One of the liveliest areas in the study of adolescent religion involves the sizable, significant, and positive association that teen religiosity has with positive life outcomes such as reduced risk taking, better educational performance, and greater self-confidence. Researchers in psychology, sociology, public health, and economics have investigated this association and concurred that it is both robust and consistent. Scholars have learned that religious adolescents are more likely to stay in school, get better grades, and complete their degrees compared with less religious and especially nonreligious adolescents. They also have learned that religiously devout adolescents have lower rates of risky behaviors, from smoking to alcohol use to sexual promiscuity, than their less religious and nonreligious peers. In addition, they have learned that religiously committed teens are more satisfied with their physical appearance, their relationships with family and friends, and their ability to talk to adults and find support among them (Regnerus, 2003, 2007; Smith, 2005). The explanation for this positive association between religiosity and life outcomes is the subject of considerable debate, but its existence is not disputed.

Scholars know less about religion among children under age 13, and what they do know largely comes through intermediaries. For example, the *Religion* & *Ethics NewsWeekly* sponsored a "Faith and Family in America" poll in 2005 that surveyed a national sample of U.S. households with children. A solid majority of household heads (62%) reported that religion was "very important" to their families, and an even larger majority (74%) indicated that it was "very" or "somewhat" likely that their children would choose as adults to remain in the faith tradition in which they were raised.

This fits with the little that is known from direct surveys of children. In 1989, the Girls Scouts, the Lilly Endowment, and the Harvard psychiatrist Robert Coles joined forces to sponsor a national survey of U.S. schoolchildren as young as 9 years old. One-half of that survey's elementary school age respondents reported that their religion was "very important" to them, another fifth reported that religion was "fairly important," and more than three-quarters affirmed belief in God. Moreover, one-third of elementary school age respondents reported a personal religious experience that "changed the direction" of their lives and one-fifth claimed that "a close relationship to God" was their "most important" goal for the future. Children thus largely follow in their parents' footsteps in religious belief and practice. Although that may be their only option, a sizable minority also chooses to embrace that faith and claim it as their own. Both surveys, as well as the NLSYR, are available from the Association of Religion Data Archives (2008; www.thearda.com).

## SPIRITUALITY IN CHILDHOOD AND ADOLESCENCE

Perhaps it was the prominence of Harvard's Robert Coles and his 1990 book, *The Spiritual Life of Children,* that made spirituality a safe topic for lesser known scholars. Perhaps it was popular campus lecturer Jonathan Kozol's (1995) bestseller about the spiritual lives of Harlem children, *Amazing Grace: The Lives of Children and the Conscience of a Nation,* published five years later, that piqued academics' attention. Perhaps it was the example of Princeton sociologist Robert Wuthnow, *After Heaven: Spirituality in America since the 1950s* (1998), which not only demonstrated how to study spirituality at the macro level but also outlined a half-century of its history in U.S. culture. Or perhaps it was the influence of an assortment of private and federal funding agencies, such as the Templeton Foundation, the Lilly Endowment, and the National Institutes of Health, whose priorities turned to underwriting spirituality research. Whatever the cause, there is no denying the broad and multidisciplinary nature of scholarly interest in spirituality since 2000.

A major area of attention has been defining spirituality and clarifying its relationship to religion. For historians, sociologists, and anthropologists, spirituality generally is defined as "the beliefs and activities by which individuals attempt to relate their lives to God or to [the sacred]" (Wuthnow, 1998, p. viii); this may or may not overlap with individuals' participation in religious organizations or engagement with religious culture. From this broader perspective spirituality and religion are like circles on a Venn diagram that variously overlap across subjects and over time. Other scholars, however, subsume one within the other, with some scholars defining spirituality within the bounds of religion whereas still others define religion as a type of spirituality and spirituality as a dimension of personality. Childhood and adolescence thus present an important place to test these theories. By examining how spirituality and religiosity develop in children and teens, scholars can refine their definitions and draw implications for religious education, human development, and larger understandings of cultural patterns and change.

## CRITICISM AND METHODOLOGICAL DIFFICULTIES

Social scientific research on spirituality is not always well received. Many scholars report that their work is marginalized in their disciplines or that there is outright hostility to it. Some critics question their findings, whereas others are hostile because they hold that religion and spirituality are dying superstitions that have no place in social scientific research. Moreover, the limited sample sizes of most studies of child spirituality and the overwhelming variety of potential spiritual forms make it difficult to draw simple generalizations from this research. There is evidence that this is beginning to change with the publication of three edited volumes (Ratcliff, 2004; Roehlkepartain et al., 2006; Yust, Johnson, Sasso, & Roehlkepartain, 2006) and the emerging scholarly community that these studies represent.

Research on adolescent spirituality is a bit more accepted, as national studies of it in the United States, Australia, and other developed countries have given scholars much to compare (Mason, Singleton, & Webber, 2007). This research, however, has numerous methodological hurdles. In the United States, for example, scholars have documented how many American baby boomers have set out to explore spiritual life (Roof,1993; Wuthnow, 1998), but few contemporary U.S. adolescents find the term *spirituality* meaningful or describe themselves as spiritual but not religious (Clydesdale, 2007; Smith, 2005). This does not mean that U.S. teens reject or lack a spiritual dimension, only that the term is vague and better ways of researching spirituality need to be devised. Thus, issues of measurement and generalizability will remain at the forefront of this field.

## THEORIES AND DEBATES

Beyond the definitional and philosophical debates that surround this field of inquiry, including challenges to the validity of religion and spirituality, there have been a number of scholarly debates. One involves stage theories of spiritual and/or religious development, including arguments among competing stage theorists and between stage and nonstage theorists. Several debates are methodological. One exists between those who give primacy to quantitative methods and those who privilege qualitative research. Another exists between those who view religion as epiphenomenal (i.e., as something that can be explained by other factors, such as social class) and those who view it as a social fact, with the former attempting to demonstrate that religious findings are spurious (i.e., due to chance) and the latter seeking to show that they are nonspurious (i.e., ''real''). This debate is most intense over interpretations of the positive association of religious involvement and life outcomes, with one side arguing that this association is a function of self-selection and social location and the other side arguing that religious involvement provides a variety of resources that directly and indirectly contribute to more positive life outcomes.

