\beta = -.065$). Thus, substance use in conjunction with sex may negatively impact motivation or ability to discuss safer sexual matters (Freimuth et al., 1992; Gold et al., 1992; Wight, 1992).

Other sociocultural and relationship variables were represented in the present model by social demographic variables that are assumed to be proxies for other underlying sociocultural processes. Table 47.1 further illustrates how HPSC skills differ by social demographic variables. There was correspondence between the univariate analyses in Table 47.1 and the multivariate modeling of these variables after controlling for all other correlates. Higher HPSC was related to being female (ΔR^2 at entry = .03, $p < .001$; final $\beta = .206$) and to being non-White (ΔR^2 at entry = .007, $p < .05$; final b: White = $-.089$, Hispanic = $-.057$). As discussed previously, women are more likely than men to talk about intimate matters (Amaro, 1995; Herold & Mewhinney, 1993; Peplau, 1983; Tolhuizen, 1989). Also, condom use is a different behavior for men than it is for women. Men may choose not to talk about condoms, but simply wear one, whereas women must communicate their desire to use a condom to their partner (Edgar et al., 1992). With regard to communication proficiency, ethnic differences revealed interesting findings. In particular, when considering proficient communicators (see Table 47.1; table note), African Americans are more likely to be highly proficient communicators (40%) as compared to Whites and Latinos (29%–30%). This parallels attitudinal data indicating that African Americans may generally be more comfortable about sexual matters (Belcastro, 1985).

What Are We Talking About?

Although sexual communication is considered to be a key sexual relationship variable of central importance for sexual health, not all studies support this view. A few studies have found no association between discussion and use of condoms (Basen-Engquist, 1992; Cline, Freeman, & Johnson, 1990; Cline, Johnson, & Freeman, 1992). Thus, high levels of sex talk is no guarantee that safe sex behavior will occur, as discussion can be used as a substitute rather than an antecedent to condom use. Indeed, sex communication may even have negative effects on HIV prevention, if it promotes ineffective precautions or creates an enhanced but inappropriate sense of trust and safety between partners (Cline et al., 1990; Cochran & Mays, 1990; Mays & Cochran, 1993). Also, to avoid personal relationship threats inherent, for some, in the discussion of sexual practices, many people may talk about AIDS in a general manner rather than discuss AIDS as it relates to their own relationships (Cline et al., 1992; Perlmutter-Bowen & Michal-Johnson, 1989; Wingood et al., 1993). Such general talk is unlikely to have any effect on safer sex practice. Indeed,

⁷Results presented here (change in R^2 at entry, p value and final b coefficients) refer to a main effects model only. Various gender and race interactions are currently being explored, but are not discussed in this chapter.

⁸The presence of a significant association between HPSC and marital status might be obscured in this sample because the new sexual partners toward which HPSC is directed are probably a mixture of primary and secondary partners (61% of the sample had two or more sexual partners in the past year).

TABLE 47.1
Health Protective Sexual Communication
by Sociodemographic Characteristics for Heterosexual Adults
in Dating Relationships (N = 837)

Sociodemographic Characteristics	N	HPSC Mean (SD)	Proficient Communicators (%)
Gender			
Male	441	20.9 (6.8) ^{***}	21 ^{***}
Female	396	25.6 (7.3)	47
Age Group			
18–29	440	23.6 (7.2) ^{**}	37 [*]
30–39	284	23.1 (7.5)	32
40–49	113	21.2 (7.9)	27

Never Married	466	22.9 (7.3)	32
Total sample	837	23.1(7.4) range: 10–40	34%

Note: Prior work has indicated that the relation of HPSC to condom use was not linear across the scale scores, and respondents in the upper one third of scores were substantially more likely to use condoms than those in either the middle or lower thirds (Catania et al., 1994b). Column two then describes proficient communicators by dichotomizing the dependent variable [the top one third higher scores (scores 27–40 = proficient communicators) versus medium to low scores (scores 10–26 = lower communicators)]. The present preliminary analyses are based on Wave II (1992) of the National AIDS Behavioral Survey, a probability telephone survey of HIV-relevant sexual behavior in the United States. Methodological details on the surveys are described elsewhere (Catania et al., 1992b). The present analysis is based on a sample of 837 respondents (a combination of a national and a high risk city sample) who reported having had sex with at least one new sexual partner in the past 12 months, were heterosexual (defined as respondents with all sexual partners of the opposite gender in the past 5 years), age 18 to 49, and who completed the HSPC 10-item scale. Asians, Native Americans, and Pacific Islanders were excluded because they were not adequately represented for analysis purposes ($n = 24$).

prior work suggests that to be effective, HPSC must be specific, intentional, and persuasive. Thus, it is important to consider what is being said specifically, and not simply conclude that because people are talking about “sex” or “AIDS” it will yield clear decisions or any decisions at all with respect to sexual health.

The art of sexual communication is not a simple matter. As studies indicate, people who are more assertive, more self-confident, better able to express their feelings and needs in the sexual arena, and have a history of taking preventive actions (e.g., were tested for HIV) are more proficient communicators. Moreover, communication may need to be integrated into the sexual repertoire and scripts in a way that does not detract from the quality of the sexual relationship. Many people find it difficult to discuss health-related sexual matters without disrupting the flow of the love-making process. Thus, many qualitative issues that have not yet been explored (e.g., timing, tact, and listening skills) may be of primary importance in learning how to discuss safe sexual practices. Finally, health protective sexual communication is likely to remain conflict laden, as long as the seemingly contradictory values related to sex remain. Sexual values such as ambiguity and explicitness, romanticism and health, trust and risk, intimacy and protection may perpetuate the difficulties surrounding discussions and decisions about safe sex (Adelman, 1991; Holland et al., 1992; Wight, 1992). With the emergence of AIDS and other STDs, new paradigms should be developed to capture the interpersonal quality of sexual encounters (Adelman, 1991, 1992a). For example, if safe sex is viewed as an adversarial process, effective negotiators may require assertiveness skills and power to obtain compliance. Alternatively, if safe sex is thought of as part of a “conversation” (Davies, Hickson, Weatherburn, & Hunt, 1993), as a “step” or movement in a dance, then it may require qualities such as imagination, adaptability, interpersonal, and nurturing skills to become a proficient communicator.

Power Dynamics in Sexual Encounters

When people come together to have sex, they are also coming together for a number of reasons that reflect social and emotional issues. Love, nurturance, altruism, and perceived attractiveness are all positive emotional elements that play themselves out in this intimate social situation. However, the process of coming together may also place partners at odds with one another. Power issues in the sexual relationship are key elements in the nature and potential resolution of these conflicts. The effects of gender differences with regard to power are particularly obvious in the sexual relationship. This section explores the issue of power dynamics in the arena of sexual health decision making.

In the context of AIDS, women are told they should protect themselves when having penetrative sex, even though men control the means of protection. To argue that women are free to choose the most rational form of protection ignores the nature of systematic inequalities in the social relationships between women and men, and the nature of social arrangements that systematically privilege male sexuality and desire (Hol-

land, Ramazanoglu, Scott, Sharpe, & Thompson, 1990a; Holland, Ramazanoglu, Sharpe, & Thompson, 1994). This is not to say, however, that gender-specific obstacles to safer sex practice are the sole responsibility of men, as many of these obstacles are rooted in women's conception and acceptance of gender roles and sexuality.

The Continuation of Male Privilege

The changes brought about by women's changing position in society have not altered, for the most part, the deeply internalized sexual scripts of male dominance and female passivity that frame heterosexual encounters (Siann, 1994). For adolescent men, the message is to have sex, and for adolescent women, the message is to avoid it. In all types of coupled relationships, Blumstein and Schwartz (1983) found that men continued to stress the need for dominance and women stressed the need not for submission, but a reluctance to dominate, and a desire for closer emotional relationships. Men are still expected to be assertive in dating and sexual relationships. They are expected to ask women out, propose marriage, and make sexual advances (Blumstein & Schwartz, 1983; Peplau, 1984). However, situations in which women dominate or in which both partners mutually decide the nature of their sexual encounters are certainly not unusual. It is important to better understand the ways in which the characteristics of each partner (e.g., age, education, social class), the nature of the relationship, and the situational context in which sex occurs condition the level and nature of power dynamics in sexual encounters.

Women's Participation in the Reproduction of Male Privilege

One important research direction that needs to be pursued is the examination of the ways in which society socially constructs women to participate in their own domination. Women often are described in terms of, and encouraged to develop, personal psychological characteristics that are pleasing to men (Amaro, 1995). These characteristics form a certain familiar cluster: submissiveness, passivity, docility, dependency, lack of initiative, and the inability to act, to decide, or to think. Asking women to place their own needs (e.g., condom use) ahead of the needs of their male partner would contradict aspects of feminine identity. In a study of women in late adolescence, Holland and her colleagues (Holland, Ramazanoglu, Scott, Sharpe & Thompson, 1990b) found that male power in heterosexual encounters was both embraced and resisted by young women in the course of negotiating sex (Holland et al., 1990a). Their reluctance to insist on condoms stemmed from an unwillingness to hurt men's feelings, and the fear that the assertion of their own needs would upset their male partners. Even in relationships defined in terms of love and trust, sexual safety was often a contradictory practice. Young women tended to silence their own thoughts and feelings for the sake of the relationship, especially when their thoughts and feelings threatened to be disruptive (Brown & Gilligan, 1992).

There are also situations in which women use aspects of gender roles to facilitate safer sex practices, but in the process, reinforce these stereotypes. For example, A. Kline, E. Kline, and Oken (1992) found that one strategy African American and Hispanic women (IDUs or the partners of IDUs) used to persuade their partners to use condoms was to focus on the male role as "protector of the family," in effect reinforcing the male role as the one in control. In Sobo's (1993) description of the experiences and understandings of heterosexual relationships of low income African American women, it was clear that practicing unsafe sex was one way to deny that one's sexual partner was unfaithful. Using a condom was seen as a signal of infidelity in their relationship, and fostered an image of their partner they did not want portrayed in their social world. However, the unintended consequence of idealizing and romanticizing such relationships indirectly reinforced the script of monogamy for women, but not for men.

The Decline of the Double Standard

One of the trends over the last 20 to 25 years has been the decline in age of first intercourse for women (Tanfer & Schoorl, 1992; Zelnik, Kantner, & Ford, 1981). A second trend is the increase in age of first marriage for both men and women and an increase in sexual relationships outside of marriage (Binson et al., 1993). One way of thinking about these trends is that they are possibly reflecting a decline in the double standard and an increase in equality between men and women. A closer inspection, however, reveals a more complicated situation. Recent work by Laumann and his colleagues (1994) found that 90% of the men and only 70% of women reported wanting sex when they had sex the first time. Besides the fact that fewer women actually wanted sex initially, the reasons they gave for engaging in sex for the first time are particularly interesting. Women were twice as likely than men to report they had sex because of affection for their partner (48% for women; 25% for men). Of those who indicated they did not want but were not forced to have sex, 10% of the men and 38% of the women indicated they had sex because of affection for their partner. In addition, younger women were more likely than older women to report not wanting their first experience of vaginal intercourse to occur when it did (Laumann et al., 1994). It appears that although more women are having sex at younger ages, fewer women engage in sex because they want to. Holland et al. (1990a) also found that for many young English women, sex was not a particularly pleasurable experience. Women valued the social relationship, not the sexual relationship. What are some of the reasons young women who do not want to have sex, willingly engage in it? What are the consequences to their sexual health? To explore this question, the data are examined from six focus groups that were part of a research project designed to investigate various dimensions of power in the context of sexual interactions among young men and women.⁹ Each of the focus group sessions lasted from 2½ to

⁹This study was supported with a grant from the American Foundation for AIDS Research (no. 02285-16-RG).

3 hours. There were between 8 and 12 participants in each group, four groups of women and two groups of men. Participants were between age 18 and 25, noncollege educated, African American, White, and Hispanic. All were sexually active and had two or more partners in the last year.

Scripting Theory

One approach to the analysis of power issues in sexual relationships involves analyzing these interactions in terms of sexual scripts, particularly cultural scripts that tend to define and reinforce male domination. Sexual scripting theory (Gagnon, 1990; Gagnon & Simon, 1973; Simon & Gagnon, 1986, 1987) addresses the structure of sexual encounters: with whom people have sex, when and where they should have sex, what they should do sexually, and why they should do sexual things. Scripts operate at three levels: cultural, interpersonal, and intrapsychic. Cultural scenarios are instructional guides that exist at the level of collective life. Interpersonal scripts operate at the level of social interaction and the acceptance and use of such scripts are the basis for continued patterns of structured social behavior. Intrapsychic scripts represent the content of mental life. In part, they are the result of cultural scenarios and the demands of interaction, and in part, they are independent of them. This section focuses on cultural scripts that reinforce male domination in heterosexual scenarios, and the ways in which young women both embrace and reject their sexual script.

One study's findings, which involved the lack of discussion between men and women regarding sex and/or risk protection, has a direct bearing on the context of power dynamics. Much of their sexual activity appears to be guided by unstated, implicitly accepted *cultural scenarios*. In interviews with men, it became clear that using protection was the antithesis of sex as they defined it. That is, sex was "supposed to be" spontaneous, not planned. Even though they often have sex in mind when dating, they felt any discussion of sex would destroy the element of spontaneity. This has implications, of course, in terms of condom use. In particular, men felt they could not look prepared because sex has to at least look spontaneous: "If you've got it [condom] right there, she's going to think, oh, you just knew this was going to happen, you just knew that you were going to get this [sex]."

Submission and Resistance

One reason women gave for having sex, even when they did not want to, was the belief that it was something they had to do to keep a boyfriend, because it was what they thought relationships were all about. When they were in their teens, they felt they would receive love if they had sex. Sex was a means of obtaining approval from men. Many of these women felt that relationships were supposed to be this way, and it was part of what was expected of them as women. These accounts of their personal experiences echo the sexual script for women. That is, cultural scripts organized sexual situations for these young women in such a way that they were not expected to exert con-

trol. Instead, the scripts legitimized submissiveness as the appropriate behavior in those situations. The following descriptions exemplify the powerful influence of the submissive script on women's sexual beliefs and expectations:

Our whole relationship was based on it (sex), and if I wanted to keep him as my boyfriend, I had to have sex with him on a regular basis. There was a lot of pressure there. A lot of pressure. ... You guys are saying the pressure's on, and that's the truth, but at the time, I thought that's what it's all about. I said, all right, I'm going to be miserable forever. That's it, sex is not going to be good, and if I'm going to have any kind of relationship at all, this is part of the equation. That's sad. I know that now.

Or, as one of the younger woman stated:

If I could change one thing, it would be not to get too involved and too trusting, because they [men] end up hurting you in the end. ... I don't regret having my baby or having sex, because *it's all a part of growing* (emphasis added).

Women interviewed attempted to empower themselves through control of their appearance. They talked about making themselves alluring through their dress in order to entice a man into having sex with them. At other times they would use this pressure as a way to gain control over sexual encounters, as a *form of resistance*. For example, one woman discussed "dismissing" men after having sex with them, telling them to leave immediately. That is, rather than withholding sex, she withheld "romance." She used this strategy as a way to make men more interested in future sexual encounters. It was her way of getting her sex partners to want to have sex with her, even though she was not particularly interested in having sex. It was her way, perhaps, of gaining control over her feelings of powerlessness. She felt she was "calling the shots." It has often been stated that in past generations women were the regulators of sex. Now, it appears, women do not regulate whether or not sex takes place, but instead they regulate what sex means. One aspect of their insurgency resides perhaps in resisting the cultural script that organizes and interprets the meaning of sex for women as attachment or commitment to the men in their lives.

Another strategy women used to resist male control of the sexual context was through the use of drugs and/or alcohol. Studies indicate that alcohol or drugs are used in sexual encounters to reduce sexual inhibitions, to make individuals feel free to pursue their amorous feelings. People also use alcohol as an excuse to have sex in situations where they really want to have sex, but find it difficult to admit that they do, to themselves (or their partners). Some young women, however, discussed alcohol use as a *form of resistance*. That is, alcohol and/or drugs was used to get through a sexual encounter they did not want. This was a premeditated action. They knew they did not want to have sex. They used alcohol to get through it, to numb themselves—it was a passive way to resist in the process of complying. This kind of passive resistance allowed them to control the subjective meaning of particular sexual

encounters, even though objectively, they were complying with what their boyfriends wanted. He may have "thought he knew what was going on," but she was in control from her perspective. Using drugs and/or alcohol was a way to do what they thought was expected of them (cultural script), to use sex as a way of getting male approval, as "a way to be loved," but to deny the powerlessness involved. Ultimately, neither partner was in control, and sex in these contexts was frequently unprotected.

The Erosion and Permanence of the Sexual Domination of Women

The introduction of the "pill" in the late 1950s set the conditions for an upheaval in the sexual balance of power between men and women. Women who came of age in 1960s were the first generation of women to have access to reliable birth control, they were the first generation of young women in large numbers to have the option of approaching sex as recreation so that they were not burdened with pregnancy or the constraints of a relationship. In the age of "free love," the double standard that afforded men permission and encouragement to experiment sexually and disapproved of women who acted in a similar manner was challenged. Although there may be an increasing egalitarianism between men and women, reflected in the greater societal indifference to the double standard, consider whether the disappearance, or at least easing, of the double standard is, in every aspect, a wonderful development for women. In the past 30 years, there have been changes in the sexual script in heterosexual relationships, yet the fundamental sexual and social inequality between men and women remain. The sexual context has changed, the rules of the game have changed. The relaxing of the double standard is a positive and potentially liberating change. It has increased the number of options open to women. However, as recent research in this area has shown, sex is still embedded in a gendered system: Sex is something that young men want and "getting it" is basically an unvarnished good for men; for young women, sex is often associated with fear and danger. Whereas women are open to sexual encounters with men, they also are much more likely than men to be forced to do something sexually that they did not want to do (Choi, Binson, Adelson, & Catania, 1998; Laumann et al., 1994). For many women, close, personal relationships veil the reality of sexual coercion, as many were forced to do something sexual by someone they trusted and knew well (Laumann et al., 1994; Muehlenhard & McCoy, 1991).

Research on Sexual Power Dynamics

Studying the distribution of power in heterosexual encounters requires asking questions about the construction of sexual meaning (Schneider & Gould, 1987). Where does meaning come from? Do women have the power to define sexual vocabularies and to create their own meaning? These questions are critical for a more complete understanding of the ways by which safer sex practices are incorporated into interpersonal scripts. What strategies do women (and men) use to ensure

safer sex practices with their sexual partners? In what ways do the images of what it means to be a man and what it means to be a woman reinforce the domination of women in heterosexual encounters? The development of a model of sexual risk behaviors that considers women's social status needs to include variables that reflect a woman's power in a specific relationship and her adherence to traditional roles (Amaro, 1995). Future work needs to extend these research efforts to include the sexual dyad, to investigate the ways in which power dynamics are socially encouraged and individually resisted, and to grapple with strategies that confront the foundation of the social inequality of women. This research will help to empower women and men to negotiate gratifying sexual lives.

Sexual Boundaries

Another important element in the sexual relationships is the boundaries placed on sexual activity with others. Relationship boundaries are determined either implicitly or explicitly by the individuals in the relationship. In sexual relationships, these boundaries concern people's beliefs about monogamy and nonmonogamy. In monogamous relationships, neither partner has other sexual partners, whereas in nonmonogamous relationships, one or both partners has sex with individuals outside the relationship. Nonmonogamous relationships tend to come about via two pathways. In some instances, there is mutual consent to having an open relationship in which one or both partners may have extra relational sexual partners. In other instances, there is no explicit agreement about the acceptability of having other partners, but one or both individuals has sex with others. These latter relationships are referred to as semi-closed.

Relationships in which there are outside sexual partners carry potential health risks; prior work suggests that men are more likely than women to have extra relational sex (Choi et al., 1994; Grinstead et al., 1993). In fact, it has been observed that many women are at risk for HIV and other STDs due to the behavior of their main sexual partner, although they themselves do not engage in risky behaviors (Dolcini & Catania, 1995; Grinstead et al., 1993). Here the focus is on women with a risky male sexual partner (WWRP). These women are often portrayed as less powerful individuals unable to protect themselves for a variety of personal, social, and/or economic reasons (Amaro, 1995; Worth, 1989). Although power issues are indeed important in sexual relationships, focusing on subgroups of WWRPs is expected to reveal a more complex picture. Women in open relationships will be expected to differ from those in semi-closed, but risky relationships.

Defining WWRPs: Open Versus Semi-Closed Relationships

Drawing from the NABS II (Catania et al., 1995), a group of 209 women from age 18 to 49, who had risky male sexual partners, was identified. A risky male partner was identified as someone who had multiple partners or who had used IV drugs in the past 5 years. Within the sample addressed here, all of the male partners had multiple partners. Each WWRP

indicated whether she and her partner had a relationship in which both partners agreed that having outside sexual relationships was acceptable.¹⁰ One third of women indicated they had an open relationship. Women in open versus semi-closed relationships were compared on a number of demographic, contextual, behavioral, and attitudinal variables in order to characterize these two subgroups.

Demographic and Contextual Characteristics: Open Relationships

It was found that WWRPs in open relationships were more highly educated ($p = .001$)¹¹ and tended to have higher incomes ($p = .09$).¹² Education has been associated with a greater departure from traditional sex roles and norms and behavioral differences have been found between low and highly educated women (Dolcini et al., 1993). There were no ethnic differences between those in open and semi-closed relationships, despite having an ethnically mixed sample of women (42% White, 39% African American, 15% Hispanic, 4% other). Open relationships tended to be shorter than semi-closed relationships (3.8 years vs. 6.4, $p < .001$).¹³ Differences in relationship length may reflect difficulties in maintaining open relationships and the constant negotiation necessary to accommodate outside sexual partners. Because all of the male partners and over half of the females in open relationships had other partners, all of the women in the sample in open relationships had to deal with these issues. Given the complexities of maintaining multiple sexual relationships, it is not surprising that only a small minority of those in open relationships were living in the same household as their male partner (4%). In contrast, almost half of those in semi-closed relationships lived in the same household. Moreover, it was found that almost a fourth of those in open relationships lived in a different city than their main partner. This situation has important implications for the geographic spread of STDs. Another factor that was expected to differ between these two groups was the presence of children in the home. It was surprising to find that there were no differences between the two groups in this regard; approximately half of all women had children living with them.

HIV/STD Related Attitudes and Behaviors

Individuals who have extra-relational sex partners can reduce their risks by engaging in health protective behaviors. There was speculation that those in open relationships would recognize the greater risks associated with their chosen lifestyle and

would engage in more protective behaviors. Neither of these was true. There were no differences in perceptions of personal risk for HIV or STDs between women in open versus semi-closed relationships. Likewise, there were no differences in condom use, and overall condom use for the sample was low (23% WWRPs always used condoms). Thus, whether the relationship was open or semi-closed, these women tended not to acknowledge their risk for HIV/STDs and were not engaging in high levels of protective behaviors.

It has been speculated that bisexuals are at greater risk for HIV/STD transmission, and in fact may be a "bridge" for disease transmission from one group to another (Chu, Peterman, Doll, Buehler, & Curran, 1992). Sexual orientation was examined within the sample of WWRPs, and found that those in open relationships were far more likely to report that either they or their male partner had same gender sexual partners (females: 7 vs. 1%, $p = .02$; males: 5 vs. < 1%, $p = .07$).¹⁴ In addition to being a marker for potentially greater disease transmission, being bisexual or having a partner who is bisexual may also reflect more liberal sexual attitudes.

Aside from sexual activity, the other primary behavior involved in the transmission of HIV is IV drug use. According to the WWRPs, one quarter of their male partners had a history of using IV drugs. Women in open relationships were far less likely to report having a partner who used IV drugs compared to women in semi-closed relationships (10% vs. 34%, $p < .001$).¹⁵ Thus, a significant proportion of women in semi-closed relationships have the potential to be exposed to HIV through multiple sources as a function of their partner's behavior.

Psychosexual Variables

We have seen substantial differences between WWRPs in open versus semi-closed relationships on a number of characteristics. Yet, little is known about why some women are in open relationships. One speculation is that there are philosophical reasons for choosing this type of relationship. Consistent with this notion are our findings that women in open relationships were less guilty about sex ($p = .04$)¹⁶ and held more liberal attitudes about sex (i.e., extramarital sex, premarital sex; $p < .001$)¹⁷ than those in semi-closed relationships. Another possibility is that open relationships develop as a function of troubled sexual partnerships. That is, one or both partners have sexual problems and engage in extra relational sex as a way to obtain sexual satisfaction. Although the WWRPs as a whole report more sexual problems than a group of matched control women (Dolcini & Catania, 1995), no differences were found between women in open versus semi-closed relationships with regard to sexual problems.

In keeping with the notion that extra relational sex takes place by the male in semi-closed relationships due to his

¹⁰The question used to determine open versus closed relationship is: "Some couples have open sexual relationships. In this type of relationship partners openly agree that one or both of them can have sex with people outside their relationship. Do you have this kind of sexual relationship with your main sexual partner?"

¹¹Chi-square

greater power, other variables were examined that might reflect imbalances in power within the relationship to see if these differed by type of relationship. The two groups of women did not differ in their ability to resist sexual encounters, to regulate the sexual relationship, or in their ability to initiate sex in the relationship. As a whole, WWRPs report less ability to regulate their sexual relationships as compared to controls, but do not differ on the other variables (Dolcini & Catania, 1995). So, there may be less control in general for WWRPs, but having a power differential does not differentiate those in open versus semi-closed relationships. The findings suggest that it is possible for people in egalitarian relationships to negotiate either a monogamous or a nonmonogamous relationship depending on their philosophical orientation.

In summary, evidence was found for two types of sexual relationships in which one or both partners were having extra-relational sex and important differences were found between women in open versus semi-closed relationships. Those in open relationships were more educated, were less likely to live with their partner, and were in relationships of shorter duration. They also held more liberal sexual attitudes, were less guilty about sex, and were more likely to be bisexual as compared to women in semi-closed relationships. Taken together, these findings suggest strong philosophical differences between women in these two groups and point to the need to examine subgroups within at risk populations, such as WWRPs.

CONCLUSIONS

This chapter has discussed emergent areas in the behavioral epidemiology of HIV, including work on sexual mixing, mapping at risk populations, and sexual relationships. Thus, it has moved from a macrolevel of analysis that examines the connections between disparate sexual dyads to a microlevel that concerns the basic unit in the transmission of sexual diseases, the sexual dyad. It is important, however, to not forget the individual in this process. Change begins with individuals, is behaviorally enacted in the bounds of the sexual dyad, and modifications within dyads produce changes in the sexual network dynamics of STD/HIV transmission.

In studying the sexual relationship, there are numerous problems that have confronted investigators in research on marital and family relationships. How do researchers conceptualize, assess, and analyze dyadic or couple information? Current approaches to studying sexual relationships are often more like a tug-o-war than a dance. Issues of altruism, mutuality, and negotiation are not being adequately addressed in the literature.

In addition, this is a culture that often views penises and vaginas as an enemy from which people need protection. Sex negative cultures are not good bases for developing healthy sexual lives. How such cultural variables influence sexual relationships is an important issue that deserves more attention than it is currently receiving. This brief look at this issue illustrates that even basic skills, such as sexual communication, vary as a result of ethnicity. Thus, ethnic-cultural issues may

contribute to the development of sexual communication skills. However, it was also found that males and females are consistently different from each other in sexual communication skills across ethnic groups. Consequently, any developmental differences that occur across ethnic groups also take place in a larger cultural context that universally produces gender differences in sexual skill development. These types of analyses, however, are still in their infancy. Researchers are far from reaching the goal of identifying the cultural institutions and related beliefs and values that shape the differences observed across grossly classified demographic variables.

Research on sexual networks is still in its infancy, and there are difficulties with existing work that relies on the ego-centric method of network identification. Ideally, researchers would want to begin with probability samples of a population and trace all of the sample member's sexual partners over a period of time, then conduct interviews with each partner. At this juncture, it is unclear how successful they would be in accomplishing tracing procedures occurring outside the context of the legal imperatives of public health agencies. Further, they do not know how deep they would need to trace in order to have an accurate picture of the size and density of sexual networks. Do they need to interview the respondents' partners, the partners' partners, and so on? Where can researchers stop the tracing process and still have an adequate picture?

Although some of this discussion of sexual mixing falls into the purview of mathematical modeling of HIV/STDs, health psychologists are of central importance in generating the behavioral data that modelers will employ. Health psychologists may also make other contributions in this area. Researchers need to know more about how to conceptualize sexual mixing patterns if they are to describe the degree of mixing among and between heterosexual population segments with multiple sexual partners, and the geographic distribution of their population. The spread of HIV/STDs nationally not only depends on the degree of mixing across and within social strata (and other behavioral and biological conditions), but, as noted previously, also depends on the "sexual avenues" connecting cities, suburbs, and rural areas (Golub et al., 1993; Wallace, 1991, 1994). What are the social and behavioral rules that govern these network structures and mixing patterns? These complexities, in addition to the unknown contributions of HIV co-factors with a high prevalence among heterosexuals (e.g., HSV-2, chlamydia; Laga et al., 1993; Siegel et al., 1992; Webster et al., 1993), strike a cautionary note to the view that heterosexual spread will not occur because of low average infectivity rates (e.g., Laumann et al., 1994). In addition, the unknowns about the population dynamics of HIV, and the continued increase in heterosexually transmitted cases, suggest that the prudent action at this juncture is to assume that at-risk heterosexuals should be the target of prevention programs promoting condom use, HIV testing, and other prevention practices; if nothing else, they may well avoid contracting one of the 15 or more other STDs currently infecting the U.S. heterosexual population.

To date, the epidemiological mapping data indicate that adult heterosexuals at risk for HIV and other STDs represent a fluid, dynamic population. Estimating changes in the size,

turnover, and prevention practices of this population segment remains an important challenge. There is a need for a series of surveys in this area to assess the reliability of past findings, and to regularly monitor how the general U.S. population is responding to HIV and other STD prevention programs.

In summary, this chapter has reviewed literature on sexual mixing and networks, and has presented new data showing that the degree of sexual mixing differs by urban setting, gender, age, and ethnic group. Recent mapping studies illustrate the fluid nature of at risk populations. This fluidity complicates the ability to predict STD/HIV disease spread. It has touched on the many social and psychological models currently being used to study sexual behaviors relevant to HIV disease, and noted some general common deficiencies in these models. A particular deficiency is the lack of work on the sexual relationship. Finally, the chapter has presented the elements of a model for understanding sexual relationships and followed this with data on four aspects of sexual relationships that are of significance for sexual health: gender differences, sexual communication, power, and relationship boundaries.

Rotem Benjamin, Erica Allen, and Susan Kwon

University of California, Los Angeles

AIDS was originally considered a disease of the gay population (Mays & Cochran, 1987). In particular, AIDS was viewed as a White gay male disease (Cochran & Mays, 1988; Mays & Cochran, 1995). However, increasingly over the years, both the highest incidence and greatest numbers of new cases of HIV infection in the United States are within ethnic minority populations, especially among African Americans and Hispanics (Karon et al., 1996; Rosenberg & Biggar, 1998). A recent study examining the prevalence of HIV infection found that the estimated rate in White males was from 3.3 to 4.9 per 1,000, but from 16.8 to 22.5 among Black males and from 9.0 to 13.0 among Hispanic males (Karon et al., 1996). Similar patterns were found for women, with estimates of from 1.7 to 2.6, 10.6 to 14.2, and 5.6 to 8.2 for Whites, Blacks, and Hispanics, respectively. Using data from 1995,

Rosenberg and Biggar (1998) showed that HIV incidence attributable to heterosexual contact is striking in its pattern among successive birth cohorts of ethnic minorities. They found that Black women have the highest incidence of infection attributable to heterosexual contact, with estimates that 1 in every 1,000 20-year-old Black women become HIV infected via heterosexual sexual routes. This compares to estimates that 1 in 2,800 similar aged Hispanic women and 1 in 15,000 White women suffer similar fates. Concurrently, the incidence of HIV infection is greater among young ethnic minority men than in White men in every transmission route, including male-to-male sexual transmission (Rosenberg & Biggar, 1998). Here, the incidence of AIDS cases attributable to male-to-male sexual contact is four times higher in Black men and two times higher in Hispanic men when compared to

White men. This discrepancy in risk is expected to widen as the incidence and numbers of new cases of HIV infection in White gay men declines (Fahey & Flemming, 1997).

In the meantime, AIDS-related research continues in the hope of finding new drugs for the treatment of AIDS and HIV infection. But the implication of these accelerating trends, shifting a greater illness burden into ethnic minority communities, presents a new challenge for researchers. Much research continues to be conducted using White male subjects. Blacks, who earlier in the history of AIDS clinical trials represented 34% of all AIDS cases (Fahey & Flemming, 1997), previously made up only 7% of the subjects in National Institute of Health (NIH) HIV/AIDS studies (Ready, 1988). Similarly, Hispanics represented 17% of AIDS cases, but were only 9% of the NIH research subjects. There are many complicated reasons for the low participation of ethnic minorities in HIV-related clinical drug and vaccine trials ranging from debatable scientific decisions to politics (El-Sadr & Capps, 1992; "Getting Cancer Patients Into Clinical Trials," 1991; Mays, 1998, 1999; Mays & Cochran, 1999). But despite this, there is growing evidence in various areas of medicine that racial/ethnic differences in disease susceptibility and drug response do exist (Pollack, Safari, & DuPont, 1983; Winchester, Chen, Rose, Selby, & Borkowsky, 1995; Zhou, Koshakji, Silberstein, Wilkinson, & Wood, 1989; Zhou, Shay, & Wood, 1993). Failure to consider these differences while attempting to develop new methods of treatment, or even possibly a cure, could have significant public health implications, particularly for ethnic minority Americans. In the hopes of encouraging consideration of these issues more fully, this chapter reviews here the existing evidence for HIV-relevant racial differences in disease susceptibility and drug dosage response.

GENETIC RACIAL DIFFERENCES RELATED TO HUMAN LEUKOCYTE ANTIGENS

A particularly useful area to consider in identifying possible racial/ethnic differences in HIV infection and disease is in distribution of Human Leukocyte Antigens (HLA) because of their relation to immune function. HLA molecules have a significant function in initiating the immune response through processing and presenting foreign antigens to T-cells, which then triggers clearance of the virus from the body. Racial variations in the genes encoding HLA Class I and II molecules have an effect on antigen presentation and may influence the host immune response. These tissue type antigens are used by the T-cells of the immune system to distinguish host cells from foreign cells (i.e., the self from the nonself). Every individual has a unique combination of HLA molecules on chromosome 6 called the major histocompatibility complex (MHC). HLA-A, HLA-B, and HLA-C are encoded by Class I genes, whereas HLA-DR, HLA-DQ, and HLA-DP regions are encoded by Class II genes. The Class II regions determine the selection of various cell membrane associated glycoproteins that serve numerous functions in the regulation of the T-cell immune response of the body (Callender & Dunston, 1987). A subset of T-cells kill viral infected cells, but ironically HIV also attacks a subset of the population called the CD4+ cells. Studying specific racial vari-

ations in the Class II region may further elucidate the role they play in the T-cell mediated immune system response to HIV infection.

Because the use of HLA typing is common for the determination of the histocompatibility of tissues for transplantation, research in this area has led to the discovery of HLA determinants associated with particular racial groups. These determinants are polymorphic, resulting in differences between races in the frequency of the alleles (gene variants) at the various HLA loci. For example, in a sample drawn in Washington, DC, HLA-A23 and A30 were four times more likely to be found in Blacks than in Caucasians (Dunston, Henry, Christian, M. D. Ofosu, & Callendar, 1989). Also, B45, Bw58, Bw53, Bw70, Cw7, DRw13, and DRw8 were also more likely to be found in Blacks. Further, unique HLA specificities are seen in the Black population. For instance, Aw34, Aw36, A19v, and Bw42 appear to be unique to Blacks (Callender & Dunston, 1987; Dunston, Hurley, Hartz, & Johnson, 1989).

Although a majority of previous HLA research focused on racial differences only between the Black and White population, presently DNA technology allows further identification of specific HLA alleles, suggesting HLA relatedness and differences with other racial groups. Osborne and Mason (1993) designed an HLA haplotype frequency table consisting of HLA alleles common to the U.S. Hispanic population. They reported similarities and differences in HLA A/B haplotypes among Hispanic Americans of both Caribbean and Mexican ancestry. They also reported that HLA A19/B12, A25/B12, A1/B17, A2;A34/B38, and A1;A3/B40 are common in Mexican Americans, whereas A9/B12, A19/B12, A29/B12, A2/B16, A28/B17, A19/B44, A24/B40 are shown to be common in Caribbean Hispanics. For example, HLA A28/B17 is 24 times more likely to be found in Hispanic Americans of Caribbean origin than in those of Mexican ancestry (Osborne & Mason, 1993).

Investigation of HLA Class II alleles in South American Indians show specific HLA haplotypes among those of Brazilian and Argentinean background (Cerna et al., 1993). In a study of three Argentinean tribes (Eastern Toba, Western Toba Pilaga, and Mataco Wiehi) and Xvantes from Central Brazil, the most common HLA allele was DPB1*0402 (Cerna et al., 1993). However, Brazilians display four DR groups: DRB1*0404, DRB1*0407, DRB1*0802, and DRB1*1402. Frequent alleles at the DRB1 locus in Argentineans were shown to include DRB1*04, DRB1*0802, and DRB1*14.

Modern genetic studies of HLA genes have made possible comparisons between Ashkenazi Jews from Eastern and Central Europe and Non-Ashkenazi Jews from Mediterranean and Asian Countries (Martinez-Laso, Gomez-Casado, Morales, & Martinez-Quiles, 1996). Common alleles found in both Jewish groups are DRB1*07, DRB1*0402, DRB1*1104, DRB1*0102. Allelic differences within the Jewish population can be illustrated in the frequency of alleles at the DR13 loci. For example, DRB1*1301 is more common in Ashkenazi than in non-Ashkenazi Jews. Furthermore, DRB1*1301 is six times more likely to be present in non-Ashkenazi Jews of Mediterranean ancestry in this subgroup (Martinez-Laso et al., 1996).

These disparate results suggest significant biological differences in HLA between races. Given the important role of HLA in immune-related disease, these racial differences may play an important, but understudied, role in HIV and may subtly influence outcomes of research directed at disease susceptibility and drug dosage response in HIV/AIDS. Studying ethnic differences in HIV disease may lead to important insights in the varied role of the viral immune response and identify new approaches for therapeutic research.

It is already known that each individual has a unique distribution of HLA alleles, and specific HLA haplotype combinations are found more frequently in different ethnic groups. Studies have also shown that with particular combinations of HLA haplotypes, the chances for long-term survival with HIV and AIDS is improved (Kaslow et al., 1990; Louie, Newman, & King, 1991; Steel et al., 1988). Yet, most of these studies have been done using data gathered from gay White men, who represent only a portion of those living with HIV and AIDS (Louie et al., 1991). In one study conducted by Louie et al. (1991) of gay White men living in 19 census tracts having the highest risk for AIDS in San Francisco, results showed that those who carried HLA DRB1* 1101, 1104, and 1201 had the worst disease outcome. The presence of DRB1* 0101 (DR1), HLA A* 2401 (A24), HLA B* (B35), and HLA C* 0401 (C4) was associated with an increased rate of progression to AIDS, whereas those with the alleles HLA DRB1* 0701 and 0702 had a slower CD4 cell decline as well as slower progression to AIDS (Louie et al., 1991). Within the study, a comparison was made between those who were symptomatic and those who were asymptomatic. The HLA alleles DRB1* 0702 and DQA1* 0201 were more frequent among HIV+ asymptomatic men compared to HIV+ men who were symptomatic. Therefore, the presence of these alleles may confer a protection against the progression of AIDS. This study also showed that CD4+ cell counts declined faster in those with the HLA allele DQA1* 0101 present, thus resulting in the more rapid progression of AIDS. The presence of the HLA combination A1-B8-DR3 was also associated with rapid CD4 cell decline (Louie et al., 1991).

Other studies of African Americans and Caucasians offer further support for the role of HLA differences and HIV/AIDS disease progression. In the heterosexual population, HLA distribution is associated with the severity of HIV infection, and the likelihood of developing AIDS. HLAs found more frequently among HIV+ African Americans are A31(19), B35, Cw6, Cw7, DR11, DR12, DQ1, and DQ3, when compared to controls. Among the Caucasian HIV+ participants, A28, A66, B48, Cw7, Cw8, DR10, DR5, DQ1, and DQ7 are associated with HIV infection. Although some haplotypes are common in the two groups, Cw4 and DR6 were more common among uninfected African Americans (M. N. Brackin et al., 1995). Thus, Cw4 and DR6 may provide protective resistance to HIV infection. On the other hand, A69(28)-B40 and B12-DR14(6) were associated with rapid progression in African Americans. In Caucasians, A28-B17-DR9 and DQ2 were associated with rapid progression, and A30(19)-B67 with slow progression. Studies of

other ethnic groups reveal associations with different alleles of the same genes (Louie et al., 1991).

Studies have also reported other HLA associations with susceptibility to HIV-1 infection as well as to disease progression. It was shown that susceptibility to infection with HIV-1 among both African Americans and Caucasians may be influenced by HLA-DQB1 alleles (Achord, Lewis, M. N. Brackin, & Cruse, 1997). Using molecular methods, Achord and colleagues (1997) found a significantly higher frequency of DQB1*0605 in HIV-1 positive African Americans as compared to HIV-1 negative African American controls. DQB1*0602 was associated with HIV-1 infection in Caucasians. Although no HLA-DQB1 marker was found to be protective against HIV-1 infection in African Americans, HLA-DQB1*0603 was found to be protective in Caucasians. These results demonstrated that different HLA molecules may be associated with HIV-1 infection or protection from infection in Caucasians and African Americans (Achord et al., 1996). Possible HLA associations with HIV-1 disease progression between different ethnic groups was also examined. HLA allele frequencies among slow progressors were compared to those of rapid progressors, stratified by race. HIV-1 infected African Americans positive for the DQB1*0602 allele exhibited slower disease progression. Kaplan–Meier survival analysis showed a mean survival time of 71.3 months for those patients without the allele as compared to 117.8 months for the African American patients who had this allele. No marker was found to be associated with rapid disease progression in African Americans. In the HIV-1 infected Caucasian group, the DQB1*0302 allele was more common in rapid progressors. Patients positive for the DQB1*0302 allele had a mean survival time of 47.5 months as compared to 70.7 months for patients without the allele as shown by the Kaplan–Meier survival analysis (Achord et al., 1997).

Numerous studies have investigated the role HLA plays in response to HIV-1. It has been shown that MHC Class II DRB1 alleles of the infant influence transmission of HIV-1 from an infected mother during gestation and delivery and the association may be influenced by ethnicity (Winchester et al., 1995). Winchester et al. (1995) found a higher frequency of the DRB1*03011 HLA allele in the infected White infants born to HIV-1 positive mothers and a higher frequency of DRB1*1501 in the uninfected group. Also demonstrated was a higher prevalence of DR13 alleles, including DRB1*1301, 1302, and 1303 among the African American and Hispanic infants studied. The DRB1 13 alleles are associated with an enhanced immune response to a specific HIV peptide and to resistance to HIV infection. The frequency of the DRB 13 alleles varied with racial ethnicity. Among the African American infants, 29% of uninfected infants were positive for these alleles, in comparison to 0% of HIV-infected infants (Winchester et al., 1995). The association of specific HLA molecules with HIV-1 susceptibility was further examined in Italian children. The DRB1*1301 allele was also found to be more frequent among infected Italian infants as compared to uninfected Italian infants born to HIV-1 positive mothers (Greggio et al., 1993; Scorza Smeraldi, et al., 1986).

In another study by Just et al. (1992), an association of HLA genotypes and susceptibility to HIV perinatal infection was found among Black infants born to HIV positive mothers. Results of this study showed the HLA DQA1*0102 allele provided a protective role whereas the allele DPB1*0101 was associated more with risk of infection. The uninfected infants had a higher prevalence of the DQA1*0102 allele than the infected infants (65% vs. 43%). Whereas the DPB1*0101 was more commonly detected among the infected infants (66%) than among the uninfected infants (43%). Additionally, infants who lack the allele DQA1*0102 and have a specific amino acid sequence of -asp-glu-ala-val- at HLA-DPB1 positions #84-87 have a stronger association with HIV infection than those infants with the specified amino acid sequence of DPB1 and the DQA1*0102 allele. Results of the study also show that the infants most protected from HIV infection, had a different sequence of amino acids at positions #84-87 of the DPB1 gene locus other than -asp-glu-ala-val-, and may or may not have had the DQA1*0102 allele.

In a study (Kilpatrick, Hague, Yap, & Mok, 1991) conducted on Scottish infants born to HIV+ mothers, the frequency of HLA DR3 was three times higher in the HIV+ infants (i.e., 13% as compared with 30%). The low rate of HIV+ infants may be due to the haplotype combination they found for this group. A3-B7-DR2 was found only in the infants who were not HIV infected, perhaps offering some form of protection. The study also confirmed the results of other studies using White samples, which indicated that A1-B8-DR3 may be associated with susceptibility (Just et al., 1992; Kilpatrick et al., 1991; Yanase et al., 1986).

These studies based on infants of different ethnic backgrounds, combined with previous studies examined, hint at the possible relevance of differences in the HLA make up of different racial groups in HIV disease. Furthermore, HLA loci have also been shown to play a role in several other diseases. For example, HLA typing of Class II region reveals significant differences between African Americans with and without Grave's disease (M. H. Ofori et al., 1996).

HLA loci are important factors in graft survival in kidney transplantation. It has been shown that the chance of graft survival increases when DRw6 allele matched in kidney transplantation (Callendar & Dunston, 1987). For kidney transplantation, in particular, race seems to have a major role in the outcome of the operation. In 1987, Blacks accounted for 12% of the U.S. population, but made up 27% of the patients with end-stage renal disease. Racial differences in ABO blood groups and MHC antigens make organ matches extremely difficult, especially because only 8% of donors are Black (Kasiske et al., 1991). For blood types O, A, B, and AB, the distribution in the White population is 45%, 40%, 11%, and 4%, respectively. On the other hand, the Black distribution is 49%, 27%, 20%, and 4%, respectively. Whereas ABO typing must be matched in the first place for tissue transplantation, exact MHC matching of HLAs is not always possible because the majority of donated kidneys are from Caucasians. Because of frequent mismatching, long-term survival of grafts is significantly lower for Blacks than for Whites (Kasiske et al., 1991). In general, when recipients had no

HLA mismatches, they suffered fewer rejections and required less cyclosporine, which is the steroid administered to enhance graft survival (Callendar & Dunston, 1987). Newer studies suggest that when equivalent Black and White kidney recipients are chosen and a cyclosporine regimen is followed, patient and graft survival are the same in Blacks and Whites (Friedman, 1991). Although accessibility of health services and everyday life and economic struggles that act as barriers in facilitating necessary daily health regimes may contribute to graft loss in poor Blacks (especially within the inner city), the effects of racially determined HLA typings still play a significant role in graft survival.

Sickle cell disease is another area in which—in this instance transfusion-related immune response—there is an association with several HLA specificities. Sickle cell disease patients commonly undergo blood transfusions in the treatment of their illness. Studies show that after receiving a transfusion, patients with HLA-B35 are six times more likely to produce antibodies against the transfused cells (alloimmunization) than patients without this antigen (Alarif, Castro, M. Ofori, Dunston, & Scott, 1986). In addition, a lower incidence of alloantibodies has been associated with the presence of HLA-DR3 and of A28 and B15 (M. D. Ofori, Saunders, Dunston, Castro, & Alarif, 1986). These associations, given the racial differences in HLA typing, indicate that Blacks may be more susceptible to alloimmunization due to transfusions received in the treatment of sickle cell disease. Indeed, in one study among Blacks, a 30% alloimmunization rate was found, whereas Whites had a 5% rate despite receiving greater numbers of transfusions (Vichinsky et al., 1990). Because Blacks comprise a low proportion of blood donors (the donor population being mainly White), differences in the antigen mismatching between donors and recipients among African Americans may account for the resulting differences in alloimmunization frequency.

Association between HLA haplotypes and susceptibility to insulin dependent (Type 1) diabetes mellitus (IDDM) has also been studied. Specifically, it has been shown that the HLA-DQ region plays a role in IDDM susceptibility (Fletcher et al., 1988; Ronningen et al., 1993). In general, among Caucasians, DR3 is almost always associated with DQw2, whereas among Blacks, DR3 may be associated with two phenotypes, DQw2 or DQw-. In a study of Black IDDM patients and Black non-IDDM controls, the haplotype DR3-DQw2 was found in all IDDM patients, whereas DR3-DQw-, common in the control group, was not found in the IDDM patients (Dunston et al., 1989). The DR3-DQw2 haplotype, therefore, seems to be a marker for insulin dependence in the Black diabetes patients studied, whereas DR3-DQw- is more likely to be associated with resistance to IDDM. Because IDDM is more prevalent among Black Americans than Black Africans, and DR3-DQw2 (found in nearly all Caucasians) is associated with susceptibility to IDDM, it is possible that the susceptibility genes for IDDM were introduced into the Black American population due to the admixture of Caucasian genes (Dunston et al., 1989).

Further studies also indicate genetic differences in the susceptibility and resistance to IDDM in the Mexican American

population. Although the incidence of IDDM among Native Americans is low, the incidence in Non-Hispanic Whites is 15/100,000 year and 9.5/100,000 year in Mexican Americans (Eisenbarth, 1986). This pattern is consistent with the lower prevalence of the European derived HLA-DR3 haplotype in the Mexican American population, which has HLA haplotypes derived from the Native American and Hispanic Caucasian admixture heritages. Furthermore, HLA-DR3 and DR4 linkage to specific HLA DQB1 alleles influences risk of IDDM (Sanjeevi et al., 1993). Recent studies show that the Mexican population contains a variety of different DR4-DRB1 alleles (Erlich et al., 1993). Namely, there are 9 different DRB1 alleles, and 16 different DRBQ haplotypes. The risk of IDDM in this population varies from highly susceptible to protective based on the DRB1 allele present. High risk haplotypes—DRB1*0402, DQA1*0301, DRB1*0405, and DQB1*0302—are of European origin. Specifically, DRB1*0405 is common in Spain and may illustrate the Hispanic Caucasian descent in the Mexican American population. Lower rates of IDDM in Mexican American controls corresponds to Native American ancestry.

Race has also been found to be a major contributor to the prevalence of diabetic nephropathy. In inner-city Blacks (e.g., from Brooklyn), Hispanics, and Native American Indians, the prevalence of non-insulin-dependent diabetes (NIDDM) is much higher than in non-Hispanic Whites (Friedman, 1991). Within these diabetic groups, there also seems to be a genetic predisposition to increased risk for diabetic nephropathy as compared to Caucasians. This disposition is associated with a genetic risk for hypertension. The rate of erythrocyte lithium-sodium countertransport is a marker for hypertension, and this rate is increased in those who develop nephropathy. In addition to this genetically inherited trait, end-stage renal disease (ESRD) due to diabetic nephropathy is caused mainly by NIDDM. Because Blacks, Hispanics, and American Indians suffer from NIDDM to a much greater extent than Whites, they also suffer from a higher prevalence of diabetic ESRD (Friedman, 1991).

Mixing of genes between races from interracial matings has led to changes in susceptibility. For example, following the introduction of Caucasian genes into the Pima Indian population, the prevalence of NIDDM has decreased commensurate with the decreasing prevalence of the Gm 3;0 5,13,14 haplotype, which is a risk factor for NIDDM (Friedman, 1991). Thus, as a function of the dilution of the genes associated with NIDDM susceptibility, the prevalence of NIDDM has decreased accordingly. Therefore, interracial mating is an important factor to consider when examining ethnic differences in disease susceptibility. As previously discussed, the distribution of HLA alleles are different among different racial groups. Thus, acquisition of genes from parents of differing ethnic backgrounds influences biologically based responses and outcomes to disease.

HLA specificities also play a role in the susceptibility to human T-cell leukemia virus Type I (HTLV-I). In the HTLV-I endemic area of Kyushu, Japan, HLA-DQw3 is associated with HTLV-I infection that is associated with T-cell leukemia (ATL). Ninety one percent of the ATL patients had

increased frequencies of HLA A26 and B39, as compared to HTLV-1 infected individuals without ATL. Thus, these alleles may be associated with predisposition to developing ATL in the course of HTLV-I infection (Uno, Kawato, Matsuoka, & Tsuda, 1988; White et al., 1996). Different alleles were observed in Black and Caribbean ATL patients in which frequencies of A36, B18, and Class II HLA-DR53 were higher (White et al., 1996).

Ethnic differences have been observed in age of onset and severity of myasthenia gravis between Chinese and Caucasians. Chinese patients were found to have less severe cases and display an earlier occurrence of this disease than Whites. Among Chinese patients, there is a strong correlation of Bw46 and DR9 with myasthenia gravis (Chen, Chiu, & Hsieh, 1993). Furthermore, the frequency of the Bw46DR9 combination was found to be increased in Chinese juvenile patients with onset before age 20 and decreased thereafter ($20\% \geq 20$ and $60\% \leq 20$). However, A1, B8, and DR3 are correlated with myasthenia gravis in Whites over age 40. Also, specific HLA combinations are associated with myasthenia gravis in other ethnic groups: HLA-DR8 and DR3 in Whites; A1, B8, and DR5 in American Blacks; and DR9 and DRw8 in Japanese.

HIV-associated diseases also show racial differences. In a study of patients with renal disease due to HIV-1 infection, known as HIV-1 associated nephropathy (HIVN), Black HIV-infected patients were more likely than Whites to develop HIVN (Bourgoignie, Ortiz-Interian, Grenn, & Roth, 1989). Moreover, whereas the majority of HIV-infected patients are White, most HIVN patients are Black. Even after taking IV drug use into account, HIVN occurs 10 times more often in Blacks. Furthermore, the predilection for HIVN cannot be attributed to differences in age, duration of disease, or to the presence of other major opportunistic infections. This suggests a strong possibility that genetic factors are responsible for the higher frequency of HIVN among Blacks (Bourgoignie et al., 1989).

Investigations have demonstrated that non-HLA genetic factors also influence susceptibility to HIV infection and the pathogenesis of AIDS. The vast majority of people are susceptible to infection with HIV. However, rare individuals remain uninfected by HIV-1 despite multiple sexual contacts with subjects known to be HIV-1 infected (Detels et al., 1996; Liu et al., 1996). In mid-1996, a naturally occurring 32-bp deletion mutation (delta 32 allele) in the chemokine receptor gene CCR5 was found in subjects who remain uninfected despite repeated, extensive exposure to HIV-1 (O'Brien et al., 1998). Before the discovery of the role of chemokine receptor genes in HIV infection, only HLA genetic factors were thought to affect susceptibility of HIV infection. Studies have since identified molecular co-receptors that HIV uses in conjunction with CD4 cell entry. The macrophage-tropic, or M-tropic HIV strains use CD4 and a chemokine receptor gene called CCR5, whereas the protein CXCR4 is an entry coreceptor for T lymphocytes-tropic (T-tropic) HIV strains only (O'Brien & Goedert, 1998). Several studies confirmed the protective role of homozygosity for a 32 base pair ($\Delta 32$) deletion in the CCR5 gene to HIV-1 infection. Rare individu-

als homozygous for this Δ CCR5 allele appear to be protected from HIV-1 infection despite repeated exposure to HIV-1 through unprotected sex with HIV-1 positive partners (Liu et al., 1996). It has been shown that genotype frequencies of the Δ CCR5 allele vary markedly across different ethnic groups. Among Caucasians in North America or Europe, about 1% are Δ CCR5 homozygous. Homozygous Δ CCR5 is rarely found in non-Caucasians. Heterozygosity of the Δ CCR5 allele is found in approximately 10% to 20% of Caucasians, approximately 6% of African Americans, 7% of Hispanics, 13% of Native Americans, and 1% or less of Asians (Dean et al., 1996; McNicholl, D. K. Smith, Qari, & Hodge, 1997; Zimmerman et al., 1997).

Similarly, Smith et al. (1997) reported that homozygosity for the Δ CCR5 was not uncommon among exposed but uninfected individuals (1%–5%), but extremely rare among infected individuals (< .1%) (Dean et al., 1996; Huang et al., 1996). The different frequency of the homozygous Δ CCR5 allele between Caucasian HIV-positive homosexual men (0%), and in highly exposed seronegative (4.5%), provides further support for the protective role of the Δ CCR5 allele (Zimmerman et al., 1997).

Whereas individuals homozygous for the Δ CCR5 allele appear to be resistant to infection, it has been shown that heterozygosity may delay the progression to AIDS in infected individuals. Infected individuals heterozygous for the Δ CCR5 experienced a delay in the onset of AIDS of approximately 2 to 4 years, as compared to individuals with the normal CCR5 gene, in several large AIDS cohort studies (Dean et al., 1996; Huang et al., 1996; M. W. Smith et al., 1997). The long-term nonprogressors of the homosexual cohorts showed more than twice the percentage of heterozygotes compared with rapid progressors (Dean et al., 1996). The data suggest that heterozygosity for the Δ CCR5 allele does not affect susceptibility to infection, but rather it may postpone progression to AIDS among those already infected. Population studies have estimated the frequency of Δ CCR5 at approximately 15% among North American or European Caucasians, but have not found any cases of Δ CCR5 among Black populations with the exception of African Americans in the United States. A global distribution of the Δ CCR5 allele shows the highest allele frequency recorded in the Ashkenazi Jewish population, 20.9%, descendants of ancient Israel and east European people, a frequency of from 2% to 5% throughout Europe and a general absence in sub-Saharan Africa peoples (Martinson, Chapman, Rees, Liu, & Clegg, 1997). In a study of the urban Brazilian population, comprised of Europeans, Asiatics, Arabians, Africans, and Native Amerindians, the frequency of the mutant allele in this population was 35%, but no homozygous Δ CCR5 individual has been discovered so far (Passos & Picanc, 1998). Differences in prevalence of the Δ CCR5 allele continue to be examined among different ethnic groups. A study of the CCR5 gene among 377 Puerto Ricans showed 94.2% nondeletion homozygote (normal CCR5 gene), 5.8% Δ CCR5 allele heterozygotes, and 0% Δ CCR5 allele homozygote (Gonzales et al., 1998). Thus, Puerto Ricans appear to resemble the U.S. Hispanic population, whose genotype frequencies were 93.3% nondeletion homozygote and

6.7% Δ CCR5 allele heterozygotes. In comparison, a study of U.S. Caucasians found 77.4% nondeletion homozygote, and 22.6% Δ CCR5, whereas African Americans exhibited 97.7% nondeletion homozygote and 2.3% Δ CCR5 allele heterozygotes (Gonzalez et al., 1998; Zimmerman et al., 1997). These findings underscore the possible importance of differential population distributions of the Δ CCR5 allele in HIV-1 infection and progression.

Recent investigations reveal that the Δ CCR5 allele is not the only genetic determinant of HIV-1 prognosis. A CCR2-64I mutation allele was discovered at a frequency of from 10% to 15% among Caucasians and African Americans (M. W. Smith et al., 1997). It was shown that CCR2-64I does not influence infection by HIV-1, but delays progression to AIDS. HIV-1 infected individuals carrying the CCR2-64I allele progressed to AIDS from 2 to 4 years later than those HIV-1 infected individuals carrying the normal CCR2 allele. Unlike the different frequency of the Δ CCR5 allele among different ethnic groups, the CCR2-64I allele mutation was found in every ethnic group tested: 98% in Caucasians, 15.1% in African Americans, 17.2% in Hispanics, and 25% in Asians. The frequency of the CCR2-64I allele was consistently lower among those who progressed rapidly to AIDS than in the nonprogressor or slow group with delayed onset of AIDS for more than 6 to 12.5 years following infection (M. W. Smith et al., 1997).

Another genetic determinant discovered to be associated with the slower progression to AIDS, not HIV infection, is homozygosity for a mutation in the 3' untranslated region of the SDF-1 gene (Winkler et al., 1998). The SDF-1 is the specific chemokine ligand for the chemokine receptor CXCR4, a coreceptor with CD4 for T-tropic HIV (HIV-1). It is postulated that the mutant allele (SDF1-3'A) blocks or down regulates CXCR4, effectively blocking infection by the T-tropic HIV-1 strain often present late in the course of HIV infection. Winkler et al. (1998) found different frequencies of the SDF1-3'A allele among different ethnic groups. Among Caucasians tested, the prevalence was 21.1%, among Hispanics 16%, among African Americans 5.7%, and among Asians 25.7%. In a study of 2,857 patients, there was a marked delay in progression to AIDS for those individuals homozygous for the SDF1-3'A allele. It was also found that the delay in progression associated with the SDF1-3'A allele was twice as long as the delay associated with Δ CCR5 or CCR2-64I alleles (Winkler et al., 1998). In another study, the ethnic diversity of the SDF1-3'A allele was reported to vary widely among the different populations (Su, Chakraborty, Jin, Xiao, & Lu, 1998). The frequency of the allele ranged from 2.9% in the African populations to 71.4% in the New Guinean population. Individuals homozygous for this allele were not found among the African populations studied, but were found among populations in North America, Europe, Asia, and Oceania. The frequency of the SDF1-3'A allele was lowest in Africa (2.9%–9.1%) and higher in American Indians, Europeans, and Asians (12.2%–36.6%). The prevalence of the allele was highest among two New Guinean highlander populations (66.7%–71.4%). The frequency of homozygotes for this allele was also highest among the two New Guinean

highlander populations (39.6%–47.6%). The global range of the SDF1-3'A allele and its genotype among various ethnic groups, and its role in delaying the onset of AIDS provides opportunities for exploring potential genetic-based therapeutic interventions (Su et al., 1998; Winkler et al., 1998).

Recent investigations have identified an allele that speeds up the development of AIDS. Martin et al. (1998) showed that individuals who are homozygous for the promoter allele CCR5P1, which influences the CCR5 gene, progress to AIDS more rapidly than those with other alleles of the CCR5 gene. The CCR5P1 directs the synthesis of other receptors that the virus uses for entry in to the CD4+ cell. Thus, the virus can replicate more rapidly, causing the individual to develop symptoms of AIDS several years earlier than those not homozygous for the CCR5P1 allele. In a study conducted by Martin et al. (1998), the frequency of individuals homozygous for the CCR5P1 gene was 12.7% among Caucasians and 6.7% among African Americans. Homozygous Caucasian cohorts exhibited a rapid progression to AIDS, but the African American homozygous cohort failed to show accelerated progression to AIDS (Martin et al., 1998). Apparently, not everyone who is homozygous for the CCR5P1 will progress quickly to AIDS. Nevertheless, approximately 10% to 17% of those patients who develop AIDS within 3.5 years of being infected are homozygous for the CCR5P1 gene, whereas others not homozygous for the CCR5P1 gene may stay symptom-free for 15 or more years.

OTHER RACIAL DIFFERENCES IN DISEASE

In another study of racial differences, inmates in two large prisons were assessed and retested for conversion of the tuberculin test to positive (Stead, Senner, Reddick, & Lofgren, 1990). The rate of conversion was twice as high for Blacks as for Whites, although all the inmates were exposed to the same environmental factors. The study raises the possibility that the reason for the high TB test conversion may be attributable to racially determined genetic differences.

Racial differences have also been observed in lipoprotein and cardiovascular abnormalities among renal disease patients (Burrell et al., 1991). In general, Blacks have lower total cholesterol (TC) concentrations, higher high density lipoprotein-cholesterol (HDL-C) concentrations, a lower TC/HDL-C ratio, a higher apolipoprotein (apo) A-I concentration, lower apo B concentration, and a higher A-I/B ratio than Whites (Burrell et al., 1991). This better lipid profile is significant in terms of heart disease and end-stage renal disease (ESRD). Racial disparity is also apparent in the levels of lipoprotein a, Lp(a). Lp(a) is strongly associated with coronary heart disease. Serum Lp(a) levels exceeding 25mg/dl are twice as likely to lead to myocardial infarction (Harris-Hooker & Sanford, 1994). Interestingly, Blacks are shown to have twice as much serum Lp(a) than Whites, yet there was no rise in the CHD mortality in Black participants studied (Harris-Hooker & Sanford, 1994). Overall, these findings may indicate that the reduced incidence of coronary disease and mortality in Black ESRD patients, despite increased incidence of hypertension overall, may be due to the genetically favorable lipid profile of

Blacks (Burrell et al., 1991). The outcome of mortality and morbidity of cardiovascular disease in African Americans is influenced by a number of other factors ranging from lack of preventive health services to racism in health care.

For over 50 years, racial differences have also been recognized in hypertensive patients (Adams, 1932). Epidemiological evidence has demonstrated clearly that some Blacks experience higher rates of elevated blood pressure during childhood (Voors, Foster, Frerichs, Webber, & Berenson, 1976) and adulthood (Hypertension Detection and Follow-Up Program Cooperative Group, 1977; Roberts & Maurer, 1981) and higher rates of target organ damage (Saunders, 1985, 1987). The significantly reduced renin levels in Blacks, as compared to Whites, is considered to be the pathophysiologic mechanism underlying differences among White and Black hypertensive patients. Although there is certainly some evidence that environmental factors may contribute to differences in the prevalence of morbidity and mortality from hypertension between Blacks and Whites, there is also an abundance of evidence of genetic differences with associated hormonal and physiologic aberrations (Saunders, 1987; Voors et al., 1976).

HTLV infection, hypertension, tuberculosis, diabetic nephropathy, and HIV-1 associated nephropathy are not the only diseases with racially different susceptibilities. They serve, however, as examples of diseases for which environmental and lifestyle factors are not sufficient to account for the observed ethnic/racial differences in frequency and morbidity. Therefore, genetic factors are a likely candidate for causal influence. Elucidation of the biologic mechanisms associated with genetic differences would confirm their role. For example, the elucidation of the CCR5 receptor in attachment of HIV to CD4+ cells provides a biologic confirmation of genetic determinants that covary with race.

ARE THERE BIOLOGICALLY BASED DIFFERENCES IN DISEASE SUSCEPTIBILITY ACROSS GEOGRAPHICAL SPACE?

The recent discovery of the Δ CCR5 allele and its differing frequency among different ethnic groups prompted numerous studies of the global distribution of the Δ CCR5 deletion allele. As we remarked earlier, an extensive population survey conducted by Martinson et al. (1997) found geographical differences in distribution. An additional study of the frequency of the Δ CCR5 allele across Eurasia revealed a range of from 0% to 14%, affirming the previous study of a north to south gradient in allele frequency and its near absence in East Asian, Middle Eastern and American Indian populations (Stephens et al., 1998). The highest allele frequency in North Europe is among the Swedes. Among the Mediterranean population the frequency is from 5% to 14%, among Greeks 4.4%, and among the Saudi and East Asian populations 0%. The data show high Δ CCR5 allele frequency among northern European Caucasians (Central Asian groups such as Tatars, Tuvinians, Kazakhs, Uzbeks, Uigurs and Azerbaijanis), and an absence among the Lebanese, Georgians, Saudis, Koreans, Chinese, and American Indians (Stephens et al., 1998). Yudin et al.

(1998) examined the allele distribution across the Russian part of Eurasia and found a 10.4% to 22.2% frequency among the West Siberian populations (whose descendants typically are from European parts of Russia). In contrast, very low frequencies of the Δ CCR5 allele were found among the Far Eastern and Native East Siberian populations.

The uneven distribution of the Δ CCR5 allele across geographic regions and racial groups has generated discussions about the rate of HIV transmission or the speed of the disease progression in different racial groups. Certain populations carrying the Δ CCR5 allele may have an increased survival advantage in the HIV epidemic, whereas those lacking the gene variant may have a higher prevalence of HIV infection and a more rapid disease progression. African Americans, having a lower prevalence of the Δ CCR5 allele, are at greater risk for HIV infection than Caucasians in the United States, when known risk factors were controlled. The global pattern of the Δ CCR5 allele and its associated effect on HIV infection and disease progression calls for closer investigations (McNichol et al., 1997).

Human T-cell Leukemia Virus (HTLV-1) may also be an important cofactor in HIV disease progression. Coinfection with HTLV-1 is thought to increase the rate of development to an AIDS state (Cohen, Sande, & Volberding, 1995). Several studies have been conducted on the seroprevalence of HTLV-I in different regions of the world. From their data, different areas of the world have been found to be endemic areas of HTLV-I. In addition to areas in Japan and the Caribbean already discussed, Levine et al. (1988) found a new high risk population in a group of Native Americans from southern Florida. In addition to this group, other areas of the United States have been shown to be HTLV-I endemic areas. Williams et al. (1988) found HTLV-I seropositivity to be high in the southeastern and southwestern United States. Robert-Guroff et al. (1985) also found a high prevalence in Eskimo populations in the Arctic.

Besides these areas of relatively high seroprevalence in North America, HTLV-I has been found in South America, particularly in southwestern Colombia (Maloney, Ramirez, Levin, & Blattner, 1989) and Venezuela (Merino et al., 1984). These results have implications for possible racial differences because in all of these studies, the HTLV-I antibody appeared to be less prevalent in Whites than in non-Whites. In addition, Levine et al. (1988) observed varying percentages of HTLV-I positive patients with non-Hodgkin's lymphoma (from < 5% in the Middle East, Asia, and Europe, to 84% in nonendemic areas of Japan). They attributed this variability to either different strains of HTLV-I or other retroviruses or to differences in the genetic susceptibility of the hosts.

IMMUNOLOGIC EVIDENCE FOR RACIAL DIFFERENCES IN HIV DISEASE

Racial differences have been found in the expression of HIV antigen p24 (HIV-Ag). HIV-Ag is used as a marker for the clinical progression of HIV infection. In HIV positive individuals, p24 prevalence increases with increasing immunodeficiency, as measured by T-cell counts. Chaisson et al. (1991)

confirmed a racial difference in the prevalence of HIV p24-Ag between Blacks and Whites (18% vs. 38%). Further, anti-p24 antibodies were detected in higher proportions of Blacks (84% vs. 65%), and Blacks had higher mean immunoglobulin levels than Whites. These results may indicate that Blacks have a more sustained humoral response to HIV infection than Whites. Similar results were found in a comparative study with AIDS patients from Uganda, Kenya, and the United Kingdom. As opposed to patients from the United Kingdom, there was no significant reduction in p24 antibodies among East African asymptomatic and AIDS patients and p24 antigenemia occurred more frequently in UK individuals (65%) (Kaleebu et al., 1991).

In a study of HIV infected injecting drug users (IDU) conducted by Gorter, Vranizan, Osmond, and Moss (1992), racial and sex differences were found in the presence of the HIV marker p24 antigenemia. Black females were much less likely to have the p24 antigenemia than Black males or White males and females. Of the cohort studied, only 1% of the Black IDU women tested positive for the p24 antigen, whereas 14% of Black men, 12% of White men, and 20% of the White women were p24 antigen-positive. The low prevalence of the HIV p24 antigenemia in Black females however, does not necessarily mean a slower progression to AIDS than Whites or Black men. Results of this study should be considered in studying HIV in ethnic minority women.

There are also other reports of important immunological differences among subpopulations that may have clinical implications (Gorter et al., 1992). In an investigation by Lucey and colleagues (1992), Blacks had significantly higher IgG and IgA levels than Whites. This observation suggests that racial differences in humoral immunity may underlie the observed racial differences in HIV antibody levels and HIV antigenemia.

A study done on malaria by Hill et al. (1991) supports the hypothesis that extraordinary polymorphism of major histocompatibility complex genes has evolved primarily through natural selection by infectious pathogens. This theory of pathogen driven MHC diversity requires that individuals of different MHC types should differ in their susceptibility to at least some major infectious pathogens. In fact, the study showed that the presence of HLA Bw53 and either the HLA haplotype DRB1* 1302 or DQB1*O501 provides the same protection as the sickle cell variant. Interestingly enough, these HLA combinations are common among West Africans (40%), but almost completely absent from Whites and Asians (0%–1%). This study suggests that malaria has influenced the evolution of polymorphic MHC genes in humans. The study opens doors into a new way of thinking. It is now possible to ask the question of whether or not HIV and AIDS are having any similar effects (Hill et al., 1991).

As suggested by the malaria study, individuals of different MHC types should differ in their susceptibility to at least some major infectious pathogens. Unfortunately, no convincing associations between HLA polymorphism and susceptibility to commonly fatal infectious diseases have yet been identified, in contrast to well-known associations between HLA and many autoimmune diseases (Hill et al., 1991).

Specific HLA combinations have been found to increase or to decrease the progression of AIDS. If each ethnic group has its own patterns of HLA combinations, then more extensive research needs to be done in order to isolate HLA or loci influencing disease progression within specific ethnic populations.

Of course, no one population is completely ethnically distinct from another, thus the high prevalence of HTLV-I and especially HTLV-II in Native American populations is particularly interesting due to the mixing of the Native American gene pool. In the United States, the Native American Indian and Black populations have intermingled, resulting in the introduction of Black genes into the Native American population. Of course, the converse is equally true. That is, a Native American predisposition could have been introduced into the American Black population. Cross-racial studies between American Blacks, American Indians, and African Blacks would further elucidate this possibility. This intermingling is useful for studies of genetic susceptibilities. Further, it cannot necessarily be assumed that all members within a particular racial/ethnic group are genetically homogeneous.

RACIAL DIFFERENCES IN DRUG RESPONSE

Racial factors play a role in drug response as well. For example, Asians have been shown to require lower dosages of a wide variety of psychotropic drugs, including neuroleptics, tricyclics, lithium, and benzodiazepines (Lin, Poland, & Lesser, 1986). Similarly, Blacks and Hispanics also require lower clinical dosages of tricyclics. Racial differences in the metabolism and sensitivity to the drug were found between Asians and Caucasians (Zhou, Adedoyin, & Wood, 1992).

Pharmacokinetic effects can vary depending on the efficiency and extent to which a given drug is metabolized. Metabolism of drugs can be measured by observing the blood concentration of the drug as a function of drug dosage. Differences in drug sensitivity are shown by observing the effects of varying drug dosages. By looking at both of these effects, researchers have determined some of the reasons behind the racial differences in drug response (Zhou et al., 1992). For example, the effects of propranolol, a beta-blocker, were examined in Chinese and American White subjects (Zhou et al., 1989). It is already known that the dosages of propranolol prescribed in China are significantly lower than those prescribed in the United States and Europe. Zhou et al. (1989) concluded that Chinese males have a greater sensitivity to propranolol based on genetic racial differences mediating the effects of the drug on heart rate and blood pressure. Whereas the actual mechanism of the increased sensitivity in Chinese is unknown, they suggest that differences in the beta-receptor sites on the heart are partly responsible. In addition, the Chinese subjects demonstrated a dissimilar metabolism of propranolol as compared to the Caucasian subjects. Chinese males were able to metabolize propranolol two times faster than Caucasians by means of ring oxidation and conjugation. As a result, Asians had lower plasma concentrations of the drug at any given dosage (Zhou et al., 1989). The twofold higher clearance of propranolol in Asians further accentuates

the sensitivity differences observed in that Asians still showed a greater response to propranolol at a given dosage, even though the drug was broken down at a greater rate in Asians than in Whites.

Zhou, Shay, and Wood (1993) studied the differences in plasma binding of propranolol between Caucasian and Chinese men. Chinese men not only have higher concentrations of unbound propranolol, but the ratio of unbound (-) to (+)-propranolol was greater in Chinese men than in Caucasian men. A larger concentration of unbound propranolol may contribute to their heightened sensitivity to the effects of propranolol.

Differences in the effects of propranolol in Black and Caucasian men have also been documented. In one study (J. A. Johnson, 1993), Black men were less sensitive to 1-propranolol than Caucasian men (Johnson & Burlew, 1992). Beta-receptors possessed a greater affinity for propranolol in Caucasian men, hence producing a greater sensitivity to beta-blockade. It was also noted that in order to occupy 92.5% of the beta-receptors, Black males needed seven times more propranolol than White males.

J. A. Johnson, Burlew, and Stiles (1995) observed that Caucasian males were more sensitive to the chronotropic effects of isoproterenol, a beta-agonist, than Black males. Black men needed twice the amount of isoproterenol than Caucasian men to attain the same response.

Ethnic differences in parasympathetic response have also been of concern to researchers. Equal doses of atropine, which induces parasympathetic blockade, were administered to eight American-born Caucasian men and Chinese men (Zhou et al., 1992). The heart rates of the Chinese participants had a significantly greater increase than those of the Caucasian participants. The plasma atropine concentration was also measured and used to correct the increase in heart rate in both groups. The Chinese men had a 2.8 fold higher heart rate for each nanogram per milliliter of plasma atropine in comparison to the Caucasian men. In addition to these findings, researchers observed that the Chinese men had a significantly higher heart rate reduction than the Caucasian men when propranolol was given along with atropine (Zhou et al., 1992). Apparently, Chinese men are much more sensitive to the effects of atropine than Caucasian men (Zhou et al., 1992). These results also support previous research described earlier that Chinese men are more sensitive to propranolol (Zhou et al., 1989).

Much research has focused on racial differences in the effects of haloperidol, a commonly used neuroleptic drug (Lin, Poland, et al., 1988). Haloperidol is a stimulator of prolactin secretion. In studies of Asians and Caucasians, Caucasians had lower plasma concentrations of haloperidol and a lower prolactin response than did the Asians subjects (Lin, Poland, et al., 1988). Even after controlling for variations in body surface area, the difference in drug response remained significant. Because researchers found no distinctions in the responses of foreign-born and American-born Asians, differences in lifestyles do not appear to be a significant factor in this aspect of drug response. Instead, the differential drug responses are likely due to genetic differences between Asians and Caucasians (Lin, Poland, et al., 1988). Lin et al. (1989) further observed in schizo-

phrenic patients that the racial difference in drug response was mainly due to pharmacodynamic factors. With fixed dosages, Asian patients had slightly greater serum concentrations of haloperidol and greater extra pyramidal symptoms. With variable dosages, Asian patients again required lower dosages for an optimal clinical response (Lin et al., 1989). As in their previous study, body surface area was controlled. Therefore, the lower dosages required for Asians appear to be due to increased sensitivity to haloperidol.

Building on these findings, Chang et al. (1991) discovered that in patients with schizophrenia, Chinese patients had higher haloperidol plasma levels than non-Chinese patients, which included Caucasians, Hispanics, and Blacks. In addition, this study examined "reduced haloperidol," the alcohol metabolite produced by the reduction of haloperidol at the benzylic ketone. The ratios of "reduced haloperidol" to haloperidol were lower in the Chinese patients than the non-Chinese patients. This suggests racially influenced differential rates in the metabolism of haloperidol.

Racial differences have also been observed in studies of anxiolytic medications. For example, studies with the benzodiazepine-like drug, alprazolam, also show that racial differences in pharmacokinetic effects exist between Asians and Caucasians (Lin, Lau, et al., 1988). Because of this, Asians require lower clinical dosages of alprazolam than Caucasians (Lin, Lau, et al., 1988). To what extent this is due to differences in behavioral factors, such as diet, is unknown, but evidence for genetic factors were strongly suggested. Zhang, Reviriego, Lou, Sjeoqvist, and Bertilsson (1990) found interethnic differences in the metabolism of diazepam, an anxiolytic sedative. In their study, Chinese subjects metabolized diazepam at a much slower rate than Caucasian subjects, suggesting that those of Chinese descent may require lower doses of diazepam. Finally, Caraco, Tateishi, and Wood (1995) discovered that their Chinese subjects possessed a slower metabolism of diazepam than the Caucasian subjects. They also observed ethnic differences in omeprazole's inhibitory effect on the metabolism of diazepam. After taking omeprazole, diazepam clearance was similar in both the Caucasian and Chinese participants. However, the area under the concentration time curve (AUC) for diazepam's metabolite, desmethyldiazepam, was significantly lower in the Caucasian group than in the Chinese group. Thus, it appears that not only do Chinese men metabolize diazepam at a slower rate than Caucasian men, but the effect of omeprazole among Chinese men is greatly reduced as compared to Caucasian men.

Lithium is another psychiatric medication that has been examined for possible racial differences in drug effects. In one study (Strickland, Lin, Fu, Anderson, & Zheng, 1995), African American and Caucasian bipolar patients displayed different drug-related responses. Specifically, African Americans evidenced much higher red blood cell lithium concentrations and a much higher lithium ratio when compared to Caucasians. They also experienced a greater number of side effects. The results hint that African Americans may require lower dosages of lithium than Caucasians.

Although studies on racial differences in the effects of psychotropic medication has clearly demonstrated possible

differences with relevance to dosing regimens, research in other major diseases is less developed with the exception of treatment of hypertension. Racial differences between Blacks and Whites in the prevalence and the sequelae of hypertension also have important therapeutic implications. Evidence that Blacks are relatively unresponsive to antihypertensive therapy is inconclusive. On the contrary, there is significant evidence that when pharmacologic interventions are combined with other environmental measures, Blacks benefit more (Hypertension Detection and Follow-up Program Cooperative Group, 1979a, 1979b). There is also strong evidence that in monodrug therapy, the optimal drugs to achieve effective control in Blacks are different from those likely to be successful in Whites (Cubeddu et al., 1986; Saunders, 1985).

Evidence for other race-related differences in treatment of hypertension also exists. For example, the pharmacokinetics of nifedipine, a dihydropyridine calcium channel blocker, differs among racial groups. Ahsan et al. (1993) discovered that Asians, South Asians in particular, had higher plasma concentrations of nifedipine after a standard dose than Caucasians. Also, the area under the plasma concentration time curve (AUC) was twice as high in Asians as in Caucasians. Sowunmi, Rashid, Akinyinka, and Renwick (1995) observed that South Asians as well as Nigerians had a significantly higher AUC and higher plasma concentrations than Caucasians. The difference of nifedipine metabolism between the three populations suggests differential bioavailability and/or differential systematic clearance.

IMPLICATIONS FOR HIV/AIDS RESEARCH

From the disparate evidence presented, it is clear that racial differences exist for disease susceptibility and drug response. In many cases, increased susceptibility or resistance to a disease is associated with known racial differences in HLA specificities, CCR5, CCR2, SDF1, and the recently discovered CCR5P1 gene (Martin et al., 1998). With the recent discoveries of these host genes, new genetic therapeutic approaches may be designed to target the specific gene variant among individuals (McNicholl et al., 1997). Furthermore, different races can have varying responses to drugs. These responses are determined by differences in absorption, metabolism, or excretion (pharmacokinetic effects) or by differences in drug sensitivity (pharmacodynamic effects) that are influenced by genetic factors (Lin, Lau, et al., 1988; Lin, Poland, et al., 1988). Because of these biologically determined differences in disease susceptibility and drug response, the importance of cross-racial factors when conducting studies of disease and developing pharmacologic interventions needs to be taken into consideration.

The multigenetic influence on HIV-1 infection and progression to AIDS, and its difference in prevalence among ethnic groups, provides a basis for therapeutic opportunities. The studies presented here that show varying frequencies of the host genes among ethnic populations provide sufficient support for the importance of considering the patient's racial genetic profile in developing appropriate therapeutic strategies. Accordingly, any research conducted must take into account cross-racial fac-

tors so that what is known about the course of the disease in any given population can be elucidated accurately.

The only mechanism by which to achieve this is through the inclusion of an ethnically representative subject population in clinical trials of HIV/AIDS drugs. This would help ensure that a particular drug in standard recommended dosage has the desired therapeutic effect in one racial group as it does in another. Without cross-racial data, the results of trials on one race may not necessarily be applicable to another race. AIDS researchers must be sensitive to these issues to prevent the approval of HIV-related therapies that may not have the same efficacy or safety profile in populations outside the gay White male community. An example of one such study, Study ACTG 116-B/117, was reviewed by the Food and Drug Administration a few years back. This study was sponsored by the National Institute on Allergies and Infectious Diseases, the leading governmental agency conducting AIDS research in the United States (Japour et al., 1995), and was designed to compare the efficacy and toxicity of didanosine (ddI) and zidovudine (ZDV or AZT) in the treatment of primary HIV infection in patients who tolerated previously more than 16 weeks of ZDV. The investigators concluded, based on information from 913 participants who were randomized at the time of analysis, ddI appeared to be more effective than ZDV in delaying time to first new AIDS-defining event or death in the study population. This benefit was seen in the subgroup of patients who entered the study with AIDS-related complex (ARC) or asymptomatic disease, but not in those with AIDS. The composition of this study population was 96% male, 82% White, and 79% from the homosexual/bisexual risk behavior group. The biological and genetic composition of this group, more homogenous than the general HIV infected population, may capitalize unknowingly on finding effects that may be influenced by unmeasured factors, thus overestimating the effectiveness of this treatment when widely applied. Although no studies have shown these findings to be detrimental, nonetheless it is important that findings from studies that lack diversity be approached cautiously as proven treatment plans for those who were not participants in the study. Further research should be conducted to determine whether results from such studies are equally effective in the populations not a part of the study.

Admittedly, the challenges of recruiting and retaining some subpopulations, especially the socially and economically disenfranchised, may be difficult, expensive and require considerable investment of time and resources (El-Sadr & Capps, 1992; Mays, 1998, 1999; Mays & Cochran, 1999). Nonetheless, by including more representative samples of the affected populations of a particular disease, more accurate and useful information can be gained. This is especially important in the development of effective HIV-related drug treatments as trends of incidence of HIV infection indicates a rise in new cases within ethnic minority groups who in the past have been the least likely to be recruited into studies.

Yet, despite 15 years of research in the quest for a cure or control of HIV/AIDS, HIV clinical studies, drug treatment, and drug and vaccine development study methodology is only in its infancy when it comes to ensuring adequate study par-

ticipation by ethnic/minorities (Mays, 1998, 1999; Mays & Cochran, 1990, 1999). This is because of a variety of complicated reasons (Mays, 1998, 1999; Mays & Cochran, 1999; Stone, Mauch, Steger, Janas, & Craven, 1997). But there are also a number of steps that can be taken to increase the likelihood of advancement of scientific knowledge in the area of biomedical research on HIV-related disease susceptibility, disease progression and pharmacologic interventions for ethnic minority groups.

The following steps are recommended: First and foremost, leadership by the federal government is critical in directing the research agenda to focus on possible racial/ethnic differences in susceptibility to infection, disease progression, and clinical and drug treatment options and strategies. This could be accomplished through the following:

1. A request by the President to the federal agencies and the Surgeon General to ensure that all clinical, vaccine, drug development, and drug treatment research scientifically demonstrates effectiveness across ethnic/racial groups.
2. Development of a mechanism (collaborative workgroups, advisory boards, or citizen consultants of experts on HIV and ethnic minorities drawn from senior researchers with strong research publication records, senior policy advisors and clinicians with long histories of working with minority populations) under the combined auspices of Office of AIDS Research (OAR), Office of Minority Health (OMH) and NIH with the charge to identify the gaps in the current NIH, OAR, and private-sector research portfolios; recommend new directions for biomedical research within NIH and OAR that would ensure better science on HIV-related racial/ethnic differences in genetic and immunologic aspects of HIV disease susceptibility, disease progression, and clinical and drug treatment strategies and options; and review the international HIV research portfolio to determine possible ethnic/racial difference research studies that could answer specific scientific questions.
3. A convening of a conference on biomedical research on racial/ethnic minorities with a series of commissioned papers. Publish and disseminate papers, develop regional and national data sharing collaborations, and provide seed funding for collaborators to engage in data analyses on issues identified as high priority by the conference.
4. Development of funding opportunities (RFAs, RFPs) targeting gaps in the biomedical research portfolio on racial/ethnic differences in HIV infection, disease progression/nonprogression, drug treatment, and clinical and drug development response.
5. Creation of a cooperative agreement for funding for collection of biological data from racial/ethnic minorities who are HIV seronegative high risk, HIV seropositive, and diagnosed with AIDS in order to develop a specimen repository, under the scientific direction of a multiethnic senior research team. This repository

could be made accessible nationally to investigators who submit proposals to the senior multiethnic research team that maintains oversight.

6. Building on previous federal initiatives designed to increase the number of ethnic minority principal investigators, development of a RFA for three funding cycles within NIAID targeting basic genetic, immunologic, vaccine, and treatment research on racial/ethnic differences under the leadership of senior/tenured minority principal investigators.
7. Development of review guidelines for NIH review committees that address not only inclusion of minorities but the inclusion of specific scientific hypotheses that explore racial/ethnic differences in genetic and immunologic responses to HIV infection, disease progression/nonprogression, response to drug development, and clinical and drug treatment strategies and options.

Whereas leadership by the federal government is essential and necessary to accelerating the science of racial/ethnic differences in susceptibility for HIV infection, disease progression/nonprogression and responses to vaccine candidates and clinical and drug treatment strategies and options, there are others who can exert leadership in this domain. For example:

1. Medical journal editors should require that when minorities are participants in studies, evidence be provided that there are no differences from nonminorities if their data are not presented separately or in comparison to nonminorities or between ethnic groups. Analyses by race/ethnicity should be required unless there is a statistical case for foregoing such procedures.
2. Researchers must take seriously the task of mastering the scientific literature on HIV in ethnic minorities in order to develop testable hypotheses that can advance the field on ethnic/racial differences in the cause and treatment of HIV infection and disease. Many investigators will find that increased attention to this body of data will not only assist in advancing science but better equip them to design racially/ethnic diverse studies and maintain study cohorts.

Finally, although the authors could envision a number of additional recommendations to urge HIV research or biomedical research on racial/ethnic differences, none is as compelling as urging mechanisms to ensure that scientific findings are translated into prevention, intervention, and treatment strategies that reach the community. Without creating mechanisms by which the findings actually reach and benefit the population being focused on, researchers lose credibility with the community and fail to achieve the fundamental purpose of science, that is, to improve the lives of others.

ACKNOWLEDGMENTS

The terms, *Black* and *African American*, are often used interchangeably in the literature. Some present-day African Americans are descended from Africans brought to this country more

than a 150 years ago. However over time there has been admixture in which African Americans share a mixed biological heritage with Native Americans, Whites, and other racially distinct populations. There are also a number of groups that within research studies are designated Black but maintain some genetic distinctions in their admixture from African Americans such as Haitians, Belizeans, or Black Puerto Ricans. In studies, the designation of Blacks or African Americans may vary in which biological heritage groups are included. Therefore, throughout this chapter the term adopted by the original author of the work being reviewed is used in order to remain true to their designation of the population.

This work was supported by grants from the National Institute of Mental Health and the National Institute on Allergy and Infectious Diseases (R01MH42584, R01MH44345, R01AI38216) and an NIMH Scientist Development Award (K21MH00878) to the third author. We thank Mary Carrington, Lovell Jones, David Carlisle, and Karol Watson for their assistance, although we assume all responsibility for the contents of the chapter.

Women and AIDS: A Contextual Analysis

Jeannette R. Ickovics
Beatrice Thayaparan
Kathleen A. Ethier
Yale University

An estimated 33.6 million adults are now infected with the human immunodeficiency virus (HIV; UNAIDS, 1999). With 16,000 people becoming infected daily, as many as 40 million people will be infected with HIV by the turn of the century. Women account for 44% of all estimated HIV infections worldwide, and the proportion of women infected is rapidly increasing in every geographic region. At the present rate of infection, the numbers of women and men infected will be equal by the year 2000. Currently, the ratio of female-to-male AIDS cases varies dramatically by region; in sub-Saharan Africa the ratio is 1:1, in the Caribbean the ratio is 1:3, in South and Southeast Asia the ratio is 1:4, and in Europe, the Middle East, North America and Latin America the ratio is 1:5 (UNAIDS, 1998).

The AIDS epidemic has undergone profound demographic changes within the United States. In 1981, when AIDS was first identified, it was considered a disease of men who have sex with men; indeed, at that time, the syndrome was called "gay-related immunodeficiency disease (GRID)" (Centers for Disease Control and Prevention [CDC], 1981). In 1985, only 6.5% of newly diagnosed cases of AIDS were among women (CDC, 1986). Thirteen years later, this percentage has more than tripled to 23% (CDC, 1998a). Through 1998, 109,311 women in the United States have been diagnosed with AIDS; more than one half have died from AIDS-related causes. Nationally, AIDS is the third leading cause of death among young women from age 25 to 44. In some U.S. cities along the eastern seaboard (e.g., Miami, New York, Newark), AIDS is the leading cause of death among women in this age group. Although AIDS-related deaths de-

creased 13% overall in 1996, deaths among women with AIDS increased 3% (CDC, 1997).

Epidemiological data on the numbers of those infected with HIV (as opposed to diagnosed with AIDS) is scarce; however, some studies suggest that an even greater proportion of women are infected than is reflected in the data on reported AIDS cases. For instance, 27% of HIV cases through 1998 were among women, as compared to 16% of all AIDS cases (CDC, 1998a). In a study of nearly 2,000 patients in Los Angeles County, California, women were 3.4 times more likely to be diagnosed with HIV than AIDS (Sorvillo et al., 1995). Thus, new patterns of HIV transmission are not necessarily reflected by the standard AIDS surveillance techniques.

There are two main routes of HIV transmission among women. These include the sharing of needles by injection drug users (IDUs) and heterosexual sex. Heterosexual intercourse is the main route of HIV infection among women globally, accounting for three quarters of all AIDS cases. However, in the U.S., only 39% of cumulative AIDS cases are documented as having been caused through heterosexual transmission, whereas 43% of all women with AIDS have a history of injection drug use (CDC, 1998a). The epidemiology appears to be shifting: Among *new* AIDS cases in the U.S. the number attributed to heterosexual contact exceeds the number attributed to injection drug use.