Because the study of religion and spirituality is multidisciplinary, larger disciplinary differences also shape debates. Psychologists and many economists privilege the individual in their models of human behavior, whereas historians, sociologists, and anthropologists hold that the whole is greater than the sum of its parts and thus prioritize cultural and social factors. Such differences will persist as long as these disciplines exist. Also, no understanding of religion or spirituality research is complete without acknowledging the wide gap between secularization and religious market paradigms: those who hold that modernization necessarily leads to secularization of religion versus those who hold that modernization creates free religious markets in which religion expands and thrives. The impact of the secularization debate cannot be underestimated—those who concur with secularization models point to lower levels of religiosity among adolescents as signaling secularization, whereas those who concur with religious market models point to persistent youth involvement in religion combined with the return to religion or spiritual exploration later in the life cycle as evidence of vital religious markets.

## MOVING FORWARD

Many of the above debates are intractable, and no additional evidence will convince partisans one way or the other. Important scholarly gains need to be made, however, in four areas: measurement, method, comparison, and interdisciplinarity. First, a greater variety of measures need to be tested, contrasted, and refined. Also, measures need to go beyond counting (e.g., ''How often do you pray?'') to matters of content (e.g., ''Describe your last prayer''), rationale (e.g., ''What outcomes do you seek when you pray?''), and respondent capabilities (e.g., age-gauged questions about prayer). Second, researchers need to diversify their methods. Augmenting a primary method is not expensive—a week spent gathering qualitative data or designing a concise Web survey are well within the resources of most researchers—and such will move scholarship past dead-end methodological debates to more substantive matters.

Third, comparative research is a pressing and widely acknowledged need. Although increasing U.S. religious diversity is attracting scholarly attention to non-Christian religious and spiritual forms, too few non-U.S. scholars or sites are engaged in this issue. Finally, researchers new to the study of religion and spirituality, as well as those long involved, need to do their interdisciplinary ''homework.'' There is much extant scholarship of high quality, and the depth and breadth of religious and spiritual phenomena leaves no room for disciplinary parochialism.

Psychologists need to read beyond psychology of religion, sociologists need to develop a taste for economic scholarship on religion (e.g., Iannaccone, 1998), and so on.

To move forward in scholarly understandings of the religious involvements and spirituality of children and adolescents will require better data, more diverse data, and wider engagement. Although a great deal of good work exists already, much remains to be done.

# RESIDENTIAL MOBILITY, YOUTH

*Residential mobility* is a form of migration that is typically thought of and analyzed as occurring within a particular country. Along with changes in the local environment that occur around children without their movement (e.g., gentrification, urban redevelopment), residential mobility is one of two ways that children's local environments can vary over the course of childhood. This variation can occur either within or across counties and states. It typically involves other family members but can occur independently of family as well. Although migration can and often does occur to or from other countries, in-depth studies of residential mobility usually have a national, rather than international, focus. The reasons for this definition are driven primarily by the availability of data: Because the goal of many studies is to understand not just how common movement is, but what changes accompany that movement, researchers often want to link children to data on specific characteristics of each residence. This level of detail is often only possible within one country.

Why is residential mobility an important part of the early life course? As the following discussion will demonstrate, geographic movement among the young population is very common and often coincides with important changes in family composition and organization, the quality of the local environment, the nature of peer groups, and educational quality. Understanding the causes and consequences of residential mobility in children's lives, as well as trends over time, is therefore an important task.

## PATTERNS OF RESIDENTIAL MOBILITY AMONG CHILDREN AND ADOLESCENTS

Residential mobility has declined slightly over time but remains a common feature of many societies. In 1948, when the United States Census Bureau began collecting information on geographic mobility, about 20% of the U.S. population moved in a 1-year period. In 2003 that number stood at about 14% (Schachter, 2004). Although

overall rates of movement have decreased over time, the distance of moves has increased, with more moves now crossing state boundaries (Schachter, 2004). Families with children are less likely to move than families without children (Long, 1972). Moving rates are higher among children than adults, however: In 2003, for example, 21.4% of children ages 1 to 4 experienced a move, versus 8.6% of adults ages 45 to 54 (Schachter, 2004). Movement among children is also common in other countries, although less so than in the United States (Long, 1992).

## THE SOCIAL DETERMINANTS OF YOUTHS' RESIDENTIAL MOBILITY

Despite the frequency of mobility, there are important differences in which children are most likely to move, both within the United States and in other societies. First, there are noticeable age differences in who moves. Rates of movement are higher among very young children and young adults than among older children and adolescents. Between 2002 and 2003, for example, more than 20% of children ages 1 to 4 and almost one-third of young adults ages 20 to 29 experienced a move, versus 16% and 14% of those ages 5 to 9 and 10 to 19, respectively (Schachter, 2004). These age differences are particularly pronounced in the United States. Rates of movement during the early life course, in both early childhood and young adulthood, are much higher in the United States than in other industrialized nations (Long, 1992).

Many social factors determine the likelihood of movement among children, and also partially explain age differences in children's rates of movement. With respect to the greater tendency of very young children to move, it is important to think about their parents' stage in the life course. Childbearing may change the characteristics that make a particular residence desirable, causing parents to place a higher priority in finding a neighborhood with low crime rates, a good educational system, and spacious housing (Long, 1992; Rossi, 1955). High rates of movement among those transitioning out of childhood—young adults ages 20 to 29—also make sense, because these are the ages at which important changes in the life course occur, including the completion of higher education, employment transitions, and the formation of new families.