Women are more likely than men to be infected with HIV through heterosexual sex for biological, epidemiological, and social reasons (World Health Organization [WHO], 1993). Male-to-female transmission of HIV is estimated to be eight

times more likely than female-to-male transmission (Padian, Shiboski, Glass, & Vittinghoff, 1997). As the receptive sexual partner in heterosexual activity, women are more at risk for HIV and other sexually transmitted diseases for anatomical reasons; the mucosal tissue lining the walls of the vagina is fragile and prone to injury. HIV found in seminal fluids and in sperm cells of seropositive men pose a great risk to their heterosexual partners (Royce, Sena, Cates, & Cohen, 1997). Heterosexual women are also at greater risk epidemiologically by virtue of sheer numbers: More men are infected with HIV, so the probability of having a seropositive partner is greater for women than for men. Finally, in many cultures women are expected to be sexually and socially subordinate to men; in such sociocultural environments, women may have limited power to protect themselves from HIV.

Risky sexual behavior does not exist in a vacuum, and as such must be examined within its developmental, social, and psychological contexts. Health psychology can contribute to the understanding of these contexts and the roles they play in disease transmission and progression. This chapter reviews the current empirical findings regarding women and HIV within an ecological perspective (Revenson, 1990). An ecological perspective considers characteristics of both the individual and the environment, including the dynamic pattern of interaction between them. This chapter is not intended to be an exhaustive review, rather it is an attempt to elucidate the complex sociocultural, interpersonal, temporal, and situational contexts that have an impact on women's risk for HIV infection. It also focuses on factors that have a potential impact on disease progression, coping and adjustment, and access to health care for women with or at risk for HIV.

In addition to addressing issues specific to women *infected* with HIV, it also considers women *affected* by the disease. Women are members of communities devastated by HIV, such as the explosive epidemics in sub-Saharan Africa, Southeast Asia, and in U.S. cities like San Francisco, Los Angeles, New York, Newark, New Haven, and Miami. These women are not necessarily infected themselves; however, they are directly affected by their roles as lovers, caretakers, or friends of those with HIV and AIDS. Subsequently, they may also be at risk for HIV infection.

AN ECOLOGICAL PERSPECTIVE

Biologists first used ecological approaches to describe the interdependence of plant and animal life in the same environmental habitat. Psychologists have articulated theoretical and empirical considerations of the interaction between the person and the environment for more than 60 years (Bronfenbrenner, 1977; Lewin, 1951/1972; Murray, 1938). As applied to health psychology, an ecological approach emphasizes that health is a result of a reciprocal and bidirectional association between individuals and the social contexts in which they live. These social contexts include individual relationships as well as the broader social, political, and cultural contexts of health behaviors and health outcomes. The ecological approach has been applied to analyses of the association between personality and disease (Revenson, 1990) and the role of sociodemographic factors on psychophysiological

responses such as heart rate and blood pressure (Anderson & McNeilly, 1991). The advantage of this approach is the recognition of the interdependence of individuals and their social contexts, and the complex associations among factors that influence health and health behaviors.

Following this conceptual model, this chapter examines four contextual domains that may influence HIV transmission and progression patterns for women at risk for HIV and those already infected: sociocultural, interpersonal, temporal, and situational contexts. The issues considered in each context are not meant to be mutually exclusive; there is overlap, as illustrated in Fig. 49.1.

SOCIOCULTURAL CONTEXT

Sociocultural factors—particularly culture and social class—have long been associated with health outcomes and health behaviors, such as differences in patients' symptom reports (Zborowski, 1958), differences in physicians' evaluation of such reports (Revenson, 1990), health seeking behavior, and adherence to prescribed treatment regimens (Kirscht, 1983; Matthews, Kelsey, Meilahn, Kuller, & Wing, 1989). These sociocultural factors may result in different cognitive models of illness and health care services as well as perceived or actual barriers to health care utilization (Revenson, 1990).

The study of women and HIV illustrates how sociocultural influences can impose a profound impact on women's health in particular (Amaro, 1995; de Bruyn, 1992; Fee & Krieger, 1993; Gay & Underwood, 1991; Gollub, 1999; Gupta & Weiss, 1993; Ickovics & Rodin, 1992; Krieger & Margo, 1990; Zierler & Krieger, 1997). These factors may determine whether preventive services are sought or whether women receive treatment for other sexually transmitted diseases that place them at increased risk for HIV transmission. Moreover, varying perceptions of and access to the medical system may have implications for women already infected with HIV. Access to antiretroviral drugs to slow the replication of HIV, as well as prophylaxis and treatment for opportunistic infections can extend life and enhance its quality for people infected with HIV. The cultural and economic conditions in which women live must be considered to understand fully the factors that put women at increased risk for contracting HIV, and the impact on the health and health care of those infected.

Cultural Factors Influencing HIV Prevention and Treatment

Norms are imparted through socialization—a process that gives individuals the knowledge, motivation, and skills to participate in their particular community; socialization provides information through social comparison processes and information exchange (Fischer, 1988; Latkin et al., 1995; Stryker & Statham, 1985). These norms regulate attitudes and behaviors, and social sanctions can result from deviation from these norms. In terms of their impact on HIV transmission, culturally determined values can influence perceptions of HIV, attitudes toward high risk behavior, norms of behavior, and the potential for behavior changes (Jemmott, Catan, Nyamathi & Anastasia, 1995). *Sex roles*, the gender-related

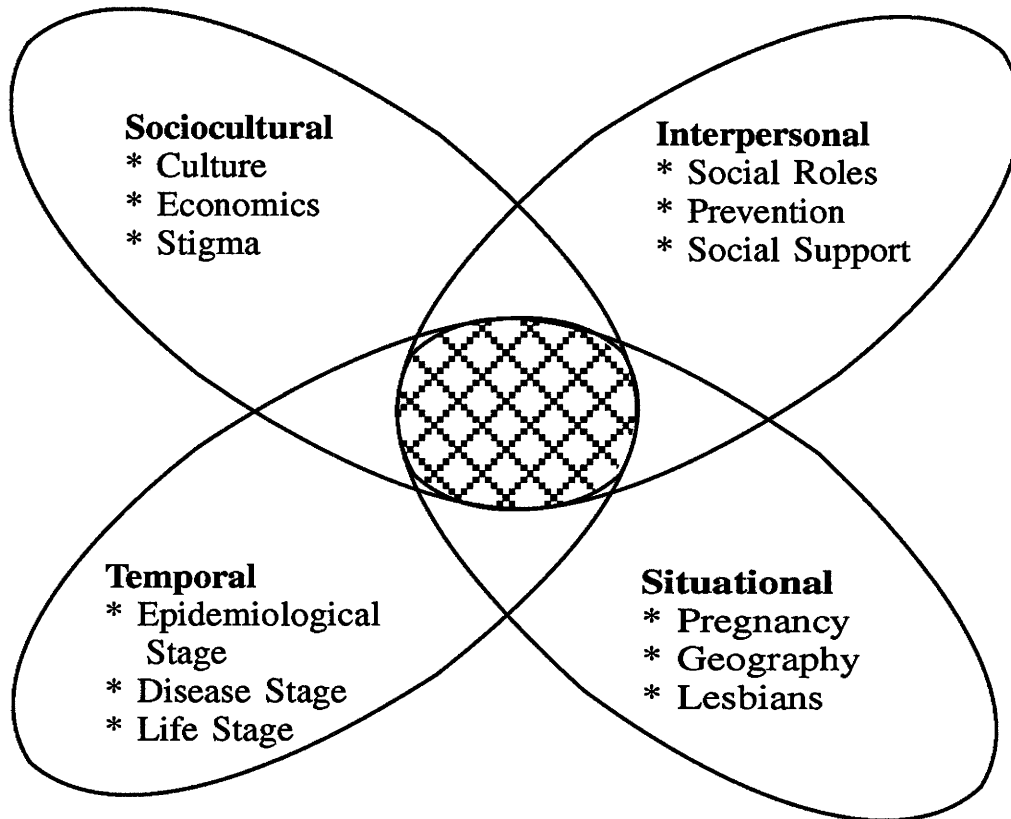

FIG. 49.1. Women and AIDS: A contextual analysis. Figure adapted from Revenson (1990).

roles determined by cultural norms regarding social interaction (Spence, Deaux, & Helmreich, 1985), can have an impact on HIV risk behavior. Even though societal endorsement of gender equality is common in the developed world, there is still resistance to the breakdown of sex roles. Individuals are pressured to conform, and may be differentially exposed to HIV-related risks as a function of their ascribed roles.

In many cases, social structures act to maintain the inequality of social relationships between men and women, which may adversely impact on women's risk for HIV. For instance, Amaro (1995) suggested that boys who have traditional views toward masculinity are more likely when they are older to have multiple sexual partners, to not know their partners very well, to not use condoms consistently, and to believe that contraception is a woman's responsibility. A woman's subordinate role increases her vulnerability to HIV because it may disable her from engaging in prevention practice, may lead her to participate in behaviors that place her at greater risk for HIV, or may increase the likelihood of sexual abuse or rape (de Bruyn, 1992; Gay & Underwood, 1991). Forced sexual intercourse is often violent and may produce bleeding; vaginal tissue can rupture during sexual intercourse, thereby increasing the ability of HIV to penetrate into the bloodstream (Piot et al., 1988).

The impact of culturally determined gender roles on sexuality and the negotiation of safer sex has been largely ignored, yet this may be one of the most important variables in predict-

ing HIV transmission (Amaro, 1995). For example, despite the dangers inherent in unprotected anal intercourse (Kimball, Gonzalez, & Zacarias, 1991), in some cultures anal sex is considered an effective contraceptive and a viable way to preserve a woman's virginity (Parker, 1987). To enhance sensation during vaginal intercourse, some women use intravaginal irritants such as herbs and hydroxides to dry the vaginal mucosa. Although this practice is believed to enhance the pleasure of sexual intercourse, the resulting abrasions to the woman's vagina increase her susceptibility to HIV and other STDs. These behaviors, which place women at higher risk for HIV transmission, result directly from cultural norms that place men in a more powerful position than women, leaving women less able to protect themselves.

Social roles and the accompanying attitudes toward sexuality, health, and health care are transmitted through cultural and religious norms. The impact of these norms on HIV transmission may partially explain racial and ethnic differences in HIV seroprevalence. In the United States, a disproportionate number of Hispanic and Black women are infected.¹ Al-

¹Following the Centers for Disease Control and Prevention, the broad terms *Hispanic* and *Black* are used. *Hispanic* refers to the ethnicity of individuals of Spanish descent often from Central and South American countries; race may be White or Black. *Black* refers to the race of persons of African or African American descent, as well as many from Caribbean countries.

though Hispanics and Blacks account for 10.3% and 12.6% of the individuals within the population (U.S. Bureau of the Census, 1997), among women with AIDS, 20.2% are Hispanic and 56.7% are Black (CDC, 1998a). Recent analyses indicate that Hispanic women are at seven times greater risk for AIDS than white woman (Klevens, Diaz, Fleming, Mays, & Frey, 1999). There is no reason to expect that race and ethnicity, per se, is responsible for these differences. Race and ethnicity serve as proxies for aspects of culture, religion, and social class that each have direct consequences for a woman's sexual behavior and her ability to prevent HIV infection, as well as her attitudes toward treatment for HIV.

For example, Black women may face cultural and social demands that increase their susceptibility to HIV infection. Cultural values emphasize family structure, gender relations, and social and economic survival; and these must be considered in the context of sexism, racism and economic oppression (Jemmott et al., 1995; Tesh, 1988). It has been argued that the sex ratio imbalance in African American communities may create a conflict for Black women: With fewer men available for intimate relationships, these opportunities are highly valued (Bennett, 1995; Worth, 1990). Moreover, this gender imbalance reinforces an existing power disparity favoring men when the desire for relationships exceeds the supply of potential partners (Guttentag & Secord, 1993). According to Mays and Cochran (1988), women may be fearful that the demand for safe sex will drive away a man; demands for condom use may be misinterpreted as lack of trust or suspicion, and may lead to accusations that the woman is sexually promiscuous, perhaps resulting in verbal or physical hostility.

Within the Latino culture, *machismo* is an attempt to institutionalize male dominance and female subordination (Barker & Loewenstein, 1997; Low et al., 1993; Torres, 1998). The tradition of *marianismo* also reinforces the inequality between men and women, relating women's nature to that of the Virgin Mary, which highlights the importance of motherhood as a primary role and focuses on deference and subordination to a greater power (Livingston, 1992). In a culture where a woman's social identity and acceptability is determined by her fertility, any contraception may pose a threat to her status in society (Kimball et al., 1991; Smyke, 1991). Such socialization can result in a feeling of powerlessness among adult women in their relationships with men (Gay & Underwood, 1991). *Simpatía* is another cultural script that emphasizes harmonious interpersonal relationships, and has been shown to be more prevalent among Latinos than Anglos (Marín, 1989; Triandis, Marín, Lisansky, & Betancourt, 1984). Some assert that it is "unacceptable" for a Hispanic woman to tell her husband to stop risky behavior or to use a condom in part because it could create conflict (Ehrhardt, 1988; Worth, 1990). Anecdotal accounts indicate that a woman's request to use a condom may be misinterpreted as a suspicion that she is already infected or an accusation of her partner's infidelity (de Bruyn, 1992). Moreover, Catholicism as the predominant religion in Latin America forbids the use of birth control. Indeed, Latinas are less likely to report using contraception (Marin, Tschann, Gomez, & Kegeles, 1993; Moscher & Bachrach, 1986).

Throughout the world, religious institutions like churches, temples, synagogues, and mosques serve as a foundation for a community's values. Religious guidelines regarding sexuality and birth control have a strong impact on members of a community (Worth, 1990). If condom use is discouraged, then women are faced with a social pressure that may increase their risk for HIV infection.² For instance, for both Catholics and Moslems, contraceptive use is forbidden. In a study of nearly 300 Moslem women in Kuwait, only 1% reported current condom use (Al-Gallaf, Al-Wazzan, Al-Namash, Shah, & Behbehani, 1995). In recent prevention efforts, United Nations and other governmental officials have begun to educate Islamic religious leaders so that they in turn would educate their communities about the importance of condom use (Simons, 1996). In Uganda, the Ministry of Health has actively sought the help of both Catholic and Muslim church leaders to campaign for safe sex by sponsoring workshops on reproductive health. Muslim leaders agreed to allow use of condoms when a partner is HIV seropositive. The Ugandan Catholic leaders continue to oppose condom use; they have chosen to advise families to change their behaviors and to remain faithful in marriages.

Culture may also have an impact on women's choices about HIV treatment. In a small study of women with HIV, Hispanic and Black women were two times more likely to delay entry into health care following a diagnosis with HIV than White women (Ickovics, Forsyth, Ethier, Harris, & Rodin, 1996). In the United States, the Black community has had a long history of distrust of public health services and research, fueled by the legacy of the Tuskegee syphilis study and a history of sterilization of women of color without their knowledge or consent (Auerbach, Wypijewska, & Brodie, 1994). Thus, they may be less inclined to seek traditional health care and may prefer alternative medical practices.

Throughout the world, there are deep cultural histories of the use of traditional healing practices. Complementary medicine is often less invasive than Western medical practices, relying on herbal remedies, botanicals, and healing rituals (Worth, 1990). In some traditions, healers are viewed as ministers of religions like Voodoo or Santeria. Recently, some conventional doctors have begun to promote the integration of both Western medicine and folk healing. These doctors claim that the combination of both traditions are better for patients because it promotes trust and respect, and encourages patients to work with their doctors to alleviate symptoms (Belluck, 1996). As a result, donor organizations and African governments have increasingly been interested in involving traditional healers in HIV/AIDS prevention initiatives (Green, Zokwe, & Dupree, 1995).

Cultural, racial, and ethnic stereotypes and expectations are generally well articulated. However, there are few studies that

²It is also important to note that some religious organizations have played a central role in the fight against AIDS by advocating HIV-related service and developing counseling programs and peer support groups (Crawford et al., 1992; Jenkins, 1995). Religious organizations that promote abstinence or sex only between married partners also may decrease the numbers of partners and reduce risk.

provide empirical evidence to support these statements. Fernandez (1995) emphasized that some of these stereotypes are outdated, and broad generalizations about racial or ethnic groups have been derived in part from clinical samples that do not account for important cultural mediators such as education, social class, and geography. It is also important to note that the incidence of HIV varies not only among Whites, Blacks, and Hispanics, but within sub-groups based on nationality, education, social class, and residence in rural versus urban settings (Menendez et al., 1990; Selik, Castro, Pappaioanou, & Buehler, 1989; Worth, 1990). This suggests that subcultures within larger racial or ethnic groups impact HIV transmission. For example, the prevalence of AIDS among Puerto Rican born Hispanics is seven times greater than the prevalence of AIDS among Mexican-born Hispanics (Selik et al., 1989). Similarly, there may be differences among Blacks based on background and country of origin (e.g., Africa, United States, Caribbean, Haiti; Jemmott et al., 1995). Thus, it is important to move the focus away from particular racial and ethnic groups per se, to gain a broader understanding of how culture works to prevent women from achieving social and economic equality within their particular communities.

Social Class and Its Influence on HIV Prevention and Treatment

Imbalances in economic situations, and subsequently in power, equality and control, have an adverse impact on women's health. Women are significantly more likely than men to be poor (U.S. Bureau of the Census, 1997). Individuals of lower social class have higher rates of morbidity and mortality from nearly all illnesses (Adler et al. 1994; Adler, Boyce, Chesney, Folkman, & Syme, 1992; Lantz et al., 1999; Pincus & Callahan, 1985; Pincus, Callahan, & Burkhauser, 1987; Rogot, 1992). The association between social class and health is said to be one of the most enduring relations in social science (Mechanic, 1994). The impact of social class on health can begin in childhood and have long-term consequences for adults' health (Williams, 1990). The disparity in health status between economic strata is found globally, and appears to vary linearly as a function of class inequalities within a given society (Adler et al., 1992).

Limited access to health care is one reason given for the social class differential in health outcomes. Poor women may also be at increased risk because they are more likely to engage in health damaging behaviors, such as excessive alcohol and drug use. Individuals of lower social classes have been shown to experience a greater number of undesirable life events (McLeod & Kessler, 1990) as well as higher levels of chronic and enduring stress (Turner, Wheaton, & Lloyd, 1995) as compared to individuals of higher social classes. In addition to differences in stress exposure, the impact of stress varies with social class. Compared to those of higher social classes, individuals of lower social classes experience greater distress when under comparable levels of stress (Kessler, 1979). Several studies also have shown that social class is related to the use of certain coping strategies in response to stress. Compared to those with less education and income, in-

dividuals in higher social classes are more likely to use active coping and less likely to use avoidant coping to manage stress (Aspinwall & Taylor, 1992; Billings & Moos, 1981).

When women are poor, they are not in a position to protect themselves from HIV. Women who are financially dependent on a husband or sexual partner may believe they have no choice but to comply with his demands (Gay & Underwood, 1991). This observation led Jonathan Mann, former director of the World Health Organization/ Global Program on AIDS, to call for the "economic emancipation" of women to prevent the further spread of HIV. The need for economic equity predates HIV. However, the neglect of the legal, medical, and social rights of women has been highlighted by the HIV pandemic. Poverty may increase a woman's vulnerability to HIV because of three conditions that it creates: lower levels of education, inadequate employment opportunities possibly resulting in commercial sex work, and the lack of adequate health care facilities (Gay & Underwood, 1991).

A condition that coexists with poverty is limited educational opportunities. When there are few educational facilities, these resources are less accessible to women. This results in lower literacy rates, thus restricting women's access to anti-HIV campaigns that rely on printed materials such as posters and pamphlets (de Bruyn, 1992). Women in impoverished environments also have less access to radio or television, and hence may remain disconnected from these communication lines.

The lack of funds for basic needs such as food and housing, is an acute reality for many women in developing and industrialized countries. Some women engage in commercial sex work to obtain money to meet such basic needs that take precedence over the perceived risk of HIV (Smyke, 1991). For example, in Thailand, one million women have joined the sex industry, explaining in part Thailand's high incidence of HIV infection (Lurie, Hintzen, & Lowe, 1995). Visiting prostitutes is common practice among local men in many Asian countries, and with the booming business of sex tourism, there is never a lack of clientele. These encounters reinforce the subordinate and economically inferior position of women.

Ironically, Lurie and his colleagues (1995) suggested that economic development programs such as structural adjustment programs, have often facilitated HIV transmission. Economic development in developing countries has led to currency devaluation, higher prices for goods, decreased availability of loans, income and consumption tax increases, reductions in government spending on health and social services for the local population, and increases in the number of migrant workers. All of these factors result in increased poverty, and in urban settings increased drug use and commercial sex work. As a result of being far from home (and as part of the cultural milieu), male migrant workers often use the sexual services of prostitutes. HIV transmission may occur between sex worker and client in the cities, then men can infect their wives or sex partners on returning home to rural villages, and subsequently their children. Women in rural areas of developing nations remain dependent on their male partners for economic support. This economic inequity combined with the cultural expectation of sexual subordination facilitates the spread of HIV.

HIV can be classified as a preventable disease, and therefore could be better controlled if adequate resources were available (Livingston, 1992). In developing countries, antiretroviral therapies are simply unaffordable, diagnostic facilities are not always available (Mann et al., 1992), and physicians often do not have proper training to handle the epidemic with regard to basic medical care or psychosocial needs of women (Ha & Ickovics, 1996). Even though there are more resources available in industrialized countries, many women still do not receive appropriate care and treatment for HIV-related disease (Shapiro et al., 1999; Solomon et al., 1999; Worth, 1990). HIV-specific primary care, gynecological care, drug treatment, and pediatric services must be integrated to facilitate access to health care services among persons with HIV (Smith et al., 1997).

It is difficult to disentangle culture from socioeconomic factors, when examining issues for women and HIV in the U.S. Poverty rates among Hispanics and Blacks are 29% and 33%, respectively, with a poverty rate of 11% among Whites (Williams & Collins, 1995). It has been argued that Hispanics and Blacks are less concerned with HIV risk because they face more immediate concerns such as food, shelter, and clothing, as well as more stressful life events that demand their immediate attention (Amaro, 1995; Mays & Cochran, 1988). Although this makes intuitive sense, there are limited data to support this empirically. In recent studies, social class has been shown to be a more important health indicator than race. Adjustment for social class may eliminate or reduce signs of racial disparity in health. Social class differences have persisted, even after controlling for race in reports of general poor health (Navarro, 1990), violent deaths (Greenberg & Schneider, 1994), illegal drug use (Lillie-Blanton, Anthony, & Schuster, 1993) and HIV risk behavior (Ickovics, et al., 2000). Williams and Collins (1995) suggested that failing to adjust for social class in studies of health can reinforce racial prejudices and stereotypes, diverting both public attention and research funding from the underlying social factors that are responsible for the pattern of risk distribution.

INTERPERSONAL CONTEXT

In this contextual analysis of women and HIV, the importance of interpersonal relationships cannot be over-stated. Because HIV is an infectious disease, it is by definition transmitted within an interpersonal network, (i.e. sexual relations or shared needles). Interpersonal relationships can be categorized as instrumental, supportive, disruptive, burdensome, or neutral (Latkin et al., 1994). The nature of women's interpersonal relationships can have important consequences for their HIV risk behavior and treatment for those diagnosed with HIV. This section considers theory and empirical findings relevant to interpersonal relationships with a focus on heterosexual and drug-using peer relationships, as well as social support for women infected by HIV and those who may be affected as loved ones and caretakers of the ill. (A discussion of women who have sex with women is presented later).

Heterosexual Relationships

The key factors in determining the risk of sexual transmission of HIV are the frequency and type of sexual activity (R. M. Anderson, 1992; Piot et al., 1988). Heterosexual intercourse with an infected partner is the primary mode of transmission for women with HIV throughout the world. Transmission occurs within the context of a sexually intimate, interpersonal relationship. Relationship involvement has been shown to be an important predictor of both the initiation and maintenance of safer sexual behavior among heterosexual women (Morrill, Ickovics, Golubchikov, Beren, & Rodin, 1996). Decisions around safer sexual behavior occur not only within the context of a single relationship, but also within patterns of sexual relationships that individuals have developed over time and possibly with multiple partners. Past unprotected intercourse is often the best predictor of future unprotected intercourse (Dublin, Rosenberg, & Goedert, 1992).

Women accommodate their sexual behavior depending on the nature of their relationship with their partner. Women in more involved relationships are significantly more likely to have unprotected intercourse (Catania et al., 1992; Hobfoll, Jackson, Lavin, Britton, & Shepherd, 1993; Morrill et al., 1996; Stark, Tesselaar, Fleming, O'Connell & Armstrong, 1996). Kippax and colleagues (Kippax, Crawford, Davis, Rodden, & Dowsett, 1993; Kippax et al., 1997) refer to unprotected intercourse in the context of certain relationship arrangements as "negotiated safety"—a strategy that depends on accurate knowledge of both partners' serostatus as well as honesty and trust in the relationship. Others (Ekstrand, 1992), however, warn that anything less than complete monogamy between two seronegative partners carries some risk of HIV transmission; therefore, condoms should always be used to maximize prevention. As failsafe as this approach may sound ("no unprotected intercourse, no risk"), it clearly does not reflect current practices observed for heterosexual women.

Some women having unprotected intercourse in a committed relationship are actually at increased risk for contracting HIV in part because assessments of partner risk often are inaccurate (Kalichman & Hunter, 1992). Sexual relationships outside of a primary relationship are often not disclosed, especially when these relationships are between two men (Carballo-Diequez & Dolezal, 1996; Mason, Marks, Simoni, Ruiz & Richardson, 1995). In one study, three quarters of men who had both male and female partners had not disclosed their sexual activity with other men to their female partners, and nearly two thirds had not modified their sexual behavior to protect their female partners from HIV (Kalichman, Roffman, Picciano, & Bolan, 1997). Studies of these men and their relationships with female and male partners suggest that many lead "dual lives," keeping their homosexual interests and activities secret from their female partners. Nearly one quarter of bisexual men who died of AIDS were married to women at the time of their death (Chu, Peterman, Doll, Buehler, & Durran, 1992).

Future research must continue to examine the nature of relationships and the interpersonal context of decision making for heterosexual women. It is important to recognize the com-

plexity of individual choice and human intimacy—including communication, partner attitudes, relative control, and power—which can be even more important in determining HIV risk behavior than individual factors (Morrill, 1994).

Drug-Related Relationships

Women who use injection drugs are at great risk for HIV because of the potential for transmission through needle sharing as well as unprotected sexual activity with an HIV-infected partner. The majority of women who inject drugs have sexual partners who also inject drugs; most are sexually active and few consistently use condoms (Weissman & Brown, 1995). Use of drugs (particularly crack cocaine) and use of alcohol and drugs before sex have been associated with a greater number of sexual partners, more unprotected intercourse, and a greater likelihood of prostitution (Chaisson et al., 1991; R. Fullilove, M. Fullilove, Bowser & Gross, 1990; McCoy & Inciardi, 1993).

Studies of the social relationships of injection drug users (IDUs) indicate that male partners play a critical role in women's drug use. Men are often the initiators of drug using activity, play a role in the progression of drug use, and are involved in women's drug-related criminal activities such as commercial sex work (Anglin, Hser, & McGlothlin, 1987; el-Bassel, Cooper, Chen, & Schilling, 1998; Hser, Anglin, & McGlothlin, 1987; Rosenbaum, 1981; Weeks et al., 1998; Worth & Rodriguez, 1987). Having a male partner who uses drugs places adolescent girls at greater risk of using drugs themselves (Amaro, Zuckerman, & Cabral, 1989). One quarter of women using the New Haven, Connecticut needle exchange program began injecting before age 18, and 39% have been injecting for over 10 years (Heimer, Kaplan, O'Keefe, Khoshnood, & Altice, 1994).

For women, drug use is closely tied to relationships with male partners. For men, drug using activity is initiated primarily through a same-sex friend. The differential contexts determining drug use also have implications for addiction and disengagement from drug use. In a study of women enrolled in methadone treatment, drug use and HIV permeated sexual, familial, and household relationships (Pivnick, Jacobson, Eric, Doll, & Drucker, 1994). More than one half of the women who lived with a sexual partner reported that their partners were currently using drugs. Almost one third of the study participants' siblings were drug users; and 70% of the women had at least one sibling who also used drugs. These data lend credence to the notion that HIV and drug use are not individual problems, but interpersonal ones.

Women who use drugs face a number of challenges to risk reduction and HIV prevention. They are likely to have a significant history of sexual, other physical or psychological abuse; feelings of powerlessness, psychological distress, and depression; lack of consistent social support and resources; and lack of accessible drug treatment (for review see Weissman & Brown, 1995). These women are at extremely high risk for HIV transmission. Although social norms among drug users have changed as a result of the HIV epidemic, making it less "acceptable" to share needles (Des Jarlais & Friedman, 1994;

Selwyn, Feiner, Cox, Lipshutz, & Cohen, 1987), most women who inject drugs report some needle sharing, often with a sexual partner (Weissman & Brown, 1995).

Finally, individuals actively using drugs are more likely to engage in antisocial behaviors, such as theft or other criminal acts to get money for drugs. These behaviors can lead to the withdrawal of drug users from mainstream society, whereby they retreat to a "drug subculture" or network, comprised of other drug users (Faulpel, 1991). Limiting contact with the members of one's drug network can reduce the frequency of drug-use. Moreover, network-oriented interventions to discourage HIV risk behaviors, such as needle sharing may be useful (Latkin et al., 1995). Unfortunately, women have had less access to needle exchange and drug treatment programs than their male counterparts; programs are notably limited for women with children and those who are pregnant (Ethier, Ickovics, & Rodin, 1996; Heimer et al., 1994). In addition to structural barriers, there may be psychological barriers to prevention; avoidant coping has been associated with increased drug use (Nyamathi, Stein, & Brecht, 1995).

Social Support: Prevention, Adjustment, Disclosure and Stigma

Social support and its association with health has received considerable research attention over the past decade. Individuals with a high degree of social support are less likely to be adversely affected by stressful situations and become ill. Moreover, if an individual does become ill, social support facilitates coping and recovery, and has a positive impact on immune function (Cohen, 1988; Cohen & Williamson, 1991; Uchino, Cacioppo, & Kiecolt-Glaser, 1996).

When the interpersonal context of women and HIV is considered, social support is a key factor, particularly when considering prevention and adjustment to a diagnosis with HIV. A woman's ability to alter high risk behavior may be connected to her social support network. Women who have more social support are less likely to appraise the conditions of their lives as threatening and more likely to use active coping techniques (Nyamathi, Wayment & Dunkel-Schetter, 1993); active coping in turn has been related to less risky sexual behavior (Nyamathi et al., 1993, 1995).

In general, women report higher levels of social support and benefit more from support than men (Hobfoll, 1986). Unfortunately, due to the nature of HIV transmission, some of the people in an infected woman's support network may be infected themselves. Wofsy (1987) suggested that women with HIV may feel profoundly isolated. Many women with HIV will not seek support or services even if available; they report being fearful of being identified with HIV due to possible stigmatization and rejection by family members or friends (Chung & Magraw, 1992; Hackl, Somlai, Kelly, & Kalichman, 1997; Lea, 1994). There can be a sense of shame and self-denigration, especially for women who are mothers. These women worry about the harm to their children, directly (through maternal transmission) or indirectly (through abandonment by death or the stigma of having an HIV-infected parent (Geballe, Grvendel, & Andiman, 1995).

plexity of individual choice and human intimacy—including communication, partner attitudes, relative control, and power—which can be even more important in determining HIV risk behavior than individual factors (Morrill, 1994).

Drug-Related Relationships

Women who use injection drugs are at great risk for HIV because of the potential for transmission through needle sharing as well as unprotected sexual activity with an HIV-infected partner. The majority of women who inject drugs have sexual partners who also inject drugs; most are sexually active and few consistently use condoms (Weissman & Brown, 1995). Use of drugs (particularly crack cocaine) and use of alcohol and drugs before sex have been associated with a greater number of sexual partners, more unprotected intercourse, and a greater likelihood of prostitution (Chaisson et al., 1991; R. Fullilove, M. Fullilove, Bowser & Gross, 1990; McCoy & Inciardi, 1993).

Studies of the social relationships of injection drug users (IDUs) indicate that male partners play a critical role in women's drug use. Men are often the initiators of drug using activity, play a role in the progression of drug use, and are involved in women's drug-related criminal activities such as commercial sex work (Anglin, Hser, & McGlothlin, 1987; el-Bassel, Cooper, Chen, & Schilling, 1998; Hser, Anglin, & McGlothlin, 1987; Rosenbaum, 1981; Weeks et al., 1998; Worth & Rodriguez, 1987). Having a male partner who uses drugs places adolescent girls at greater risk of using drugs themselves (Amaro, Zuckerman, & Cabral, 1989). One quarter of women using the New Haven, Connecticut needle exchange program began injecting before age 18, and 39% have been injecting for over 10 years (Heimer, Kaplan, O'Keefe, Khoshnood, & Altice, 1994).

For women, drug use is closely tied to relationships with male partners. For men, drug using activity is initiated primarily through a same-sex friend. The differential contexts determining drug use also have implications for addiction and disengagement from drug use. In a study of women enrolled in methadone treatment, drug use and HIV permeated sexual, familial, and household relationships (Pivnick, Jacobson, Eric, Doll, & Drucker, 1994). More than one half of the women who lived with a sexual partner reported that their partners were currently using drugs. Almost one third of the study participants' siblings were drug users; and 70% of the women had at least one sibling who also used drugs. These data lend credence to the notion that HIV and drug use are not individual problems, but interpersonal ones.

Women who use drugs face a number of challenges to risk reduction and HIV prevention. They are likely to have a significant history of sexual, other physical or psychological abuse; feelings of powerlessness, psychological distress, and depression; lack of consistent social support and resources; and lack of accessible drug treatment (for review see Weissman & Brown, 1995). These women are at extremely high risk for HIV transmission. Although social norms among drug users have changed as a result of the HIV epidemic, making it less "acceptable" to share needles (Des Jarlais & Friedman, 1994;

Selwyn, Feiner, Cox, Lipshutz, & Cohen, 1987), most women who inject drugs report some needle sharing, often with a sexual partner (Weissman & Brown, 1995).

Finally, individuals actively using drugs are more likely to engage in antisocial behaviors, such as theft or other criminal acts to get money for drugs. These behaviors can lead to the withdrawal of drug users from mainstream society, whereby they retreat to a "drug subculture" or network, comprised of other drug users (Faulpel, 1991). Limiting contact with the members of one's drug network can reduce the frequency of drug-use. Moreover, network-oriented interventions to discourage HIV risk behaviors, such as needle sharing may be useful (Latkin et al., 1995). Unfortunately, women have had less access to needle exchange and drug treatment programs than their male counterparts; programs are notably limited for women with children and those who are pregnant (Ethier, Ickovics, & Rodin, 1996; Heimer et al., 1994). In addition to structural barriers, there may be psychological barriers to prevention; avoidant coping has been associated with increased drug use (Nyamathi, Stein, & Brecht, 1995).

Social Support: Prevention, Adjustment, Disclosure and Stigma

Social support and its association with health has received considerable research attention over the past decade. Individuals with a high degree of social support are less likely to be adversely affected by stressful situations and become ill. Moreover, if an individual does become ill, social support facilitates coping and recovery, and has a positive impact on immune function (Cohen, 1988; Cohen & Williamson, 1991; Uchino, Cacioppo, & Kiecolt-Glaser, 1996).

When the interpersonal context of women and HIV is considered, social support is a key factor, particularly when considering prevention and adjustment to a diagnosis with HIV. A woman's ability to alter high risk behavior may be connected to her social support network. Women who have more social support are less likely to appraise the conditions of their lives as threatening and more likely to use active coping techniques (Nyamathi, Wayment & Dunkel-Schetter, 1993); active coping in turn has been related to less risky sexual behavior (Nyamathi et al., 1993, 1995).

In general, women report higher levels of social support and benefit more from support than men (Hobfoll, 1986). Unfortunately, due to the nature of HIV transmission, some of the people in an infected woman's support network may be infected themselves. Wofsy (1987) suggested that women with HIV may feel profoundly isolated. Many women with HIV will not seek support or services even if available; they report being fearful of being identified with HIV due to possible stigmatization and rejection by family members or friends (Chung & Magraw, 1992; Hackl, Somlai, Kelly, & Kalichman, 1997; Lea, 1994). There can be a sense of shame and self-denigration, especially for women who are mothers. These women worry about the harm to their children, directly (through maternal transmission) or indirectly (through abandonment by death or the stigma of having an HIV-infected parent (Geballe, Grvendel, & Andiman, 1995).

derstand or cope with their own illness at home, in school, or other social settings. The social environments of many children with HIV also are challenged by poverty. Special services for HIV-infected youth and their families are essential (Huba & Melchior, 1999).

Among adolescents and young adults, AIDS rates are rising rapidly. Approximately 7000 young people, aged 15 to 24, get infected with HIV throughout the world each day (UNAIDS, 1999). Extremely high HIV seroprevalence rates have been documented in teenage women attending antenatal clinics throughout Africa (Rwandan HIV Seroprevalence Study Group, 1989; Ryder et al. 1989; Wade et al., 1992; Wilkins et al., 1989).

Since 1990, the number of AIDS cases among U.S. teenagers has more than tripled. Twenty-five percent of new HIV infections in the United States are estimated to occur among those between age 13 and 20 (Office of National AIDS Policy, 1996). Two young people become infected with HIV every hour of every day; of these, more than one third are female. HIV prevalence among young women has increased 36% to 45%; in contrast prevalence among young men is stable or declining (Rosenberg & Bigger, 1998). Young heterosexual women represent a next wave of the epidemic; those most at risk include young women from northern inner cities, those who use crack cocaine, those who have multiple sex partners, and those who have prevalent STDs (Holmberg, 1996; Rosenberg & Bigger, 1998; Wortley & Fleming, 1997). High rates of gonorrhea, chlamydia, and syphilis are associated with the rapidly rising rates of AIDS among adolescents and young adults (Hein, Dell, Futterman, Rotheram-Borus, & Shaffer, 1995; Laga et al., 1990; Plummer et al., 1991). Three million STDs per year are reported in the United States among teens 15 to 19 years old (CDC, 1998c; Kaiser Family Foundation, 1998). Adolescent females have higher STD rates than any age and gender group (Berman & Hein, 1999). Women with other STDs have a risk of contracting HIV, if exposed, that is 3 to 50 times that of an uninfected person (St. Louis, Wasserheit, & Gayle, 1997). Despite these risks, only 8% of young women believe that they are personally at risk of getting an STD (Kaiser Family Foundation, 1998). A young woman's interpersonal relationships can have a profound impact on her STD and HIV risk behaviors (see section on *Interpersonal Context*); if she is powerless in a relationship, then she is less able to negotiate condom use.

Behavioral, psychological and social factors place adolescents at high risk for HIV transmission: sexual experimentation, initiation of high risk behavior (including drug use), a sense of invulnerability and immortality, less well-developed cognitive and social processes, and less access to age-appropriate social and medical services (Ickovics & Rodin, 1992; Moss, 1994). While sexual experience and reports of multiple sexual partners declined among adolescent males from 1991 to 1997, there was no significant decrease among adolescent females (CDC, 1998c). In national studies of American high school students, from 62% to 76% reported having had sexual intercourse by age 18 (CDC, 1998c; Laumann, Gagnon, Michael, & Michaels, 1996). Sexually active adolescents often engage in sex with high risk partners, have multiple sexual

partners, and use condoms inconsistently, if at all, (DiClemente et al., 1992; Durbin et al., 1993; Kann et al., 1996; Millstein & Moscicki, 1995; Morris, Harrison, Knox, Tromanhauser, & Marquis, 1995; Orr & Langefeld, 1993; Rickman et al., 1994; Rotheram-Borus, Meyer-Bahlburg, & Koopman, 1992). Nearly 20% of sexually active teenagers have had four or more different sexual partners (Kann et al., 1996). Up to two thirds of sexually active adolescents report no use or ineffective use of contraception (Clark, Zabin, & Hardy, 1984; Harris, 1986). It is critical to learn more about HIV and STD risk within the context of adolescent pregnancy, where young women not only fail to protect themselves, but may actively seek pregnancy (Merrick, 1995) leaving them vulnerable to other risks associated with unprotected sex.

Resistance to explicit sex education in schools has created a structural barrier for prevention among American youth (DiClemente, 1998; Jemmott, Jemmott & Fong, 1998; National Institutes of Health, 1997). It is important to remember, however, that those most at risk include gay youth, runaways or homeless youth, those who have lost a parent to AIDS, and illiterate adolescents. Growing up in communities touched by HIV—whether urban centers, suburban neighborhoods, or rural towns—adolescents may feel a great sense of fear and hopelessness about any attempt to stop the spread of disease.

Young adult women (age 25–40) continue to be one of the fastest growing groups newly diagnosed with AIDS and dying of AIDS-related complications in the United States and globally. Decisions around childbearing have major implications for HIV risk, and these are considered primary reproductive years. On the one hand, women who are actively seeking pregnancy are at risk for HIV because they are having unprotected sex. On the other hand, in an effort to prevent pregnancy, women may unwittingly put themselves at risk for HIV and other STDs. Currently available contraceptives have differential effects on reducing the risks of unintended pregnancy and STDs. Hormonal contraception, which is most effective at reducing risk for pregnancy, is least effective at reducing risk for STDs, resulting in a “contraceptive trade-off dilemma” (Cates, 1996). New methods of contraception, such as long-acting injectable depot medroxyprogesterone acetate (Depo Provera) and implantable levonorgestrel (Norplant), are extremely effective at preventing pregnancy; however, they provide no protection against HIV and other STDs. Further, the more effective the chosen contraceptives are for preventing pregnancy, the less likely individuals are to use condoms to prevent STDs (Polaneczky, Slap, & Forke, 1994; Santelli, Davis, & Celantano, 1995; Weisman, Plichta, & Nathanson, 1991). Overall, condoms are the best single contraceptive method for preventing both pregnancy and STDs; more behavioral research is necessary to identify the determinants of condom use for protection against pregnancy versus disease.

The partners of midlife and older heterosexual women rarely use condoms. Indeed, unprotected sex becomes more common with the onset of menopause and diminished pregnancy-related concerns (AARP, 1994). Biological changes such as decreased vaginal lubrication and the thinning of the vaginal walls may also place postmenopausal women at in-

creased risk for HIV transmission. Research focused on substance use among midlife and older women and their partners has been limited, but some do use injection drugs. If and when HIV infection does occur, older women find that social support is especially limited (AARP, 1994).

Eighteen percent of women with AIDS in the United States are over age 40 when diagnosed with AIDS (CDC, 1998a). However, health care providers often do not recognize HIV risk behavior for their female patients in midlife. Women diagnosed with HIV at age 50 or older are more likely than younger women to have never used a condom prior to their HIV diagnosis and are more likely to be diagnosed with HIV while hospitalized (i.e., already symptomatic; Schable, Chu & Diaz, 1996). It is estimated that among Americans age 50 or older, the prevalence of having at least one risk factor for HIV infection is 10% (Stall & Catania, 1994). Lack of knowledge about HIV interventions and their own risk of infection place older women at risk for HIV (Yates, Stellato, Johannes & Avis, 1999; Zablotsky, 1998). Older patients may also experience difficulty adjusting to disease and accessing health care and social support due to their limited educational experience and social isolation (Schable et al., 1996). Finally, therapeutics used to treat or prophylax against HIV-related disease have not been tested for drug interactions among some of the most common drugs that midlife and older women may be taking, such as hormone replacement therapy, and medications for hypertension, hypercholesterolemia, or depression.

HIV seems to accelerate the entire developmental life cycle. What individuals would normally experience over the course of decades is experienced over the course of years: death of friends and loved ones, loss of physical and sexual functioning, deterioration in cognition and memory, and the effects of aging on their bodily appearance. Life events that occur "off time" with regard to the normative life cycle are considered more stressful—particularly when events are premature, allowing no time for anticipatory coping or planning (Revenson, 1990). Selwyn (1996) articulated the anomalies in the usual pattern of the family life cycle, in which death crowds out life, and inflicts a cruel and painful destruction of the family, across multiple generations.

Disease Stage/Natural History and Progression

For women and men, the basic biological processes that accompany HIV are likely to operate in the same way (Fauci, Pantaleo, Stanley, & Weissman, 1996); however, sex differences in the clinical manifestations of HIV are prevalent. Anemia, irregular menses, mucocutaneous candidiasis, vaginitis, genital herpes, dysplasia, and cervical cancer are common in HIV-positive women (Korn & Abercrombie, 1997; Massad et al., 1999; Sun et al., 1997). Most sex differences in disease manifestation have been documented in areas in which women and men differ fundamentally (i.e., gynecological complications); however, these manifestations were not fully realized as symptomatic of progression to AIDS for women until years into the AIDS epidemic. In areas where there has been no clear documentation of differences between men and women (e.g., neurological compli-

cations), it is unknown whether this is a result of null findings or due to the lack of information on women and HIV available in research (Fox-Tierney, Ickovics, Ceretta, & Ethier, 1999).

Evidence regarding sex differences in the clinical course of HIV disease and survival rates have been inconsistent. Many recent studies do not report sex differences in the rate of clinical progression (Chaisson, Keruly, & Moore, 1995; Cu-Uvin et al., 1996; Smith & Moore, 1995). However, Farzadegan et al. (1998) found that women with the same viral load as men had a 1.6 times greater risk of AIDS, indicating perhaps that disease progression for women is more rapid than for men.

The HIV Epidemiology Research Study (HERS) was one of the first prospective cohorts designed to study the impact of HIV on women's health (Smith et al., 1997). It demonstrated an increased prevalence of vaginal and oral yeast infections, oral lesions, and human papilloma virus (HPV) among women with HIV compared to their HIV-negative counterparts. Extremely high levels of depression, and social and emotional stress were reported by women with HIV as well as by the uninfected, at-risk women (Moore et al., 1999). Moreover, early findings indicated that many women with HIV did not receive adequate medical care, despite scientific advances in the realm of HIV treatment (Smith et al., 1997).

There has been tremendous progress in the clinical care for people with HIV. Persons infected with HIV are living longer and the quality of life has improved. Clinical care has become more complex as effective treatments are developed, including combination antiretroviral therapies and prophylaxis to prevent disease complications. A critical breakthrough in effective treatments was established with the development of a new class of drugs called *protease inhibitors* that reduce viral replication of HIV (Deeks, Smith, Holodniy, & Kahn, 1997). Critical issues still remain with regard to the widespread use of these drugs; among the most important issues are cost and strict patient adherence so that viral resistance does not occur. In the United States, women have had significantly less access to quality care, including less access to therapeutic drugs (Shapiro, et al., 1999; Solomon, et al., 1999). In the developing world, basic therapeutic agents are still unavailable, let alone more sophisticated medications—for women or men.

Epidemiological Changes in HIV

The dynamic quality of the HIV epidemic has been documented both globally and in the United States; epidemiologic patterns indicate changes that are detrimental to women. For example in Thailand, as in other Asian countries, the epidemic has progressed from injection drug users to commercial sex workers, their male clients, and, finally to other sexual partners of these men (e.g., wives), and their children.

In the United States and European countries, the epidemiological waves have been different. HIV was first diagnosed among men who have sex with men (CDC, 1981). The view of HIV as a "homosexual disease" had an indirect but serious impact on women with HIV, in part because early research on HIV focused almost exclusively on men (Ickovics & Rodin,

1992). Women who contracted HIV in the early years were misdiagnosed or were diagnosed late because they were not considered at risk.

The "second wave" of the epidemic was characterized as a disease of drug users and prostitutes (Miller, Turner, & Moses, 1990; Treichler, 1988). Identifying commercial sex workers as a potential source of transmission resulted in a stereotype that treated women as "vectors" of disease (Livingston, 1992). Consequently, female sex workers were often blamed for the spread of the disease. In Brazil, groups of sex workers (usually all female) infected with HIV have been arrested and/or deported to rural areas (de Bruyn, 1992). Ironically, no cultural stigma was attached to their male clients (Bergman, 1988).

In its initial diagnoses, biomedical research identified "risk groups" in its evaluation of AIDS-infected populations. This categorization often stigmatized the target groups and the associated populations. The linkage of "unacceptable" behaviors (i.e., sex and drug use) and a deadly disease created a hostile climate for HIV-positive individuals (de Bruyn, 1992; Livingston, 1992). To avoid problems associated with stigmatization, the public focus must be shifted toward identifying "risk practices." HIV is a disease whose reproduction depends on individuals' behaviors, not personal attributes. Understanding the changing epidemiology and the temporal context of HIV disease is critical so that informed decisions can be made about prevention and treatment for those with HIV and those most at risk of infection. With the movement from the broad perspective of the epidemic back to considering the lives of individuals affected, the unique life situations surrounding each individual touched by HIV must be recognized.

SITUATIONAL CONTEXT

This final context considered as part of the ecological approach to HIV disease comprises factors that are specific to an individual or to a group of persons. A given situation may limit or enhance the possible responses of an individual. In this section, women infected or at risk for HIV and possible situations that may uniquely or differentially affect them are considered. Specifically, pregnancy, parenthood, and HIV testing, women in sexual relations with other women, and women living in rural environments are addressed.

Pregnancy, Parenthood, and HIV Testing

Currently, more than 80% of women with AIDS are of child-bearing age (CDC, 1998a). Personal and literary accounts emphasize the importance of motherhood in the lives of many women. Some women seek to get pregnant after they find out that they have HIV, because they want to leave "something or someone behind." Others find out that they are HIV positive when they are pregnant. The choice to keep the child and the risk of the child being HIV-infected may be a source of great stress. In addition, permanency planning for children (i.e., caretaking and legal arrangements for the children after the death of the parents) is an immediate concern (Geballe et al., 1995).

Findings from an AIDS clinical trial (i.e., ACTG 076) demonstrated that zidovudine (ZDV) can prevent mother-to-child HIV transmission. These data indicated that the risk of vertical transmission can be reduced by two thirds—from 25% to 8%—when zidovudine is taken during pregnancy, administered during delivery, and taken by the newborn for 6 weeks postpartum (Conner et al., 1994). The release of these findings has been associated with an increase in ZDV use during pregnancy and a decline in HIV transmission from mothers to infants (Cooper et al., 1994; Lindegren et al., 1999). There is still limited understanding about the mechanism through which ZDV exerts its protection. In addition, it is critical to understand why ZDV fails to prevent perinatal transmission in some cases. High maternal HIV-1 RNA level is one of the strongest predictors of perinatal transmission risk (Dickover et al., 1996; Mofenson et al., 1999); ZDV reduced maternal viral load prior to delivery, which significantly decreased the probability of HIV transmission from mother to child. Obstetrical factors are also important predictors of transmission (Landesman et al., 1996).

Following the release of these critically important findings, the U.S. Public Health Service developed practice guidelines for the use of ZDV to reduce vertical transmission and for the implementation of universal counseling and voluntary HIV testing of pregnant women (CDC, 1995). In 1999, the Institute of Medicine went further, recommending *routine* prenatal testing of all pregnant women (Stoto, Almaro, & McCormick, 1999). Guideline objectives are to increase HIV testing rates (i.e., toward 100%) so that pregnant women with HIV can be diagnosed and treated, thus reducing perinatal transmission.

Although prenatal HIV testing may diagnose seropositive women who did not know their HIV status, questions remain about the linkage to services for these women and their children. Access to these services are necessary if women with HIV are to be offered prophylactic Zidovudine therapy to prevent vertical transmission, and to receive care for their own HIV-related medical conditions. Earlier studies suggest that women diagnosed with HIV during pregnancy were more likely to delay seeking health care (Ickovics et al., 1996), or fail to obtain regular HIV-related care for themselves altogether (Butz et al., 1993). Many women with HIV also have reported health care discrimination, restricting access to services (Lester, Partridge, Chesney, & Cooke, 1995). Finally, primary prevention must also be a priority: insuring that women get the information and skills they need to protect themselves from HIV transmission—*before* they get pregnant.

The value of an HIV diagnosis during pregnancy via routine prenatal testing is emphasized by recent evidence that indicates that elective caesarian-section (Anonymous, 1999), single dose nevirapine (Guay et al., 1999; Musoke et al., 1999), and abbreviated regimens of zidovudine prophylaxis (Shaffer et al., 1999; Shapiro et al., 1999; Wade et al., 1998) can reduce risk of perinatal transmission. Identifying women with HIV during pregnancy provides an important opportunity to optimize the health care of women and children, reduce the risk of vertical transmission, and enable women to make informed reproductive and healthcare choices.

Women Who Have Sex With Women: Affected and Infected by the AIDS Epidemic

The role of lesbians and bisexual women in the HIV epidemic has been characterized almost exclusively as one of activists and care givers (Corea, 1992; Rieder & Ruppelt, 1988). Lesbians and bisexual women have been strong advocates through local community agencies and nonprofit organizations—visible on the front lines of the political battles to make treatment, services, and clinical trials more readily available and more affordable. They have been important partners in effective community mobilization for gay men and for women with HIV-related disease. As members of the gay community, women who have sex with women often have been the providers of emotional, physical, and financial support to their gay male friends. They are likely to have experienced multiple AIDS-related losses of friends and loved ones. As such, their psychosocial needs must also be considered in any review of the impact of the HIV epidemic on women.

It is also important to acknowledge that women who have sex with women (WSW) are infected with HIV. The earliest case report of likely female-to-female transmission of HIV appeared in 1984 (Sabatini, Patel, & Hirschman, 1984). A woman with AIDS reported that she had only had sex with women and did not have any other risks for HIV infection (e.g., no injection drug use, no blood transfusion). Additional cases were documented because the individuals presented for medical care (Sabatini et al., 1984; Marmor et al., 1986; Monzon & Capellan, 1987; Rich et al., 1993) or were participating in HIV-related research on another topic (Perry, Jacobsberg, & Fogel, 1989); no systematic recruitment or sampling strategies were used.

Other existing research studies including women with HIV (e.g., HIV/AIDS surveillance, blood donor studies) have not provided evidence of female-to-female transmission (Castro et al., 1988; Chu, Beuhler, Fleming, & Berfelman, 1990). The restrictiveness of these categories used to determine infection source (i.e., women's HIV transmission is classified as having occurred through heterosexual sex or injection drug use if they have had sex with at-risk men or injected drugs since 1978) may underestimate transmission that actually occurred through sex between women. In addition, much of the sexual risk behavior data in the HIV/AIDS reporting systems are inconsistent and/or missing, particularly information concerning sexual contact with women (Kennedy, Scarlett, Duerr, & Chu, 1995; Morrow, 1995).

Women who have sex with women have exposure to vaginal secretions, blood, and menstrual fluids that may place them at risk for HIV. HIV has been detected in cervical and vaginal secretions (Belec, Georges, Steenman, & Martin, 1989; Clemetson et al., 1993; Henin et al., 1993; Van de Perr, DeClerq, & Coniaux-Leclerc, 1988; Vogt, Witt, & Craven, 1986, 1987; Wofsy et al., 1986; Zorr, Schafer, & Dilger, 1994). In their account of possible female-to-female transmission, Marmor et al. (1986) reported that the sexual contact between the women included oral and digital vaginal

contact, oral-anal contact, contact during menses, and vaginal bleeding as a result of sexual contact. A growing body of literature suggests that other sexually transmitted infections, such as herpes simplex, human papilloma virus (HPV), bacterial vaginosis, trichomoniasis, and gonorrhea can be transmitted between women sexually (Berger et al., 1995; Edwards & Thin, 1990; Ferris, Batish, Wright, Cushing, & Scott, 1996; Kellock & O'Mahony, 1996; O'Hanlan & Crum, 1996).

A lack of knowledge about the sexual behaviors of HIV-infected women has led to misperceptions about the transmission risk among women who have sex with women. Among a group of HIV infected women recruited because of a history of injecting drug use and HIV-related sexual risk behaviors, 18% reported ever having sex with a woman and 6% reported sex with a woman in the past 6 months (Moore et al., 1996). Other researchers have reported that substantial proportions of STD clinic patients and drug users reported sex with women and/or bisexual or lesbian self identity (Bevier, Chiasson, Heffernan, & Castro, 1995; Deren et al., 1996). Given rates of same sex behavior by HIV-infected women and the lack of prevention guidelines for this group of women, female-to-female transmission may be a more significant public health risk than was previously thought.

Behavioral research suggests that women who have sex with women may engage in other behaviors that put them at risk for HIV (Gomez, 1995; Stevens, 1993). Among HIV-infected and high risk women, women with female partners may engage in more drug using and sexual HIV risk behaviors than women who only have sex with men (Bevier et al., 1995; Deren et al., 1996; Friedman et al., 1995; Harris et al., 1993; Moore et al., 1996).

Women who have sex with women who would like to practice safer sex also face obstacles. Products used for protection against HIV and other STDs include latex gloves and dental dams, items traditionally used in medical settings. Because these are not designed for, or marketed and packaged for sexual use, they are difficult to obtain and often expensive (Stevens, 1994). In addition, they may not provide adequate protection against infection (e.g., dental dams are often too small).

Finally, there is often tension between a focus on the specific prevention needs of lesbians and bisexual women *versus* the need for prevention programs to target the *behaviors* that put women at risk (rather than a particular sexual orientation). Few prevention programs have been designed to address the sexual issues of women having sex with other women; there has been a scarcity of information on acceptable safer sex activities and safer sex materials, communication skills within the context of a lesbian relationship, and personal risk appraisal as it pertains to the sexual relationship between women (Morrow, 1995). Investigators must acknowledge the diversity of behavior within sexual self-definition, creating behavior-based messages that are widely applicable, while gaining an understanding of the unique prevention issues pertaining to women who have sex with women.

Geography Is Destiny: Coping With HIV in Urban Versus Rural Settings

Another important situational context for women with HIV is their geographic location. In an urban environment, women are more likely to be infected or at high risk for HIV transmission. Because HIV first hit the urban centers in the United States, it is likely that women in the cities are also more likely to be affected by AIDS-related losses. In a community-based study of women in a medium-sized city, 72% reported knowing at least one person who had died of AIDS; 30% knew four or more people who had died of AIDS including family members and close friends (Ickovics, Druley, Morrill, Grigorenko, & Rodin, 1998). Access to health care, risk of social isolation, and stigma are also important issues for women with HIV in urban areas.

HIV has also hit the U.S. heartland. People are becoming infected in rural areas throughout this country. The greatest proportionate increases in the U.S. epidemic are occurring in the south and midwest (CDC, 1996). In addition, individuals who moved to urban centers and became infected there, are returning home to families of origin for care as their disease progresses (Cohn et al., 1994). Distance often compounds issues of access to health care in numerous ways: availability of transportation; cost and time needed to travel to a clinic, including taking time off from work for routine medical visits and arranging for child care; lack of a supportive community to assist with daily needs, social support, or medical attention. Although the stigma for HIV-positive women is great everywhere, it may be greater in rural areas due to fear of identification and isolation. Furthermore, because the number of HIV cases in rural areas is limited, understanding and compassion about HIV/AIDS may be more limited as well.

In 1996, it was estimated that 23,000 people with AIDS lived in rural regions of the United States (Shernoff, 1996). The escalating numbers of patients with HIV resulted in increased demands for medical care, and these medical facilities were unstable before the HIV epidemic. Many rural communities still have had limited contact with the HIV epidemic, resulting in fewer opportunities to develop social services and medical treatment services for persons with HIV and their family members. Long distances to medical facilities and the reluctance of medical personnel to provide care to persons with HIV are significant barriers to medical care in rural areas (Gunter, 1988; Heckman, et al., 1998). Coordinated care (e.g., primary HIV care, gynecological care, drug treatment, mental health services) may be particularly difficult to obtain in rural areas. Lack of employment opportunities, unsupportive work environments, and a shortage of mental health professionals were identified as significant barriers for persons with HIV in smaller communities (Heckman et al., 1998).

Increases in HIV seroprevalence rates in rural regions in Africa also have been documented (Boerma, Urassa, Senkoro, Klokke, & Ngweshemi, 1999; Kane et al., 1993; Mulder, Nunn, Wagner, Kamali, & Kengeya-Kayondo, 1994). Increased seroprevalence in rural regions is due in part to seasonal migration for employment in urban areas as well

as sexual mixing within these small geographic rural areas (Boerma et al., 1999; Kane et al., 1993; Lurie et al., 1995). Despite the profound magnitude of the HIV epidemic in Africa and the spread of HIV into the countryside, there has been limited attention to HIV disease in rural Africa. In a study of 482 people in rural Senegal, it was surprising to learn that 29% of the men and 13% of the women had never even heard of AIDS (Lagarde, Pison, & Enel, 1996). Awareness and access to adequate health care must increase.

To address HIV disease among women in rural communities, we must strengthen and supplement informal networks of family members, neighbors, and civic and religious organizations, as well as increase the availability of more formal sources of support and health care for persons with HIV and their families (Shernoff, 1996). Tartaglia (1996) focused on the importance of religious institutions, suggesting that churches are historically and functionally among the most influential of rural institutions. Special efforts are required to overcome the challenges in rural communities where diversity and anonymity are outside the norm (Anderson & Shaw, 1994). The development of satellite health clinics (Heckman et al., 1998) and telephone-linked support groups (where telephones are available) have been suggested as ways of bringing services to individuals where they live (Rounds, Galinsky, & Stevens, 1991).

CROSS-CUTTING THEMES AND CONCLUDING COMMENTS

An ecological perspective provides an excellent heuristic within which to frame a discussion about women with HIV and those at risk. This model allows for an examination of a wide array of factors—broadening the discourse to consider women within the social contexts of their lives. The determinants (e.g., sexual and drug-using behavior) and consequences (e.g., coping with diagnosis, caretaking, access to treatment) are embedded within sociocultural, interpersonal, and temporal and situational contexts. In this final section, the implications of this ecological approach for prevention, treatment, research and policy in the arena of women and HIV are considered. The section concludes with the role that health psychology can play in this evolving epidemic.

Prevention

Thus far, there is no available cure for AIDS and no medical vaccine to prevent the acquisition of HIV. Primary prevention is the only “magic bullet”; condoms and abstinence are the only ways of decreasing risk of HIV through sexual transmission (Elias & Coggins, 1996). The economic and social reasons discussed earlier make this approach difficult for many women (See section on *Sociocultural Context*). Inexpensive, effective and acceptable female controlled barrier methods, virucides and microbicides must be developed and distributed to provide more options for safer sex (Gollub, 1995; Elias & Coggins, 1996). Recently, the female condom has been introduced as a method for STD prevention; if used consistently and correctly, the risk of STD transmission is reduced by 97% in each act of

intercourse. Methods that offer protection, but not contraception would be particularly useful in those cultures where a woman's status is determined by her fertility.

Prevention interventions that are both gender specific and culturally sensitive must be emphasized to promote health enhancing behaviors and reduce health damaging behaviors. Health professionals must be trained in "cultural competency" to best meet their clients' diverse educational and linguistic backgrounds as well as their emotional and practical support needs (de Bruyn, 1992; Livingston, 1992; Smyke, 1991). There is a critical need to balance concern for cultural sensitivity with direct attention and candid discussions of sexual behavior and drug use—considered "off limits" in nearly every culture. Moreover, women must be empowered with assertion and negotiation skills to enhance their ability for noncoercive decision making (Livingston, 1992). Until women can have more complete control of their lives, HIV infection will continue to be the outcome of their social, physical, and economic subordination. And for women who are in control but still engaging in risky behavior, they must be educated about the likelihood of HIV infection and methods of prevention.

Although a complete description of prevention interventions is beyond the scope of this chapter, it is important to note that many targeted HIV prevention programs have included women (for reviews see Exner, Seal, & Ehrhardt, 1997; Ickovics & Yoshikawa, 1998). Programs have focused on preventing high risk sexual and drug using behavior among pregnant women (Hobfoll, Jackson, Lavin, Britton, & Shepherd, 1994), poor women in urban housing developments (Sikemma et al., 2000), women in primary health care clinics (Kelly et al., 1994; Shain et al., 1999), and adolescents (St. Lawrence et al., 1995). These studies and others have provided evidence for the effectiveness of cognitive behavioral group interventions (see for reviews Kalichman, Carey & Johnson, 1996; Kelly et al., 1997).

Finally, with regard to prevention—early adolescence may represent a "critical window" for establishing low risk behaviors (Barone et al., 1996; NIH, 1997). It is well documented that behavior change is difficult to promote and maintain. Teaching safer sex to children and adolescents before they become sexually active may make it more likely that safer sexual behavior is initiated and sustained. In a report to the President, the Office of National AIDS Policy (1996) called for immediate and direct action to reduce HIV among adolescents in part by implementing intensive HIV education and prevention programs in schools, religious organizations, and community groups. This must be done to prevent the continued spread of HIV among adolescents, despite political and moral arguments to the contrary.

Treatment

The clinical complications of HIV-related illness place a huge strain on medical and social services in both the public and private sectors, and in countries throughout the world (CDC, 1996). There have been few other occasions in scientific history that clinicians and investigators have been compelled to

move so rapidly from "the bench to the bedside." Recently, there have been several breakthroughs in the treatment of disease with protease inhibitors and combination antiretroviral therapies. However, questions persist about how these scientific breakthroughs will affect the health care and quality of life of average women infected with HIV. (See section on *Temporal Context, Disease Stage/Natural History and Progression*).

Women who are infected with HIV should have access to the broadest range of treatment options. Unfortunately, given high rates of poverty, that is not always the case, especially in the developing world. In the United States, women are more likely than men to receive their health care through the social service system; ease of access and the quality of care received by people who rely on Medicaid and Medicare has not been uniformly good (Bastian et al., 1993). With the broad expansion of managed care, federal welfare reform, and cuts in health and social service benefits in many states, health care for women with HIV may become even more scarce and difficult to obtain.

Treatment for HIV during pregnancy has become a particularly challenging issue. Although zidovudine is the only medication approved as safe and effective for the prevention of vertical transmission, it is considered "suboptimal treatment" when used by itself to treat adult HIV-related disease (CDC, 1998b). Physicians are prescribing combination therapy for pregnant women; however, it is unclear which strategy is best for both mother and child because the clinical trials have not yet been completed. Women should receive information on the benefits and risks of all drugs during pregnancy to enable them to make fully informed decisions. Information must be given in culturally, linguistically, and age-appropriate language. Women's reproductive decisions must not jeopardize on-going care. Voluntary HIV testing should be available to all women so that they can make informed decisions about maintaining or terminating a pregnancy.

Women with HIV need coordinated care including primary care, specialized services for HIV-related illness, gynecological services, psychological, social and legal services, case management for assistance with obtaining entitlements, family support, drug treatment, and coordinated access to pediatric and adult medical services if they have children. All of these supplemental services require a commitment to provide funding for comprehensive care. Due to continued epidemic spread and longer survival following diagnosis, the numbers of women living with HIV continues to expand; their medical, social, legal and other needs grow more complex.

Finally, identification and treatment of other sexually transmitted diseases is a critical point for intervention. In a randomized controlled study in Tanzania, Grosskurth et al. (1995) randomly assigned six communities to enhanced services for the diagnosis and treatment of STDs, and six matched communities were provided no enhanced services. Although there was no significant change in self-reported sexual behavior, there was a 40% reduction in HIV incidence among individuals in the intervention communities. This indicates the importance of integrated treatment services, and is

the first study of its kind to indicate the effectiveness of community treatment interventions to slow the spread of the HIV epidemic.

Research

Traditional theories of behavior change have provided a good foundation for HIV prevention research (e.g., Health Belief Model: Rosenstock, 1974; Theory of Reasoned Action: Azjen & Fishbein, 1977; Social Cognitive Learning Theory: Bandura, 1977). However, as the HIV epidemic has moved forward, it became clear that these models were limited. They were originally formulated for domains other than sexuality and drug use, and it was assumed that the behavior in question is under individual, volitional control. Traditionally, the interpersonal and situational processes and competing predictors of risk have not been taken into consideration (see for review, Auerbach et al., 1994). However, some theoretical adaptations have occurred, and these have provided important frameworks for new and ongoing HIV research (e.g., AIDS Risk Reduction Model: Catania, Kegeles, & Coates, 1990; Diffusion Theory: as adapted by Kelly, 1997).

The ecological model described in this chapter provides a broad approach, incorporating sociocultural, interpersonal, temporal and situational factors that may influence risk behavior or response to disease. It appears that investigators are trying to encompass a broad range of factors in new theoretical models; whereas this adequately reflects the complexity of behavior, it makes it difficult to test in a specific research study. Revenson (1990) suggested at least two reasons why context has generally been ignored in health research: It may be difficult to specify which aspects of social context may be important for an individual or a group; and, typically, investigators seek to eliminate threats to validity by ruling out the effects of "extraneous" variables, eliminating unwanted sources of variance.

Theoretical approaches in the realm of HIV and AIDS continue to evolve, and research agendas have moved forward, with or without a theoretical foundation. Investigators have called for research (in general) that integrates basic biological, epidemiological, psychological, and social factors to better understand transmission of HIV through sex and drug use (e.g., Auerbach et al., 1994; Coates, Temoshok & Mandel, 1984; Ickovics & Rodin, 1992; Kelly & Kalichman, 1995; NIH, 1997). Structural factors—such as class, race/ethnicity, gender relations, and community—that increase risk for HIV, affect progression of disease, and provide points of intervention have also been highlighted.

In terms of conducting research, methodological challenges persist, such as the reliance on self-reported behavior, development of adequate measures of risk behaviors and their predictors, longitudinal follow-up of study participants, and the generalizability of results from one study sample to the population (i.e., diverse populations such as homeless women, users of community health clinics or drug treatment programs, school-based or out-of-school adolescents; Catania, Gibson, Chitwood, & Coates, 1990). Given the complexities of HIV, research should be interdisciplinary and in-

clude multiple methodologies for data collection (e.g., quantitative, qualitative, ethnographic, objective health indicators).

To gain a real understanding of how HIV affects women, biologically, psychologically, and socially, women must be included in research (Rodin & Ickovics, 1990). Moreover, research on women and HIV must not be driven by past trends, but rather by important scientific issues and opportunities in the present and future of the epidemic. An important focus may be on distinctive patterns of behaviors and social conditions among specific subgroups of women; targeted prevention interventions could then follow. In the second decade of the AIDS pandemic, it is surprising that research on women with HIV and those most at risk continues to be limited. A cadre of researchers has been mobilized, however, and as we enter the next decade, understanding of factors affecting the lives of both women and men should be enhanced.

Policy

AIDS is a preventable disease, and the behavior placing the public health at greatest risk may be occurring in legislative and other decision making bodies. (NIH, 1997)

An independent, nongovernment consensus panel convened by the National Institutes of Health (1997) called on government and policy leaders at all levels to reverse policies that place the public at risk and to take the lead in implementing proven, lifesaving public health strategies. This panel strongly endorsed the use of needle exchange programs, youth education on safer sex, and better availability of drug abuse treatment to diminish the spread of HIV. The panel highlighted the government leadership and policy changes in AIDS-stricken countries such as Thailand and Uganda as models of how public policy can effectively reduce the spread of AIDS, saving lives and reducing the costs of the epidemic.

Because AIDS is primarily a sexually transmitted disease, it strikes adolescents, young adults, and people in early middle age; these are the very people on whom society relies for production and reproduction. Lost productivity has social and economic consequences for schools, hospitals, factories, and governments. In countries that are not yet industrialized or are in the process of industrializing, AIDS threatens economic development itself (United Nations, 1999).

There has been increased awareness of policy issues that affect women with HIV/AIDS and those most at risk; however, current public policy has not always been developed in their best interest (Ethier et al., 1996). Public policies can influence research funding, treatment access, and cost, and social protection against bias and discrimination. In general, women with HIV and those most at risk have not had a strong advocacy group to work on their behalf to change public policy to better address their needs. Current rates of HIV and projections for the future indicate that women throughout the world will be affected increasingly by the AIDS pandemic in the years to come. The impact of this pandemic cannot be measured solely by counting the number of people infected or ill. For every person infected with HIV, there are countless

others who are affected by the impact of the disease as family members, neighbors, colleagues, and friends. Priorities for prevention, treatment, and research must be established at many levels (e.g., local, regional, national, international), and those in positions of power (or those with access to the powerful others) must insure that these priorities are addressed in a systematic and comprehensive fashion.

The Role of Health Psychology in the Understanding of Women and HIV

Women with HIV and those at risk for HIV do not represent a homogenous group. However, all may have to confront issues unique to women such as power differentials in intimate relationships, the need for treatment of gynecological complications of HIV, and issues with regard to pregnancy, reproductive decision making, and parenthood. Health psychology and behavioral medicine can play an important role in enhancing understanding of the problems faced by women infected with HIV and those most at risk.

Matarazzo (1980) described the field as broadly addressing: the promotion and maintenance of health, the prevention and treatment of illness, the identification of etiologic and diagnostic correlates of health, illness and related dysfunction, and the improvement of the health care system and health policy formation. The complexities of HIV—as highlighted by the ecological approach that takes into consideration sociocultural, interpersonal, temporal, and situational contexts—are best addressed through interdisciplinary investigations and clinical practice. This is a challenging domain, and researchers must rise to the challenge through scientific excellence as well as the courage and compassion required to address the needs of women with HIV, those most at risk, their family members and loved ones.

Living With HIV Disease

Sheryl L. Catz
 Jeffrey A. Kelly
Medical College of Wisconsin

The first cases of AIDS were identified in the United States nearly two decades ago. Many characteristics of AIDS quickly set the disease apart from other illnesses. One was the early association of AIDS with casual sex, and with homosexual behavior in particular. Initially and briefly known as “gay-related infectious disease” (GRID), AIDS appeared as a disease carrying unique stigma related to homosexuality, drug use, and other lifestyle issues that elicit social disapproval. Although other sexually transmitted diseases (STDs) have long been known, few are as fatal and there is little modern precedent—other than syphilis in the era before antibiotics—for a debilitating, incurable, fatal sexually transmitted infection. Especially in the AIDS epidemic’s early years, there were widespread fears (bordering at times on hysteria) concerning possible disease transmission during everyday social contact. Although much has changed in public understanding of AIDS and in attitudes toward persons with the disease, these changes are not universal and AIDS still carries considerable stigma.

There has also been a steady progression in scientific and medical knowledge about AIDS and in progress toward more effective treatments for the disease. Two of the early benchmarks in this progression were the identification of human immunodeficiency virus (HIV) infection as the agent responsible for the illness and a reconceptualization of the disease process away from its focus on AIDS alone and toward a larger spectrum of HIV-related conditions. As the pathogenesis of HIV-related disease became better known, treatment advances have also occurred and, in recent years, have dramatically advanced. Although AIDS continues to

take many lives, new treatments hold out the promise of longer and healthier life for some persons with HIV disease.

Kobayashi (1997) pointed out that the psychosocial and coping issues that confront people living with HIV/AIDS have changed throughout the history of the disease, in large part related to the evolution of treatments for HIV/AIDS. From a point early in the AIDS epidemic when the disease was seen as invariably fatal and effective treatment did not exist, HIV medical care has evolved to the point where both patients and health care providers can now approach disease management from at least a guardedly optimistic perspective. These treatment advances have also influenced the psychological coping issues faced by persons living with HIV. Psychological interventions remain critical for helping patients cope with the ramifications of HIV disease and benefiting from new treatments, as they have throughout the history of AIDS. However, and in parallel with HIV medical care advances, the psychological needs of persons with HIV are different than earlier in the AIDS epidemic.

This chapter describes psychological issues raised by HIV treatment advances. This discussion focuses on mental health and health behavior aspects of HIV disease, and on the interplay between medical advances and psychological care needs. Attention is especially focused in four areas: potential adjustment and coping challenges faced by persons living with HIV in this era of new HIV medical advances, issues related to patient adherence to new HIV treatment regimens, sexual or drug use risk behavior among HIV-seropositive and seronegative persons, and the emerging nature of HIV as a serious, chronic, but often manageable disease.

PSYCHOLOGICAL AND COPING CHALLENGES FACING PERSONS WITH HIV IN AN ERA OF NEW TREATMENTS

Although HIV was known to be the agent responsible for AIDS since the early 1980s, little was understood about the nature of the virus and there were at first no effective treatments for HIV disease. Prophylactic and palliative care were available to manage some AIDS-related opportunistic diseases, but no medical interventions were able to directly target the underlying HIV infection responsible for those diseases. Psychosocial research on AIDS in the early 1980s often found—not surprisingly—evidence of pervasive depression, suicidality, and adjustment disorders among predominantly young persons diagnosed with a debilitating, fatal, frightening, and highly stigmatized disease (e.g., Dilley, Ochitill, Perl, & Volberding, 1985; Perry & Tross, 1984). In this early era, one technological advance with important psychosocial ramifications was the availability of antibody tests beginning in 1985. From a medical standpoint, the ability to identify persons with HIV who had not yet developed AIDS opened new opportunities for their participation in clinical drug trials. On a societal level, increased compassion and activism followed the knowledge that HIV could not be transmitted through casual contact (Kobayashi, 1997). Given the limited treatment options at that time, a central question facing many at-risk individuals was whether or not to get “tested.” Knowing their serostatus might help prevent the spread of HIV to others, but did little to protect individuals from facing what was often feared to be a “death sentence.” Because most cases of HIV infection and AIDS occurred within the gay community and among injection drug users’ (IDUs) social networks, the coping resources of persons in these communities were also often taxed by their experiences with multiple AIDS-related deaths (Martin & Dean, 1993).

Following the development in 1987 of the first antiviral medication, zidovudine (AZT), HIV prognoses and treatments were viewed somewhat more hopefully (Rabkin, Williams, Neugebauer, Remien, & Goetz, 1990). Mental health research at the time also began to identify more complex patterns of coping and adjustment to HIV disease (Folkman, Chesney, Pollack, & Coates, 1993; Hays, Turner, & Coates, 1992) and more individual variation in how persons psychologically adapted to their illness (Williams, Rabkin, Remien, Gorman, & Ehrhardt, 1991). However, this initial hopefulness was followed by disillusionment as the long-term benefits of available antiviral therapies like AZT alone came into doubt. Despite these concerns, research indicated that whereas some individuals experienced considerable levels of psychological distress, many people living with HIV disease coped relatively well with their illness and often maintained hope for their long-term health outlook (Rabkin et al., 1997).

Throughout the late 1980s and early 1990s, perceptions of physical and emotional well-being among people living with HIV seemed closely tied to results from laboratory markers of disease progression that measure changes in immune function (i.e., CD4 lymphocyte counts). For example, a CD4

count falling below 200 became an important psychological turning point because this laboratory value served as the immunological benchmark for defining an AIDS diagnosis (CDC, 1992). Willingness to initiate or continue treatment was often influenced by a person’s ability to tolerate drug side effects and beliefs concerning whether the benefits of available treatments outweighed their deleterious effects on quality of life (Nannis, Temoshok, Smith, & Jenkins, 1993).

New HIV Treatments and Technology

Basic science research has shown that the viral replication cycle is characterized by very rapid proliferation of HIV, with up to 10,000 billion particles produced and destroyed daily (Ho et al., 1995). Because HIV replicates so rapidly, it can quickly mutate to become drug resistant. Improved understanding of these viral dynamics led to the development of new treatment tools. By 1996, several major medical advances would profoundly alter the nature of clinical HIV care. Diagnostic markers became available to quantify disease status by directly measuring levels of “viral load” (HIV RNA) in blood plasma. These assays provided important information about the progression of viral replication that complemented available CD4 markers of immune functioning. Shortly thereafter, a potent class of medications called protease inhibitors were developed and combined with other new or existing antiretrovirals that together targeted HIV at multiple points in its replication cycle. Combinations of highly active antiretroviral therapies (HAART) quickly came into widespread clinical use (Carpenter et al., 1998). HAART regimens are typically triple drug combinations which include a protease inhibitor (i.e., indinavir, saquinavir, nelfinavir, ritonavir) and two nucleoside analogues (i.e., zidovudine, lamivudine, stavudine, zalcitabine, didanosine). When combined, three (or sometimes even more) of these drugs slow viral replication, reduce viral load, and diminish the development of resistant viral strains. HAART regimens have changed the face of AIDS care because they are capable of suppressing plasma viral load to undetectable levels, increasing CD4 levels, improving clinical outcomes, and decreasing AIDS-related mortality (Carpenter et al., 1998; Deeks, Smith, Holodniy, & Kahn, 1997; Hammer et al., 1997). For the first time in the history of HIV disease, medical care providers have potent antiviral medications and methods to directly monitor their effectiveness in suppressing viral replication.

Emerging Psychological Adjustment Issues

The advent of powerful new combination treatments for HIV has raised a host of new issues related to social and psychological coping with HIV disease. One set of issues involves whether, how well, and for how long patients derive benefits from the new regimens. Different treatment outcomes and disease course trajectories may create very different sets of adjustment issues. Many people who were seriously ill experience significant improvements in health after beginning HAART. For some, this reversal of HIV disease progression

is well-sustained. However, other patients are unable to tolerate or absorb the medications and must quickly stop HAART or switch to different regimens (Carpenter et al., 1998). Still others experience treatment failure following an initial period of earlier treatment response. People with HIV who begin HAART regimens while they still have relatively good immune functioning are most likely to have a favorable virological response to treatment (Fatkenheuer et al., 1997). However, some asymptomatic individuals experience iatrogenic effects of HAART that negatively impact quality of life. Different life issues, medical decisions, and coping responses may arise in each of these situations.

Shortly after they were introduced in the United States, protease inhibitors were widely publicized as "near cures" for HIV disease. Many people living with HIV respond to HAART with dramatic and well-sustained improvements in health and well-being. This phenomenon has been described by some as providing a chance for persons with HIV to lead a "second life" (Rabkin & Ferrando, 1997). How persons adapt from a focus on early death from AIDS to the prospect—but not the guarantee—of longer life is not yet known. To date, there has been little research describing psychosocial adjustment among persons for whom viral replication is successfully suppressed. However, stressful life events and new decisions may accompany the experience of having such a "second lease" on life (Kelly, Otto-Salaj, Sikkema, Pinkerton, & Bloom, 1998; Klein, 1998; Rabkin & Ferrando, 1997). For example, questions about when and whether individuals should return to work, or begin or end relationships, are likely consequences of the health reversals that may follow successful treatment. In addition to enhancing their quality of life, improvements in functioning may also create stress. It can be difficult for persons to make a rapid transition from anticipating declining health and death to holding a more optimistic health outlook that requires planning long into the future. For example, some persons with HIV or AIDS have traded their life insurance policies for cash or incurred debts in the expectation of an early death. Others who qualified for disability entitlements or Medicaid assistance after leaving work or lost personal assets may have difficulty regaining economic self-sufficiency. The high costs of HIV medications—often \$10,000 to \$15,000 per year—can lead to challenging dilemmas when eligibility for medication entitlements due to disability may be lost through a return to employment, but when employment income is insufficient to pay for the medications needed to remain healthy.

In addition to economic stressors, other sources of social stress can emerge during shifts from relatively poor to good health. Grief responses may be exacerbated or rekindled by "survivor's guilt" when individuals escape the fate of partners and friends who died of AIDS-related complications earlier in the epidemic. Improved health and feedback about lower viral load may also precipitate changes in current living situations and relationships. Previous decisions to live near better medical services or with family members who could function as caretakers may need to be re-examined. The scope of life goals is likely to alter, necessitating new decisions about changing careers, resuming education, or reproduction

options. Expectations of living a longer life or the possibility that new medications might reduce HIV infectivity could, for instance, lead to increased choices to have children. Life change, whether positive or negative, can be stressful. It is not yet clear to what extent HAART-related life changes create adjustment difficulties for persons with HIV disease or the way best to facilitate smooth transitions.

There are also direct ways in which HAART regimens may diminish rather than enhance quality of life. Some of the common side effects associated with protease inhibitors include nausea, diarrhea, fatigue, and headaches. Difficulty tolerating medication or following complex and frequent dosing schedules may interfere with activities of daily life. Meal times, travel, and work or leisure activities often need to be carefully coordinated with times when various pills must be taken or when side effects are most likely to impair functioning. Recent research with persons taking these regimens suggests that many patients are very concerned that medication taking has too much become a central focus of their lives (Stone et al., 1998).

As protease inhibitor use in clinical settings has increased, it has become evident that many persons living with HIV disease (up to 50% in some studies) do not respond well or do not maintain viral suppression responses to the new regimens (e.g., Deeks, Loftus, Cohen, Chin, & Grant, 1997). This raises an important question of how these individuals cope when they learn that they themselves did not get an opportunity for a "second life." Rabkin and Ferrando (1997), Kelly, Otto-Salaj, et al. (1998), and others have raised the possibility that HAART treatment failure could precipitate considerable psychological distress, pessimism, and coping problems. This is particularly so because, unlike the common disappointment with earlier treatments, failure of HAART regimens takes place in the context of media reports of "miraculous" new treatments or personal contacts with others who have experienced dramatic health gains. On a societal level, this raises the concern that there will be a "re-marginalization of the dying" in terms of HIV service provision and public policy, and increased opportunities for HIV discrimination (Klein, 1998).

At the individual level, personal perceptions and explanations of treatment outcomes can play a large role in determining psychological responses to HAART. Because strict medication adherence is necessary for treatment success, individuals who do not respond well to HAART regimens may make an attribution that they have failed the regimen rather than that the regimen has failed for them, thus reacting with guilt, low self-esteem, or depression. Such self-blame and discouragement may be especially salient when treatment failure follows a period of initial treatment success. Alternatively, persons who observe others doing well on a HAART regimen but are themselves unable to tolerate the regimen may experience negative situational attributions, hopelessness, anger, or mistrust of medical advances. In either case, uncertainties and realistic fears that future antiretrovirals will also not work are likely to color the perceptions of persons who experience failure of HAART regimens (Rabkin & Ferrando, 1997).

ADHERENCE: BEHAVIORAL INFLUENCES ON MEDICAL OUTCOMES

Although coping is generally viewed as a mental health issue, the ways in which individuals cope with HIV disease and with antiretroviral treatments also carry implications for two important areas of their health behavior: treatment adherence and transmission risk practices. Less adaptive coping and greater affective distress have been associated with greater problems adhering to HIV treatment regimens (Singh et al., 1996). HIV-infected persons experiencing high levels of psychological distress may also be more likely to display patterns of continued unprotected sexual activity (Kelly, Murphy, Bahr, Koob, et al., 1993). This suggests that interventions for emotionally distressed persons living with HIV disease may carry not only psychological benefits, but also public health and medical treatment outcome benefits.

The goal of successful antiretroviral therapy is to achieve maximal sustained viral suppression (Carpenter et al., 1998). Clinical benefits may result from even partial viral suppression. However, near-total suppression of HIV viral load is necessary in order to minimize the development of drug resistant viral strains. Virological failure of HAART is characterized by the development of multidrug resistance and a resumption of rapid viral replication. Cross-resistance may occur within classes of antiretroviral medications, so failure of one HAART regimen is likely to make success with subsequent regimens less likely. Durable viral suppression in response to combination antiretroviral therapy is the medical outcome of most critical importance for the long-term success of HIV care. For that reason, it is critical that patients adhere fully, immediately, and continuously with HAART regimens. Failure to do so can render the regimen ineffective and lead to drug resistance that reduces the likely success of future treatment.

Adherence in medication taking behavior has been linked to medical outcomes in several studies (Hecht, Colfax, Swanson, & Chesney, 1998; Montaner et al., 1998). In one clinical study of persons with HIV infection taking protease inhibitors at a San Francisco hospital, those who reported high levels of medication adherence were over four times more likely than those who reported medication nonadherence to achieve an optimal level of viral suppression (Hecht, Colfax, et al., 1998). An association between less than perfect protease inhibitor adherence and failure to sustain maximal viral suppression has also been demonstrated in a large clinical drug trial (Montaner et al., 1998). Thus, even short "drug holidays" or occasional missed doses of protease inhibitors may be sufficient to facilitate the emergence of drug resistance and treatment failure (Katzenstein, 1997). Even more so than for past HIV treatments or for drug regimens used to treat many other chronic diseases, therapeutic efficacy of HAART is greatly determined by treatment adherence.

Treatment Adherence Issues

Medication adherence has become a prominent behavioral issue in HIV care. The urgency of improving antiretroviral medi-

cation adherence has been widely acknowledged by the HIV medical community, with the importance of adherence formally recognized in antiretroviral treatment guidelines (Carpenter et al., 1998). In a national survey of physicians and patients, Gallant and Block (1998) found that 89% of HIV care providers rated treatment adherence as a serious problem. Of 359 patients on combination therapy regimens interviewed, 43% reported lapses in antiretroviral adherence during the previous week and 26% said they had not adhered to the regimen in the past day. Both physicians and patients in the study described regimen complexity as an important reason for nonadherence. Furthermore, the necessity for following regimens strictly over time was especially problematic, with the length of self-initiated drug holidays reported to increase with longer durations of treatment (Gallant & Block, 1998).

Such findings are not surprising given the tremendous behavioral burden associated with combination therapy. HAART regimens are extremely complex; regimens requiring 20 to 30 pills taken daily are not uncommon. HIV treatments are now expected to be chronic and lifelong in their duration. Because taking HAART necessitates maintaining such complicated medication taking habits over extended time periods, adherence problems are likely to be the rule rather than the exception. Since the objective of HAART regimens is often to prevent onset of HIV disease in persons who are infected, they can be construed as chronic preventive regimens. Such preventive interventions may be particularly likely to produce nonadherence. The general chronic illness literature shows that only about one half of patients adhere to interventions that are preventative or long term (Podell, 1975; Rosenstock, 1975). As many as 80% of patients may be partially nonadherent at some time during the course of any chronic illness (Dunbar-Jacob, Burke, & Puczynski, 1995). In general, patients are less likely to adhere to complex regimens (Agras, 1989) or regimens that include multiple medications (Blackwell, 1992). All of these are characteristics of HIV HAART regimens.

In addition to regimen characteristics, several factors investigated in the context of other chronic illnesses are relevant to HIV medication adherence (Ickovics & Meisler, 1997). These include characteristics of the disease, provider, and patient. Adherence may vary with differences in disease severity, although adherence problems have been observed among those who are seriously ill as well as those who are asymptomatic. Research with other diseases has also established a link between medical provider characteristics and patient behavior. The quality of provider/patient interactions, communication styles, and clinic environment factors can impact adherence (DiMatteo et al., 1993). Psychosocial factors, including greater social support and less psychological distress, have also been associated with adherence across a variety of chronic illnesses. However, reliable predictors of nonadherence at the level of individual patient characteristics have been difficult to identify. Nonadherence can occur among individuals of all ages, social classes, and ethnic groups (DiMatteo & DiNicola, 1982). In short, every person managing a chronic disease is at some risk for treatment adherence problems. This means that interventions to improve

adherence require an identification of specific barriers to adherence throughout the course of treatment.

Much may also be learned about relevant barriers from investigations of adherence to previous HIV treatments. Before the development of HAART, a number of studies examined adherence to AZT monotherapy (Eldred, Wu, Chaisson, & Moore, 1998; Muma, Ross, Parcel, & Pollard, 1995; Singh et al., 1996; Smith, Rapkin, Morrison, & Kammerman, 1997). There is evidence that provider relationships and psychosocial factors (including social support, coping, and depression) contribute to AZT treatment adherence among persons with HIV (Morse et al., 1991; Mostashari, Riley, Selwyn, & Altice, 1998; Shelton et al., 1993; Singh et al., 1996). For example, patient perceptions of physician communication style and the presence of good emotional supports were found to be positively associated with antiretroviral adherence in a study undertaken with incarcerated women (Mostashari et al., 1998). One important longitudinal investigation of antiretroviral adherence conducted in a veteran's hospital suggested that treatment adherent patients with HIV disease had lower levels of depression and more adaptive coping than those who were not adherent (Singh et al., 1996). Another common finding among many early investigations of antiretroviral adherence involves the importance of patient beliefs. Even for relatively simple regimens like AZT monotherapy, patient beliefs in their ability to adhere to antiretroviral therapy have been related to higher rates of adherence (Eldred et al., 1998). Furthermore, patient beliefs concerning the efficacy or personal benefits of antiretrovirals appear to influence medication adherence. The perceived ability of AZT to improve health, to prolong life, or to provide protection from AIDS-related illness has been linked to medication taking patterns and to treatment drop-out (Aversa & Kimberlin, 1996; Geletko, Ballard, & Mathews, 1995; Muma et al., 1995; Samet et al., 1992; Smith et al., 1997). Perception that the benefits of treatment outweigh its limitations and drawbacks were also especially important influences on adherence to AZT regimens (Geletko et al., 1995; Muma et al., 1995; Nannis et al., 1993). It is likely that similar factors will prove relevant for understanding adherence to new HAART treatments as well.

Due to the powerful impact of adherence on treatment outcomes, effective behavioral interventions to promote HAART regimen adherence are urgently needed. The development of these interventions will require an identification of factors that influence adherence to combination therapies. It will also require the refinement of adherence assessment methodologies. Accurate measurement of patients' adherence to medication regimens has proven extremely challenging in the behavioral medicine field. These measurement issues are difficult even for regimens that require only once-a-day dosing of single medications. Because HAART regimens involve many more daily doses of multiple medications, assessment of adherence to new HIV therapies is complex. No gold standard exists for assessing treatment adherence. Consequently, the strongest way to measure adherence behavior is through a multimethod approach in which an array of complementary assessment techniques is used.