In addition to life course transitions among young adults and young parents that explain the higher mobility of the oldest and youngest children, a number of other factors determine the likelihood of geographic movement during childhood. Children who live below the national poverty line are more likely to move than their wealthier peers, as are children whose parents are not married. For both groups of children, reduced economic status and access to the resources necessary to live in certain locations are a source of instability. Children of divorced parents are also more likely to spend time at the residences of multiple family members over the course of childhood, increasing rates of mobility. Poverty and family structure may also influence children's likelihood of movement in combination with one another: Children who live with only one parent are more likely to experience poverty than children in two-parent homes, making their living situation even more economically unstable (South & Crowder, 1998). Particularly high rates of poverty and divorce in the United States, and the economic and occupational instability that accompany them, may also explain higher rates of movement among children in the United States than in other countries.

The type and scale of a child's move are equally important to rates of residential mobility. Although there are not striking differences in rates of movement among Black, Latino, and non-Latino White children, there are large differences in the types of moves that children experience by race/ethnicity. Black children in particular, and Latino children to a lesser degree, are more likely to move from one poor neighborhood to another, whereas non-Latino White children are more likely to transition to wealthier environments (Quillian, 2003; Timberlake, 2007). With respect to the scale of a move, parents' education plays an important role. Children with highly educated parents are not much more likely to move than other children. Among children who do move, however, the distance of the move is greater (Schachter, 2004).

Many factors—including the stage in children's and parents' life course, families' economic well-being, family organization, and parental education—work independently and in combination with one another to determine whether and how far a child will move. These causes also contribute to different patterns of residential mobility across societies. Although the factors discussed are known to be particularly salient in shaping mobility trends, there are other important contributors as well, including urban versus rural residence and housing tenure (Rossi, 1955).

## THE CONSEQUENCES OF RESIDENTIAL MOBILITY FOR CHILDREN

Children can be influenced by residential mobility in both positive and negative ways, which are not yet fully understood by researchers. A change in a child's local environment can be thought of as involving two parts: a move (regardless of its direction) and a change in the quality of neighborhood conditions. With respect to a move, residential mobility may adversely influence children, whether or not it involves an improvement in surroundings. Some researchers, for example, define the number of times a child's household moved while growing up as an indicator

of family stress, and find that this measure is associated with a lower likelihood of high school completion (Haveman, Wolfe, & Spaulding, 1991).

This way of thinking about children's residential mobility assumes that all moves, whether they involve an upward or downward shift in the quality of surroundings, influence children equally. This may not be the case, however, and relates to the second component of a move: the extent to which it involves a change in the quality of a child's environment. Because children consistently exposed to disadvantage may be subject to more adverse influences than those who only briefly experience poor and unsafe surroundings, residential mobility out of a disadvantaged neighborhood may benefit children if it brings access to better housing, more positive peer role models, and a better educational system (Goering & Feins, 2003). This positive change may outweigh the disruptive influence of moving. On the other hand, if children move frequently between similarly poor or wealthy neighborhoods, then the combination of frequent disruption due to mobility and consistent exposure to disadvantage may be harmful to children. Researchers are trying to understand the extent to which children's exposure to disadvantage varies over time due to residential mobility, with the hope of disentangling the potentially different influences of residential mobility and exposure to disadvantaged environments (Jackson & Mare, 2007; Timberlake, 2007).

### IMPLICATIONS AND FUTURE RESEARCH

Much is known about patterns of children's residential mobility in the United States and in other societies. Very young children and young adults are the most likely to experience mobility, and mobility among children of all ages is much higher in the United States than in other industrialized nations. The determinants of residential mobility are also well understood, with clear differences in which children move by families' economic status, marital status, education, and stage in the life course.

Our understanding of the consequences of residential mobility for children's well-being is less developed. Although residential mobility appears to be a meaningful predictor of children's success and well-being, it is not clear if this applies equally to all types of moves. Research in this area is necessary and important in order to gain a thorough understanding of how children's welfare changes over time as they move.

## RESILIENCE, CHILDHOOD AND ADOLESCENCE

Resilience research is guided by the following question: Why do some children experience significant adversity but grow up to be well-adjusted adolescents and adults? Some children are exposed to conditions such as war, poverty, or abuse but are able to overcome these adversities and become healthy, productive members of society, whereas other children exposed to the same circumstances develop mental health problems. Those who achieve positive developmental outcomes in the context of significant risk or adversity are considered to be resilient.

### RESILIENCE CONCEPTS

The study of resilience involves three critical components: risk factors, protective factors, and positive adaptation. A risk factor is a condition, context, experience, adversity, or individual characteristic exposure to which has been shown to increase the probability that an

individual will experience maladjustment. Researchers have identified risk factors for child maladjustment at the individual, family, and community levels. Individual-level risk factors include factors such as depressogenic cognitive style and negative temperament. Family risk factors include factors such as parental divorce, parental mental illness, and substance use. Community-level risk factors include factors such as neighborhood violence, high neighborhood poverty, and the presence of multiple outlets for selling alcohol to minors.

Risk factors tend to be positively intercorrelated so that children exposed to one risk factor are likely to be exposed to others as well. Risk factors negatively impact child development by disrupting the satisfaction of basic needs and goals or impeding the child's accomplishment of developmental tasks, such as adjusting to school and developing friendships. In general, the more risk factors a child experiences, the greater the chances he or she will develop adjustment problems. For example, using a large sample of members of a health maintenance organization (HMO), Vincent Felitti and colleagues (1998) found that exposure to four or more risk factors in childhood predicted a 4- to 12-fold increase in the odds of developing problems in adulthood, including alcoholism, drug abuse, depression, and suicide attempts. Thus, it is the cumulative effect of exposure to multiple risk factors that makes children most vulnerable.