Outcome measures that may prove useful for determining the effectiveness of behavioral interventions to promote HAART adherence include patient self-report instruments, self-monitoring techniques, electronic dose monitoring instruments, prescription refill data, pill counts, clinic appointment keeping records, serum assays of medication levels, and clinical markers expected to coincide with regimen adherence. Each of these methods has both benefits and drawbacks. For instance, self-reports of adherence are relatively inexpensive and efficient to administer, but are indirect measures that consistently tend to overestimate good adherence. On the other hand, electronic monitoring of medication container opening behavior can overestimate poor adherence when pill bottles are opened less often or at different times than pills are actually taken. Electronic monitoring systems may also be costly and relatively inconvenient for patients to use. Biological, as well as behavioral, indices of adherence can reflect a great deal of measurement error. Direct assays of medication levels are expensive and often unavailable, are susceptible to inaccuracies due to individual variations in bioavailability, and tend to measure information only about the most recent dose taken rather than overall levels of adherence. Caution must also be used when interpreting biological markers, such as CD4 counts or viral load values, as evidence of medication adherence. Although biological markers are objective measures of medical outcome, changes in these indices also reflect factors other than adherence such as pretreatment disease severity and history of resistance to previously prescribed medications.

In spite of the continuing need for more advanced measurement technologies and more complete modeling of adherence predictors, the clinical demand for interventions promoting antiretroviral adherence has been so pressing since the development of protease inhibitors that a variety of interventions are being attempted by care providers. The development of HIV treatment adherence interventions can be informed by previous research. However, relatively few empirically validated adherence interventions are to be found even in the general, non-HIV treatment literature (see Dunbar-Jacob et al., 1995; Haynes, McKibbin, & Kanani, 1996, for reviews). Of the randomized, controlled intervention studies of long-term medication adherence that have been conducted, only those including very complex and intensive interventions have demonstrated effects on adherence (e.g., Bailey et al., 1990; Haynes et al., 1976; Logan, Milne, Achber, Cambell, & Haynes, 1979; Saunders, Irwig, Gear, & Ramushu, 1991). No studies to date have shown maintenance effects, and none have indicated which intervention components are most effective. Nonetheless, a number of adherence promoting strategies have been suggested by the literature. These generally include enhancing the use of social support resources, increasing self-efficacy regarding the ability to follow treatment plans, improving patient education about the expected positive and negative consequences of medication regimens, modifying the treatment environment to minimize barriers to keeping appointments or refilling prescriptions, enhancing patient-provider relationships by promoting trust and good communication skills, and employing basic behavioral techniques. These techniques include goal

setting and behavioral contracting, self-monitoring and self-reinforcement, social reinforcement, the provision of behavioral or medical outcome feedback, the use of environmental reminders or specially organized medication dispensers, and the tailoring of regimen dosing schedules to fit daily routines.

Interventions for promoting adherence to HIV medications can build on such strategies. The need for effective strategies to improve adherence to HAART regimens is perhaps one of the greatest challenges faced by behavioral scientists in this new era of HIV treatment. It is a challenge that must be met with innovation and multidisciplinary cooperation. Controlled trials of adherence interventions at the level of the service system, provider, and patient must be undertaken. It is essential that interventions be developed that maximize the involvement of patients in the management of their own care, and foster collaborative, problem-solving approaches to the initiation and maintenance of adherence to HAART. Successful medication adherence carries significant health benefits for individuals living with HIV, as well as public health benefits by reducing the possibility of new infections with drug-resistant HIV strains.

HIV TRANSMISSION RISK BEHAVIOR

Past research on the effects of HIV serostatus knowledge on sexual risk behavior has shown that most persons aware of their HIV-positive status reduce or avoid engaging in activities that could transmit infection to others (Cleary et al., 1991; Higgins et al., 1991). On the other hand, these studies also indicate that a substantial minority of HIV-seropositive persons have difficulty in consistently refraining from unprotected sexual behavior. Approximately one third of young gay or bisexual seropositive men in a San Francisco cohort reported they had recently engaged in unprotected anal intercourse (Lemp et al., 1994), with similar levels of unprotected sex reported in samples of HIV-infected injection drug users (Rhodes, Donoghoe, Hunter, & Stimson, 1993; Singh et al., 1993) and cohorts of gay men (Robins et al., 1994). Factors that differentiate HIV-seropositive persons who do from those who do not engage in unprotected sexual activities following awareness of their serostatus include levels of psychological distress (Kelly, Murphy, Bahr, Koob, Brasfield et al., 1993), coexisting substance use patterns (Kalichman, Kelly, & Rompa, 1997; Robins et al., 1994), relationship characteristics and comfort in disclosing HIV serostatus to sexual relationship partners (Remien, Carballo-Diequez, & Wagner, 1995), and psychological controls related to sex (Centers for Disease Control and Prevention, 1996). Persons most likely to report continued patterns of risky activities are those with high levels of current psychological distress, poor coping, concurrent substance use problems, difficulty in disclosing their serostatus, limited social supports, and poor levels of sexual self-control. One randomized outcome study found that a small group intervention that improved coping skills and social supports for depressed persons living with HIV produced not only changes in mental health indicators but also reductions in levels of subsequent unprotected sexual be-

havior (Kelly, Murphy, Bahr, Kalichman, et al., 1993). This suggests that if people are assisted in effectively coping with their HIV disease, they are also more likely to be able to successfully self-manage risk in their sexual lives.

The availability of combination antiretroviral therapies for the treatment of HIV disease, media heralding of HIV treatment advances as "near cures" or cause for "great hope" in the conquest of AIDS, and optimism due to a reduction in death rates from AIDS may be influencing public perceptions concerning the severity of AIDS and perceptions about the need to maintain safer sex. Dilley, Woods, and McFarland (1997) found evidence of diminishing concerns about becoming HIV-infected among some gay men in San Francisco. Kelly, Hoffmann, et al. (1998), in a community sample survey of gay and bisexual men in the midwest, found that AIDS was still perceived as a serious threat among most men. However, 13% felt that AIDS is a less serious threat than it was in the past and nearly 20% of HIV-positive men on combination therapy regimens said they personally practice safe-sex less often since HIV medical treatments have advanced. Whether similar perceptions of diminished AIDS severity are occurring among heterosexual men, women, adolescents, or IDUs has not yet been examined.

It is possible—but not yet well-established *in vivo*—that at least some individuals with undetectable plasma HIV viral load levels may have lower HIV transmission infectivity (Vernazza et al., 1997). However, persons who have been nonadherent with HAART regimens or those who have not responded well to the treatments can develop HIV strains that are resistant to antiretroviral medications. Transmission of drug-resistant virus to sexual or needle-sharing partners is a potentially serious concern because individuals who contract drug-resistant HIV are unlikely to benefit optimally from currently available treatments. There is evidence that sexual transmission of multidrug-resistant viral strains has already taken place (Hecht, Grant, et al., 1998; Imrie et al., 1997).

Traditionally, HIV prevention efforts have been construed primarily from the perspective of encouraging HIV-seronegative persons to remain uninfected. HIV-seropositive persons have been seen primarily as in need of care services, not prevention efforts. Although these needs remain, the changing nature of the HIV epidemic and the populations now most threatened by it call for a broader perspective. Given that persons at greatest risk for contracting HIV are younger, more disenfranchised, and more disadvantaged than ever before, effective HIV prevention for high risk seronegative populations will increasingly also need to include services such as substance use, social, and youth services. While persons living with HIV will continue to require a variety of care services, some will also require ongoing behavior change encouragement, support, and counseling. In this context, it will be important for service providers to remain cognizant that persons living with HIV continue to be sexual beings and may require ongoing support in areas such as serostatus disclosure to potential partners, avoiding high risk practices, and handling situations that could otherwise result in risky sexual or drug use activities. As persons with HIV

live longer and healthier lives, the challenges of maintaining these behavior changes will be greater and more sustained.

HIV AS A CHRONIC DISEASE

Since very early in the HIV epidemic, there has always been the hope—articulated throughout the years in the health care provider community, the AIDS activist community, and the community of persons living with HIV—that HIV infection might someday become a serious, chronic, but manageable, disease. Advances in medical treatment are bringing this hope closer to reality. It is still too early to declare success in making HIV disease manageable; too many patients still do not derive or maintain benefit from even the newest antiretroviral combinations, and the history of HIV disease is one with many treatment hopes that did not prove durable. Nonetheless, the potential outlook for many persons living with HIV is brighter than it has ever been before. To a large extent, psychological and behavioral medicine interventions will play a key role in determining whether this potentially hopeful outlook will endure. The effective treatment of persons living with HIV will require that difficult problems be addressed. These include promoting adherence to difficult medical regimens that are remarkably unforgiving of lapses; assisting patients in coping with successes, failures, and uncertainty in their health outlook; and encouraging the avoidance of transmission risk behavior among both seropositive and seronegative persons.

When AIDS first appeared, many aspects of the disease were startling because they were new. HIV/AIDS continues to remain, in many respects, a unique disease by virtue of its stigmatized public perception, sexually transmitted infectious characteristics, concentration within certain communities and social networks, and the coping challenges that confront persons with HIV. To a very great extent, American society has not yet come to terms with the types of policies—including improved sexual education for young people, ensuring ready access to condoms, and needle exchange for out-of-treatment IDUs—that will prove essential for stopping the epidemic. However, medical aspects of HIV disease and, more specifically, the roles for health psychologists to contribute to HIV prevention and care are coming to resemble the psychological profession's role in other chronic disease areas. What has been learned about promoting treatment adherence in diseases such as hypertension, diabetes, and other illnesses can be applied to the newer problem of HIV treatment adherence. Lessons learned in helping people cope with serious chronic diseases with uncertain long-term outlooks such as cancer can provide a framework for assisting patients with HIV to cope with similar uncertainties. Behavioral medicine paradigms and principles useful in other health behavior areas can guide efforts related to HIV. What is learned in the HIV/AIDS behavioral medicine area can, in turn, contribute to efforts to assist persons with diseases other than AIDS. There is not a need to reinvent the wheel of behavioral medicine knowledge for health behavior problems experienced by persons with HIV. However, there is a need to make the wheel turn faster given the urgencies of this disease.

Finally, the challenges created by AIDS will continue to evolve. There have already been important changes in the demography of the American HIV epidemic. Persons contracting HIV are younger, poorer, more disenfranchised, and more estranged from traditional health and mental health service systems than ever before. Substance abuse has become even more closely intertwined with HIV risk than in the past, and groups now most vulnerable to HIV disease (including drug-involved and impoverished women, young and ethnic minority men who have sex with men, IDUs, and the homeless) are populations highly underrepresented in the behavioral medicine field. For all of these vulnerable groups, coping, mental health, treatment adherence, and transmission risk avoidance efforts are likely to be exceptionally difficult. They will require that health psychologists develop new culturally tailored approaches, service delivery mechanisms, and—perhaps—sensitivities. Ultimately, meeting these challenges will also expand and benefit this field.

Cultural Diversity and Health Psychology

Hope Landrine

Elizabeth A. Klonoff

*San Diego State University / University of California-San Diego
Joint Doctoral Program in Clinical Psychology*

Two social factors that play a role in everyone's health (Bubker et al., 1989) are the nature and quality of their jobs/work environments (J. V. Johnson & Johannson, 1991; Karasek & Theorell, 1990; Sauter, Hurrell, & Cooper, 1989; Schor, 1991), and their socioeconomic (SES) status (Marmot, Kogevinas, & Elston, 1987; Schnall, Landsbergis, & Baker, 1994). Because U.S. minority groups tend to occupy low status jobs characterized by high job strain and low job control and stability, the nature of their work undoubtedly contributes to their differential morbidity and mortality (Amick, Levine, Tarlov, & Walsh, 1995). Likewise, because many minorities live in poverty (Amick et al., 1995), low SES also plays a role in minority excess morbidity and mortality through a variety of mechanisms (Baquet, Horm, Gibbs, & Greenwald, 1991; Coulehan, 1992; Hampton, 1992; Marmot & Theorell, 1988). These include low access to medical care (Blendon, Aiken, Freeman, & Corey, 1989) and high exposure to stress (King & Williams, 1995), air pollution (Brajer & Hall, 1992), toxic waste sites in their neighborhoods (Commission for Racial Justice, 1987), and carcinogens at work (Gottlieb & Husen, 1982; Samet, Kutvrit, Waxweiler, & Key, 1984).

Although these factors (along with low education) have been demonstrated to play a significant role in the health status of minorities, they nonetheless remain social rather than cultural variables. Social variables are parts (aspects), processes (mechanisms for maintaining), and products (results) of social stratification that may or may not be valued by, and are beyond the control of Whites and minorities alike (Landrine, Klonoff, Alcaraz, Scott, & Wilkins, 1995). Cultural variables, on the other hand, are factors that are purpose-

fully transmitted to successive generations through socialization because they are valued (Landrine, 1992; Landrine & Klonoff, 1996a; Landrine, Klonoff, & Brown-Collins, 1992). Manuscripts on culture and minority health abound, but almost always focus on social variables and fail to mention any cultural factors. Poverty, low education, and unemployment, however, never have been aspects of anyone's culture.

Alternatively, other research on culture and minority health rightly ignores social variables as such to focus instead on the role of acculturation. These studies have found that acculturation contributes significantly to the variance in minority health behavior and morbidity irrespective of the minority group in question. For example, studies have found that acculturation plays a role in weight and dieting among Japanese (Furukawa, 1994) and Chinese (Schultz, Spindler, & Josephson, 1994) Americans, and in chronic disease among Cambodian Americans (Palinkas & Pickwell, 1995). For Mexican Americans, acculturation has been demonstrated to play a role in hypertension (Espino, 1990); AIDS risk and knowledge of AIDS transmission (Epstein, Dusenbury, Botvin, & Diaz, 1994); cancer knowledge and risk reduction behaviors (Balcazar, Castro, & Krull, 1995); compliance with medical treatments (Pachter, Susan, & Weller, 1993); cigarette smoking among children, adolescents (Landrine, Richardson, Klonoff, & Flay, 1994), and adults (G. Marin, B. V. Marin, Otero-Sabogal, Sabogal, & Perez-Stable, 1989; G. Marin, Perez-Stable, & B. V. Marin, 1989); use of health services (Wells, Golding, & Hough, 1989); dietary patterns (Gardner, Winkleby, & Viteri, 1995); salt consumption and exercise frequency (Vega et al., 1987); and chronic disease

morbidity (Balcazar et al., 1995). For African Americans, studies of acculturation and health have only just begun because the African American Acculturation Scale (AAAS; Landrine & Klonoff, 1994a, 1996a) is a recent instrument. Nonetheless, studies using the AAAS similarly have found that levels of acculturation among African Americans play a role in hypertension (Landrine & Klonoff, 1996a); smoking (Klonoff & Landrine, 1996, 1999a; Landrine & Klonoff, 1996a); knowledge of AIDS transmission (Klonoff & Landrine, 1997a); coping styles and psychiatric symptoms (Landrine & Klonoff, 1996a); alcohol use (Klonoff & Landrine, in press); and frequency of experiencing racial discrimination (Landrine & Klonoff, 1996a, 1996b), with racial discrimination also contributing uniquely to the variance in smoking and hypertension.

Such studies are an important step in the direction of focusing on cultural rather than social variables and thereby bringing cultural diversity to health psychology, but they are nonetheless troubling. This is because these studies demonstrate that the extent to which minorities participate in their own indigenous culture versus that of the dominant White society (levels of acculturation) plays a role in minority health, but they simultaneously rarely reveal precisely *what it is* about the indigenous culture that accounts for the acculturation effect. Acculturation, after all, is merely a psychometric abstraction, like a first principle component. As such, it summarizes and represents the plethora of indigenous cultural beliefs and practices adhered to by traditional, half-adhered to by bicultural, and rejected by highly acculturated minorities. Like other mathematical abstractions in psychology, however, acculturation has been reified (i.e., *mistaken for a cultural variable or entity itself*). The cultural beliefs, values, and practices that constitute the *rs* in the correlation matrix and the independent variables of scientific relevance have been largely forgotten. Acculturation, however, like poverty and low education, similarly is not an aspect of anyone's culture; it is not a value, belief, ritual, or practice purposefully transmitted to successive generations.

Hence, research on cultural diversity and health, whether it focuses on social variables or on a reified abstraction, never addresses culture insofar as it never highlights the specific cultural independent variables that contribute to minority health behavior, morbidity, and mortality. Culture then seems "an incredibly well-kept secret in psychology" (Shweder & LeVine, 1984), something everyone whispers about, but never exposes or confronts. Because culture is such a well-kept secret, it is easy to assume that minority health beliefs and practices could not possibly differ so much from those of biomedicine that they necessitate significant changes in the content and process of delivering interventions and care to minority populations, let alone contradict health psychology's findings and knowledge. This chapter challenges that assumption by presenting those neglected, hidden health beliefs and practices.

The information presented here is a brief summary of decades of research in medical anthropology, where the health beliefs and practices of American minority groups (and of people in other cultures across the globe) have been thor-

oughly analyzed—but their role in subsequent health behavior has not. Hence, all biomedical, empirical studies (in preventive medicine, public health, etc.) on the role of these beliefs and practices in health behavior, morbidity, and mortality also are discussed, but the number of these, relative to the anthropological ones, is small. Nonetheless, this chapter assumes that all of the health beliefs and practices of minorities play a significant role in their health whether or not this has been demonstrated empirically to be the case. That assumption is logical because acculturation has been shown to play a significant role in the health behavior, morbidity, and mortality of all minority groups, and the health beliefs and practices described here are the "why" and the "how" of that ubiquitous, acculturation effect. Thus, this chapter does not address the role of acculturation in minority health, but instead focuses on the factors beneath that variable. Likewise, it devotes little time to rates of specific diseases, or to data on health damaging behaviors among minorities because that information is available elsewhere (e.g., Amick et al., 1995; Harwood, 1981; Polednak, 1989; Ruzicka & Kaye, 1989; Spector, 1996). Instead, it presents only a brief paragraph on the major health problems of each minority group and then turns to neglected cultural variables relevant to that group's health. Similarly, it ignores social variables such as poverty (not because they are unimportant but) because they are not cultural variables. The exception is that the chapter briefly addresses the role of current and historical racism in minority health. Although discrimination against minorities is a social variable, the ubiquitous distrust of Whites that it has produced is a cultural variable, that is, a set of attitudes regarding Whites and White health professionals that is purposefully taught to successive generations and impacts minority help seeking and compliance with treatment.

First, the chapter summarizes the health beliefs and practices of each of the four major American minority groups (Latinos, Asians, African Americans, and Native Americans, respectively). Because these four categories represent literally thousands of ethnic/cultural and language groups, far more are omitted than are included, and generalizations are made that should be understood as unavoidable rather than as stereotyping. In each case, however, the description is meant to apply only to the traditional (orthodox, prototypical) members of the cultures in question, with the understanding that bicultural and acculturated members of these cultures deviate from them, yielding subsequent intracultural heterogeneity in beliefs and practices. Next, a brief summary is provided that highlights the similarities among the four major cultural groups and arrives at a preliminary model of the proximal and distal social and cultural variables in minority health that can be used to organize future research. Finally, the implications of the findings are discussed and specific conclusions and suggestions are presented for research and practice in a more culturally diverse and sensitive health psychology.

LATINO AMERICANS

The term *Latino* is used to refer to a culturally heterogeneous population of Americans with Spanish surnames, including

those with Mexican, Puerto Rican, Cuban, Central American, and South American heritage. Because all of these groups cannot be discussed here, the focus is on Mexican Americans, who, as is demonstrated here, are by and large prototypical of the Latino population as a whole.

Health Problems of Latinos

The leading causes of death among Latinos are summarized in Table 51.1 by gender, along with the leading causes of death among other minority groups. As shown, the major health problems of Latinos include high rates of heart disease, injuries, neoplasms, cerebrovascular disease, diabetes, and AIDS (U.S. Department of Health & Human Services [DHHS], 1996).

General Cultural Factors Influencing Health Behavior

Racism and Distrust of Whites. Among the many cultural factors influencing Latino health behavior is a distrust of Whites that is a response to “centuries of colonial domination, oppression, and exploitation by Anglo-American society” (Ginorio, Gutierrez, Cauce, & Acosta, 1995, p. 241). This anti-Latino racism has ranged from U.S. appropriation of lands belonging to Mexico, to contemporary job and housing discrimination, to violence against Mexican, Central, and South American citizens, new immigrants, and refugees (Ginorio et al., 1995). Its effects on Latino help seeking, although rarely addressed, cannot be overestimated (Atkinson, Morten, & Sue, 1993; Ginorio et al., 1995). Research on the role of distrust of Whites in Latino delay in seeking and compliance with treatment is needed, and may reveal that such distrust contributes to the data in Table 51.1.

Mexican American Beliefs About Illness

Like the other sociocentric¹ cultures to be discussed here, Mexican Americans view health holistically, drawing few distinctions between mind and body, between religion and medicine, or among physical, emotional, spiritual, and social processes (Clark, 1970; Farge, 1977; Rubel, 1960; Schreiber & Homiak, 1981; Spector, 1996). Harmony, or balance, among all of these is understood as the definition of health, and imbalance, or disruptions of harmony, as the foundation of illness. The three major causes of illness (disharmony) rec-

ognized in Mexican American folk medicine (or *ethnomedicine*, the medical knowledge of a culture) are strong emotions, imbalance of a variety of naturalistic variables, and supernatural factors, in sharp contrast to the etiological constructs of biomedicine (Baca, 1969; Castro, Furth, & Karlow, 1984; Currier, 1966; De la Cancela & Martinez, 1983; Spector, 1996). Traditional and acculturated Mexican Americans alike endorse these three causal attributions for illness. For traditional Mexican Americans, such folk medical beliefs persist in pure form and may constitute the entirety of their medical knowledge. For more acculturated Mexican Americans, these beliefs persist in one of two ways: For some, the beliefs coexist alongside biomedical concepts in a compartmentalized system of dual beliefs (Castro et al., 1984; Farge, 1977; Spicer, 1977), whereas for others folk medical beliefs are integrated with those of biomedicine, with biomedical causes of illness (e.g., viruses) viewed as explaining the “how,” and cultural causes explaining the “why” of disease, such that the latter remain more important (Farge, 1977; Spector, 1996; Spicer, 1977).

Emotions. Emotions are viewed as the principal cause of illness and occupy a status in Mexican American folk medicine analogous to the position of micro-organisms in biomedicine. The amount or dosage of specific emotions, along with the nature and seriousness of the diseases produced by them, are highly differentiated, with emotions ranked in terms of their pathogenicity; the latter is a function of the tendency of a specific emotion to persist (in an individual over time) rather than of its pleasantness or aversiveness (Clark, 1970; Fabrega, 1974; Spector, 1996). Anger, envy, and worry are particularly pathogenic because they tend to persist, and hence these emotions occupy a place of prominence in the folk etiological beliefs of traditional and acculturated Mexican Americans alike (Castro et al., 1984), as well as in the ethnomedicine of other Latino cultures (including those of Puerto Ricans, Cubans, and Central and South Americans; Harwood, 1981; Klein, 1978; Spector, 1979, 1996; Spicer, 1977). Emotions are viewed as inevitable, but as forces that should be discharged quickly (in talk or action) to maintain emotional homeostasis and a relatively flat affective presentation; illness is understood as produced when the body carries an excessive load of emotions. Given the pathogenicity of affect, interpersonal relations have disease implications. Family arguments, separations, frightening (traumatic) experiences, unemployment, and other social and interpersonal factors are viewed as distal causes of disease because of the emotions (proximal cause) they elicit. Relationships then are key variables not only in the cause but also in the cure and prevention of disease, and maintaining interpersonal harmony thereby occupies a place of prominence in minority beliefs about health promotion and disease prevention. As will be shown, the latter view characterizes the prevention beliefs of all sociocentric cultures.

In addition to reflecting emotional states and interpersonal relations, disease also is understood as the result of the imbalance of naturalistic factors such as hot and cold. Although anger, envy, worry, and fright are understood as the

¹Throughout this chapter, the cultures of minority groups are referred to as *sociocentric cultures*, an anthropological term meant to distinguish them from the individualistic or *egocentric cultures* of White Western Europeans and Americans (Fabrega, 1974; Shweder & LeVine, 1984). These two types of cultures differ in their fundamental assumptions about the nature of the person and of the person-environment relation. The former endorse mind/body, self/other, and person/environment holism, whereas the latter endorse dualism in each of those domains. These beliefs, in turn, sculpt cultural differences in health beliefs and practices. The many differences between egocentric and sociocentric cultures will become clear in the chapter.

TABLE 51.1
The 10 Leading Causes of Death in 1993 by Gender and Ethnicity

Cause	Overall	Men					Women				
		White	Black	Native American	Asian	Hispanic	White	Black	Native American	Asian	Hispanic
Diseases of heart	1	1	1	1	1	1	1	1	1	2	1

Note: Adapted from U.S. Department of Health and Human Services (1996). *Health United States 1995*. DHHS Pub. No. (PHS) 96-1232. Hyattsville, MD: Public Health Service, Centers for Disease Control and Prevention, National Center for Health Statistics.

major proximal causes of disease in all Latino cultures, the balance of hot and cold is understood as playing an additional, powerful role in health (Baca, 1969; Castro et al., 1984; Clark, 1970; Kay & Yoder, 1987; Spector, 1979, 1996; Steffenson & Colker, 1982).

The Ubiquitous Hot/Cold Theory of Disease. Beliefs regarding the balance of hot and cold are an important aspect of the folk medical beliefs of all Latino cultures (Currier, 1966; Farge, 1977; Messer, 1987; Rubel, 1960), including those of Mexicans, Puerto Ricans (Fabrega, 1974; Harwood, 1971, 1981), Guatemalans (Cosminsky, 1975, 1977; Logan & Morrill, 1979; Weller, 1983), and Cubans (and others) in their homelands as well as in the United States (Spector, 1979, 1996). Indeed hot/cold theory also has been found in Asia (Leslie, 1976; Poyneer, 1983; Tran, 1980), Morocco (Greenwood, 1981), Malaysia (Laderman, 1987; Pool, 1987), Africa (Horton, 1967; Namboze, 1983), China (Gould-Martin, 1978), India/southeast Asia (Armarasingham, 1980; Khare & Ishvara, 1986; Nichter, 1987), and Korea (Kendall, 1987), as well as among the American members of these cultural groups (Harwood, 1981; Gould-Martin, 1978; Spector, 1979,

1996). Likewise, hot/cold beliefs even have been found among isolated cultures such as some South American Indian tribes (Colson & de Armellada, 1983; Messer, 1987). Hence, the imbalance of hot and cold may be the (non-White) world's most common causal attribution for illness.

The precise origin of the hot/cold theory of disease and how it became so widespread remain topics of debate among medical anthropologists and historians. Beliefs about the balancing of opposites or "humors" appear to have arisen independently and simultaneously in ancient Greece, India, and China, and then to have spread through trade and conquest (Laderman, 1987; Messer, 1987), with 16th-century Spanish humoral theory (a derivation of earlier Hippocratic theory) spread in this manner to the many conquered lands that became Latin America. Evidence suggests, however, that some version of hot/cold theory arose independently in all sociocentric cultures, and that the hot/cold theories of conquerors and traders were accepted simply because they were consistent with these preexisting, indigenous beliefs (Laderman, 1987). This is clearly the case for the Aztec, Maya, and Zapotec (Messer, 1987), and for the Akawaio, Pemon, and other isolated, South American Indian tribes who speak neither English nor Spanish and could not have borrowed

these ideas from Spanish and other Old World countries during the conquest (Colson & de Armellada, 1983). Theoretically, the belief that changes in heat or cold produces disease could arise independently in all sociocentric cultures because these cultures regard the line between person and environment as a thin, semi-permeable membrane (Landrine, 1992) that permits changes in the environment to cause changes in the mind and body (Fabrega, 1974; Landrine, 1992).

The sociocentric hot/cold theory of disease posits that the healthy body is the result of the balance or equilibrium between the contrasting qualities of "hot" and "cold." Illness is seen as resulting from disequilibrium after internal or external exposure to excessive amounts of "heat" or "cold" and hence is treated by restoring that balance. Hot and cold are not simply temperatures, but also are qualities of individuals, medicines, emotions, foods, places, symptoms, diseases, health interventions, cures, and objects, all of which are categorized as such in folk medicine. Water, "cold" (in terms of temperature or spice) foods, and air are ordinary sources of "cold" and must be neutralized by eating "hot" foods, using *emplastos calientes* (hot poultices), or drinking hot drinks to avoid development of symptoms and illnesses classified as "cold" (Clark, 1970; Currier, 1966; Farge, 1977; Harwood, 1971, 1981; Kay & Yoder, 1987; Spector, 1996). Likewise, strong emotions, exposure to the sun, and "hot" foods are mundane sources of heat requiring cure (restoration of balance) through eating "cold" foods or medicines, use of *emplastos frios* (cold poultices), or rubbing the body with a raw egg (a "cold" treatment and common Latino folk cure called "sweeping") to avoid developing hot symptoms. Hence, traditional Mexican and other Latino Americans will not comply with medications or interventions that they classify as "hot" if they also classify their illness as such, and instead only comply with treatments understood to be the opposite of the symptoms (Harwood, 1981). In addition, as already mentioned, Mexican American folk medicine also attributes illness to wind, drafts, or air ("mal aire," bad air). These are typically linked to the hot/cold theory of disease as a type of "cold" (night air in particular) that can enter the body through its various cavities and result in illness. As will be seen, Native, African, and Asian Americans (in particular) also attribute illness to wind/air. Recent empirical studies have confirmed etiological beliefs regarding hot/cold and air/drafts even among acculturated, minority college students (Landrine & Klonoff, 1994b).

In summary, all Latino cultures view health as harmony within the body, between people, and between people and environmental and spiritual realms. Consequently, disruptions in relationships, violations of behavioral and moral taboos (creating disharmony), and disruptions in emotions or in the environment are all seen as causing diseases that are simultaneously physical, psychiatric, social, and moral in nature. This holism characterizes all sociocentric cultures (internationally as well as within the United States), such that imbalance and disharmony are central to Asian, African, and Native American beliefs about illness as well. Likewise, all sociocentric cultures lack the mind/body dualism of biomedicine and thereby draw no lines between emotional versus physical symptoms, nor do they classify disease into those two broad categories. Hence, across minority cultures in the United States and around the

globe, people presenting depression expect to be asked about their diets and exercise patterns, and those presenting pain expect to be asked about their morals, emotions, and relationships (Harwood, 1981). This ubiquitous mind/body holism plays a role in the equally ubiquitous biomedical misconception of minorities as "somatizers." One cannot, of course, "somatize" (move events from the mind to the body side of the dualism) in the absence of the dualism on which the Western construct of somatization rests. Hence, such holism also plays a role in Latino dissatisfaction with health care providers interested only in symptoms related to one side of the dualism (Schreiber & Homiak, 1981) and in Asian American confusion regarding the dualist classification of care providers (Hare, 1993; Hoang & Erickson, 1985; Poyneer, 1983).

Mexican American Folk Disorders

Just as the medical knowledge of relatively powerless ethnic groups (within the United States and around the world) is called "folk medicine" to distinguish it from ("real") biomedicine, so too the cures developed by these groups are called "folk cures"; the healers of these groups are called "folk healers"; and disorders specific to these groups are called "folk disorders." Folk disorders, or culture bound syndromes, then are diseases (reliable, observed constellations of symptoms) exhibited only by a specific ethnic/cultural group (Simons & Hughes, 1985).² The folk disorders and folk cures of Mexican Americans and of other minorities have received

²Some have argued that the use of the adjective "folk" to qualify the medical knowledge and diseases of Others is inherently racist. This is because the term privileges the knowledge and illness experience of White Western Europeans/Americans while dismissing those of all other ethnic groups by relegating them to the lesser "folk" (i.e., superstition) domain (Baer, Singer, & Johnson, 1986; Pachter et al., 1993). Importantly, the term *folk illness* in particular seems little more than a "means of excluding the illness experience of a minority group from resources available to others" by denying it legitimacy (Pachter et al., 1992, p. 286). Hence, folk disorders (among minorities within the United States and around the world) are not possible diagnoses in any diagnostic system (the DSM, or the ICD), and receive little biomedical research attention or efforts to find cures for them despite their prevalence and the fact that minorities do die from them. This "unwillingness to seriously respond to an illness experience outside of the biomedical paradigm," despite the morbidity and mortality associated with folk disorders, persists because it serves Western biomedicine's efforts to "enforce its hegemonic position as the 'broker' of health and health care" (Pachter et al., 1992, p. 286). Of course, a wide diversity of White Western (European and American) ostensible illnesses, such as infantile colic (Sampson, 1989), hypoglycemia (Hunt et al., 1990; Klonoff & Biglan, 1987), premenstrual syndrome (Ruble, 1977), and menopausal "hot flashes" (MacPherson, 1981; McCrea, 1983), along with White Western magical disease causes such as "stress" (Young, 1980) qualify as folk disorders and folk etiological concepts (respectively) insofar as they are endorsed and exhibited almost exclusively by this ethnic/cultural group. Indeed, because these disorders and this etiological factor ("stress") have "no standardized diagnostic criteria [and] consist primarily of subjective symptoms [that] resolve in a relatively brief period" (Sampson, 1989, p. 583), they are more prototypically "folk" (i.e., superstition, bogus, or psychosomatic) than are any of the folk illnesses of minority groups.

little attention from biomedicine (health psychology included) despite their prevalence and persistence, and so are addressed briefly here. It should be noted, however, that the exception to this neglect is folk cures that cause minority illness or death, for these have received considerable attention from mainstream health scientists. The inordinate attention paid to toxic/lethal minority folk cures is reasonable from a public health perspective. However, when that attention is viewed in the context of the total neglect of folk disorders and of helpful cures, it also may be a means for biomedicine to address cultural diversity while simultaneously reinforcing the cultural hierarchies purportedly challenged by that focus. This chapter assumes that (1) folk disorders represent "real" biomedical diseases that have yet to be identified because of ethnocentric neglect by biomedicine (Simons & Hughes, 1985); that (2) folk cures are more or less effective treatments (whose mechanism of effect is currently unknown); and that (3) this accounts for the prevalence and persistence of both in many cultures for many centuries.

The major folk disorders of Mexican Americans are summarized next, and demonstrated to hold for other Latino cultures within the United States and around the globe as well; this is followed by a discussion of Latino folk healers and cures.

Caida de la mollera ("fallen fontanelle") is a disorder restricted to infants of both sexes and characterized by inability to suck the breast or bottle, persistent fever and diarrhea, inordinate restlessness and crying, and vomiting. Mexican American folk medicine argues that *caida* occurs when the mollera (the fontanelle of the parietal or frontal bone of the cranium) falls and leaves a "soft spot" as a result of an infant fall from some height or suddenly withdrawing the nipple from the infant's mouth during breast feeding. The fallen fontanelle, according to folk theory, results in a downward projection of the palate that inhibits the infant's ability to ingest food and causes the symptoms observed (Rubel, 1993; Rubel, O'Neill, & Ardon, 1984; Trotter, 1985a, 1991; Trotter, Ortiz de Montellano, & Logan, 1989). *Caida* has been recognized in all Latino cultures for many centuries, including Spain, Mexico, and Central and South America (Baca, 1969; Currier, 1966; Ingham, 1970; Spicer, 1977; Trotter, 1991). The brief biomedical attention devoted to *caida* has led to the conclusion that it is the Latino folk name for dehydration among infants in which, however, cause and effect have been reversed in folk understandings. Specifically, Latinos, observing the loss of subcutaneous fluid over the fontanelle (a result of dehydration caused by infant diarrhea) seem to have mistaken this effect (depressed fontanelle and the exaggeration of palatal rugae) as the cause of the symptoms observed (Simons & Hughes, 1985; Trotter et al., 1989). Enteric diseases, with ensuing diarrhea and dehydration among infants, are common in Latino cultures across the globe and within the United States (Simons & Hughes, 1985; Trotter et al., 1989).

Empacho ("indigestion infection") is a disorder afflicting children and adults of both sexes and characterized by lack of appetite, stomachache, intestinal pain and cramping, diarrhea, abdominal swelling, and vomiting. In folk medicine, the disorder is said to be due to a poorly digested piece of food becoming lodged in the intestines because the food was toxic (e.g., unre-

frigerated dairy products), or because the person was socially obligated to eat when not hungry (an emotional cause; Rubel, 1960). *Empacho* has been recognized by a diversity of Latino cultures for centuries and is a common complaint among Mexicans (Baer & Ackerman, 1988), Mexican Americans (Martin, Martinez, Leon, Richardson, & Acosta, 1985; Rubel, 1993; Rubel et al., 1984; Trotter, 1985b, 1991), Guatemalans (Weller et al., 1991), and Puerto Ricans (Harwood, 1981), and occasionally results in death. Typical folk cures for *empacho* include drinking teas and massage of the stomach and intestines (Trotter, 1981a) by a Mexican (*curandera*), Puerto Rican (*santiguador*), or Guatemalan (*sobador*) folk healer. Other common folk treatments for *empacho* are toxic and detailed later here. The brief biomedical attention devoted to *empacho* has concluded that it is an enteric disease secondary to eating foods that are not fully cooked and/or to allergy to milk products (Patcher et al., 1992).

Mal ojo (the "evil eye") can afflict anyone of any age or gender (although more common among women), and is characterized by the sudden onset of a plethora of somatic and psychiatric symptoms, including severe headache, anxiety, depression, crying, insomnia, and rashes. According to folk theory, it is caused by the envious or admiring gaze of a strong person at a weaker one, with the emotion-laden stare subjecting the victim to disease provoking, excessive affect. If not treated, it is said to advance to a fatal stage (*ojo pasado*) characterized by uncontrollable coughing, vomiting, and eventual death. Hence, when the symptoms of *mal ojo* appear, victims immediately retrace their steps in an effort to locate the person who caused the symptoms. This person then touches the victim to rupture the effect of *mal ojo* by symbolically atoning for and taking back the emotion (Baca, 1969; Clark, 1970; Schreiber & Homiak, 1981; Trotter, 1981a, 1991). *Mal ojo* has been recognized in a variety of Latino cultures for many centuries, has been associated with deaths, and is one of the folk disorders believed to necessitate the intervention of a *curandera*, a Mexican folk healer (Babb, 1981; Trotter, 1981a; Trotter & Chavira, 1981; G.H.D. Smith, 1995). Although no biomedical studies of *mal ojo* were found, several reviews indicate that belief in this disorder spans many cultures, as demonstrated later here.

Susto ("fright" or "soul loss") is the best-known of the Latino culture-bound syndromes and has been found among Mexicans and Central and South Americans in their homelands, as well as among the American members of these minority groups (Clark, 1970; Klein, 1978; Martin et al., 1985; Rubel et al., 1984; Rubel, 1960, 1993; Trotter, 1981a, 1982, 1985a, 1991). As is shown here, Asian/American and Native American cultures also recognize a disorder called fright or soul loss that has symptoms and a folk etiology matching that of Latino *susto*, such that "magical fright" may be the single most common folk disorder in the (non-White) world. *Susto* can afflict people of any age or gender (but is more common among women and children), and according to Latino folk medical theory, is caused by a frightening or traumatic experience (i.e., excessive emotion). Common precipitating experiences include being deserted by a husband, being physically assaulted, and the death of or serious injury to a loved one.

The trauma of this frightening experience is said to cause the soul to become dislodged from the body (leaving the individual immobilized and helpless), with this soul loss manifested in a sudden onset of anxiety, fatigue, muscular weakness, severe appetite loss, fever, vertigo, and nausea. Additional symptoms depend on the stage of the disorder, and include stomachache, diarrhea, and vomiting (in early stages, *susto nuevo* or *tripa ida*); languor, anorexia nervosa, inability to urinate, and lack of motivation to do everyday tasks (in middle stages, *asustado*); and wasting away until an early, untimely death in advanced stages (*susto pasado* or *mal de delgadito*). Little biomedical attention has been devoted to *susto* despite the deaths associated with it. Some (Rubel et al., 1984) have suggested that it is a form of hysteria. Others (Bolton, 1981) have suggested that it is severe hypoglycemia (because, in addition to the folk cure "sweeping," *susto* is treated by ingesting sugar), or vitamin B deficiency coupled with anemia (Trotter, 1982). There is little evidence for these hypotheses given the absence of biomedical investigations of patients with *susto*.

Mal puesto ("bewitchment," or evil hex or curse) is the belief in witches (*brujas*) or sorcerers (*brujos*) and in their ability to curse or hex someone (manifested in illness). It has been found in all Latino cultures across the globe and within the United States (Clark, 1970; Harwood, 1981; Ingham, 1970; Kay & Yoder, 1977; Rubel, 1960, 1987; Schreiber & Homiak, 1981; G.H.D. Smith, 1995; Trotter & Chavira, 1981), as well as among the many other cultural groups discussed here. In Latino cultures, the symptoms of being hexed or bewitched (*embrujada*) include exhibitionism, psychotic symptoms, and screaming and crying (in conjunction with any host of physical symptoms). No biomedical studies of *mal puesto* were found.

Other Mexican and Latino American folk disorders that have received less attention from medical anthropologists are: *bilis*, an anxiety disorder due to upsetting emotional experiences; *latido*, a folk name for anorexia nervosa; *chipil*, an emotional disturbance in infants; and *pasmo*, a postpartum illness afflicting women who violate the restrictions (e.g., no intercourse, baths, spicy foods) associated with the *la dieta* or *la cuarentena* (the 40-day period of convalescence following delivery), and manifested in swelling, septicemia, and other serious symptoms. *Latido* and late stages of *susto* are identical to anorexia nervosa; the well-known low prevalence of that eating disorder among minority women (Landrine, 1995) may be an artifact of biomedicine's refusal to recognize folk disorders.

Frequency of Folk Disorders. The prevalence of the aforementioned folk disorders among Mexican and other Latino Americans is unclear because studies report inconsistent results and employ populations from different geographical regions. For example, Trotter (1982), in a study of 198 current ailments reported to him by a small group of subjects, found that 3% of these were folk disorders (with *susto* the most common). Alternatively, Rivera's (1988) review of the literature revealed that 95% of Latinos reported experiencing at least one episode of a folk illness in their lifetimes, whereas H. W.

Martin et al. (1985) found a differing prevalence rate that differed from both of these. Likewise, because treatment from *curanderas* (folk healers) is sought exclusively for folk disorders (*empacho*, *mal ojo*, and *susto* in particular; see G.H.D. Smith, 1995), rates of utilization of *curanderas* are an indirect measure of prevalence of folk disorders. Accordingly, Rivera's (1988) review found *curanderas* consulted by 5% (of northern) to 23% (of southern) California Mexican Americans, and by 32% to 80% of Mexican Americans in other geographical regions. The studies of Trotter (1991) and others suggest that almost all Mexican Americans, irrespective of level of acculturation, are aware of the folk disorders and readily admit knowing someone who suffers from one, but may deny experiencing a folk disorder themselves.

Mexican American Folk Healers

The Mexican American community has a wide variety of folk healers (Anderson, 1970; Babb, 1981; Ingham, 1970; Schreiber & Homiak, 1981; G.H.D. Smith, 1995; Trotter, 1985a; Trotter & Chavira, 1981; Weaver, 1973) who have counterparts in all other Latino American communities. These indigenous therapists include (but are not limited to) the following:

Yerberos ("herbalists") are men or women who specialize in the herbal home remedies used by laypeople to treat biomedical and folk illness, and have long been an important health resource in Mexican and other Latino American neighborhoods. Although there are no data on the frequency with which they are consulted, the ubiquitous use of herbal home remedies reported in all ethnographic studies (Maduro, 1983; Trotter, 1981a, 1981b) suggests that they are a mainstay of the Latino folk health care system.

Parteras (women) are midwives (who often are both folk and former biomedical practitioners) specializing in the delivery of infants. They are particularly common and deliver the majority of the babies in the Rio Grande Valley of Texas and other parts of the borderland states, as well as in other Latino and in African American communities (Babb, 1981).

Sobadoras (women) are masseuses who use massage and prayer to treat muscular pains, joint dislocation, *caida*, and *empacho*, and may use spiritual cures as well (Babb, 1981).

Señoras ("wise women") are older women specializing in the treatment of folk disorders (particularly those afflicting infants), who also sometimes act as midwives (Babb, 1981).

Espiritualistas ("spiritualists") treat biomedical disorders (with prominent psychiatric symptoms) and folk disorders through a combination of massage, herbal remedies, prayer, trance, and spirit mediumship. The latter magico-religious practices distinguish them from other healers, and they have counterparts in Puerto Rican, Cuban, and African American communities (Anderson, 1970; Babb, 1981; Ingham, 1970; Laguerre, 1981; Schreiber & Homiak, 1981; G.H.D. Smith, 1995)

Curanderas are the most common and most frequently studied of the Latino folk healers because their system of healing (called *curanderismo*) is ancient, diverse, and well-established (Rivera & Wanderer, 1986; Kiev, 1968; Maduro, 1983; G.H.D. Smith, 1995; Torres, 1983; Trotter, 1980; Trotter & Chavira, 1981). *Curanderas* (usually women) can be found in every urban center, and often (and increasingly) have a sophisticated knowledge of biomedicine that they use in conjunction with folk cures (Applewhite, 1995; De la Cancela & Martinez, 1983; Mayers, 1992; G.H.D. Smith, 1995). For example, Dona Elena Avila, a *curandera* practicing in New Mexico, has graduate degrees in nursing, and was the clinical coordinator of UCLA's Neuropsychiatric Institute and Director of Maternal-Child Nursing at Thomason Hospital in El Paso (G.H.D. Smith, 1995). She is widely known for integrating the interventions of biomedical nursing with those of *curanderismo*. The modern *curandera's* consulting room thus contains indigenous herbs, palm leaves, crosses, and poultices, as well as medical instruments, hypodermic needles, and antibiotics. Classic *curanderismo* includes at least 1,100 folk cures (Anderson, 1970, detailed 1,135 of these) that range from herbal remedies to inhalation and sweating therapies, to prayers, incantations, and magico-religious rituals. *Curanderas* are consulted primarily for treatment of folk disorders, but also are sought for treatment of chronic illness in children, and for recalcitrant, socially disruptive symptoms in adults (depression, alcohol and drug abuse, impotence).