A protective factor is an individual-, family-, or community-level factor that decreases the likelihood that an individual exposed to significant risk will develop problems or increases the chances he or she will experience positive adaptation. Protective factors facilitate positive adaptation by either promoting children's competencies or by reducing the child's exposure to adversity. Like risk factors, protective factors have been found across levels (e.g., individual-level factors such as high child intelligence; family-level factors such as positive parenting; and community-level factors such as availability of positive mentors). It is important to note that a protective factor is not something that simply produces good outcomes in general but, instead, reduces the effects of a risk factor.

Positive adaptation can be conceptualized as the occurrence of developmental outcomes that are substantially better than would be expected given a child's exposure to specific risk factor(s). For example, children who attend underperforming schools in poverty-stricken neighborhoods are at risk for low academic achievement and behavior problems. Students experiencing positive adaptation in this circumstance would be those demonstrating high academic achievement and prosocial behavior. These students would be considered resilient.

Although resilience research is similar to several other approaches to studying child and adolescent development, such as risk research and the study of child competence, there are important differences as well. Whereas risk research has focused on predicting negative outcomes and the study of competence has focused on positive outcomes, resilience research considers both negative and positive outcomes, as well as the protective factors that account for positive adaptation in the context of risk. Resilience researchers also seek to understand the dynamic processes that explain the processes by which an individual achieves positive outcomes despite being exposed to adversity; including emotional and cognitive mechanisms, gene-environment interactions, and neuroendocrine responses.

## HISTORY AND EVOLUTION OF THE RESILIENCE FIELD

The systematic study of resilience began to evolve in the early 1970s as a handful of pioneering researchers identified subgroups of children at risk for psychopathology who were characterized by surprisingly high levels of competence. Whereas most scientists of the time disregarded positive outcomes among high-risk children as unimportant anomalies, researchers such as Norman Garmezy and Michael Rutter described and sought to understand the reasons for these phenomena. For example, Garmezy (1974) observed that most children identified during childhood as at risk for schizophrenia did not ultimately develop mental disorder in adulthood. He laid out a four-stage strategy for studying the development of severe psychopathology that included (a) examining early forms of competence and incompetence; (b) identifying variables that differentiate low- and high-risk children; (c) conducting longitudinal studies to predict patterns of outcomes among vulnerable children; and (d) testing interventions to evaluate whether changing early predictive variables influences later competence.

Around the same time, Rutter (1979) described the cumulative risk phenomenon, in which a child's susceptibility for later disorder increases exponentially as a function of the number of stressors experienced. Using an epidemiological sample of children living in inner-city London, Rutter compared groups of children based on the number of family stressors (e.g., marital conflict, low socioeconomic status [SES], paternal criminality, or maternal psychiatric disorder) they faced. He discovered that children exposed to one stressor were no more likely to have a psychiatric disorder than those who had zero stressors, whereas children with two stressors were 4 times as likely, and those with four or more stressors were nearly 20 times as likely, to have a disorder than children who had only one or no stressors. However, Rutter pointed out that a sizable minority of children who suffered a combination of stressors did not have a mental disorder. He also identified a variety of potential protective factors that were suggested by prior

research (e.g., female gender, high-quality education, high levels of parental supervision, and good parent-child relationships).

In the 1980s groundbreaking studies by Rutter and Garmezy, among others, led to new conceptualizations of major constructs, methods, and data-analytic strategies for examining resilience processes and outcomes. In addition, Emmy Werner and Ruth Smith published *Vulnerable but Invincible* (1982), a book describing a longitudinal study that would become a landmark in the resilience field. Over multiple decades, these researchers followed a population of infants born in 1955 on the island of Kauai, Hawaii. They discovered that children with a combination of risk factors including chronic family poverty, poorly educated parents, and perinatal stress (e.g., premature birth) tended to develop learning and behavioral problems in childhood and adolescence. Werner and Smith identified a variety of protective factors, such as early sociability, family cohesiveness, and social support from extended family and friends, that differentiated high-risk, resilient children from those who later developed problems.

The 1990s witnessed an explosion of studies using the concepts and methodologies initiated by these early resilience pioneers. As the field has evolved, researchers have increasingly clarified concepts and terminology, expanded the types of risk and protective factors and processes examined, and recognized that resilience may not be stable across development or different domains of adjustment. In the next section, this entry reviews some of the main protective factors that have been identified by resilience researchers studying children at risk for mental health problems.

## PROTECTION IN THE CONTEXT OF RISK

Resilience researchers have identified a variety of factors across multiple domains that buffer children against the negative effects of adverse circumstances.

**Family Protective Factors** Protective factors within the family have received the most attention in resilience research, because the family is the most proximal and stable of children's contexts. Early resilience research suggested that having a close relationship with at least one parent was protective across various adverse situations (Garmezy, 1974; Rutter, 1979; Werner & Smith, 1982). Subsequent research has shown that the protective effects of the parent-child relationship occur at different developmental stages. For high-risk infants, having a secure attachment with one caregiver is a protective factor for many outcomes throughout the life span (Sroufe, 2002). In childhood and adolescence, warm, close relationships with mothers or fathers protect children against the negative effects of poverty, parental mental illness, and parental alcoholism (Luthar, 2006). In adolescence, higher levels of parental monitoring also have been shown to protect against the negative effects of risky peer and community contexts (Dishion & McMahon, 1998).

**Community-based Organizational Protective Factors** Children living in impoverished neighborhoods often face multiple adversities, with each adversity increasing the likelihood of exposure to other adversities. For example, living in poverty increases the likelihood of parental mental health problems and exposure to antisocial peers and community violence. The cumulative exposure to multiple adversities puts children at risk for mental health problems. However, positive experiences in child care, schools, and community contexts can be protective in these environments. For example, in low-income neighborhoods, infants and toddlers in high-quality child care (i.e., those with highly educated and trained child care providers, low child-to-adult ratios, and low staff turnover) tend to be more securely attached to their mothers and less likely to be delinquent later in life (NICHD Early Child Care Network, 2002). For older children, having a warm and trusting relationship with an adult in the community, such as a teacher, coach, or mentor, can lead to positive outcomes in high-risk environments.

**Individual Characteristics** Individual characteristics of the child have also been the focus of resilience research; but this research typically involves community and family factors as well, because these contexts are instrumental in shaping children's characteristics. One of the most widely studied child characteristics is high intelligence, which has been shown to protect children from negative outcomes and lead to positive outcomes across a variety of adverse circumstances, even after controlling for the association between intelligence and family SES (Masten, 2001). In infancy and toddlerhood, having an easy child temperament or being able to appropriately regulate emotions has been shown to exert protective effects, whereas having a difficult temperament is a risk factor for negative outcomes under stressful conditions (Calkins & Fox, 2002). In childhood and adolescence, active coping strategies, coping efficacy, high self-esteem, internal locus of control, and positive thinking have been found to protect children against the negative effects of adversity (Sandler, Wolchik, Davis, Haine, & Ayers, 2003).

**Friendships** The quality of peer relationships and social networks are also an important context in which resilience research has been productive. Being accepted by peers and having a supportive relationship with at least

one friend protects children from the negative effects of adversity. At the same time, peer rejection and association with deviant peers increase adolescents' vulnerability to behavior problems in high-risk environments. Research has also shown that association with deviant peers is protective against depression among antisocial adolescents living in inner cities (Seidman & Pedersen, 2003). This finding suggests that while having deviant friends may contribute to increased behavior problems, having friends (even if they are deviant) may lead to less depression. This is an example of the complexity involved in identifying risk and protective factors in resilience research because one factor (e.g., association with deviant peers) may be both risky and protective depending on the outcome of interest.

## IMPLICATIONS OF RESILIENCE RESEARCH

Resilience researchers have amassed a wealth of knowledge about factors that promote healthy adjustment among children at risk. Prior to the 1970s, researchers had little knowledge of positive influences on children's development in the context of risk; consequently, they lacked information needed to develop interventions to prevent adjustment problems among high-risk children (Rutter, 1979). Since the late 1970s, findings from the resilience literature have provided the impetus for the development and evaluation of a wide range of interventions that build protective factors. Preventive interventions have been developed to counteract the negative effects of risk factors such as neighborhood disadvantage, family poverty, low SES, premature birth, parental divorce, death of a parent, abuse, and trauma. The following sections provide examples of interventions that have been designed to build protective factors to counteract one of these risk factors: parental divorce.

**Parental Divorce** Each year, more than 1 million children experience parental divorce in the United States. Although the majority of children whose parents divorce do not develop serious problems, these children are at increased risk for a host of difficulties, such as conduct problems, academic underachievement, and increased rates of mental health and substance abuse disorders in adulthood. Several interventions have been shown to reduce children's risk of experiencing significant difficulties following parental divorce by bolstering known protective factors.

**Family Programs** Two parenting-based preventive interventions have been shown to help children adjust to parental divorce: Parenting Through Change (PTC) and the New Beginnings Program (NBP). Both programs build protective factors by teaching parents effective disciplinary practices and promoting warm parent-child relationships. Randomized experimental evaluations of these interventions have shown that children whose parents participated in PTC or NBP had fewer conduct problems several years later compared to children in control groups (Martinez & Forgatch, 2001; Wolchik, Sandler, Weiss & Winslow, 2007). In fact, positive effects of the NBP have been found on a wide range of adolescent outcomes 6 years after the intervention, including lower rates of diagnosed mental disorder, fewer mental health problems, lower substance use, fewer high-risk sexual behaviors, higher self-esteem and higher grade point averages. The protective effects of NBP were most pronounced for children who were at the highest risk for problems when the intervention began, which is consistent with research showing that children exposed to multiple risk factors are the most vulnerable and, consequently, most in need of interventions to build protective factors.

**Child Programs** Two preventive interventions have been shown to promote resilience among children experiencing parental divorce by promoting individual protective characteristics, specifically child coping skills. The Children's Support Group (CSG) and Children of Divorce Intervention Project (CODIP) are group-based programs designed to give children emotional support, correct misconceptions about divorce, and teach coping skills (e.g., emotional expression, problem-solving skills, and anger management) to help them adjust well to parental divorce. Evaluations of both programs have shown increases in child competence and reductions in internalizing (e.g., depressive symptoms) and externalizing (e.g., noncompliance) problems 1 to 2 years following intervention compared to no-treatment control groups (Stolberg & Mahler, 1994; Pedro-Carroll, Sutton, & Wyman, 1999).

## FUTURE RESEARCH

The field of resilience has made important contributions to understanding child development within the context of adversity and has laid the groundwork for interventions that can improve child well-being by building protective processes identified through resilience research. In the years ahead, it is expected that scientists will continue to expand the search for protective factors by increasingly attending to genetic and biological factors in addition to psychological mechanisms, as well as examining protective factors that may be specific to ethnic and cultural subgroups (e.g., ethnic pride or collectivist family values). Finally, findings from resilience research will continue to be used to develop theory-based intervention strategies for improving the lives of children at risk.

## SCHOOL CULTURE

Efforts to improve the academic performance of schools typically focus on their formal, structural characteristics, such as curricular offerings and test scores. Yet, social and behavioral research has amassed a good deal of evidence that the more informal, social characteristics of a school—for example, the general quality of relationships among students or between students and teachers—also contribute to its students' academic performance and healthy development. The *culture* of a school matters. School culture is an important topic to consider when studying the life course because it captures how various life course trajectories (e.g., social development and educational attainment) intersect within specific contexts in one stage of life in ways that influence transitions into and through subsequent stages of life.