Estimates of the frequency of consulting *curanderas* vary widely with methodology employed. In face-to-face interviews conducted by Latinos, rates range from 23% to 80% (Rivera, 1988), depending on the questions asked, geographical region, and the decade in which the study was conducted. Alternatively, in the more impersonal methodology used in the Hispanic Health and Nutrition Examination Survey (HHANES; Higgenbotham, Trevino, & Ray, 1990), only 4.2% of Mexican Americans reported seeking assistance from a *curandera* (or other folk healer) in the past year. Although still a considerable utilization rate, this may be lower than the true rate because HHANES assessed only past-year (vs. lifetime) use of *curanderas*, and used an impersonal procedure in a culture that values highly personal contact (Atkinson et al., 1993). Likewise, when use of folk healers is examined by assessing home use by lay people of cures typically recommended by *curanderas* and herbalists, rates are again extremely high and range from 50% to 95% (Applewhite, 1995; De la Cancela & Martinez, 1983; Mayers, 1992; Trotter, 1980, 1981a, 1981b).

Mexican American Folk Cures

Discussion of the diversity of folk cures used by Mexican and other Latino Americans is beyond the scope of this chapter. The reader is referred to Anderson (1970) for an overview of 1,135 cures, and to the major studies on *curanderas* for other cures and healing rituals (Kiev, 1968; Maduro, 1983; Rivera & Wanderer,

1986; G.H.D. Smith, 1995; Torres, 1983; Trotter, 1980; Trotter & Chavira, 1981). The most common cures include massage, changes in diet, social support, teas, herbal remedies, rest, saunas, and prayers (conducted conjointly), as well as "sweeping." In the latter, a whole, unbroken, raw egg ("cold") is rubbed on the patient's body (or is placed in water under the patient's bed) to absorb the "heat." Crosses made from palm leaves are used along with prayers that are said in threes throughout the cure; massage, herbal teas, herbal remedies, and a salve made from chili powder and olive oil are used as well, along with discussion of the patient's interpersonal relationships. Sweeping is used in all other Latino American cultures as well.

Toxic Herbal Remedies for Empacho. Although there are few studies assessing the pharmacological efficacy of the herbal remedies used in Latino American folk cures, those that exist suggest that all of these herbs contain potent, chemically active ingredients that therefore can be effective treatments for fever, pain, and the like, or can be lethal (Trotter, 1985a). Most attention has been devoted to those that are toxic or lethal, and specifically to the toxic/lethal herbal remedies found in the medicine cabinets of most Mexican American households. Two of these toxic/lethal remedies used for the treatment of *empacho* are *greta* (lead oxide) and *azarcon* (lead tetroxide); both are available throughout Mexican American communities in *yerberias* (herb shops) and consist of 89% and 93% elemental lead, respectively. Many cases (case studies) of lead poisoning (among children in particular) as a result of these remedies have been reported among Mexican Americans (Baer & Ackerman, 1988; Baer, de Alba, Cueto, Ackerman, & Davidson, 1989; Centers for Disease Control, 1981, 1983b; Trotter, 1985a, 1985b). However, no systematic studies of the frequency of use of these lead-based remedies have been conducted. Hence the role this folk cure (undiagnosed, low-level lead poisoning) plays in Mexican American physical and mental health and in intellectual deficits among Mexican American children remains unknown. Although Trotter (a medical anthropologist) identified several other toxic herbs in the medicine cabinets of Mexican Americans, such as *asoque* (containing mercury) and *anil* (laundry bluing, containing toxic aniline dye), no studies have been conducted on these. The need for research on Mexican American effective and toxic folk cures is clear.

Finally, several studies suggest that Latino American knowledge of folk medical theories, folk cures, and folk healers plays a role in their help seeking, health behavior, and compliance with treatment (e.g., Applewhite, 1995; H. W. Martin et al., 1985; Mayers, 1992; Nall & Spielberg, 1967; Schreiber & Homiak, 1981; Spector, 1979, 1996). This is supported by the many studies of the health behavior impact of levels of acculturation among Mexican Americans cited in the Introduction here.

Puerto Rican Americans

Numerous studies indicate that Puerto Rican health beliefs, practices and folk cures are similar to those already detailed for Mexican Americans, including the predominance of the

hot/cold theory of disease, notions of health as symbolic balance, and the attribution of illness to wind/drafts and witches or evil spirits (Harwood, 1971, 1981). Belief in the disease causing effects of evil spirits and other supernatural forces and entities is far stronger and more prevalent among this group than among Mexican Americans however, with 30-40% of normal and 90% of psychiatric patient Puerto Ricans seeking cures from spirit mediums for physical and psychiatric symptoms believed to be so caused (Harwood, 1971, 1977, 1981). This no doubt represents the strong influence of African cultures on the island: Unlike Mexican-Americans, but similar to African Americans and to people from Afro-Caribbean cultures (e.g., Cubans, Haitians), Puerto Ricans hold spiritist beliefs that dominate their concepts of illness, and they participate in healing cults/religions such as *mesa blanca* and *santeria* as a result. Details of these magico-spiritist religions/healing cults cannot be discussed here but are detailed elsewhere (Harwood, 1977, 1981; Paulino, 1995); they are similar to voodoo, however (Paulino, 1995), which is discussed in the African American section. To be noted here is that many Puerto Ricans firmly believe that each individual has a guardian angel (present from birth), and each person is influenced by it as well as by the numerous disembodied spirits of deceased and divine beings, all of whom play an active role in determining life events and health and disease. The activity of these spirits, whether acting on their own or in conjunction with witches and sorcerers, is understood as the sole proximal cause of all disease, with all other (Latino and biomedical) causes viewed as distal and secondary.

Mal ojo and *empacho* are recognized as folk disorders by Puerto Ricans, and both are commonly found among this group as well (Harwood, 1981). However, other folk disorders specific to Puerto Ricans also have been identified. These include "states" of the blood, such *sangre gruesa* (thick blood) and *sangre debil* (weak blood). These etiological concepts and folk disorders are common among African American and Afro-Caribbean cultures (Laguerre, 1981) and so are discussed in the section on African Americans. The other (and most well-known) Puerto Rican folk disorder is the *ataque de nervios* (attack of the nerves, or "worry"), which is so common and well researched that it is often called the "Puerto Rican Syndrome" (Harwood, 1981). This disorder can be exhibited by anyone (but is common among women after a traumatic experience), and consists of anxiety, depression, shouting, screaming, tearing one's clothing, and tonic and clonic convulsions, all viewed as socially acceptable responses to trauma (Harwood, 1981). This syndrome is similar to Latino *susto* (Rubel, 1993), and nearly identical to African American, Central American, and Afro-Caribbean "worry," or "worriation," as discussed later here. Finally, three types of indigenous healers are recognized in the Puerto Rican community: spiritists, herbalists, and *curanderas*. The treatment provided by these healers is identical to that provided by their counterparts in Mexican American and other Latino communities, with the exception of the spiritists whose interventions are more mystical and similar to those of voodoo priests.

ASIAN AMERICANS

The term *Asian* refers to Americans whose cultural background/ethnicity is Chinese, Indian, Japanese, Korean, Sinhalese, Pakistani, Filipino, and southeast Asian, where the latter term refers to Vietnamese, Cambodian, Thai, and Laotian (including the Mein, Hmong, Kha, Yao and other hill tribes of Laos). Because the health beliefs and practices of all of these ethnic groups cannot be covered in a single chapter, the focus is on a few groups who can be regarded as prototypical and representative of others; this is the reason for the focus on the Chinese, whose folk medical system has shaped those of many other Asian groups.

Studies of Health Problems of Asian Americans

The major health problems confronting Asian Americans (Table 51.1) are heart disease, cancer, cerebrovascular disease, chronic obstructive pulmonary disease (COPD), diabetes, pneumonia, and influenza (USDHHS, 1996). The major health problems of southeast Asian refugees are high rates of hepatitis B, tuberculosis, anemia, and intestinal parasites (Catanzaro & Moser, 1982; Hoang & Erickson, 1982), along with depression (Root, 1995; Westermeyer, Vang, & Neider, 1983) secondary to witnessing war and torture, and to separation from family left in southeast Asia (Root, 1995).

General Cultural Factors Influencing Health Behavior

Three of the many global, cultural factors that influence the health behavior of Asian Americans are racism and distrust of Whites, fear of shame, and language barriers and indigenous health schema.

Racism and Distrust of Whites. Like the other ethnic groups discussed here, Asian Americans have long been the victims of White racism and exploitation, much of it legitimated in laws such as the 1882 Chinese Exclusion Act, the 1908 Gentleman's Agreement, the 1917 Barred Zone Act, the 1922 Cable Act, 1945 War Brides Act, the 1964-1965 Immigration Act, and the 1979 Refugee Act. These laws systematically excluded dark-skinned Asians; outlawed miscegenation; permitted only men to immigrate in order to serve as cheap, manual laborers; or allowed only women to immigrate who were then sold (75% of Chinese women in California at the turn of the century) as sexual slaves to White American men (Root, 1995). Other examples of anti-Asian racism include violence and discrimination against the Japanese in the 1930s and 1940s (culminating in their internment in camps); current neglect of the many needs of the Hmong despite their dedicated service to the Central Intelligence Agency (CIA) during the Vietnam war (Adler, 1995); and ongoing discrimination (in housing and other services) and violence against Asians because they are viewed (since the 1970s) as responsible for America's economic woes (Atkinson et al., 1993; Root, 1995). The 1986 Civil Rights

Commission Report on Anti-Asian Activities revealed repeated cases of the murder of Asian Americans by Whites who blame Asians for their unemployment, as well as ongoing vandalism, job discrimination, and assault (Atkinson et al., 1993). This historical and current social context of White violence and racism has been neglected, but it nonetheless may play a role in Asian American reticence to seek help from White health care providers, with subsequent dangerous delays in seeking treatment. The role of anti-Asian racism and violence in smoking, alcohol use, and other health problems among Asian Americans has never been investigated.

Shaming Practices and the Fear of Shame. All sociocentric cultures understand individuals as existing only by virtue of and in relation to others, rather than as independent, encapsulated selves. People are understood as members of families (as husbands, mothers, daughters, and sons) first and as individuals second (rather than the other way around as in egocentric cultures). Indeed, in many sociocentric cultures, people are viewed as synonymous with such family roles and it is not believed that there is an individual lurking behind a role that he or she may be uncomfortable occupying (Landrine, 1992; P. Lewis & E. Lewis, 1984; Marsella, DeVos, & Hsu, 1985). Hence, in all sociocentric cultures, interdependence, mutual obligation, and reciprocity characterize interpersonal relationships; the needs of the family have priority over those of the individual; and maintaining interpersonal harmony is highly valued. In Asian cultures, these sociocentric attitudes and values (regarding mutual obligation in particular) do not simply influence or characterize, but instead dominate the emotional, cognitive, and behavioral life of traditional members (Atkinson et al., 1993; P. Lewis & E. Lewis, 1984; Marsella et al., 1985; D. Sue & D. W. Sue, 1993).

In Asian cultures, people are understood as owing an eternal, bottomless debt to their parents for bringing them into the world and caring for them as a child. Such a debt can never be repaid and is akin to an infinite bank loan whose collateral is the offspring's existence. Hence, offspring are eternally obligated to pay only the interest (that continues to accrue) on this loan in lieu of the principal. These interest payments consist of obedience, respect, achievement, and behavior that conforms to social norms, and are understood as a minor request (as the very least an individual can do) in light of the principal. When Asians violate social or moral norms, they incur shame (*tiu lien*) or "loss of lien" (loss of face). To violate social norms and incur loss of lien is analogous to refusing to pay even the interest on a generous, unpayable loan from parents. The response of parents and the community to such behavior is much like a bank's would be in a similar situation: The person's social credit—the presumption of trust, confidence, dignity, and respect—is revoked by parents, and the person's social credit rating destroyed throughout the community, making it impossible for loans (social support, respect, trust, confidence) to be secured elsewhere.

Thus, to incur shame and be subjected to shaming practices means that the person who violated a norm is treated by their families and the entire community as a pariah (i.e., a despised outcast who is condemned, distrusted, avoided,

mocked, and rejected by all). All social, family, and community support (along with acknowledgment of the person's existence) are immediately withdrawn, and no one trusts the person's words or deeds any longer. Individuals are left alone with their mistakes etched like a scarlet letter on the forehead, while the community points and stares in disdain, and then turns its back. Simultaneously, aspersions are cast on the parents: Just as individuals would doubt the good judgment of a bank that gave loans to unemployed, unreliable people who had no means or intention of repaying them, so too parents are regarded as poor moral guides, and hence as unreliable people (who cannot be trusted) themselves when their offspring incur shame. This practice of shaming seems cruel only if the context of reciprocity is ignored. When a community is based on reciprocity, it is imperative that each person attempt to repay what they have received; an individual who takes but fails to reciprocate even so little as appropriate conduct and conformity threatens the foundation that undergirds the social structure and must be punished lest the presumptive trust that is community weaken and crumble. It is then not surprising that no fear is greater among traditional Asians than that of incurring shame and shaming practices; the behavioral conformity seen among many traditional Asians makes sense in this context.

Because symptoms of all types are understood as shameful, fear of loss of lien inhibits both help seeking and the disclosure of symptoms when help is finally sought. Symptoms are understood as shameful for two reasons. The first is that symptoms are understood as at least in part reflecting violations of taboos, and hence, their mere presence raises questions about the morals of self and family. In addition and more importantly, having symptoms (being ill) means that individuals will need to be cared for by their family and indeed, might be a burden on them. Illness thereby increases their obligations—increases what they owe to an intolerable, impossible level of debt from which they have no hope of ever being free—and so is more shameful still. To disclose illness to health care providers or researchers is to disclose this state of poverty and debt, and is thus a means of incurring further shame. Such beliefs are held by Chinese (Gould-Martin & Ngin, 1981; Spector, 1996), Japanese (Norbeck & Lock, 1987), and many southeast Asian cultural groups (Barney, 1980; Hoang & Erickson, 1985). Consequently, traditional members of many Asian American cultures fail to disclose the nature and history of their symptoms and problematic health behaviors for fear of incurring shame (Gould-Martin & Ngin, 1981; Hoang & Erickson, 1985; Norbeck & Lock, 1987; Tran, 1980). Assurances regarding confidentiality do not lessen this reticence to disclose or lessen the patient's fear of loss of lien through such disclosures (Hoang & Erickson, 1982, 1985). Health professionals then face patients who have sought help but are reluctant to disclose why, and researchers face subjects who will not answer questions or who simply deny all symptoms and problematic health behaviors. For many southeast Asians (unlike Chinese) the fear of shame also leads to delaying help seeking as long as possible (Hoang & Erickson, 1982, 1985; Muecke, 1983a, 1983b; Strand & Jones, 1983; Tran, 1980). How can diagnosis, treatment, or

research be achieved when people will not describe their symptoms? Essentially, traditional Asians expect health professionals to discern their problems by making statements about the person's possible problem, and then attending to the person's *nonverbal* (rather than verbal) responses (Gould-Martin & Ngin, 1981; Tran, 1980); this allows traditional Asians to disclose physical and psychiatric symptoms viewed as shameful without actually disclosing them.

Language and Indigenous Schema. Even when traditional people (from southeast Asian cultures in particular) reluctantly disclose their symptoms, the validity of these self-reports must remain suspect because of indigenous health schema and culturally specific uses of medical terminology that violate the understandings of biomedicine. Vietnamese and Hmong may disclose feeling "hot," for example, but this refers to hot-cold beliefs or malaise rather than to fever (Cheon-Klessig, Camilleri, McElmurry, & Ohlson, 1988; Hoang & Erickson, 1985). Other traditional southeast Asians might state they have hepatitis and mean by this only that they have itching, because hepatitis is understood as a liver disease that causes itching (Hoang & Erickson, 1982, 1985; Muecke, 1983a, 1983b). Alternatively, because Hmong folk understandings of the liver are analogous to American folk understandings of the heart (as the seat of emotion), Hmong complaints of "liver pain" are actually reports of depression, equivalent to reporting a "broken heart" (Cheon-Klessig et al., 1988). Still other traditional southeast Asians might disclose kidney trouble, and mean by this that they are impotent or have some other sexual dysfunction, because the kidney is understood as the location of sexuality (Hoang & Erickson, 1985). Hence, both language differences and the presence of indigenous health schema are cultural factors that influence health behavior of traditional Asian Americans. These may lead biomedical practitioners and researchers to misinterpret people's reports, and can lead Asian patients to misinterpret the practitioner's words as well. Biomedical information provided to minority patients is processed through indigenous health schema, and can be misunderstood and inaccurately recalled when it cannot be assimilated into preexisting health beliefs (Steffenson & Colker, 1982). This can result in unwitting noncompliance, namely, noncompliance due to the inability to integrate and recall directives (Steffenson & Colker, 1982).

With these general cultural factors affecting health behavior outlined, the discussion turns to the health beliefs, practices, folk disorders, and indigenous folk remedies of a variety of Asian American cultures.

Chinese Americans

Beliefs About Health and Illness

Chinese American concepts of health are based on the philosophy and teachings of Tao (604 BC). According to these doctrines, harmony with the universe and its forces is the essence of health, and illness is construed as imbalance or disharmony. Specifically, health is understood as the result of the balance of the two opposing, complementary forces

(called ethers) of Yin and Yang. Yin and Yang work together with six other variables to determine health and illness: the hot/cold polarity, poison, blood, Chi, wind, and the seven emotions. These seven variables are understood as the only causes of illness (Gould-Martin & Ngin, 1981; Hare, 1993; Kaptchuk, 1983; Maciocia, 1989; Spector, 1979, 1996).

Yin and Yang. Yin and Yang are understood as opposite forces that comprise the universe and each person. Yin is viewed as negative energy, coldness, wetness, darkness, and femaleness, and is believed to store strength, conserve energy, and restore physical vitality. The inside and the front of the body are construed as Yin, as are diseases of the winter and spring. Yang is viewed as positive energy or force, lightness, warmth, dryness, fullness, and maleness. The surfaces of the body and the back are construed as Yang, as are diseases of the summer and fall. When Yin and Yang are in balance, the person is healthy. Disruption in this balance or harmony is viewed as the sole proximal cause of any and all diseases and pain. Internal (e.g., aging, personality, fatigue, poor diet, lifestyle) and external (e.g., other people, the weather, micro-organisms) factors are understood as additional causes of disease, but as distal (indirect) causes that play a role by altering Yin or Yang (Gould-Martin, 1978; Gould-Martin & Ngin, 1981; Ludman & Newman, 1984). Whereas these concepts at first appear inscrutable at best, they are analogous to biomedical constructs. Specifically, Yin might be thought of as analogous to the parasympathetic and Yang to the sympathetic nervous system. Stress and viruses then disrupt the balance of these, and the ensuing imbalance has health implications and consequences.

Wind refers literally to the wind, as well as to any draft. Symptoms and illnesses understood as caused by wind are those whose names rhyme with the Chinese word for wind; such problems are treated by bed rest (Gould-Martin & Ngin, 1981; Spector, 1996). Wind (like the other causes here) is understood as a distal cause of illness that alters the fundamental balance of Yin and Yang (proximal cause). *Hot/cold* beliefs have been found in all sociocentric cultures, Chinese (B. Chang, 1974; Gould-Martin, 1978), and all southern Asian cultures included. For example, these beliefs figure prominently in the health schema of the ayurvedic (Indian) folk medicine that dominates India, Sri Lanka, and all of southern Asia (Kapferer, 1983; Khare & Ishvara, 1986; Nichter, 1980, 1987). For Chinese and Chinese Americans, as for other sociocentric cultures, hot and cold are properties of illnesses, foods, treatments, and medications, and it is believed that these must be balanced and regulated to maintain health (see Gould-Martin & Ngin, 1981, for Chinese American classification of symptoms, food, and cures as hot, cold, or wind). For Chinese and Chinese Americans, however, hot and cold are understood as subsumed by the Yin-Yang polarity. *Poison* refers to any symptom entailing swelling, pus, or itching, and is understood as the distal cause of such conditions. Symptoms and illnesses attributed to poison are treated by cold treatments and foods. *Blood* refers literally to blood, and *Chi* to a mythical energy or force understood as the "breath of life," and as flowing through a system of pathways called *me-*

ridians that are viewed as analogous to blood vessels and capillaries. Chi is construed as blocked when severe illness or chronic pain appears, and treatment consists of freeing the flow of Chi through acupuncture or acupressure; the sole reason d'etre of the latter two well-known treatments is to manipulate the flow of Chi (Kaptchuk, 1983; Maciocia, 1989).

Finally, *the seven emotions* (joy, anger, worry, contemplation, grief, apprehension, and fright) are understood as important distal causes of illness insofar as full, direct expression of emotion disrupts social harmony, and such disruptions are disease provoking. Hence, many have been taught that it is inappropriate to display emotion (and particularly, to complain) in the direct ways recognized in the West, leading Chinese and other Asian Americans to be misunderstood as emotionally flat. Chinese and other traditional Asian Americans have learned a full array of complex, rich, and subtle ways to express emotion and to complain, however, and these are nonverbal rather than verbal. It is (often erroneously) assumed by traditional Asians that outsiders can "read" these nonverbal complaints. Hence, health professionals are assumed to be trained in reading nonverbal behavior, and therefore are expected to know what is wrong with patients, how much pain they experience, and the treatment they desire simply by looking at them. Verbal complaints and descriptions of symptoms by patients or research subjects thereby are brief or even absent. In addition, because emotions are viewed as disease provoking, traditional Chinese physicians use psychological interventions (along with physical ones) for physical symptoms. Psychotherapy then is not recognized as a separate treatment to be sought from a specialist (but instead understood as part of all treatment) and the Western system of dualistic healers is regarded as confusing (Hare, 1993). This increases the tendency of traditional Asians to bring psychological complaints to those treating their physical problems, resulting in their being viewed as "somatisizers" (Gould-Martin & Ngin, 1981; Hare, 1993).

Chinese Folk Disorders

Fright refers to a folk illness characterized by listlessness, fever, crying, and lack of appetite. It is common among children and understood as the result of the soul getting lost after a frightening experience. It is treated with the "Protect-infant pill" (*po-yin taan*), crushed pearl powder, and other folk remedies that are readily available in Chinese grocery stores and herb shops (Gould-Martin & Ngin, 1981; Spector, 1996). The symptoms and epidemiology of this folk disorder are remarkably similar to Latino *caida* and thus raise questions regarding the possible role of enteric disease, diarrhea, and dehydration for Chinese children as well; that possibility has never been investigated.

The evil eye is a folk disorder widely recognized throughout Asia (including China, India, and southeast Asia), as well as in Africa and Mediterranean cultures (Pasquale, 1984). In each of these cultures, beliefs about this folk disorder, the role of gaze and envy, and the symptoms associated with the folk disorder match those reported by Latinos (as detailed earlier here). Beliefs in the evil eye are common among traditional

American members of these diverse cultural groups (Harwood, 1981).

Chinese Health Attitudes

Traditional Chinese Americans view the body as a gift from their parents rather than as a personal possession, and feel obligated to their parents and families to maintain their health. Because illness is shameful (as discussed earlier), traditional Chinese Americans seek preventative care and seek assistance for symptoms early (Gould-Martin & Ngin, 1981), whereas traditional southeast Asian Americans delay seeking help for the same reasons (Hoang & Erickson, 1982, 1985). Paradoxically, however, traditional Chinese Americans may not disclose their symptoms or medical histories because they expect health professionals to intuit the problem as described earlier. Hence, traditional Asians distrust long diagnostic interviews and tests and view the need for these as a sign of the health professional's or researcher's incompetence (Gould-Martin & Ngin, 1981; Leslie, 1969, 1976). Likewise, the interpersonal norm of *jang* requires silence, modesty, and avoidance of speaking about oneself, and similarly leads to a quiet waiting for the professional to intuit problems. Other health attitudes of traditional Asians include the expectation that family members will be included in all phases of a treatment viewed as their responsibility, and that health professionals will conduct themselves in a polite, authoritative, and distant manner. Making jokes or being warm and friendly are viewed as inappropriate, result in lack of confidence in the treatment and treatment provider, and hence in lack of compliance (Gould-Martin & Ngin, 1981). Taking medication is aversive for traditional Chinese Americans and hence, medications tend to be taken only until symptoms are relieved and then discontinued. If symptoms are not obvious (e.g., in hypertension) medications probably never will be taken. Translating pharmacological and behavioral interventions into terms consistent with folk understanding (e.g., the restoration of balance, the unblocking of Chi) may be necessary to achieve compliance with any type of treatment, including behavioral interventions (Gould-Martin & Ngin, 1981).

Asian American Folk Cures

In the Chinatowns of U.S. cities, indigenous healers known simply as "Chinese Doctors" are readily available and consulted for care instead of, or conjointly with, seeking treatment from biomedical practitioners (Chan & J. K. Chang, 1976; Hare, 1993). The "Chinese doctor" takes a holistic approach to health, and uses acupuncture, teas, rest, massage, acupressure, and/or moxibustion (use of heat) to restore health (Hare, 1993). In addition, there are several culturally specific folk treatments (particularly for pain) that are commonly used by the layperson and folk healer alike throughout the Chinese American community. These interventions are also practiced by the laity and folk healers of a variety of other Asian American groups as well, including the Hmong, Mien, Lao, Cambodian, and Vietnamese. Only the four most common of these treatments are summarized here.

Coining (Cao gio). The term *cao gio* literally means "to scratch the wind," and is a treatment for symptoms understood as caused by wind or "bad wind" in the body. Such symptoms include cold, cough, pain, vomiting, and headaches. Coining entails applying a menthol oil or ointment to the painful or symptomatic area, and then rubbing a coin vigorously over that spot. The coining is usually between the ribs on the front and back of the body, as well as along the trachea, the inner aspect of both upper arms, and/or along the sides of the spine because these are the areas associated with "wind" (breathing). The procedure leaves reddish-purple scars on the coined spots and these are taken as verification that "bad wind" was the cause of the symptoms. The procedure is uncomfortable and results in long-standing but superficial, ecchymotic spots on the coined areas in a pattern resembling strap marks, such that it appears that the person has been whipped (Ashworth, 1993; Buchwald et al., 1992; Gilman et al., 1992; McClenon, 1993; Yeatman et al., 1976, 1980). Coining is used particularly on children who have upper respiratory infections, and its scars are commonly misunderstood as signs of child abuse (Ashworth, 1993; Yeatman et al., 1980). Asian Americans are often charged with child abuse for using a folk treatment that is (for them) analogous to a White American treating a child's cold with chicken soup and tea. Some of these intercultural misunderstandings have had tragic consequences, including a case in which a Vietnamese father was falsely accused and then convicted and imprisoned for child abuse because of coining; He then committed suicide because of the shame of his conviction and imprisonment (Ashworth, 1993). Coining is used by Vietnamese, Hmong, Mien, Lao, Cambodian, and Chinese.

Burning (Poua). Burning is a treatment based on the Chinese theory of moxibustion, a set of principles that attribute certain symptoms to excess cold; the purpose of burning is to apply heat and thereby restore the balance of hot and cold that is seen as essential to health. Originally, parts of the moxa herb were used, but today any weedlike grass is used. This is peeled and allowed to dry; then the tip is dipped in heated oil, ignited, applied to the skin in the area requiring treatment, and held there until clear, obvious burns have been achieved. Laotians and Cambodians may use yarn, and Thai may use lit cigarettes instead of weeds for burning treatment. The area burned is contingent on the site and nature of the symptoms. Joints are typically burned on listless infants, the forehead burned for other symptoms, and the buttocks and fingers burned for enuresis and temper tantrums, respectively. In other cases, burns are scattered about the body of an adult, in a pattern following the meridians. The treatment is extremely painful and is the intervention of last resort. Because this treatment results in serious burns across the body, is it likely to be misinterpreted as a sign of spousal or child abuse, whether or not cigarettes are used to burn (Ashworth, 1993; Buchwald et al., 1992; Gilman et al., 1992; Justice et al., 1992; McClenon, 1993; Yeatman et al., 1976, 1980). Burning is used by Vietnamese, Hmong, Mien, Lao, Cambodian, and Chinese.

Cupping (Ventouse). This (originally French) folk treatment is practiced by a variety of Asian cultural groups, and its precise form varies from group to group. The underlying principle across groups is to create a vacuum inside a cup by igniting alcohol-soaked cotton inside the cup. When the flame extinguishes, the cup is immediately applied to the skin of the painful or symptomatic site. Suction is created, and the skin is pulled up into the mouth of the cup. The cup remains in place for 15 to 20 minutes, or until the suction can be easily released. The treatment is extremely painful. The suction is believed to exude the noxious/poisonous elements or substances by "cupping the poison," or "cupping the bad wind." It is believed that the greater the bruising that results from this treatment, the more serious the underlying disorder. Cupping leaves circular, ecchymotic, and painful burn marks in vertical rows of two to four cup marks on both sides of the chest, abdomen, and back, or, one single cup mark on the forehead. Cupping is used to treat pain of any type, particularly among adolescents and adults. This treatment is used by Vietnamese, Hmong, Mien, Lao, Cambodian, and Chinese in particular, and tends to be misunderstood as abuse (Ashworth, 1993; Buchwald et al., 1992; Gilman et al., 1992; McClenon, 1993; Yeatman et al., 1976, 1980).

Pinching (Bot gio). In this treatment, tiger balm (a mentholated ointment) is massaged into the area before the skin is pinched. For some Asian groups (e.g., Hmong), the area is pinched and then pricked with a needle until blood is drawn. Pinching (in all its varieties) is believed to exude "bad wind" and/or poisonous elements. It results in nonsymmetrical scars and bruises that may be found anywhere on the body, but are particularly likely to be found between the eyes, along the trachea, in a necklace pattern around the base of the neck, and along the spine. Pinching is used to treat pain, exhaustion, cough, lack of appetite, fever, and minor illnesses. It is an extremely common practice among the Hmong, Mien, Vietnamese, and Cambodian (Ashworth, 1993; Gilman et al., 1992; McClenon, 1993; Tran, 1980; Yeatman et al., 1976, 1980).

Korean Americans

The health beliefs and healing practices detailed earlier have been found among Koreans and Korean Americans (Choe & Lee, 1975; Kendall, 1987; P. C. Kim & Pak, 1983; Y. K. Kim & Sich, 1977; Lee, 1966; Roh, 1970; Sich, 1981), whose ethnomedicine is a derivation of traditional Chinese medicine. Several folk disorders specific to Korean Americans also have been identified (Pang, 1994). These include *Hwabyung* (a form of depression with marked somatic symptoms), *Han* (a form of depression with extreme guilt), and *Shinggyongshaeyak* (a somata-psychic syndrome resembling what biomedicine once called "neurasthenia"). These folk disorders, like the health beliefs and practices detailed thus far, have received no attention from researchers in health psychology, and are ignored by biomedicine (i.e., medicine, public health) as well.

Southeast Asian Americans

The general Asian cultural factors affecting health behavior outlined earlier in this section hold for traditional southeast Asians. Norms regarding silence, prohibitions against speaking about oneself, obligation to parents and family, and fear of loss of lien all play a role in health behavior (Barney, 1980; Poyneer, 1983; Tran, 1980; Uba, 1992; Westermeyer et al., 1983). The health beliefs of southeast Asian Americans are diverse and depend primarily on religion, and secondarily on whether the person has adopted Chinese or ayurvedic (traditional Hindu) health schema. On the whole, however, all of these folk understandings attribute illness to the interplay of supernatural and physical forces, and draw no distinctions between religious and medical beliefs (Westermeyer, 1988). The four major religions in question are as follows.

Buddhism is the belief that life is suffering (including pain and disease), that all suffering stems from desire, and that disease is to be eliminated by eliminating desire (through meditation and other spiritual means). Symptoms thereby are inherently shameful manifestations of desire; seeking treatment for pain or other symptoms is delayed, or treatment (though sought) will not be followed (Hoang & Erickson, 1982, 1985; Westermeyer, 1988).

Confucianism, on the other hand, is a set of behavioral guidelines and ethics entailing respect for and obedience to social hierarchies, and the worship of ancestors. Its health implications are that believers expect health professionals (who represent an extremely high status group) to behave in a superior, authoritarian manner, and tend to comply precisely with all treatment recommended by these superiors (Hoang & Erickson, 1985; Muecke, 1983a, 1983b).

Taoism is the belief in TAO, the creative principle that organizes the universe; all things progress naturally toward perfection and harmony (toward TAO) and hence no steps should be taken to interfere with this. Seeking treatment for symptoms violates this because it is an active step taken (an "unnatural action") to alter the natural progress of events. Hence, seeking treatment is delayed; treatment, if sought, is refused or passively accepted but (covertly) not complied with; and surgery, invasive diagnostic procedures, and even the drawing of blood are prohibited.

Animism is common among Laotian hill tribes (Hmong, Yao), and is the belief that gods, demons, and evil spirits are the only proximal cause of illness, which therefore is to be treated by an indigenous healer, or a shaman. "String-tying" is one health practice associated with these beliefs, and consists of tying a black string around an individual's wrist or waist to communicate with deceased ancestors and prevent or cure illness (Erickson & Hoang, 1980; Hoang & Erickson, 1982, 1985; Muecke, 1983a).

Each of these very different systems of religious beliefs not only has obvious implications for health behavior but is also a system of health beliefs; each entails the view that balance and harmony are synonymous with health, and that curing consists of reestablishing those (Poyneer, 1983). In

addition to these views, southeast Asian Americans may have adopted global, Indochinese folk medical schema (a derivation of traditional Chinese medicine), or the folk medical beliefs of ayurvedic (traditional Indian) medicine. The former recognizes natural (wind, diet), supernatural (gods, demons, evil spirits, spells) and metaphysical (the balance of Yin, Yang, hot and cold) causes of illness (Cheon-Klessig et al., 1988; Tran, 1980). Ayurveda, on the other hand, is the medicine of Hindu culture, and stems from Sanskrit texts of the first through eighth centuries (Fleischman, 1976–1977). It consists of the belief that the cause of all disease is imbalance among the three vital essences or *dosha* (*kapha*, or phlegm; *pitta*, or bile; and *vayu*, or wind), with the sole cause of this imbalance being an unhealthy diet. Changes in diet and use of herbal remedies are the only cures recognized as valid by followers of ayurveda and the only cures used by a vaid (ayurvedic healer) to restore health (Ghandi, 1965).

Three attitudes hold across these systems of health beliefs and religions, and are more or less prototypical of southeast Asians irrespective of specific culture: (1) Surgery is unacceptable because it mutilates the body and the soul is understood as attached to various body parts (Cheon-Klessig et al., 1988; Hoang & Erickson, 1982, 1985). (2) Traditional healers are sought and folk remedies (described previously) used prior to seeking help from practitioners of biomedicine (Buchwald et al., 1992; Cheon-Klessig et al., 1988; Gilman et al., 1992; McClenon, 1993) by approximately 70% of these populations, with subsequently low health service utilization until late stages of disease when symptoms are extreme (Barney, 1980; Cheon-Klessig et al., 1988; Strand & Jones, 1983; Westermeyer et al., 1983). And, (3) appointments for treatment, waiting to see professionals, and preventive care are regarded as confusing, nonsensical "foreign" concepts (Hoang & Erickson, 1985; Tran, 1980).

Laotian/Hmong Folk Cures. The folk remedies detailed earlier (e.g., cupping, burning, etc.) are used by traditional southeast Asian Americans. In addition, however, Laotian Americans (Hmong, in particular) frequently use two other folk remedies as well, and both have major health implications. The first (and the most common folk remedy for pain among Hmong Americans) is an herbal medicine that is inhaled or smoked and contains large quantities of opium—something its users may not know and that accounts for its effectiveness (Rubio, Ekins, Singh, & Dowis, 1987; R. M. Smith & Nelsen, 1991; Westermeyer, 1974, 1988). Opium remains the major cash crop for the Hmong in Laos (where it once was legal to grow; Barney, 1980; Westermeyer, 1982), and many still routinely smoke opium for health purposes freely and openly in the streets of Laos (Westermeyer, 1974, 1982, 1988). Hence, use of an opium herbal remedy has a long cultural history and so continues among refugees in the United States. It has resulted in frequent opium addiction, serious health problems, and prosecution (for receiving packages from overseas containing crude solid opium) among Laotian Americans (Cheon-Klessig et al., 1988; Logue, 1983; Westermeyer, 1974, 1988). To complicate matters, southeast Asian refugees, understanding that Americans use aspirin and

acetaminophen for pain, now tend to mix these with the opium remedy. This toxic combination results in deaths among Hmong American children in particular (Cheon-Klessig et al., 1988; Logue, 1983; Rubio et al., 1987; R. M. Smith & Nelsen, 1991; Westermeyer, 1974, 1988). The percentage of southeast Asian patients whose symptoms are related to undisclosed, chronic opium use is unknown.

The second folk remedy used by Hmong (and Thai) refugees is a set of herbs for curing illness believed to be caused by various evil spirits. These herbs include *Tshuaj Rog*, *Tauj Dub*, *Ntiv*, *Nkoj Liab*, *Niam Tij*, and others, are dispensed by Hmong American shamans (*Txi neng*) in herb shops, and are as common in Hmong and Thai American medicine cabinets as are aspirin for most Americans. Although most of these herbs have yet to be fully analyzed, a few of them have been demonstrated to contain arsenic and lead. Consequently, like Mexican Americans (Centers for Disease Control, 1981, 1983a), cases of lead poisoning due to folk remedies are frequent among southeast Asian American children (Centers for Disease Control, 1983b).

Sudden Death Hmong Folk Disorder. "Nightmare" is a prevalent Hmong folk disorder and is the only Asian folk disorder to receive attention from biomedicine, no doubt because it is *the leading cause of death* among Hmong men. Nightmare consists of awakening from sleep with a feeling of extreme fear and panic; followed by total or partial paralysis and a sensation of pressure in the chest; the feeling or perception of an alien being (animal, human, or spirit) in the room; and culminating in sudden, unexplained death (Adler, 1995; Holtan, Carlson, Egbert, Mielke, & Thao, 1984; Parrish, 1988). This folk disorder has come to be known as *Sudden Unexplained Nocturnal Death Syndrome* (SUNDS) by biomedicine. Deaths from SUNDS are frequent: In 1981 to 1982, the death rate for 25- to 44-year-old male Hmong from this syndrome was equal to the sum of the rates of the five leading causes of death in all non-Hmong U.S. men of the same age (Holtan et al., 1984). Nightmare is not influenced by religion (traditional Asian vs. Christian), and was frequent in Laos prior to immigration but did not lead to any deaths in the native country (Adler, 1995). From 74% to 97% of Hmong believe this disorder to be caused by the nocturnal visit of an evil spirit who presses the life out of the victim (Adler, 1995; Holtan et al., 1984). Such beliefs are consistent with the Hmong view that every household and environment (e.g., the water, the fields, the mountains) is replete with spirits (Cheon-Klessig et al., 1988) who determine events, including health and disease. Hmong also believe that the failure to engage in traditional rituals (as they did in Laos) accounts for the disorder's new ability to kill (Adler, 1995). Although men and women suffer from nightmare attacks, virtually all the deaths have been among men (Adler, 1995). A similar folk disorder appearing at night, causing sudden death and known as "nightmare," was recognized by the ancient Greeks and Romans, and is currently recognized by the French (who call it *cauchemar*), Germans (*Alpdruck*), Mexicans (*pesadilla*), and Poles (Holtan et al., 1984).

AFRICAN AMERICANS

This section refers to a heterogeneous population of Americans who descended from African slaves,³ who themselves descended from the indigenous peoples of western Africa. Although the term *African American* encompasses African, Haitian, West Indian, and other Caribbean Americans, the data reported here are based on those traditionally construed as American "Blacks" in U.S. racial classification schema (Landrine & Klonoff, 1996a), rather than those of Caribbean ancestry.

Studies of the Health Problems of African Americans

The leading causes of death among African Americans are shown in Table 51.1. The major health problems of African Americans include the highest (age-adjusted) rates of cancer and cancer mortality of all ethnic groups (Baquet & Gibbs, 1992; Baquet et al., 1991; USDHHS, 1987, 1995); high rates of diabetes (USDHHS, 1995; Klonoff, Landrine, & Scott, 1995); prevalent hypertension (estimated at up to 34% of the population); excess cardiovascular disease (USDHHS, 1987; Rivo, Kofie, Schwartz, Levy, & Tuckson, 1989); prevalent obesity (Burke et al., 1992; Kumanyika, 1987, 1994; Nesper, Thomas, Semenya, Thomas, & Gillum, 1986); and high rates of AIDS (USDHHS, 1995, 1996). These health problems are in part the result of three problematic health behaviors among Blacks: high rates of cigarette smoking among adults (Centers for Disease Control, 1988; Fiore et al., 1989; Novotny, Warner, Kendrick, & Remington, 1988) coupled with low rates of quitting smoking (Orleans et al., 1989; Royce et al., 1993); poor diets and nutrition (Block & Subar, 1992; Gerber et al., 1991; Kant, Block, Schatzkin, Ziegler, & Nestle, 1991; Serdula et al., 1995); and lack of exercise (Burke et al., 1992; C. E. Lewis, Raczynski, Heath, Levinson, & Cutter, 1993). These three problematic health behaviors transcend social class, occupation, and education. Hence, although health psychology and related disciplines readily attribute the problematic health behaviors and excess morbidity of African Americans to such social factors, those factors cannot alone account for the data, and neglected cultural variables there-fore also must be involved (Hildreth & Saunders, 1992; Landrine & Klonoff, 1996a).

General Cultural Factors Influencing Health Behavior

Racism and Distrust of Whites. That Blacks have experienced profound racism historically and continue to experience it currently is well-known (Bell, 1992; Dovidio &

³Although all African Americans descended from indigenous Africans, not all descended from slaves, because not all Blacks in the United States during the colonial era were slaves. At any time, 15% were free. Indeed, American Blacks represent three distinct genetic populations with vastly different precolonial and colonial era histories (Sowell, 1978, 1994); this point is discussed further later.

Gaertner, 1986; Landrine et al., 1995). Such racism persists as a factor in the daily lives of Blacks whether at work (Idson & Price, 1992; Krieger, 1990), leisure (Cose, 1993), or when seeking health care (Harrison, 1994), and its frequency and impact cannot be exaggerated. For example, a scale was constructed to measure the frequency and appraisal of racism in Blacks' lives (Landrine & Klonoff, 1996a, 1996b). Racism was operationalized as a set of specific racist acts or *racist events* (e.g., being called a "nigger," being followed by the police or store security guards) that are analogous to the generic stressful life events and hassles that dominate stress research. Studies using our Schedule of Racist Events (SRE; Landrine & Klonoff, 1996a, 1996b) revealed that 98% of Blacks reported experiencing some type of racist event in the past year irrespective of their gender, age, education, and socioeconomic status. The frequency of racist events experienced also predicted smoking (Landrine & Klonoff, 1996a, 1996b) and hypertension (Krieger, 1990) among Blacks better than all status variables combined.

Foremost among the global, cultural factors that play a role in Black health and health behavior is a profound, ubiquitous distrust of Whites that is a response to this racism (Jones, 1993; Landrine & Klonoff, 1996a, 1996b). That distrust is taught to successive generations, and so is a cultural variable (Helms, 1990; Landrine & Klonoff, 1994a, 1996a; Thompson, 1994). Black distrust of Whites is legion and thus has been measured through a variety of scales including the *Cultural Mistrust Inventory* (Terrell & Terrell, 1981), and the *Cultural Mistrust Subscale* of the African American Acculturation Scale (see Landrine & Klonoff, 1996a, for a review of both). In several investigations, it was found that African American's distrust of Whites transcends their social class and education, and plays a role in anxiety, somatic, and depressive symptoms, as well as in prevalence rates of hypertension and cigarette smoking, with all of these higher for Blacks high in cultural mistrust (Klonoff et al., 1996; Landrine & Klonoff, 1996a, 1996b). Likewise, others have found that Black acceptance of health information provided by Whites is mediated by such cultural mistrust (Kalichman, Kelly, Hunter, Murphy, & Tyler, 1993; Mays & Cochran, 1988).

Although traditional Blacks distrust Whites as a whole, they distrust White health professionals in particular and even more so, and distrust information on and interventions regarding AIDS provided by such professionals most of all (Jones, 1993). Health workers/researchers have repeatedly found that many Blacks believe that HIV is an artificially created virus, and that AIDS prevention programs are a ruse for infecting Blacks with it as part of a larger, genocidal conspiracy to annihilate the Black population (Jones, 1993). Surveys in 1990 and 1992 (Jones, 1993) consistently report such attitudes, along with a rejection of AIDS treatment and prevention programs (Jones, 1993). AIDS blood tests and donating blood are viewed by 54% of Blacks as a mechanism for purposefully infecting them with HIV; AZT is viewed as a poison meant to eliminate Blacks; the encouraged use of condoms is perceived as a plot to decrease Black births; and the distribution of clean needles to addicts is seen as an effort to increase substance abuse in the Black community (Jones, 1993). *Tony Brown's Journal*, a pop-

ular and influential Black discussion program on PBS (Public Broadcasting System), and articles in the *Los Angeles Sentinel* (the largest, West coast Black newspaper) and *Essence* (a national Black magazine) have all repeated the view that the HIV virus and AIDS prevention programs are the genocidal conspiracy of White health scientists (Jones, 1993). Consequently, for example, in 1988, a federal AIDS prevention program in Washington, DC had to be halted because Blacks refused to submit to household blood tests, and Black city officials similarly suspected that the program was a (disguised) genocidal experiment (Jones, 1993).

Blacks' specific distrust of White health professionals and of the AIDS-related information they provide are both a response to a single racist event in history, namely, the Tuskegee Syphilis Study. This experiment is rarely mentioned in health psychology articles, undergraduate or graduate texts, and is virtually absent from health psychology articles about Blacks and AIDS, thereby implying that health psychologists may not be aware of it. The Black (and the gay) community, however, is aware of it, and that knowledge has shaped Black health behavior and attitudes (e.g., above) more profoundly than any other event.⁴ Because the importance of the Tuskegee experiment to current Black health behavior cannot be overestimated, a summary of it is provided here based on Thomas and Quinn (1991), Jones (1981, 1993), Silver (1988), and Brandt (1988); the reader is referred to Jones (1981, 1993) for the details of the experiment.

The Tuskegee Syphilis Experiment, 1932–1972. In 1928, the Public Health Service (PHS) had recently completed a study of the prevalence of syphilis in rural, southern Blacks and found a rate of 25%.⁵ As part of this syphilis-control demonstration project, the PHS also provided free treatment for the Blacks they tested to prove that Blacks could be treated successfully for the disease with the two drugs of the time (arsphenamine and mercury). With this successful demonstration project in hand, the PHS proposed a new project to the Julius Rosenwald Fund (a Chicago-based group dedicated to improving the health of Blacks) to expand the project throughout Black communities in the south. The Rosenwald Fund supported that project, knowing that Blacks would trust

⁴Indeed, the Tuskegee experiment also initially determined the gay community's attitudes about AIDS; gays explicitly mentioned the experiment as the reason for their initial belief that HIV was a virus constructed by the federal government to annihilate the gay population (Jones, 1993).