### DEFINING AND STUDYING SCHOOL CULTURE

Culture is an esoteric concept that is not easily defined. A general definition is the established patterns of activity, symbolic structures, and products within a given society. Culture can also exist on the level of the group or organization, such as the school (Coleman, 1961). A school's established patterns of activity can include rituals that are officially organized (e.g., participation in sponsored clubs or the clustering of students by grade or achievement level) and those that arise organically from repeated interactions among students and teachers (e.g., dating rules, sharing a common vocabulary). Its symbolic structures refer to taken-for-granted norms about how students and teachers are supposed to act, what they are supposed to value, and what kinds of emotions are acceptably felt and displayed. For example, drinking alcohol may gain students high social status in one school but low social status in another. Cultural products of the school can be tangible commodities, such as a winning sports team, or they can be more intangible, such as the perceived quality of the young people it is producing. Importantly, a school culture is tapped into broader cultures (e.g., American society) and subsumes different subcultures (e.g., jocks vs. nerds, White vs. Black, young vs. old). Yet, over time, an overarching culture typically arises in the school that is a system of rules, values, and beliefs that creates opportunities for behavior, interpersonal interaction, self- and other-assessments, and social advancement, whether individuals are conscious that this is happening or not (Carter, 2007; McFarland & Pals, 2005; Pianta & Walsh, 1996).

Not surprisingly, then, social scientists have long been interested in school culture. Some school culture researchers conduct in-depth ethnographies of a single school or a small number of schools. Sara Lawrence-Lightfoot (1983) illustrated this approach in *The Good High School*, which focused on six very different high schools widely considered to be successful within their own contexts—for example, an inner-city public school with a higher than expected graduation rate and an elite private school that is a pipeline to Ivy League colleges. Lawrence-Lightfoot constructed a portrait of a good high school based on the cultural commonalities across these schools, such as mutual respect between principals and staff and a general sense of community among students, parents, and school personnel.

Other school culture researchers rely on survey data. For example, Laurence Steinberg, B. Bradford Brown,

and Sanford Dornbusch (1996) worked together to survey thousands of students in California and Wisconsin, which allowed them to map out common peer crowds such as the *preps*, *rebels*, and *burnouts*. As another example, the National Education Longitudinal Study is collected and made publicly available by the Department of Education, whereas the National Longitudinal Study of Adolescent Health is made publicly available by the National Institutes of Health. The former study sampled parents, students, counselors, teachers, and principals in thousands of schools across the United States. These data allow researchers to compare how values and expectations of different actors in the school intersect (e.g., commonly shared goals, alienation between young and old) in ways that contribute to student performance (Lee & Smith, 2001). The latter provides a census of 132 schools in the United States. Aggregating student responses to identify prevailing norms in a given school has revealed, for instance, that adolescents avoid risky behavior when they attend schools in which students, on average, are close to their teachers, regardless of their own feelings about teachers (Crosnoe & Needham, 2004).

The ethnographic approach can elucidate important cultural patterns in any one school, and the survey approach facilitates comparisons across diverse schools. Thus, these approaches to studying school culture provide maximum value when partnered.

## THREE MAIN AREAS OF SCHOOL CULTURE RESEARCH

Contemporary scientific inquiry into school culture is largely traceable to the enormously influential, occasionally polarizing work of the late sociologist James Coleman (1926–1995). First, Coleman's 1961 book, *The Adolescent Society*, was based on an intensive study of Midwestern high schools. It argued that American high schools house peer cultures that are in direct opposition to conventional society and often undermine the basic goals of school administrators and parents. This idea of a monolithic, defiant teen culture has been largely refuted over the years, but the basic premise that schools are *the* site of youth culture is still an underlying theme of school research.

Schools can be broken down into clearly defined peer groups that share common social and academic positions in the school. For example, those referred to as *geeks* tend to develop a social identity through their repeated interactions in high-level coursework year after year, whereas those generally considered *popular* come together in clubs and teams. In both cases, proximity and shared status create meaningful peer groups (Field et al., 2005). Within a school, disparate groups then aggregate into a larger peer culture, with more powerful actors better able to define the rules of school social life. *School Talk*, in which Donna Eder, Catherine Evans, and Stephen Parker (1995) detail the hypersexualized nature of middle school, offers a startling glimpse into the power struggles that set the tone of school peer culture. They describe how coaches' denigration of signs of femininity in their athletes eventually infected the entire school culture, primarily because those athletes had such power and status among their peers. Boys who could not live up to this masculine ideal and girls who resisted their subjugated place paid a price in mental health, popularity, and attachment to school and school personnel. In this school, the peer culture of the school was toxic, even if the more formal, structural components of the school were of high quality.

Second, Coleman's 1966 study *Equality of Educational Opportunity*, also known simply as the Coleman Report, was a landmark federal report on inequalities among American schools. Controversially, it concluded that family, community, and school culture—not school funding—were often deciding factors in racial and economic differences in academic achievement. The Coleman Report had many methodological flaws and some regrettable policy applications (e.g., busing and the consequent White flight phenomenon), but its essential message that reforming schools requires transforming values and attitudes, not just pumping in money, has lived on.

This message that efforts to improve schools must start with positive changes to school culture has fueled interest in *caring* schools. In such a school, teachers realize that effectively instructing students in a given curriculum first requires that they and their students see each other as worthy of support, attention, and acceptance (Noddings, 2002). Angela Valenzuela's 1999 book, *Subtractive Schooling*, reveals the pitfalls of school cultures that lack widespread caring. In a Texas high school, the staff had a general tendency to view the cultural heritage of the largely Mexican immigrant student body as a disadvantage rather than a resource, which created an emotional disconnect in the classroom that hampered the ability of even well-trained teachers to motivate their students. Racially divided schools such as this one clearly demonstrate the politics of caring. For example, research has revealed how minority students emphasize modes of talk, dress, and interaction that symbolize their racial heritage, which school personnel then take as evidence that these students do not care about academics—setting in motion a self-fulfilling cycle that can eventually disengage students of color from school (Carter, 2007; Tyson, Darity, & Castellino, 2005).

Fortunately, social scientists have begun to identify ways to build school cultures that are more caring. One strategy, complex instruction, purposely creates student work partnerships across racial lines (Cohen, 1994). These partnerships allow students and their teachers to observe the unique contributions that people from different backgrounds can make to a group, which alters cross-group expectations and feelings of connectedness that can then build into more positive school cultures.

Third, the later years of Coleman's career were spent developing the theoretical concept of social capital, which refers to the different aspects of social connections that serve as resources for school success. It is akin to financial capital, only the currency is not money but something more personal. What do students need to get ahead academically and how can they get it at school? These questions are major foci of school culture research.

High expectations are one resource. Because students often rise to meet the expectations of parents, teachers, and peers who challenge them (Weinstein, 2002), those attending schools in which performance standards for all students are high are immersed in social capital. Another resource is information. Even smart, motivated students get off-track if they do not have practical knowledge about the schooling process. For example, Ricardo Stanton-Salazar (2001) has documented how some bright, goal-oriented Mexican-origin students do not make their way to college because they do not know about college coursework requirements or when to take their Scholastic Aptitude Test (SAT). Thus, a school in which a student has a high probability of tapping into information channels—through contacts with teachers, savvy peers, or the parents of peers—is high in social capital. A third resource is instrumental assistance. A school has social capital, therefore, when it can make available numerous people in the larger school community who are willing and able to help its students with schoolwork, projects, and applications (Morgan & Sorenson, 1999).

For all three resources, the school is an opportunity structure for social contacts and interactions that provide some tangible benefit for academic endeavors. Not surprisingly, socioeconomically advantaged schools are more likely than other schools to provide social capital, which is precisely why socioeconomic integration plans are gaining political momentum (Kahlenberg, 2001). Yet, even socioeconomically disadvantaged schools can develop cultures rich with social capital. Catholic schools, for instance, often serve working-class student populations, but their common curriculum, high performance standards, and more personalized instruction and mentoring have generally resulted in relatively high performance rates. In other words, a surplus of social capital can make up for a deficit of financial capital (Bryk, Lee, & Holland, 1993).

## THE IMPORTANCE OF SCHOOL CULTURE AND SCHOOL CULTURE RESEARCH

The commonality among these three themes is the idea that schools can be compared according to the quality and nature of social relations among the people in the school and the common modes of behavior, belief, and values that emerge from these relations over time. These social elements of schooling have traditionally been deprioritized by educational policies (such as No Child Left Behind of 2001) and evaluations that focus on the more concrete aspects of schooling, such as course offerings, teacher training, per pupil expenditures, and class sizes. Yet, the rich history of school culture research clearly suggests that this is a mistake. The culture of a school helps to determine whether the school is equipped to fulfill its educational mission and whether its students are able to achieve academic success and socioemotional well-being.

## SCHOOL READINESS

Schooling is a central aspect of childhood in most cultures around the world. In the United States, kindergarten has traditionally been viewed as the beginning of formal schooling, and most U.S. children attend kindergarten at or around age 5. However, educators and researchers have begun to focus more closely than in the past on the skills, knowledge, and habits children have upon entering formal schooling, often referred to as their *school readiness*, which is developed in the early childhood years. Because there is mounting evidence that these early competencies have a significant influence on children's later school success and life trajectories, experts have become increasingly aware of their central role in overall child and human development.

Although different early childhood experts define school readiness in different ways, there is general consensus that skills that promote later reading, writing, and mathematics development are important aspects of school readiness. Some dimensions used by the U.S. Department of Education to measure school readiness include a child's ability to recognize letters of the alphabet, count to 20 or higher, write her or his name, and interact with storybooks (U.S. Census Bureau, 2008). Beyond academic skills, many experts also cite motor skills and physical development, language development, and social and emotional growth as key school readiness components (Rouse, Brooks-Gunn, & McLanahan, 2005). As the National Governor's Association's Task Force on School Readiness (2005) explained:

> Ready children are those who, for example, play well with others, pay attention and respond positively to teachers' instructions, communicate well verbally, and are eager participants in classroom activities. They can recognize some letters of the alphabet and are familiar with print concepts (e.g., that English print is read from left to right and top to bottom on a page and from front to back in a book). Ready children can also identify simple shapes (e.g., squares, circles, and triangles), recognize single-digit numerals, and count to 10. (p. 1)

Pamela High and the American Academy of Pediatrics's Committee on Early Childhood, Adoption, and Dependent Care (2008) classified four conceptualizations of school readiness in the research literature on education and child development:

1. the idealist/nativist view, which emphasizes a child's developmental maturity, particularly in such areas as self-control and the ability to work with peers and follow directions;
2. the empiricist/environmentalist model, which focuses on the knowledge and behavior a child has been taught;
3. the social constructivist perspective, in which the major focus is on the community values and expectations to which a child has been exposed;
4. the interactional relational model, the one most widely recognized by child developmentalists, which emphasizes the individual child, the environment in which he or she learns and develops, and the ongoing interaction between the two.

Researchers have developed and used numerous standardized tests to measure school readiness, and, given the multidimensional nature of school readiness, these tests vary widely (Rock & Stenner, 2005). One of the

most commonly used testing instruments, the Peabody Picture Vocabulary Test–Revised, measures a child's vocabulary size by presenting the child with pictures on cards, which he or she is required to match with a stimulus word that is read aloud. The Wechsler Preschool and Primary Scale of Intelligence–Revised is a wider-ranging battery of tests used to assess individual learning patterns in such areas as vocabulary, word reasoning, object assembly, and comprehension. The Stanford–Binet Intelligence Test measures cognitive ability in areas such as verbal reasoning, abstract/visual reasoning, quantitative reasoning, and short-term memory. More recently developed testing instruments, such as those used in the Early Childhood Longitudinal Study–Kindergarten, focus not only on cognitive development and skills but also on social/behavioral and physical/motor skills (Rock & Stenner, 2005). Despite the wider range of school readiness components measured by recent tests, however, many early childhood advocates question the reliability of these assessments to predict school readiness and express concern about the overuse of standardized measures to make educational decisions that may have long-term effects on a child's future schooling (High & Committee on Early Childhood, Adoption, and Dependent Care, 2008).