⁵Whether all of these Blacks had syphilis or had lupus misdiagnosed as syphilis, is a reasonable question to raise. This is because lupus (an incurable, autoimmune disorder of unknown cause) is extremely prevalent in Black women (but not men). Its symptoms include sores similar to those seen in syphilis, and its auto-antibodies frequently lead to false positive syphilis test results even today (see Klonoff & Landrine, 1997b). Hence, when both men and women were tested by the PHS, rates of (ostensible) syphilis were 25%, 35%, and 40%; but, when the PHS later tested only Black men (such that the diagnosis of syphilis probably was accurate) rates of syphilis were 15%. That the Black community of the 1930s was replete with syphilis remains as a "fact" in this historical literature and one that warrants critical reassessment.

the PHS and would participate in light of the prior (1928) PHS work in Black communities. Hence, from 1929 to 1931, Black women and men throughout the south were again recruited to participate in a syphilis control project, and were tested for syphilis, with positive test results found for 35% to 40% of the population. The procedures used to recruit Blacks and gain their trust and cooperation were the most culturally tailored to date. They included recruitment through Black churches and conducting the blood tests in those churches; enlisting the assistance of Black church leaders who encouraged Blacks to participate; gaining the cooperation and participation of local agencies; enlisting the assistance of the Tuskegee Institute (a prestigious, Black institute); using local Black medical staff from Tuskegee to do the testing; getting Blacks released from work (without loss of income or job) to be tested; providing food and a free physical exam; and having a Black nurse from the community establish a relationship with each subject and provide each with transportation to the testing site.

Finally, the PHS took the additional culturally sensitive step of translating syphilis into the language of Black folk medicine to facilitate cooperation. Because Blacks believed (since slavery) that various "states" of one's blood ("high," "low," and "bad" blood) played an etiological role in all illness, syphilis was described to them as a type of "bad blood"—it was presented in a manner consistent with their indigenous health schema.

Hence, Blacks were told by local Black religious and other leaders that "government doctors" wanted to test and treat them for "bad blood." Given the source of the message, convenience of testing sites, and the incentives entailed, Blacks cooperated fully and enthusiastically. Blacks were never told, however, that the "bad blood" in question was a highly contagious, serious disease that was transmitted sexually and from mother to fetus. Given that they would be treated for syphilis, explaining exactly what it was in terms other than "bad blood" seemed unnecessary to the PHS.

When the testing phase was complete and the need for treatment established, the next step was to initiate treatment (which at the time was an expensive, 1-year course of two drugs for each infected person). However, this did not occur because the PHS lost their funding. The Depression decimated the Rosenwald Fund that had supported the project; without its financial support, the PHS could not conduct the treatment phase. The PHS was no more satisfied with this outcome than anyone who loses a grant would be, and wanted to salvage something publishable from the years of identifying and testing Blacks, and of establishing a successful, grassroots network for doing so. Thus, they decided to conduct a study on *untreated* syphilis in Black men that has come to be known as the Tuskegee Syphilis Experiment. The PHS believed and hoped that if it could demonstrate that the disease was as damaging to Blacks as it was to Whites, funding for treating Blacks could be secured in the future.

Hence, in 1932, the elaborate network and culturally sensitive procedures (detailed previously) for recruiting Blacks were used again to recruit a new sample of 600 Black men (only) for research purposes. The men were divided into 399 with syphilis and 201 healthy controls, and the plan was to

compare them over a course of 9 months. The PHS told the new sample (like prior ones) that they would be tested and treated for "bad blood," again with no explanation regarding the transmission of syphilis. Importantly, however, this time the PHS was lying insofar as no treatment was planned or would be forthcoming. Many men were given some treatment for fear that if they did not experience some relief, they would cease participation in the project. The treatment provided was purposefully less than half of the dose of the two drugs needed to cure syphilis. Neither the subjects nor the Tuskegee Institute was told the true purpose of the study.

When the initial 9-month period was over, the PHS did not want to relinquish the project because it viewed the Blacks as an enormous opportunity to study the long-term manifestations of untreated syphilis. The rationale for the study changed from empirically demonstrating the need to provide better health care for poor Blacks, to exploiting those Blacks for research and publication purposes. Thus, the study continued for the next 40 years, ending in 1972 only because the press discovered and exposed it. For that 40-year period, numerous foundations, government agencies, and universities colluded in the project by sending staff to examine the men and publish articles about their irreversible cardiovascular and neurologic damage, or by assisting in keeping the project a secret from the general public. Penicillin was discovered in the 1940s to be a cheap, effective cure for syphilis (one that the PHS readily could afford), leaving the PHS with little justification for failing to treat the men. But, meetings were held in the 1940s at which it was concluded by the PHS and others that the experiment not only had to continue but had to continue "to endpoint" (until each man died) because the data from the men's autopsies would make an "invaluable," "incomparable" scientific monograph. Hence, penicillin was withheld from the men for 30 years. Between the 1940s and 1970s, all of the men had heard about penicillin and believed it could cure their "bad blood." To stop them from seeking penicillin elsewhere, the PHS convinced the men that it not only would not cure but might kill them, and then took extra steps to isolate the men from other sources of biomedical information and care. This included assuring that no local hospital or clinic (these provided with the men's names) would treat them. Indeed, numerous federal, state, and local agencies conspired repeatedly to assure that these men never received treatment. This included agreements with the government and war departments to assure that the men either were not drafted for World War II (because all draftees were treated with penicillin) or, if drafted, would not receive treatment and would not serve. Other agencies and public officials conspired to keep the men's untimely deaths from cardiovascular complications a secret from the public, and arranged death certificates for that purpose.

For the 40 years of the project, the Tuskegee men were subjected to annual, barbaric (i.e., rushed and without anesthesia) lumbar punctures (along with X-rays) for research purposes only, and were told that these were shots of medicine to cure them. As a result of these repeated, poorly conducted lumbar punctures, some men died and others developed irreversible headaches or paralysis. Scientific articles on the men's severe

neurologic and other symptoms, as well as on their brief life spans (relative to healthy Blacks) appeared throughout journals in the 1940s, 1950s, and 1960s and did not hide the nature of the protocol. Nonetheless, physicians, scientists, and editors who read these articles did not object to the study, despite its obvious immorality and the current civil rights movement. Just one person, Peter Buxton, tried many times to stop the experiment, and failing to do so, finally revealed it to the press. When the story appeared in the July 25, 1972, issue of the *Washington Star*, almost all of the Tuskegee men had died painfully and prematurely. The response to the study was outrage among Blacks, Whites, scientists, physicians, Congress, and the White House. Congressional investigations and hearings were convened in 1972 and 1973 (at which the few surviving men spoke) and these shaped future federal guidelines (i.e., current ones) for the treatment of human subjects in research—requiring, first and foremost, that subjects give full, informed consent to participate. In 1974, a \$10 million out-of-court settlement was reached between the U.S. government and the Tuskegee survivors and their heirs. It paid each \$5,000 to \$37,500 in exchange for promises to file no further action. Most of these funds were returned to the U.S. government in 1977–1978 because heirs had failed to come forward within the 3 years stipulated by the settlement. Finally, in 1997, President Bill Clinton publicly apologized to the Black community for the Tuskegee Experiment.

The Legacy of Tuskegee. In the Black communities around the nation, the story of the Tuskegee study is told to each generation, accurately or (equally often) inaccurately, as a study in which Blacks were purposefully infected with syphilis in order to study them (Jones, 1993). Although the latter inaccurate story is the basis for the Black belief that their community was purposefully infected with HIV for research purposes, accurate knowledge of the study has had equally negative consequences. For Blacks, the study is far more than an example of racism. Rather, it is also understood as proof that White health scientists (particularly those with federal funds) and the federal government are involved in conspiracies against Blacks in which lies are told to Blacks about their diseases and health; Blacks are denied available treatment and allowed to die; Black churches and leaders are not told the truth and are used to further White genocidal ends; and Blacks are used for publication purposes (Jones, 1993; Thomas & Quinn, 1991). In the context of Tuskegee, current Black distrust and rejection of White health scientists, of information about AIDS, and of AIDS prevention programs is understandable, particularly because 1972 was not that long ago. Indeed, efforts to culturally tailor AIDS prevention programs for the Black community are especially likely to raise the specter of Tuskegee, because such strategies (e.g., involving Black health care providers and conducting the project through churches) are identical to those used to fool Blacks in the past. Thus, Black leaders (e.g., from the Nation of Islam; see Thomas & Quinn, 1991) respond to AIDS prevention programs with suspicion and ask how Blacks can know that current efforts are not Tuskegee again (Jones, 1993; Thomas & Quinn, 1991). This suggests that what health psychology re-

searchers often assume to be a Black lack of knowledge about AIDS transmission and risk factors (Kalichman, Hunter, & Kelly, 1992) can instead be a conscious rejection of biomedical evidence in favor of genocidal theories by both uneducated and highly educated (including physicians) Blacks alike (Jones, 1993; Klonoff et al., 1996). Although many ethnic groups (e.g., Latinos; see Klonoff et al., 1996) believe that AIDS can be contracted by donating blood or by having a blood test, such beliefs among Blacks arose in an historical context that lends them a different meaning, namely, distrust (rather than lack) of information.

Hence, suspicions about AIDS are one example of the legacy of the Tuskegee Experiment. Indeed, a recent study (Klonoff & Landrine, 1999b) found that one in four Blacks currently believe that the HIV virus was created by the federal government to annihilate the Black population. These beliefs were more common among Black men (the subjects of the Tuskegee Study) than among women. These AIDS conspiracy views were predicted by high (rather than low) education and by frequent experiences with racism. This suggests that such views represent the rejection of biomedical information by educated Blacks in favor of conspiracy theories that are consistent with their knowledge of history and their experiences in a racist world.

A second example of the legacy of Tuskegee is that much of the Black community firmly believes that the easy availability of drugs (crack cocaine in particular) in their communities is the result of those drugs being distributed there by the federal government as part of a (continuing) genocidal conspiracy (Jones, 1993). Hence, well-known Black delays in seeking and noncompliance with treatment, as well as failure to alter unhealthy lifestyles, may all be at least in part a function of similar generalizations from Tuskegee and subsequent distrust and rejection of health information provided by Whites. It does not make sense, for example, that Blacks, irrespective of education, seem to know as little about the dangerous consequences of cigarette smoking (Klesges et al., 1988; Martin, Cummings, & Coates, 1990) as they ostensibly know about AIDS prevention. This apparent lack of health-related information on a variety of topics even among Blacks with college degrees can only be explained as a rejection of such information as a result of Tuskegee, and hence as the sad legacy of that study (Klonoff et al., 1996).

With the importance of Black distrust of Whites and the Tuskegee study outlined as global cultural factors influencing Black health behavior, the next section focuses on specific cultural health beliefs and practices.

Beliefs About Illness

The health beliefs and practices of traditional African Americans are by and large derivations of those of the west Africans who came to the United States as slaves (Baer, 1985; Bailey, 1987, 1991; Brandon, 1991; Goodson, 1987; Hall & Bourne, 1973; Hill, 1973; Hill & Matthews, 1981; Holloway, 1991; Jacques, 1976; W. Jordan, 1975, 1979; Laguerre, 1987; Mulira, 1991; Sexton, 1992; Snow, 1974, 1977, 1978, 1983; Watson, 1984). These beliefs have been influenced minimally by Euro-

pean American beliefs, but strongly by Native Americans beliefs because indigenous Indians and slaves had many contacts throughout the colonial era (e.g., Native Americans provided sanctuary for runaway slaves and the two groups established cooperative, free communities). Prior to the civil war, the health of slaves was maintained primarily by slave owners out of self-interest (Jackson, 1981) and secondarily by slave women healers who used African remedies (Goodson, 1987; Holloway, 1991; Landrine & Klonoff, 1996a). With the end of the war and the emancipation of the slaves, biomedical services were denied to the freed Blacks (Charatz-Litt, 1992; Cooke, 1984; Goodson, 1987; Jackson, 1981; Jacques, 1976; Spector, 1996). Consequently, west African health beliefs, cures, and traditional healers were all that remained, and the latter became solely responsible for Black health care during Reconstruction (Cooke, 1984; Tallant, 1946). At that point, a folk system of medical beliefs and practices (dominated by west African herbalism and voodoo, and colored by Native American practices) crystallized, and became the African American ethnomedicine that continues among contemporary, traditional Blacks (Hill & Matthews, 1981; Holloway, 1991; Jackson, 1981; Jordan, 1975, 1979; Sexton, 1992). Discrimination against Blacks by biomedicine, as patients (Harrison, 1994; Hildreth & Saunders, 1992; Morias, 1967) and professionals (e.g., Black physicians were not allowed to be members of the American Medical Association until 1965, see Charatz-Litt, 1992) in part accounts for the strength and persistence of Black folk medicine.

West African cultures view people as fundamentally a spirit and a process rather than as a material entity, and have no word for "religion" because all things are essentially spiritual and religious (Mbiti, 1975). So too, traditional African Americans view people not as matter but as a spirit or soul (Barrett, 1974; Holloway, 1991; Jules-Roseta, 1980), and hence view all people and things as connected to and influencing all others on a spiritual or mystical plane (Bailey, 1991). Few distinctions are drawn among mind, body, spirit, and nature, or between religion and medicine, and health-related beliefs and practices are infused with a spirituality that is even more pronounced than that of the other sociocentric cultures described here (Jackson, 1981; Warner, 1977; Watson, 1984). Hence, Blacks classify illness as natural (consistent with the spirit, plan, and laws of God, nature and the universe) or unnatural (inconsistent with the foregoing), with these two types of illness having different symptoms, causes, and cures (Bailey, 1991; Flaskerud & Rush, 1989). This system of classification of illness is the most common one used by contemporary traditional African Americans (Bailey, 1991) and persists as the dominant nosology in the west African cultures from which African Americans descended (Holloway, 1991).

Natural Illnesses. Illnesses classified as natural are those viewed as subject to the laws of God and nature, and so are understood as normal and predictable (Snow, 1974, 1977, 1978, 1983). All illnesses that have mild or acute, nonfrightening, time-limited symptoms that can be prevented and easily cured are classified as natural (Bailey, 1991). These illnesses are believed to be the (proximal) result of lack

of balance or harmony, whether they are understood as due (distally) to forces of nature, or to punishment for sin. Forces of nature believed to cause natural illness include exposure to cold or heat; impurities that enter the body through air, food, or water; improper diet and lack of moderation in habits (Flaskerud & Rush, 1989; Hill & Matthews, 1981; S. M. Johnson & Snow, 1982); and various cycles and phases of life, the moon, the tides, and the planets (Cooke, 1984), all of which effect only the exposed person. Illness that is construed as punishment for sin (breach of taboo), on the other hand, can befall the sinners or their relatives, and children in particular. Because natural illnesses are part of God's plan, they are understood as curable, with those due to forces of nature treated by biomedicine and prayer, and those understood as due to sin relieved only through prayer and assistance of religious or spiritual experts (Snow, 1974, 1978).

Unnatural Illnesses. All remaining illnesses (those whose symptoms are fatal, incurable, progressive, frightening and confusing, extreme, bizarre, or psychiatric) are classified as unnatural. These illnesses are understood as the result of malevolent forces and supernatural entities that disrupt the harmony and balance of the universe and thereby interrupt God's plan (Snow, 1974, 1983). Etiological agents include evil or Satan (Snow, 1983; Warner, 1977); ghosts, other spirits, and possession by these (Holloway, 1991); and hexes, curses, and spells due to witchcraft or voodoo (Cooke, 1984; W. Jordan, 1975, 1979; Laguerre, 1987; Mulira, 1991; Snow, 1983; Paulino, 1995; Warner, 1977). Treatment of unnatural illnesses necessitates the use of not only spiritual remedies such as prayer and laying on of hands, but of magico-religious, traditional remedies such as charms, herbs, special teas, and salves, and use of root doctors or voodoo healers, with biomedical interventions deemed ineffective. Microscopic disease causing agents (e.g., viruses) are understood by traditional African Americans as causes of illness as well, but as merely the "how" rather than the "why" of illness (Spector, 1996). Recent surveys of African American adults who were diverse in education, social class, and geographical region of residence support the aforementioned literature. For example, recent studies found a strong belief in the healing power of prayer; a tendency to seek health care from ministers (primarily) or root doctors (voodooists); classifying illness as natural versus unnatural; and attributing illness to supernatural causes among traditional Blacks but not among Whites (Landrine & Klonoff, 1994a, 1994b, 1996a). Likewise, in a survey of African Americans in Detroit, Bailey (1991) found use of the dichotomous nosology and its causal attributions for illness. Thus, the primary (proximal) causes of illness recognized by traditional African Americans are natural (cold, poor diet) and supernatural (God's punishment, effects of evil) factors, with the latter given more weight.

African American Folk Healers and Healing Practices

Like other sociocentric cultures, traditional African Americans view the ability to heal as a sacred gift, and healers as blessed or highly spiritual people (Baer, 1981, 1985; Hall &

Bourne, 1973; Hill & Matthews, 1981; Sexton, 1992; Watson, 1984). The diversity of indigenous healers (e.g., ministers, spiritual leaders, folk doctors, grannies, midwives, advisors, prophets, and root or voodoo doctors) recognized are categorized into three broad types (Baer, 1981, 1985). The first are those who learned healing from elders or received training in biomedicine, and hence can only heal simple, natural illnesses caused by forces of nature. The second type received the "gift of healing" from God through a religious experience and can heal all natural illness irrespective of cause. The third and most powerful healers are those understood as born with the "power of curing" (a sign of which was present at their birth), who are hence capable of curing natural and unnatural illness (Baer, 1981; Snow, 1974; Watson, 1984). Of these many folk healers and healing practices, space here permits a discussion of only four specifically African American (rather than Afro-Caribbean) ones: ministers, midwives, herbalists, and voodoo practitioners.

- *Ministers* are consulted for advice and healing for a diversity of problems, including psychiatric and physical symptoms and interpersonal crises. They provide social support, information, prayer, and guidance, and play a powerful role in the health decisions and behaviors of many traditional Blacks (Hill & Matthews, 1981; Landrine & Klonoff, 1996a; and Watson, 1984, in particular).
- *Midwives* are the most common traditional folk healers in the Black community. This is because the practice of midwifery is an ancient African tradition (the word *midwife* is the English translation of the Congo word "healing-woman") and was introduced to the United States by the slaves. Midwifery was one of the few African healing practices that slave owners allowed slave women to perform, such that the tradition continues in the Black community (Holloway, 1991). Midwives are consulted for advice on pregnancy, childbirth, and gynecological issues, and deliver infants (Bailey, 1991; Hill & Matthews, 1981).
- *Herbalists* use a set of herbal remedies derived originally from the botanical knowledge of slave women (Goodson, 1987; Mitchell, 1978), crystallized during Reconstruction (Cooke, 1984; J. J. Jackson, 1981). Whereas the prevalence of herbalists remains unclear, their existence does not insofar as a variety of herbalists have shops throughout the urban and rural Black communities around the nation (Baer, 1985; Bailey, 1991; Goodson, 1987; Jacques, 1976; W. Jordan, 1979; Mitchell, 1978) and are regularly consulted for care. The treatment of herbalists consists of recommending that people decrease the salt and fat in their diets and decrease their stress, along with ingesting an herbal remedy (Bailey, 1991). The most common herbal remedies used include sassafras tea, dandelion and valerian root, epsom salt, garlic tablets, vinegar, and lemon juice (Bailey, 1991), along with cream of tartar, leaf tea, catnip tea, jimson weed, huckleberry, holly, goat's milk, cattle blood, and other herbs (see Mitchell, 1978; Payne-Jackson & Lee, 1993; and

Boyd, Shimp, & Hackney, 1984, for detailed lists of herbs and their therapeutic purposes). Many of these remedies (e.g., ingesting astringent substances to control diabetes; see Bailey, 1991) are based on underlying concepts of restoring symbolic balance (between, in this example, "bitter" and "sugar" [diabetes, "sweet"]). Others are based on the view that "flushing" "impurities" from the body through the use of herbs restores balance and health, and still others are meant to restore balance to ethnomedical entities such as "high," "low," "thin," and "weak" blood. Importantly, herbalists are typically consulted to prevent, control, or cure the diabetes and hypertension that are prevalent among Blacks, with biomedical treatments ignored by the Blacks in question. For example, Bailey (1991) found that, when told by a physician that they had hypertension, 62.7% of poor, Detroit Blacks did nothing about it (did not comply with biomedical treatment), and an additional 26.5% consulted an herbalist for care instead of complying with biomedical treatment. Belief in Black folk medicine clearly impacts help seeking and other health-related behavior (Bailey, 1987).

Toxic Herbal Remedies. Like the arsenic-, lead-, and opium-based herbal remedies of Latino and Hmong Americans, only those few African American folk cures that have caused serious illness or death have received scientific attention. Foremost among these is sassafras tea, a drink made from the root bark of the sassafras tree. The use of sassafras in drinks and of sassafras leaves as poultices originated among the slaves and Navajo of the colonial era (Vogel, 1970), whose cures were often adopted by Whites (e.g., the African practice of midwifery and of inoculations) because they were effective. Sassafras leaves then became so popular that they were used throughout the nation through the 1950s to control bleeding, and were the main ingredient in tea and root beer (Haines, 1991; Hand, 1980). The use of sassafras ceased in 1960 when the Food and Drug Administration demonstrated that safrol (the active chemical constituent) was toxic and caused ataxia, hypothermia, hypertension, liver cancer, and other symptoms. Sassafras nonetheless is sold in Black herbalists' shops, and is one of the most frequently used herbal remedies (Bailey, 1991) among Blacks, with occasional toxic consequences (Haines, 1991). The role of this folk remedy in prevalent hypertension and liver disease among African Americans has never been investigated.

- *Voodoo.* Although the number of people who still practice *voodoo* in the United States is unclear, it is clear that voodoo practitioners (called "root doctors," or conjurers) and their followers persist (W. Jordan 1975, 1979; Laguerre, 1987; Matthews, 1987; Mitchell, 1978; Mulira, 1991; Sexton, 1992; Simpson, 1978; Spector, 1996; Tingling, 1967), and are quite prevalent in specific communities (e.g., New Orleans and the Sea Islands of Georgia and the Carolinas). Voodoo (often called "root work") came to the United States in the late 1600s with the slaves from west Af-

rica who had belonged to an African religion that worshipped a god they called *Vodu* (pronounced voodoo) simply because the Dahomean (west African) word *vodu* means god, spirit, or deity (Mulira, 1991; Simpson, 1978; Tallant, 1946). In the states, Whites quickly came to call the slave deity, the religious/healing sect, its members, priests, and rites and practices voodoo (Tallant, 1946). The term *hoodoo* simultaneously emerged among Whites to refer to the negative practice (i.e., to harm others) of voodoo (Mitchell, 1978; Mulira, 1991), and both terms (voodoo and hoodoo) came to dominate in 1947. Because voodoo was a religion that slaves would not relinquish and purposefully transmitted to successive generations of thousands of Blacks (Simpson, 1978), the World Order of Congregational Churches recognized voodoo as a bona fide religion in 1945 (Mulira, 1991; Simpson, 1978); this increased its acceptance among nonbelievers and may or may not have increased its followers (Mulira, 1991). Voodoo is a prevalent religion today in Trinidad, Brazil, and Haiti, as well as in the specific U.S. geographical regions already mentioned (Mulira, 1991).

Voodoo as practiced by contemporary, traditional African Americans is a set of health and healing practices with three components. The first is mystical and entails manipulating universal energy, contacting spirits, conjuring, hexing, and casting spells through a variety of rituals and dances for the benefit of the ill person who has sought help. The second is psychological and entails providing social and emotional support, and reaffirmation of faith and community for the ill person, along with songs and intense prayer. The third component is herbal folk medicine, that is, the use of botanical roots for cures (hence, practitioners are sometimes called root doctors and voodoo rites called rootwork). In voodoo rootwork, however, the herbs used extend well beyond those identified previously, and include ancient cures such as blackroot, kidney weed, and the "life-everlasting-plant" (believed to prolong life and act as a charm against illness), which are combined with rituals, charms, concoctions, dances, prayers, songs, and pieces of wood joined together in specific patterns and believed to possess magical power (Matthews, 1987; Mitchell, 1978; Mulira, 1991). Because those who use the life everlasting plant (in conjunction with prayer) in particular tend to be free of illness and to live to an extremely old age, it is the most common folk remedy used by Blacks, Native Americans, and Whites of the Sea Islands (Holloway, 1991). In addition, *gris-gris*, the symbols of voodoo, are often used to prevent illness. Powders and oils (often colored in symbolic ways) that are highly and pleasantly scented are often used as good *gris-gris*, whereas oils and powders with vile odors serve as bad *gris-gris*. A variety of colored candles are also used, with the color of the candle signifying the intention of the ritual (Mitchell, 1978; Mulira, 1991; Spector, 1996). One component of voodoo, that of putting a "fix", hex, or curse on another, is well-known because several unexplained deaths have been associated with this practice (Meador, 1992; Mulira, 1991; Spector, 1996); it is

believed that no one survives a voodoo hex and that there are no rituals or cures that can reverse it.

Santeria is an additional, separate health/healing and religious cult among African and Cuban Americans (Harwood, 1977; Holloway, 1991; Paulino, 1995; Sandoval, 1977). This Afro-Caribbean religion arose among the west African slaves who were imported to Cuba in the 1700s to cultivate tobacco and sugar. It consists of a combination of west African (Yoruba) and Spanish-Catholic beliefs, and includes beliefs in reincarnation; use of African magical and occult techniques, including herbal medicine, spells, hexes, curses, and witches; beliefs and practices from Latino espiritism and Hispanic humoral medicine; and the frequent (well-known, controversial) use of animal sacrifices and animal blood for religious and health purposes (Brandon, 1991). Although a discussion of this religion/healing cult is beyond the confines of this chapter, it should be noted that Santeria has many followers in the United States. Although the majority of these are Cubans, substantial percentages are African American, Puerto Rican, and European American (Brandon, 1991). Santeria is an important, Afro-Caribbean religion/healing tradition whose many health beliefs, indigenous healers, and healing practices are used by some unknown (but substantial) percentage of American minorities (Brandon, 1991).

Healing Practices and Health Beliefs of Black Muslims. Although Islam is one of the fastest growing religions in the United States, few studies have investigated the impact of Muslim health care beliefs and practices. There are many different Muslim sects, and many Islamic cultures (Kemp, 1996). Some of the sects (e.g., the Nation of Islam) are comprised entirely of African Americans (7% of Blacks are Muslims), and others (e.g., the Sunni and the Shiite) consist of Arab, non-Arab middle Eastern, African, African American, Asian, or Anglo members. Health beliefs and practices common to these diverse sects include the Islamic diet, which is kosher in the traditional sense of that term. Thus, eating from dishes or with utensils that have had contact with forbidden foods is prohibited, and forbidden foods include pork products and beans. Consequently, many foods conceptualized as traditional African American "soul foods" (e.g., black-eyed peas with ham, ham hocks, pork ribs, pork chops) are not allowed; this yields an enormous (religious) diversity in African American dietary practices that is largely ignored in national nutritional studies (Spector, 1996). Because of these dietary restrictions, Black Muslim inpatients refuse to eat, eat only foods brought in by family members, or require a vegetarian diet with which health care providers must comply (Kemp, 1996). Likewise, diabetic Black Muslims will refuse to take insulin manufactured from pork pancreas (a common source of insulin). One important Muslim ritual is the fast of Ramadan, a 30-day period during which adult Muslims fast from sunup to sundown. During this time, no meat is eaten and only one meal per day (in the evening) is consumed. Some Muslims interpret the fast to mean abstinence from all food, water, and medicine for the 30 days, whereas others allow water and/or medicine only during the day (Kemp, 1996). Consequently, prescriptions will not be taken as prescribed or at all during this period.

African American Folk Disorders

A diversity of folk disorders and ethnomedical entities among African Americans have been identified and include clots, tedders, gas, ear noises, states of blood, falling out, and worriation, to name a few. Because a discussion of all of these is beyond the scope of this chapter, the discussion focuses briefly on states of blood, falling out, and worriation.

States of Blood. In Black folk medicine, blood is believed to take on a variety of "states" (e.g., bad, bruised, high, low, thin, thick, and weak blood) that are manifested in or cause illness (Bailey, 1987, 1991; Jackson, 1981; Weidman, 1979). For example, *bruised blood* is believed to be darker than normal, unable to circulate, the result of injury, and to be a cause of illness. *High blood*, on the other hand, refers to blood believed to collect in high spots of the body (e.g., the head) due to poor diet and stress, and manifested in dizziness and episodes of falling-out; many Blacks equate high blood pressure with this folk disorder and that, in part, explains their tendency to use folk herbal and other remedies for hypertension. Similarly, *low blood* refers to a folk condition in which a person is believed to lack enough blood (due to poor diet) and is seen as the cause of weakness and malaise. Finally, *bad blood* is a folk condition that originally referred to blood contaminated by toxins or by supernatural forces and thereby causing serious illness; after the Tuskegee study, however, the term came to mean (and currently means) blood contaminated by syphilis.

These notions regarding states of blood are west African in origin and are found in a diversity of African and Afro-Caribbean cultures, including among Cubans, Puerto Ricans (as mentioned previously), and others. Thus for example, Haitians (in the United States and Haiti) recognize a diversity of similar states of blood, including *san cle* (thin blood) and *san febl* (weak blood), which are both believed to cause psychiatric symptoms; *san epe* (thick blood believed to be the cause of hypertension); *san jon* (yellow) and *san noa* (dark) blood, which are both believed to cause incurable disease; and *move san* (bad) and *san gate* (spoiled) blood, which are due to venereal disease and magical fright, respectively. U.S. Haitians also believe that blood turns to water as a result of excess alcohol use, and that this in turn causes tuberculosis (Harwood, 1981). Likewise, Haitian Americans recognize a folk disorder called *gaz*, which is similar to African American concepts of "gas" and Asian concepts of "wind" in which (cold) air or wind is believed to enter the body and cause symptoms at the point of entry: Wind/gas entering the ears is believed to be the cause of headaches and mouth pain; wind/gas in the legs is seen as the cause of rheumatism; wind/gas entering the stomach is seen as the cause of abdominal, intestinal, and back pain, and so on.

Falling Out. This folk disorder is confined almost exclusively to women and seen primarily in Blacks, and secondarily in Cubans and other Afro-Caribbeans (e.g., Haitians, Bahamians). Although Blacks constitute 17% to 22% of the population, they account for at least 50% of cases of falling

out (Lefley, 1979a, 1979b; Weidman, 1979). In falling out, an individual whose medical history is negative for drug or alcohol use, seizure disorder, head injury, cardiovascular disease, diabetes, or abnormal blood pressure, and who currently does not appear to be under great stress, suddenly and inexplicably loses consciousness and consequently either falls out of her chair (hence the term) or simply drops where she stood. The period of unconsciousness is brief (1–10 minutes), and the individual returns to normal consciousness without fatigue, amnesia, or other seizure-related signs. The cause of this folk disorder is unknown and little biomedical research has been conducted on it (save a few case studies that used the Draw-A-Person and Rorschach tests to attribute it to hysteria), despite its prevalence among African Americans. This folk disorder is so common that it has given rise to the Black colloquialism "to fall out" (e.g., "I fell out" or "We fell out"), meaning to laugh so hysterically that one falls out of a chair and rolls on the floor (Landrine & Klonoff, 1996a).

Worriation. Worriation (the name used by Blacks), or nerves (*ataque de nervios*, the name used by Latinos), is a folk disorder specific to Black, Latino (Mexican, Central American, and especially Puerto Rican), and some Afro-Caribbean women (Camino, 1989). An enormous number of studies have been published on this folk disorder and emphasize its symptoms (e.g., Hill, 1988; Hill & Matthews, 1981; Nations, Camino, & Walker, 1988), and epidemiology (e.g., Davis & Whittin, 1988). Its symptoms are those of severe anxiety disorders (e.g., anxiety, panic attacks) and include marked somatic complaints. Some of the somatic symptoms (e.g., vague aches and pains, dizziness, heart racing, "jittery" stomach) are seen in anxiety disorders, whereas others (e.g., sudden rashes on and itching of the feet) may not be, and are presented frequently enough to raise questions about the ostensible psychiatric nature of this disorder. Although women exhibiting this disorder typically attribute it to excess stress or worry (hence the name), the cause has not been identified. Underlying endocrinological disorders (e.g., thyroid or adrenal dysfunctions) and lupus, both of which are exacerbated by stress and manifested in anxiety and rashes, are possibilities (see Klonoff & Landrine, 1997b) that have yet to be investigated.

NATIVE AMERICANS

The term *Native American* is used to refer to a culturally heterogeneous and geographically dispersed population that descended from the indigenous peoples of North America. The Native American population has been categorized in a variety of ways, including classification into 365 state-recognized tribes, 200 tribal language groups, and 511 distinct cultural/political groups recognized by the federal government (U.S. Bureau of the Census, 1983; LaFromboise, 1993). Because data on this plethora of groups cannot be summarized here, the focus is on the health beliefs and practices of Navajo and Crow tribes as more or less prototypical of the Native American population as a whole. There has been a great deal of contact among (and consolidation of) Native American tribes, resulting in overlap in health beliefs and practices that

render the Navajo and Crow examples here representative of the population as a whole.

Studies of Health Problems of Native Americans

Major overview studies of Native American health are provided by Manson (1982), Manson and Dinges (1988), and Sievers and Fisher (1981). The major health problems of Native Americans are high rates of obesity and diabetes (Nelson et al., 1988; Pettit, Baird, Aleck, Bennett, & Knowler, 1983; Savage & Bennett, 1992; Sievers & Fisher, 1981); heart and cardiovascular disease (Coulehan, 1992; R. F. Gillum, 1988; R. F. Gillum, B. S. Gillum, & N. Smith, 1984); gall bladder disease and cancers of the gall bladder and biliary tract (Boss, Lanier, Dohan, & Bender, 1982; Hampton, 1992; Morris, Buechley, Key, & Morgan, 1978; Weiss, Ferrell, Hanis, & Styne, 1984); alcohol abuse (LaFromboise et al., 1995; May, 1982; Greig, P. S. Walker, & R. D. Walker, 1992; Weibel-Orlando, 1984); fetal alcohol syndrome (May, 1992); cirrhosis (USDHHS, 1996); depression and suicide (LaFromboise et al., 1995; Red Horse, 1992; Shore & Manson, 1981); and cervical and lung cancer (S. W. Jordan & Key, 1981; Gottlieb & Husen, 1982; Lanier & Knutson, 1986). High lung cancer rates are due to increased cigarette smoking and to working in uranium mines. The leading causes of death among Native Americans are shown in Table 51.1.

General Cultural Factors Influencing Health Behavior

Two of the many global cultural factors that influence the health behavior of Native Americans are racism and distrust of Whites, and the belief in noninterference.

Racism and Distrust of Whites. All of the ethnic groups discussed in this chapter have experienced profound White racism, oppression, and exploitation, which form a larger historical and social context from which health behavior, morbidity, and mortality are not readily separated. For Native Americans, this racism has taken the form of confiscation of tribal lands; slaughter and extermination on a scale equivalent to attempted genocide; and treaties formed but then broken by the U.S. government, culminating in the relegation of Native Americans to impoverished Indian reservations that are both ghettos and internment camps (LaFromboise, 1993). This history, coupled with the continuing "missionary zeal" of White professionals (who wish to rescue the "backward" Indians from their ways) have led to a deep distrust of White health professionals (LaFromboise, 1993). Isolated incidents of Whites who were trusted and then violated that trust (e.g., the White teacher who from 1979 to 1988 molested 94 Native American children at a reservation school) only increase that distrust and increase Indian reticence to seek help from any outsider (LaFromboise, 1993). The role of this history and social context in Native American health status and help seeking has yet to be fully investigated; it must be suspected, however, that it contributes significantly

to Native American high rates of depression, suicide, and alcohol abuse.

Noninterference. Whether Native American cultures are characterized by the goal of living an artful (Acoma), peaceful (Hopi), or beautiful (Navajo) life, all are devoted to achieving and maintaining tranquility, cooperation, unselfishness, giving, kindness, respect and appreciation for all life forms, and communion with the land and nature from which people cannot be separated (Bryan, 1985; Hoxie, 1989; LaFromboise et al., 1995; Witherspoon, 1970, 1973, 1975). The profound significance of appreciating and respecting all living things and regarding all life forms as sacred cannot be overstated, and is manifested in a noninterventionist philosophy. This is the belief that people should leave things alone out of respect and appreciation for who and what they are; that deep affection consists of not intervening, disturbing, manipulating, or changing; that those who truly regard others and the planet as inherently priceless will "mind their own business" and let things be. Although this philosophy and these values have obvious benefits, there are negative implications as well. For example, this live-and-let-live philosophy is manifested in a laissez faire approach to the weaning and toilet training of children, as well as in a high tolerance for physical and psychiatric symptoms in others, with subsequent delays seeking treatment (Dinges, Trimble, Manson, & Pasquale, 1986). When coupled with the reticence to seek treatment from outsiders because of a social and historical context of White racism and missionary zeal, the delays in help seeking can be serious (Dinges et al., 1986; LaFromboise, 1993).

With these two general factors in mind, the next sections review the evidence on Native American health beliefs and practices, and highlight the Navajo and Crow as prototypical examples.

Navajo Indians

The Navajo are the largest Native American tribe (Deuschle, 1986), and are more likely than other tribes to be urban, with 54% of Navajo residing in major cities (Taylor, 1988). Along with the increasing urbanization of the Navajo, there has been a corresponding steady decline in urban, traditional Native American health care centers in the past two decades, leading Navajo to appear increasingly in biomedical settings for care (Campbell, 1989), and hence to be the Native Americans most likely to be encountered.

Beliefs About Illness

Like the other sociocentric cultures discussed here, the Navajo view health holistically, and hence do not draw distinctions between physical, spiritual, and social entities, or between religion and medicine (Avery, 1991; Deuschle, 1986; Kunitz & Levy, 1981). Harmony, or balance, among the physical, spiritual, and social faces of reality are understood as the foundation of health, and imbalance in these is central to illness. Disruptions in balance and harmony, along with the influence of a diversity of natural and supernatural

forces, are the only causes of illness recognized by traditional members. In the Navajo language, there are no words for or concepts relating to microscopic disease-causing agents (Frisbie, 1987; Kunitz, 1981; Kunitz & Levy, 1981; Sorrell & B. A. Smith, 1993). The major proximal causes of illness recognized are violation of a behavioral taboo, witchcraft, soul loss and spirit intrusion, ghosts, and natural phenomena (thunder, lightning, animals), the set of which are sometimes called the negative values (Adair & Deuschle, 1970; Avery, 1991; Deuschle, 1986; Frisbie, 1987; Kunitz, 1981; Kunitz & Levy, 1981; Sorrell & B. A. Smith, 1993).

Breach of Taboo. Some form of breach of taboo is the most frequent and most powerful cause of illness recognized, and is believed to play a role in all illness irrespective of other causes. The two types of breach of taboo are engaging in prohibited acts (e.g., incest), and contact with taboo, dangerous (disease-producing) objects; such breaches then cause illness through several complex causal chains. For example, sibling incest is understood as the cause of generalized seizure disorder, but may or may not be assumed to have been committed by children with that disorder. This is because grand mal seizure disorder also is called "Moth sickness" due to the belief that the moth is the principal etiological agent. According to folk beliefs, the original incest between siblings was committed by the Butterfly People in the mythic past who twisted and convulsed like moths in a flame. By virtue of the belief that "like causes like" (that causes and their effects are similar), people who exhibit convulsions are understood as behaving like a moth and hence as suffering from "Moth sickness," whether or not they engaged in sibling incest. Similarly, it is believed that a witch can cause people to touch a moth or make the people "wild," such that they act like a moth; these people will eventually commit sibling incest and develop grand mal seizure disorder. Hence, although breach of taboo is understood as the cause of convulsions, the path from breach to symptom may be complex and indirect. Indeed, Navajo believe that one major cause of illness in adults is a breach of taboo committed by their mothers when pregnant with them (Avery, 1991; Deuschle, 1986; Frisbie, 1987; Kunitz, 1981; Kunitz & Levy, 1981).

Witchcraft. Witchcraft is understood as another common cause of illness and takes three forms: witchery, frenzy witchcraft, and sorcery. *Witchery* is the primary form of witchcraft among the Navajo and is mentioned in their creation myths. Witches always are associated with the dead (taboo dangerous objects) and with incest (taboo behavior), and hence witchery entails a breach of taboo. To become a witch, a person must kill a relative (a sibling usually) and eat part of that person's body; witches are also said to live in incestuous unions. Witches work their evil by touching their intended victim with a powder made from the flesh of corpses (thereby bringing the victim into contact with a disease provoking taboo object), and by transforming themselves into animals and manipulating their victim's behavior; hence, witches cause disease by manipulating their victims into breaching a taboo. *Sorcery* is similar to witchery, but sorcerers use their victims

nails, hair, or other excreta to cause disease. Because these bits of the victim are understood as possessing the victim's characteristics and as a proxy for the person, things done to them are believed to happen to the person. These bits of the victim are exposed to dangerous (etiologic) taboo objects (e.g., lightning, graves), thereby forcing the victim to unwittingly breach a taboo and become ill. Finally, *frenzy witchcraft* entails ingesting the datura plant, which contains scopolamine and hyoscyamine and produces hallucinations and other psychiatric symptoms that are summarized by the folk term "frenzy." This form of witchcraft is used to manipulate women so that they can be seduced and manipulate men into gambling away their savings; in all cases, the victim unwittingly breaches a taboo during the frenzy and hence becomes ill (Adair & Deuschle, 1970; Deuschle, 1986; Kunitz, 1981; Kunitz & Levy, 1981).

Soul Loss A person's soul, or "wind" (*honich'ih*, Holy-Spirit-Wind; see Haile, 1943, and McNeley, 1973), is understood as entering the body immediately after birth and departing to the afterworld at death; at both of these points the wind-soul is understood as only loosely attached to the body and so able to detach readily without disease implications. Thus, ghosts of dead elderly or infants have no health implications, whereas ghosts of those who died when the wind-soul was firmly attached to the body are believed to cause disease in others. This concept is somewhat similar to the loss of soul discussed for other ethnic groups previously here. *Spirit Intrusion* refers to the possession of a person's wind-soul by an evil supernatural spirit; this is said to be manifested in disease. *Ghosts and evil spirits* also are believed to cause illness (the ghosts of departed relatives in particular). Finally, *natural phenomena* understood as disease provoking include whirlwinds, water, hail, animals, and lightning. Lightning is considered particularly pathogenic and includes all things that are slender or move in a zigzag pattern like lightning (e.g., snakes, arrows). A diversity of animals are believed to cause disease, including bear, coyote, snake, ant, moth, insects, certain reptiles, and all fish (Adair & Deuschle, 1970; Kunitz, 1981; Kunitz & Levy, 1981).

Indigenous Healers and Healing Practices

Traditional Navajo religion focuses on maintaining harmony and tranquility among people, the supernatural, and the earth. Because illness is understood as disharmony, religion and religious rituals are health oriented, and there is no distinction between religion and medicine. Although there is considerable religious diversity among the Navajo, the Native American Church (peyote-ism) dominates. This religion began among the Comanche Indians in the 1930s, and then spread to an enormous number of other tribes (other Plains Indians as well as tribes of the prairies and Rocky Mountains; Kunitz, 1981; Kunitz & Levy, 1981). The brevity (one night vs. the traditional eight nights) and ensuing low cost of the healing ceremonies of the Native American Church (relative to the lengthy, expensive traditional ceremonies of most tribes, including the Navajo) account for its birth during the Depression and its con-

tinued expansion and popularity. The healing practices of the Native American Church entail far more than ingesting peyote, and include reintegration of the symptomatic individual into the community, ritualized group confession, atonement, social support, advice, prayer, and caring.

As indicated by earlier examples, all sociocentric cultures draw few if any distinctions between religion and medicine. Importantly, however, this means that health beliefs and healing rituals are sacred and consecrated. Hence, whereas other ideas may change, health beliefs and practices remain stable, and little incorporation of biomedical concepts occurs despite education and acculturation (Adair & Deuschle, 1970; Deuschle, 1986; Kunitz, 1981; Kunitz & Levy, 1981). For example, although Navajo recognize that some diseases are contagious, their own system of folk medical beliefs does not include any etiologic agents that could cause a contagious disease (Adair & Deuschle, 1970). Likewise, many Navajo have contact with biomedical views through the Indian Health Service (IHS)⁶ and many increasingly select mainstream health careers (Haller & Aitken, 1992). Nonetheless, biomedical beliefs are understood but not adopted; they are viewed (and respected because all knowledge is respected) as White knowledge and beliefs that are good for White people, whereas Navajo knowledge and beliefs are good for Navajo. Thus, Adair and Deuschle (1970) and Medicine (1981) found no evidence of incorporation of biomedical views or curing techniques among Navajo ceremonialists, despite the long presence and influence of the IHS. Biomedical services are used by Navajo because of the belief that only White medicine can relieve the symptoms of certain (usually infectious) diseases. Biomedical interventions and drugs are understood, however, as merely alleviating the symptoms, rather than as truly curing the underlying cause of disease; the underlying cause is understood as detailed earlier and only cured by a traditional ceremony (Adair & Deuschle, 1970; Kunitz & Levy, 1981).

Traditional healers play a prominent role in all Native American cultures (e.g., Jilek, 1974a, 1974b; Sandner, 1978, 1979) and are known as medicine men and women, witch-doctors, shamans, or native healers, as well as by indigenous labels such as *angakok* (Eskimo) and *wiscaca waka* (Lakota). Navajo traditional healers (or ceremonialists) perform healing ceremonies called sings (Sandner, 1978, 1979). These are sacred, curative rituals that aim to restore harmony (to treat the underlying problem) rather than to remove symptoms per se (Frisbie, 1987), and require from 6 to 10 years to learn (Kunitz & Levy, 1981). A sing entails prayers, chants, and social support. Practices of medicine men and women include diagnos-

ing the cause of disharmony and then restoring it through a combination of sings, herbal remedies, massage and other physical manipulations, sand paintings, and dancing rituals (Avery, 1991; Deuschle, 1986; Kunitz, 1981; Kunitz & Levy, 1981; Sandner, 1979). Diseases and corresponding sings are named and classified in terms of the etiologic agent understood to be the cause of the problem. Thus, symptoms understood as caused by evil are healed with the Evil Way chant, whereas those caused by wind or lightning are healed with the Wind and Shooting (Lightning) Way chants, respectively. There are many of these sings, each for a specific physical or psychiatric symptom, including the Night Way, Plume Way, Earth and Beauty Ways; the Life Way and Flint Way (for injuries and chronic physical disorders); and the Coyote Way, Hand Trembling Way, Frenzy Witchcraft Way, Moth Way, Mountain Top Way, and Twirling Way. These are used prior to and conjointly with biomedical services.

Traditional healers and ceremonialists from neighboring tribes (e.g., Hopi) often are invited to participate in Navajo healing rituals (Kunitz, 1981; Kunitz & Levy, 1981). Such cooperation among a diversity of tribes, along with participation in the transtribal Native American Church, in part accounts for the similarities in the health beliefs and practices of many Native American tribes. In addition, the 1934 Indian Reorganization Act permitted reservation peoples to reorganize for the purpose of self-government, and led to the formation of large, cooperative, consolidated reservation-based groups composed of several tribes. Although these cultural/political groups are now referred to as tribes, they are not tribes in the traditional sense. Examples of consolidated tribes include the Kiowa-Comanche-Apache, Cheyenne-Arapaho, and the Northwest Affiliated Tribes (Deloria, 1983). Such overlap and cooperation has resulted in similarities in health beliefs and practices. Although the health beliefs and practices of the Sioux (composed of 15 distinct tribes), Chippewa (composed of 19 distinct tribes), Potawatomi (composed of 4 distinct tribes), Crow, and Navajo are not identical (and there is considerable variance within each of these groups as well), the underlying principles, values, spiritual nature, and healing caring practices of Navajo and Crow health systems are representative of others. Navajo ceremonialists, like the traditional healers of many cultures discussed thus far, are older, wise people whose power to heal is understood as magical and/or sacred in origin. This power permits the indigenous healers of many cultures, the Navajo ceremonialist included, to make an immediate diagnosis simply by looking at the patient. Hence, long diagnostic interviews and testing are unusual and cast aspersions on the competence of biomedical practitioners (Kunitz & Levy, 1981).

There are almost no studies of the extent to which Navajo comply with biomedical treatment (Kunitz, 1981; Kunitz & Levy, 1981), although there are several indicating that incorporating Navajo beliefs and practices increases compliance (Atteneave, 1974; Deuschle, 1986; Fleming, 1983; Frisbie, 1987; Jilek, 1971; Manson, 1982; Manson & Dinges, 1988; Sorrell & B. A. Smith, 1993). For example, in some settings, medicine men have been permitted to perform sings in patients' rooms with the family attending (Frisbie, 1987), and in

⁶The IHS is the major federal agency charged with providing health care to Indians (*forever*) in exchange for Indian lands captured or surrendered to the U.S. government in treaty agreements throughout the late 1800s and early 1900s. Originally administered by the war department, the IHS was transferred to the Department of the Interior's Bureau of Indian Affairs, and then was established in 1955 as a division of the PHS. General medical and surgical services have been provided by the IHS since its inception, and mental health services were added in 1965. The IHS is the major provider of health services for all Native Americans irrespective of residence (cities vs. reservations), directly or indirectly through subcontractors.

others traditional and biomedical healing rituals have been used conjointly, with patient compliance and rate of recovery enhanced in both cases (Deuschle, 1986). Similarly, Frisbie (1987) discussed many successful ways in which Native American health practices and beliefs have been accommodated by biomedical settings, including establishing a Native Science Healing Room (designed by two singers) at the Gallup, New Mexico, Medical Center. Less dramatic efforts that nonetheless increase compliance include assuring patients that blood and urine samples will not be used for witchcraft, describing how such samples will be disposed of, and having medicine men bless both in- and outpatient facilities to ward off the ghost infections that result from prior deaths in or associated with the setting (Sorrell & B. A. Smith, 1993). Evidence also suggests that Navajo will not comply with treatment without consent of family and permission of the elder woman (Navajo are matriarchal) who makes treatment decisions for tribe members (Deuschle, 1986; Sorrell & Smith, 1993).

Thus, unlike the many other cultural groups discussed here, Native American indigenous healers and healing ceremonies (from a diversity of tribes) have been treated with (a modicum of) respect by biomedical practitioners, and efforts have been made to integrate these into mainstream care in order to increase patient compliance and recovery (Atteneave, 1974; Fleming, 1983; Haller & Aitken, 1992; Jilek, 1971; Manson, 1982; Manson & Dinges, 1988). Physicians, psychotherapists, and nurses often attend traditional healing ceremonies and medicine men are invited to participate fully in case conferences and treatment planning and delivery (Atteneave, 1974; Bergman, 1971, 1973a, 1973b; Haller & Aitken, 1992; Jilek, 1971; Manson, 1982; Manson & Dinges, 1988). Indeed, two schools designed to train biomedical practitioners in Native American healing have been established and funded by the federal government (Bergman, 1971, 1973a, 1973b) for mental health professionals. Some (e.g., LaFromboise, 1993) have attributed these unique cooperative efforts to the 1978 American Indian Religious Freedom Act (PL 95-134), which guarantees these ceremonies the same protection granted to other religions under the constitution. However, many of the healing cults of other minorities (e.g., African American *voodoo*) have been recognized as religions and churches since the 1940s (Simpson, 1978; Tallant, 1946) and yet their traditional healers are rarely similarly integrated into biomedical settings and services or afforded respect as experts. The difference may be that White Americans have hostile attitudes and feelings of cultural superiority where people of African and Latino descent are concerned, but have romantic fantasies and mythical beliefs about Native Americans that render them alone an attractive, desirable, exotic-primitive minority group (Deloria, 1983). Native American scholar Vine Deloria Jr. (1983) argued that such fantasies, along with considerable guilt about the historical treatment of Native Americans, account for the common tendency of Whites to claim Indian ancestors (e.g., that there is an "Indian princess" in their family line). Such fantasies account for the respect afforded to Native American healers as well: Whites do not proudly proclaim fantasized, Black or Mexican ancestors, and White health professionals similarly

have exhibited little interest in consulting with indigenous healers of these cultures (Landrine & Klonoff, 1996a).

Crow Indians

Health Beliefs, Practices, and Healers. Like the other cultures discussed here, Crow Indian health beliefs are characterized by holism and hence entail no distinctions among physical, spiritual, and social realities; all entities, processes, and phenomena are intimately connected, might be understood as faces of a single unified process or reality, and thus are in a sense one (Frey, 1987; Hoxie, 1989). Harmony, tranquility, and balance among these various faces of reality is understood as health, and disharmony or imbalance as illness (Bryan, 1985; Buehler, 1992; Frey, 1987; Hoxie, 1989; Vogel, 1970). In addition to such imbalances, illness is understood as caused by evil spirits and other supernatural factors, natural phenomena, and by witches. Crow beliefs about the causes of illness are similar to Navajo beliefs and to those of many other Native American tribes. Rituals, ceremonies, and sacred objects are the major healing practices used by Crow Indians to prevent and cure illness, and entail chants and prayers in a manner similar to those of Navajo and other tribes. There are four major Crow rituals/ceremonies:

Sun dances consists of fasting, praying, and dancing for 3 to 4 days to heal illness or injury, and are conducted conjointly with treatment from a medicine woman/man who uses sacred objects (usually a sacred eagle feather fan).

Prayer rituals are used for prevention and healing, and are conducted by a family member under the guidance of a medicine woman/man or clan aunt/uncle.

Smudging rituals are part of the prayer rituals in which sacred herbs are burned to ward off the malevolent spirits understood to cause illness; this practice is particularly common when hospitalization occurs and is conducted in the hospital.

Sweat baths (sauna) are used by Crow and by many other Plains Indian tribes for healing and preventing illness (Bryan, 1985; Buehler, 1992; Frey, 1987; Hoxie, 1989; Vogel, 1970).

Sacred objects used for preventing and healing illness and injury include amulets, tobacco, peyote, and various herbs. For example, herbs such as cedar and sage, are used in Smudging Rituals and also are hung over doorways to prevent illness by warding off malevolent spirits. Tobacco smoke is used in Sun Dances, and peyote is ingested during other sacred rituals. Among the diversity of amulets, the most common is the umbilical cord pouch, a small, leather pouch in which one's own umbilical cord is stored to protect oneself from illness and to assist individuals in finding their true life path; umbilical cord pouches are worn by traditional and transitional (bicultural) Crow alike (Bryan, 1985; Buehler, 1992; Frey, 1987; Hoxie, 1989; Vogel, 1970).

Crow indigenous healers are spiritual/religious leaders who are understood as possessing a sacred, magical power to prevent and heal specific illnesses, and clan aunts and uncles also maintain the health of clan members. The clan is the ma-

major social unit of Crow culture, with each person being a member of one of eight matrilineal clans. Each clan has one or more clan aunts/uncles who provide "spiritual mediation" (a combination of Prayer Rituals and Sun Dances) to achieve recovery from illness and solve social and other problems. These cultural healers and healing practices are consulted and used prior to seeking help from biomedical practitioners (Buehler, 1992). Even those who label themselves as transitional (bicultural) or modern (acculturated) Indians use traditional healing and healers conjointly with biomedicine (Frey, 1987) because traditional healing is sacred and cannot be rejected anymore than religion can be rejected. These healers, along with the Crow population, represent many different religions. Individual Crow may belong to one of several Christian denominations as well as one of the many Crow Churches (such as the Tobacco Society and Sun Dance Religion), or they may belong to the Native American Church. Each of these churches has its own additional, highly specific health beliefs and practices, although all such beliefs entail attributing illness to imbalance/disharmony and to the actions of malevolent spirits and supernatural entities. Although it is clear that Crow (and other Indian tribes) use the biomedical services provided by the IHS, we found no data on their compliance with treatment.

SUMMARY

Similarities Among Minority Groups

Table 51.2 provides a summary comparison of the major health beliefs and practices of American minorities that were detailed in this chapter. As shown, there is remarkable similarity among minority groups in their holistic assumptions, definitions of health, causal attributions for illness, folk disorders, and types of healing provided by indigenous healers, with some of these factors being identical. These striking similarities are not coincidences, but rather they reflect the worldview of sociocentric cultures.

As noted here, across the globe and across cultural groups within the United States, two distinct worldviews (or metaphors we live by) can be identified. The first is the (mind/body, self/other, and person/environment) holism of sociocentric cultures, and the second is the dualism of more egocentric (individualistic) White Western cultures. When holism is the basic assumption of a culture, it is necessarily the case that balance is emphasized, and that maintaining emotional, bodily, interpersonal, spiritual, and universal harmony (homeostasis) is viewed as essential to health. Likewise, in the context of holism, the boundaries between body and the world are so thin that natural and supernatural entities and forces readily traverse it. Thus, there is necessarily a high degree of interaction between body and others, body and the environment, body and mind, and body and spiritual/universal forces. Consequently, such factors, along with interpersonal relations, gain primacy as etiological agents. Thus, the hot/cold theory of disease, and a belief in the etiological significance of spirits, natural and supernatural entities, interpersonal relations and of emotions hold across sociocentric

cultures, and disease has social and moral implications. This holism stands in stark contrast to White Western dualism in which the body is understood as separate from the mind, others, the environment, and the gods/universe. In the context of such dualism, disease is primarily understood as the unidirectional invasion of alien forces that break through defenses to attack the body as nation-state. Thus, the many differences between the cultures of minorities and that of the dominant group in our society where health beliefs, practices, and behavior are concerned are predictable from the framework of holistic versus dualist worldviews.

Of particular importance is the difference in the etiological significance of emotions in these two worldviews. In sociocentric cultures, emotions are viewed as integrated with bodily and social processes, and indeed in many cultures are viewed as localized to specific regions of the body. Hence, physical events (diseases) have emotional and interpersonal implications (and vice versa). Alternatively, in the West, even within the "new holism" of contemporary health psychology, emotions are still nonetheless basically understood as psychological processes that can be readily distinguished from bodily and environmental events. Hence, although it is increasingly believed that emotional and interpersonal events can have physical implications, disease nonetheless is understood as a physical (rather than a moral, spiritual, and social) event (Fabrega, 1974; White & Marsella, 1982). Thus, minorities—but not Whites—view illness as shameful because of its moral/spiritual implications, and as a family rather than as an individual event. This difference between the true holism of sociocentric cultures and the pseudo-holism (beneath which dualism persists) of Western biomedicine becomes problematic when those who participate in holism are treated by those who participate in dualism (Fabrega, 1974; Hare, 1993).

A Preliminary Theoretical Model of Minority Health

The information presented in this chapter (and the striking similarities among minority groups) suggest a tentative, theoretical model of the role of cultural variables in minority health, depicted in Fig. 51.1. As noted in the Introduction, social status variables such as poverty and low education obviously play a role in the health status and behavior of minorities and so are included in the model, but as distal predictors only. Distal predictors are variables that the set stage (are necessary) for but are not sufficient to predict morbidity, mortality, or health behavior; such variables act indirectly as a diathesis. Hence, for example, although poverty plays a role in high rates of cigarette smoking, obesity, hypertension, and failure to exercise among Blacks, these health problems also persist irrespective of social class, education, and occupation, such that status variables alone do not account for them. Poverty and low levels of education are then distal predictors that play an indirect role in the health status, behaviors, and problems in question and account for only a small percentage of the variance. These social status factors play a role in minority health primarily through their ability to predict access to

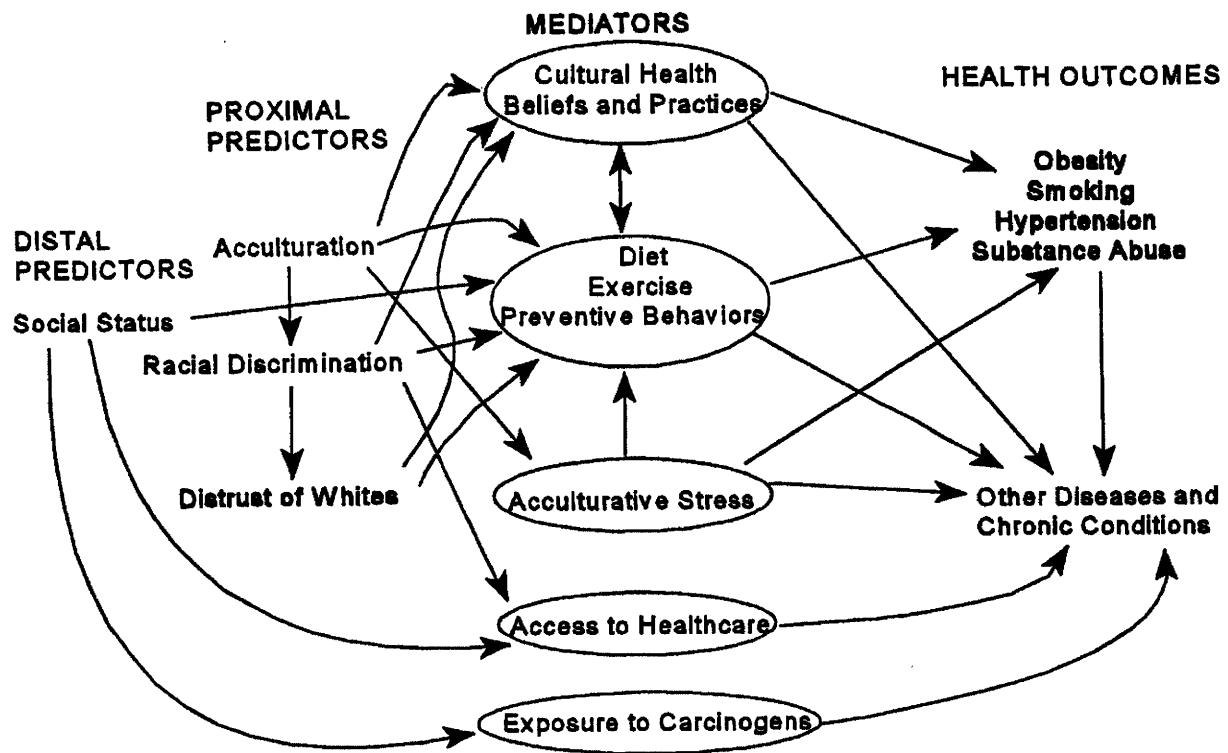

FIG. 51.1. Theoretical model of variables in minority health.

health care and exposure to carcinogens, and do not predict health beliefs and practices.

Proximal predictors, on the other hand, are variables that directly influence health behavior, morbidity, and mortality, and account for the majority of the variance in those. In the tentative model (based on this review), the proximal predictors are discrimination, distrust of Whites, and levels of acculturation. Theoretically, discrimination plays a role in minority health in two ways. First, racist discrimination against minorities may limit their access to care and alter the nature and type of care they receive. In addition, discrimination predicts the extent to which minorities distrust Whites and the health information and programs they provide. This, in turn, in part predicts health beliefs and practices, participation in prevention programs, and other important (mediator) variables. Levels of acculturation also play a role insofar as they predict the degree of participation in the many health beliefs and practices of the ethnomedical systems detailed here. The cultural health beliefs and practices in question then are important (moderator variables and) predictors of health behavior. The three proximal predictors are theoretically related insofar as there is less discrimination against acculturated minorities (who are more similar, culturally, to Whites) than against their traditional counterparts (as was demonstrated empirically; Landrine & Klonoff, 1996a); in turn, discrimination is related to the degree of distrust of Whites and the health information and programs they provide. This model is only a

tentative one, and is provided in an effort to bring coherence to the various factors that impact minority health, and in the effort to place neglected cultural variables in the center of that picture. This model can be used to form specific empirical hypotheses that may better predict minority health behavior and lead to insights regarding tailoring prevention and treatment programs for minorities.

CONCLUSIONS

Landrine and Klonoff (1992) argued that White Western health schema entail the assumption that only health experts have knowledge of illness and of curing. Consequently,

it is often assumed that the curing relationship is one in which a community of experts brings information and health care to a lay community for which both are lacking. Western cultural concepts of "delivering" and "providing" "service" and "care" to "recipients" and "target populations" who may not "comply" with "treatment regimens" highlight the [Western] representation of the victim of illness as a knowledgeable, empty container into whom both reified illness and reified cures are poured. (Landrine & Klonoff, 1992, p. 268)

It was argued that this null hypothesis view of minorities is incorrect because minorities, instead, are participants in living,

complex, dynamic cultures, each of which has its own, centuries-old system of folk medicine. This chapter has provided a mere glimpse of those systems of ethnomedicine to demonstrate that minorities have—not nothing, but—a wealth of health information, beliefs, practices, services, and care within their own communities. It then seems self-evident that the interventions of health psychology and related disciplines must be adapted to fit within these preexisting, indigenous cultural frameworks if they are to be successful. This is particularly because these preexisting systems of ethnomedicine cannot be dismissed, because they are neither trivial, limited to a few members of the culture, nor limited to conceptualizing and treating folk disorders. Rather, they are alive and dynamic in the sense that they continually adapt to and incorporate new biomedical diseases and cures to render them coherent for the culture's members. Thus, for example, Haitian Americans have incorporated AIDS into their preexisting health framework, and understand the disease as a punishment for taboo behavior, most likely to appear in those who have a diathesis of "bad blood" (Farmer, 1990; Hippolyte, 1993). Likewise, Latinos (*curanderas*, in particular) also have incorporated AIDS into their ethnomedical understandings. Although AIDS is understood as caused by a virus that can be transmitted sexually and perinatally (the "how"), it also is believed to be caused by evil spirits (the "why"), and to occur among those who have a diathesis of exposure to mal aire and a chronic imbalance of hot/cold (the "why"; Flaskerud & Cavillo, 1991; Rivera, 1990). Similarly, African Americans have incorporated AIDS into their preexisting ethnomedicine, and, although they likewise understand its viral etiology (the "how"), they nonetheless view it as an "unnatural illness" strongly tied to taboo behavior and punishment for it (the "why"; see Flaskerud & Rush, 1989). Systems of ethnomedicine are alive, dynamic, and highly adaptable to biomedicine, and biomedicine must become similarly dynamic and adapt to ethnomedicine.

Research Suggestions

Racism. This review indicates that racism plays a role in minority health, and warrants serious scientific attention. Racist discrimination may play a direct role as a culturally specific stressor that impacts smoking, alcohol use, diet and other health-related behaviors as well as immunological functions, just as other stressors do. The Schedule of Racist Events (SRE; Landrine & Klonoff, 1996a, 1996b) can be used to investigate the role of racist events in Black health, and may serve as a model for future scales to assess racist discrimination and its health impact for other minority groups. Investigations of the frequency and prevalence of racist events in the lives of all minorities, and of their role in health behavior and morbidity, are obviously long overdue. Studies of how minorities cope with racist discrimination are also needed insofar as coping may mediate the racist stress-symptom relationship.

Studies of the role of ethnic discrimination in minority health are important not only because of the variance that such discrimination no doubt accounts for, but for an additional reason as well, namely: Ethnicity is more than a marker

for culture and history. It is also a marker for a plethora of social, contextual, and structural inequalities, deprivations, and processes strongly related to health. To fully elucidate the factors underlying differential morbidity and mortality by ethnicity, studies must address this social aspect of ethnicity along with the cultural dimension. The role of long neglected cultural variables in the health of minorities should and indeed must be examined, but "in the context of families embedded in a wider societal context conditioned by federal policies that enable or constrain public health programs and community development" (Harrison, 1994, p. 93). To focus solely on cultural variables is to deny "that health and health care are situated in a wider social context structured and constrained by principles of racial [and ethnic] hierarchy and forces of racism" (Harrison, 1994, p. 93). The danger in focusing on the role of cultural factors in the health of any ethnic-minority group is that research may take a "victim-blaming" turn (Hoff, 1994) in which the consequences of ethnic stratification, deprivation, and exploitation are erroneously attributed to the "culture" or the cultural "lifestyle" of politically and economically subordinate groups. "Victim-blaming is alive and well" in health psychology and related disciplines (Hoff, 1994, p. 96), but can be combated by focusing on both the social and the cultural dimensions of ethnicity via examining culture within the context of ethnic stratification, prejudice, and discrimination.

Distrust of Whites. Likewise, investigations of the role of distrust of Whites (secondary to historical and current racism) also are needed. This review indicates that all minorities distrust Whites to some extent. This distrust no doubt plays a role in seeking and complying with treatment provided or recommended by Whites, as well as in acceptance and trust of health information (and associated prevention programs), and willingness to participate in research and interventions. These studies are particularly needed for Blacks in light of the evidence presented here on the legacy of Tuskegee. Like studies of the impact of racism, investigations of minority distrust of Whites are long overdue, and the absence of both can only be explained as a function of the culture of health psychology and health psychologists.

Health Beliefs. Systematic studies of the prevalence among each minority group of the health beliefs detailed here are badly needed. The extent to which the health beliefs are endorsed, the extent and manner in which they are integrated with biomedical understandings, and the relationship between ethnomedical beliefs and status variables must be understood before the health implications of the beliefs can be carefully examined. Then, the relationship between ethnomedical beliefs and health behavior must be systematically investigated; the latter studies can use any major theoretical model of the belief-behavior relationship (e.g., the health belief model, the theory of reasoned action). What is clear in this chapter is that health psychology's knowledge of people's health beliefs (based on studies of Whites) applies to Whites alone, and bears no resemblance to the beliefs held by American minorities.

Generalizations from studies based on Whites clearly are inappropriate. New instruments are needed to investigate the causal attributions of sociocentric people, and new models of the health beliefs-behavior relationship may be needed as well given the vast differences between holistic and dualistic worldviews.

Folk Healers/Health Practices. Systematic studies of the prevalence among each minority group of the diversity of folk healers detailed here are needed, along with careful examination of the extent to which minorities frequent indigenous healers for care. Presence of and contact with indigenous healers appears to play a role (in some studies cited here) in minority compliance with treatment and so must be assessed.

Folk Cures. Similarly, studies of the nature of the cures used and recommended by indigenous healers are needed, and the extent to which minorities comply with these versus biomedical cures must be assessed. Investigations of the effectiveness of these cures are badly needed and may shed light on their persistence in minority communities. The extent to which minorities experience symptom relief after ingesting herbs and attending prayer meetings cannot be ignored given how frequently these treatments are sought. Likewise, however, studies of the frequency of use of toxic/lethal folk remedies are needed to prevent unnecessary health problems and deaths among minorities, children in particular. The undisclosed chronic use of toxic/lethal folk remedies may play a role in symptoms presented and in recalcitrant health problems among minorities, and must be investigated to better understand minority morbidity and mortality.

Folk Disorders. Analysis of the prevalence, epidemiological distribution, symptoms, and stages of folk disorders is needed. These disorders have been reported reliably by minorities for centuries, and neglect of them cannot be justified. Studies are needed that identify the nature of the underlying dysfunction entailed in these disorders, and no doubt will find that each corresponds to a known (in all probability) or unknown "real" pathogenic process. *Susto*, *mal ojo*, *ataque de nervios*, and worry, for example, may represent a form of posttraumatic stress disorder, or underlying endocrine dysfunction, and other folk disorders appear to correspond to enteric pathology no doubt secondary to the poor living conditions of many impoverished minorities. Investigations of SUNDS are obviously needed, given that it is the leading cause of death for Hmong men. To continue to ignore reliable constellations of symptoms from which many people suffer or die simply because they are exhibited solely by minorities and violate current disease nosologies can only be regarded as racist.

Practice/Intervention Suggestions

Health education, promotion, and intervention programs must be tailored in a manner that renders them consistent with the folk medicine and folk medical beliefs of each minority

group, African Americans included. Unlike other minorities, African Americans alone have been regarded as a cultureless "race" (a genetically distinct group) despite their genetic variability (Landrine & Klonoff, 1996a; Sowell, 1978, 1994). Hence, health-related research on and interventions for them have focused on social variables (such as poverty) and on biological factors presumably correlated with ostensible race. Consequently, African Americans have received more research attention from health psychology⁷ than all other cultural minorities, but simultaneously and paradoxically also have received the least attention to cultural factors in their health. Numerous references have been provided in the section on African Americans to highlight that they have as much of a culture as any other minority group. Their culture clearly includes a long-standing system of ethnomedicine that must be addressed by health psychology. Continuing to ignore minority health beliefs and practices (as most of medicine and virtually all of health psychology do; see Klonoff et al., 1995) by attributing their differences and lack of compliance to their lack of education or poverty cannot continue. Such responses to diversity are racist insofar as they render differences deficits, and are Procrustean efforts to render minorities more or less "White," despite the cultural limbs lost. Efforts to include, rather than dismiss, diversity might use the following guidelines:

1. Culturally specific health concepts can be readily included in treatment suggestions and programs by adding them to biomedical directives. Nothing is lost by suggesting that people engage in the health rituals (prayer, teas, rest) that they intend to engage in anyway, but the biomedical intervention will be perceived as more legitimate because it meets the patient's expectations. Translating interventions into the language of ethnomedicine also may be beneficial. Again, nothing is lost by suggesting that antihypertensive medications (for example) lower blood pressure and unblock chi (for the Chinese), decrease the "heat" in the body (for Latinos), or maintain balance and homeostasis (for all minority groups).
2. Likewise, family members may need to be included in treatment planning and delivery. It may be beneficial to discuss and present health problems as a family issue necessitating action on the family's part. This strategy can be used not only with individual patients, but also in community health promotion and disease prevention programs. Strategies that give control and responsibility for the intervention to family, community, or religious leaders may be similarly useful.
3. Finally, indigenous healers can be incorporated into practice and communitywide interventions as an integral aspect of the intervention.

Each of the previous suggestions is consistent with successful strategies that have been used with traditional Native

⁷We operationalize this as number of articles published in *Health Psychology* 1982-1992, see Klonoff et al. (1995) for an empirical analysis of this by race/ethnicity.

Americans. These strategies have not been applied to other minority groups despite their clear, empirically demonstrated success with Native Americans; adopting these as a general approach to minority groups seems appropriate. When the intervention is for a community, these strategies are likely to be successful because at least some community members will be traditional and endorse ethnomedicine. When the recipient of the intervention is an individual patient, however, the success of these strategies is contingent on assessment of the extent to which that minority patient is traditional and therefore endorses ethnomedical beliefs and concepts. Harwood (1981) suggested asking the following questions as a means for assessing this with individual patients:

- What do you think has caused your problem?
- Why do you think it started when it did?
- What do you think your sickness does to you? How does it work?
- How bad (severe) do you think your illness is? Do you think it will last a long time, or will be better soon in your opinion?
- What kind of treatment would you like to have?
- What are the most important results you hope to get from treatment?
- What are the chief problems your illness has caused you?
- What do you fear most about your sickness? (p. 29)

If patients' answers suggest that they are not traditional in their health beliefs, then the strategies suggested here are not necessary.

The previous suggestions are only a few of the many changes in the content and process of delivering interventions to minorities that are needed. Other changes are contingent on the specific ethnic minority group to whom services are to be delivered, and may require new assessment procedures to (for example) address fears of loss of lien and reticence to disclose symptoms. Each of these recommended strategies is, in a sense, simple insofar as it is readily accommodated by standard, biomedical practice. Simultaneously, however, culturally tailoring programs to minorities in the ways outlined here is not as simple as it might at first seem. This is because the biomedical view of what an illness is (a reified entity housed within an individual) and the sociocentric, holistic concept of illness (a process located everywhere but manifested in an individual) are diametrically opposed understandings. Biomedical health education and disease prevention programs, no matter how culturally tailored and sensitive, necessarily reflect and communicate their underlying, dualistic assumptions, and these are destructive to minority cultural life. As Fabrega (1974) put it:

the spread of modern medicine should be seen, not as a process that simply erodes and takes the place of native views and practices, but rather as a pervasive undermining (with consequent disarticulation) of established modes of thinking, feeling, and behaving. In [sociocentric cultures] conceptions about disease, indeed experiences of and with disease, are isomorphic with those that articulate one's personal identity and also give meaning to social relations.

What is more, all of these form the fabric of what we may term "medical care." It is not surprising, then, that the intrusion of Western medicine into such a setting brings with it more than decreased infant mortality and rates of infectious diseases; it brings with it the destruction of the previously mentioned unity in social relations, body and self. Insofar as it operates through specialized occupational and suboccupational groups (nurses, internists, psychiatrists, surgeons, etc.), medicine tends to segmentalize the person in various ways. Each of these groups has a perspective that is organized by separate premises, obligations, and explanations, all of which are in conflict with native understandings. Problems are somewhat arbitrarily divided into "mental" versus "physical," "social" versus "medical," "Natural" versus "superstitious," thereby producing disarticulations. In other words, what to [sociocentric people] is a single crisis having broad ramifications is in this new system or view a heterogeneous collection of "problems," each of which has a separate cause and locus. In this process of differentiation and specialization, Western medicine ... fragments and undermines the native cultural system. (pp. 246-247)

The difficult task faced by health psychology and related disciplines in this increasingly multicultural society then is not so much that of culturally tailoring interventions for minorities, nor even of creating cooperative systems of care that include both biomedical and indigenous healers and cures. Rather, it is to do so without disrupting the holism that undergirds minority understandings of health, and also provides the web that ties people to each other, and to their environment and their gods. Holism is not a view about health, but rather is a view of life and the universe that is merely reflected in health beliefs and practices. It is holism as a metaphor people live by that we must take care to protect.

Subject Index

A

- Above average effect, 197
- Adherence
 - Dietary, 573
 - Interventions, 576
 - Measures of, 574, 575
 - Medication, 573
 - Patterns of, 572
 - Predictors of, 573, 574
 - Quantitative assessment of, 572
- Affiliation, 202, 203
- African American Acculturation Scale, 852, 866
- Aging
 - Age at disease onset and, 471
 - Definition of normal, 470
 - Depression and, 471
 - Gender and, 471
 - Health related quality of life and, 473
 - HRT and, 472
 - Period/time effects, 470, 471
- AIDS and behavior change, 3
 - Condom use and, 5, 6, 7, 8, 9, 10, 12, 15
- AIDS risk reduction model, 782, 783
- Alcohol
 - Cancer and, 287
 - Cognitive disorders and, 289
 - Crime and, 293
 - Family and, 291, 292
 - Fetal effects and, 289, 290
 - Heart disease and, 286
 - High risk behaviors and, 292, 293
 - Hormonal changes and, 289
 - Hypertension and, 287
 - Injury and, 290
 - Liver disease and, 288
 - Neurochemical mediators, 299
 - Pancreatitis and, 288
 - Peptic ulcer and, 288
 - Role performance and, 291
 - Stroke and, 287
- Alcohol abuse, 281, 282
 - Animal studies of, 298
 - Attention-allocation model of, 303
 - Behavior-genetic research
 - Adoption studies, 295
 - Family studies, 295
 - Genetic marker studies, 296
 - Twin studies, 295
 - Vulnerability studies, 296, 297, 298

- Economic cost, 282
 - Etiology of, 300, 301, 302, 303
 - Familial influences in, 304
 - Mass media effects, 305
 - Psychiatric diagnoses and, 283, 284, 285
 - Stress response dampening model of, 303
 - Tension-reduction hypothesis of, 302
- Alcohol dependence, 281, 282
 - Anger, 65, 66, 71, 72
 - Antigen, 106
 - Appraisal, 68
 - Assisted reproductive technologies (ART)
 - Definition of, 560
 - Psychological consequences of use of, 563, 564, 565
 - Asthma, 451, 452
 - Attribution and effect on illness, 33
 - Attributional Style Questionnaire, 180
 - Autobiographical memory, 406
 - Autonomic nervous system, 85, 86, 87, 92

B

- Behavior change
 - Interventions and, 15
 - Measurement techniques
 - Action alternatives and, 8
 - Attitude measurement, 11
 - Relevant referents and, 7
 - Personal characteristics and, 8
 - Emotional reactions, 13
 - Perceived normative pressure, 12
 - Perceived outcomes and, 7
 - Self-efficacy, 14
 - Self standards and sanctions, 13
 - Stages of change, 5
 - Variables related to, 5
- Behavioral medicine
 - Definition of, 96
- Behavioral prediction, theories of, 4, 5
- Behavioral change, theories of, 4, 5
- Biofeedback
 - Definition of, 87, 96, 97
 - Disorders, 98, 99
- Body Mass Index (BMI), 263

Burnout

- Definition of, 415
- Depersonalization and, 416
- Emotional exhaustion and, 416
- Sources/outcomes of, 418
- Job-person fit and, 420, 421, 422
- Organizational health and, 423
- Reduced personal accomplishment and, 416
- Social support and, 422

C

- Cancer
 - Stress
 - Biobehavioral model of, 709
 - Biological pathways and, 713
 - Bone marrow transplantation and, 716
 - Compliance to treatment and, 712, 713
 - Delay of treatment and, 714
 - Diagnosis and, 714, 715
 - Disease course and, 713
 - Health behaviors and, 712
 - Interventions, 717, 718, 737
 - Perceived risk of, 728
 - Prevalence, 727
 - Quality of life and, 711
 - Recovery/long-term survival and, 718, 719, 720
 - Recurrence/death and, 720, 721
 - Sexual dysfunction and, 719
 - Treatment and, 715, 716
 - Treatment morbidity and, 717
 - Cancer intervention
 - Adult, 758, 759
 - Children, 764, 765, 772
 - Cancer screening
 - Breast cancer
 - Barriers/facilitators, 528, 530
 - Current status, 528
 - Interventions, 531
 - Cervical cancer
 - Barriers/facilitators, 530
 - Current status, 530
 - Interventions, 532
 - Colorectal cancer
 - Barriers/facilitators, 531, 532
 - Current status, 531

- Interventions, 532
- Caregiving
Beneficial effects of, 483, 484
Mental health outcomes of, 480
Physical health outcomes of, 481
Theoretical models of, 478, 479
Work/leisure activities and, 482
- Care receiving
Beneficial effects of, 486
Mental health outcomes, 487
Physical health outcomes, 488
Theoretical models of, 484, 485
- Center for Epidemiologic Studies depression scale, 355
- Citizen participation, 614
- Chronic illness
Childhood
Asthma, 451, 452
Beliefs about illness, 450
Coping and, 391, 395, 396, 397
Demographics and, 395
Environment/culture and, 393
Optimism, 395
Personality and, 394, 395
Positive adjustment to, 388
Social support and, 393, 394
- Classical conditioning, 253
- Closed brain injury, 587
- Cognitive clarity, 202, 203
- Cognitive Errors Questionnaire (CEQ), 125
- Cognitive Social Health Information Processing (C-SHIP) model, 730
- Commonsense model of self regulation, 20, 574
- Community coalitions, 614, 615, 618
- Community intervention
Community development and, 596
Ecological principles and, 594, 595
Empowerment and, 596, 603
Evaluation of, 604
Mass media and, 597
Policy and, 599
Process of, 601, 602, 603, 604
Researchers and, 605
Social cognitive theory, 595
Social ecology perspective, 593
Social marketing and, 596
Strategies of, 598
- Community participation, 619, 620, 621
- Community Trial for Smoking Cessation (COMMIT), 600
- Condition-specific control, 52, 53
- Conditioned health threat, 740
- Conflict Tactics Scale (CTS), 553
- Consortium for the Immunization of Norfolk's Children (CINCH), 613, 615, 616, 617, 618
- Content Analysis of Verbatim Explanation Technique (CAVE), 180
- Control, *see* Perceived control, Locus of control
- Cook-Medley Hostility Scale, 77, 149
- Coping, 181
Childhood chronic illness and, 450
Chronic illness and, 391, 395, 396, 397
Pregnancy and, 504
Transplantation and, 453
- Coronary heart disease
Psychosocial factors
Biobehavioral mechanisms, 663, 664
Epidemiologic evidence, 662
Prevention and treatment, 664, 665
- Counterdependence, 354
- Crowding, 366, 367
Immune function and, 368
Motivation and, 370
- Psychological health and, 368
Psychophysiological studies and, 368
Psychosocial resources and, 369
- Cultural Mistrust Inventory, 866
- Cytokines, 107, 108, 112
- ## D
- Diabetes, adolescents
Dangerous neighborhoods and, 444
Organization in community and, 442
Risk-taking behaviors and, 445
Stage-environment fit model and, 443
- Diet
Barriers to change, 521
Interventions, 521
Overweight and, 520
Practices, 521
- Disability, 582, 585, 586
- Disclosure
Academic functioning and, 342
Affective/well being measures and, 342
Benefits of, 339, 340
Cancer research and, 340
Clinical benefits of, 344
Cognitive and linguistic changes and, 345
Employment functioning, 342
Health reports and, 341
Immune function and, 342
Inhibition and, 344
Short-term effects of, 342
Traumatic memory research and, 345
- Disengagement, 65, 67, 71, 74
- Domestic violence, *see* male partner violence
- Double standard, 790
- ## E
- Ecological momentary assessment (EMA), 410, 411
- Emotional suppression/repression, 65, 66, 67, 71, 73
- Ethnicity
Health status and, 429
Hypertension and, 430, 431
Cardiovascular reactivity and, 431
Coping resources and, 435
Racial stress, 432
SNS effects and, 434
Socioecologic stress and, 433
Socioeconomic status and, 432
Sodium effects and, 434
- Experience sampling method (ESM), 410, 411
- Eustress, 355, 356
- Explanatory style, 180
- ## F
- False consensus effect, 197
- Framingham Type A Scale, 147
- ## G
- Gate control theory, 118, 127, 128
- Gender differences in sexual relationships, 785
- Glasgow Coma Scale, 587
- ## H
- Handicap, 583
- Hardiness, 177, 178, 353
- Health behavior model, 145, 146
- Health belief model, 3, 4, 39, 53, 146, 151, 574, 729
- Health beliefs/practices
African Americans, 865, 868, 869
Folk healers, 869, 870
Folk disorders, 872
Healing practices, 870, 871
Racism/distrust of Whites, 865
Tuskegee Syphilis Experiment, 866, 867
Voodoo, 871
- Asian Americans
Language and indigenous schema, 861
Racism/distrust of Whites, 859
Shaming practices, 860
- Chinese Americans, 861
Folk cures, 862, 863
Folk disorders, 862
Health attitudes, 862
Yin and Yang, 861
- Latino Americans, 852, 853
Emotions, 853
Folk cures, 858
Folk disorders, 855, 856, 857
Folk healers, 857
Hot/cold theory of disease, 854
Racism/distrust of Whites, 853
- Native Americans
Healers/healing practices, 874, 875, 876, 877
Racism/distrust of Whites, 873
- Southeast Asian Americans
Folk cures, 864, 865
Religions, 864
Sudden Death Hmong Folk Syndrome (SUNDS), 865
- Health locus of control, 51, 181, 239
- Hematopoiesis, 106
- HIV, 3, 157
Chronic nature of, 847
Epidemiology of, 778
Highly active antiretroviral therapies (HAART), 842, 843
Psychological adjustment with, 842
Transmission risk behavior, 846
Treatment adherence, 844, 845
Treatment of, 842
- Women
Caretaking and, 824
Drug-related relationships and, 823
Heterosexual relationships and, 822
Lesbianism/bisexuality and, 828
Life stage of, 824, 825
Policy, 831
Pregnancy/parenthood and, 827
Prevention, 829, 830
Research, 831
Sociocultural influences and, 818, 819, 820
Social support and, 823
Social class and, 821
Treatment of, 830
Urban vs. rural settings and, 829
- Hostility, 65, 66, 71, 72, 149, 150, 158
- Hot/cold theory of disease, 854
- Hypertension
Biofeedback and, 704
Environmental manipulation and, 702
Physical exercise and, 701
Placebo/suggestion and, 703, 704
Psychotherapy and, 701, 702
Relaxation therapy and, 704, 705
Sodium intake and, 698, 699
Weight management and, 700
- ## I
- Ideographic Functional Status Assessment, 188
- Illness behavior model, 146, 151

- Illness (Problem) representation**
 Attributes of, 22, 68
 Adolescent transition, 37
 Bidirectionality of emotion, 25
 Coping, 23, 24, 27
 Culture and language, 37
 Emotional responses, 24, 29, 30, 31, 69
 Fear, 21
 Health outcomes, 39, 69
 "hot" cognition, 30, 31
 If-then rules, 28, 40
 Interpreting somatic and social factors, 35
 Later life transition, 38
 Negative affect and symptoms, 26, 27
 Problem solving episodes, 24, 29, 30, 31
 Sharing of, 36
 Social observation-comparison, 36, 37
 Somatic and social factors, 35
 Structure of, 23
- Immune system conditioning, 105, 108**
 Behavioral effects of infection and, 112
 Chemotherapy and, 110
 Stress and, 111
- Immunity**
 Chronic stressors and, 685, 686
 Definition of, 106
- Intervention studies, 688**
 Lab stressors and, 689, 690, 691
 Measures, 685
 Naturalistic stress and, 688
- Impairment, 582**
- Infertility**
 Adjustment among families created by, 565
 Background, 559, 560
 Prevention of
 Delayed childbearing, 566
 Sexually transmitted diseases, 565
 Psychological reactions to, 561
 Stress and coping framework and, 561
- Injuries in childhood, 454**
- Internal-External scale (I-E scale), 51**
- Interoceptive conditioning, 89, 90**
- Ischemia**
 EKG measures of, 670
 Lab studies, 669, 673
 Pathophysiological mechanisms, 674, 675, 676
 Predictive value of, 677, 678
 Prevalence during physical and mental tasks, 671
 Psychological factors in, 672
 Triggers of, 672, 673
- J**
- Jenkins Activity Survey, 147**
- John Henryism, 435**
- L**
- Learned helplessness, 54**
- Life Events and Difficulties Schedule (LEDS), 323**
- Life expectancy, 428**
- Life Orientation Test (LOT), 77, 155, 179**
- Locus of control, 236**
 Definition of, 51, 70
 Limitations, 53
- Lorig's Arthritis Self-Management Program, 245**
- M**
- Male partner violence**
 Attitudes toward women and, 552
 Chronic pain and, 547
 Chronic pelvic pain and, 546
- Definition of, 542**
 Gastrointestinal disorders and, 547
 General prevalence and patterns of, 543, 544
 Misdiagnosis of, 550
 Personal fears and, 552
 Physician involvement
 Personal barriers, 551
 Systematic barriers, 551
 Pregnancy and, 545
 Prevalence in medical care settings, 544
 Protocol in medical departments regarding, 549, 550
 Retraumatization and, 551
 Mapping studies, 781, 782
 Marlowe-Crowne Social Desirability Scale, 77, 150, 156
 Maslach Burnout Inventory (MBI), 416
 Mass psychogenic illness, 201, 202
 Millon Behavioral Health Inventory, 156
 Minnesota Heart Health Program (MHHP), 601
 Multidimensional health locus of control, 181
 Multidimensional health locus of control scale (MHLC scale), 52
- N**
- National AIDS Behavioral Survey, 785**
- Natural Killer (NK) cells, 107, 110, 328**
- Negative affect, 354**
- Neuroticism, 152, 153, 300**
- Nicotine**
 Activity level and, 254
 Attention and, 255
 Body weight regulation and, 254
 Effect on central nervous system, 251
 Neuroendocrine system and, 252
 Neurotransmitter system and, 252
 Reinforcement and, 251
 Self-administration, 250, 251
 Stress and, 256, 257
- Noise**
 Coping behaviors and, 374
 Immune function and, 374
 Methodological problems in research of, 378, 379
 Motivation and, 375
 Physical health and, 371
 Psychological health and, 374
 Psychophysiological outcomes and, 371, 372, 373
- Numeracy, 739**
- O**
- Obesity**
 Definition of, 263
 Morbidity and mortality and, 265
 Prevention of, 268
 Psychosocial consequences, 266
- Open brain injury, 587**
- Open relationships, 792, 793**
- Operant conditioning, 87, 89, 91, 253**
 Clinical application, 91
 Pain behaviors and, 120
- Optimism, 70, 155, 179, 751**
 Chronic illness and, 395
- Orientation to Life Questionnaire (OLQ), 177**
- Outcome evaluation, 71**
- Overdependence, 354**
- P**
- Pain**
 Cognitive factors and, 122, 123
 Cognitive-behavioral model, 129, 130
 Coping strategies, 125, 126
 Diathesis-stress model, 128, 129
 Gate control theory, 118, 127, 128
 Physiological processes, 130, 131, 132
 Unidimensional sensory model, 118
- Pain prone personality, 119**
- Pawtucket Heart Health Program, 596, 601**
- Perceived Competence Scale (PC scale), 54**
- Perceived control**
 Appraisal, 50
 Definition of, 49, 101
 Measurement of, 51, 54
 Operationalization of, 51
 Personal and situational variables, 55
 Placebo effect, 101, 102
 Primary vs. secondary, 50
 Study of, 50, 51
- Perceived health competence scale, 54**
- Perceived risk**
 Breast self examination and, 734
 Comparative risk and, 732
 General determinants of, 733
 Mammography screening and, 734
 Measurement of, 731, 732
 Sun protection and, 736
- Personal Views Survey, 178**
- Personality**
 As a risk factor of illness, 62, 63, 64, 65
 Context, 62
 Chronic illness and, 394, 395
 Definition of, 60
 Five factor taxonomy, 140, 141, 142, 300
 Measurement
 Content, 75
 Content relevance, 76, 77
 Structure, 76
 Stress moderation models, 144
 Structure of, 61, 62
 Type A, 139, 147, 148, 149
- Pessimistic attribution style, 70**