## VARIATIONS IN SCHOOL READINESS

One of the main reasons why school readiness has received increased attention is that research has shown that children enter kindergarten with widely varying levels of many of the skills and competencies that make up school readiness. Early childhood researchers have studied a host of factors to determine whether they contribute to a child's cognitive development and skills in the preschool years, including physical health, family structure, parenting styles, and weight at birth (Rouse et al., 2005). Research has consistently shown that socioeconomic status—a cluster of factors that includes family income as well as a child's access to learning resources and parents' level of educational attainment and expectations—is one of the variables most strongly associated with school readiness. Valerie E. Lee and David T. Burkam (2002), authors of *Inequality at the Starting Gate*, reported that the average cognitive scores of children in the highest socioeconomic category are 60% higher than those of children in the lowest category. Moreover, a frequently cited book by Betty Hart and Todd R. Risley (1995) notes that 3-year-olds whose parents have "professional" jobs have vocabularies that are 50% larger than those of children from working-class families and twice as large as those of children whose families receive public assistance.

Researchers also have found school readiness gaps among students of different racial, ethnic, and language groups. Overall, Black, Hispanic, and American Indian students have been found to have significantly lower prereading, premathematics, and vocabulary skills at school entry than White and Asian American students. A report by Richard Rothstein and Tamara Wilder (2005) noted that the average Black student begins school at the 40th percentile in school readiness, compared to the 57th percentile for the average White student. In addition, data on California kindergartners drawn from the U.S. Department of Education's Early Childhood Longitudinal Study showed that fewer than one-fifth of the children for whom English was a second language scored above average on reading and mathematics tests (Gándara, Rumberger, Maxwell-Jolly, & Callahan, 2003).

As many researchers in education and other fields have noted, race and ethnicity are often closely aligned with socioeconomic status. In an analysis of school readiness gaps by race, ethnicity, and socioeconomics, Greg Duncan and Katherine Magnuson (2005) pointed out that whereas 10% of White children live in poverty, 37% of Hispanic and 42% of Black children do. They also find that, although it is difficult to quantify the effects of poverty and other components of socioeconomic status on school readiness, there is evidence that socioeconomic status differences play a significant role in these early learning gaps by race and ethnicity.

School readiness gaps by race, ethnicity, and socioeconomic status are of particular concern to educators and researchers because of strong evidence that they are associated with what have been called "achievement gaps" in later schooling, all the way up through high school, which in turn affect children's future job choices and overall life trajectories. Throughout K–12 schooling, Black and Hispanic students, on average, score lower on most measures of academic achievement than their White and Asian American peers. A widely cited analysis by Meredith Phillips, James Crouse, and John Ralph (1998) in the Brookings Institution book *The Black–White Test Score Gap* suggests that about half the Black–White gap on standardized test scores at 12th grade can be attributed to gaps that exist at 1st grade. Similarly, Rothstein and Wilder (2005) estimated that Black, Hispanic, and low-income students are, on average, 2 years behind their peers in reading and math by the end of fourth grade, 3 years behind by eighth grade, and 4 years behind by twelfth grade.

## EFFORTS TO BRIDGE SCHOOL READINESS GAPS

One of the most widely prescribed solutions to closing socioeconomic and other gaps in school readiness has

been improving access to preschool across racial, ethnic, and socioeconomic groups. Data reported by the National Institute for Early Education Research at Rutgers University indicate that more than 70% of 3-year-olds from families with incomes of more than $100,000 attend preschool, compared to less than 40% of 3-year-olds from families with incomes of less than $60,000 (Barnett & Yarosz, 2007). The wide availability of federally funded Head Start preschool programs, which target low-income communities, and the growing number of state-funded preschool programs have closed the gap in preschool attendance between Black and White children: Black children now attend some form of preschool in slightly greater percentages than their White peers; about half of 3-year-olds and more than 75% of 4-year-olds. Hispanic children, however, still attend preschool in the lowest numbers: Only about 30% of Hispanic 3-year-olds and 60% of Hispanic 4-year-olds attend preschool (Barnett & Yarosz, 2007).

Researchers question why the gaps in school readiness persist even as some gaps in preschool attendance have closed, and some point to what they say are differences in the quality and focus of the programs attended by high-income and low-income children. Economist Jane Waldfogel (2006), author of *What Children Need*, emphasizes the difference between *preschool*—which can include a wide range of services such as home care, private day care centers, and Head Start—and *prekindergarten* programs that are usually connected with school districts and are specifically designed to teach children the kinds of skills they will need in kindergarten and the first few years of elementary school. Whereas Head Start is an important resource for many children who might otherwise have no access to preschool, Waldfogel and other researchers have cited evidence that some Head Start programs do not promote school readiness as effectively as the best-quality private programs or school-based prekindergarten.

There also is evidence that access to school-based prekindergarten programs may have the potential to narrow school readiness gaps along racial, ethnic, and socioeconomic lines. One study conducted by Katherine Magnuson, Christopher Ruhm, and Jane Waldfogel (2004) found that students who had attended prekindergarten had higher reading and math skills upon entering school than those who had not; moreover, children from low-income homes, many of whom were Black, Hispanic, or from immigrant families, experienced long-lasting benefits from the prekindergarten programs. Another study of 339 New Jersey children randomly assigned to either full-day or half-day prekindergarten found that those who had attended the full-day program had better literacy and mathematics skills than those in the half-day program—and that full-day prekindergarten seemed to narrow school readiness gaps between children from upper- and lower-income homes (Robin, Frede, & Barnett, 2006).

## GREATER AWARENESS OF SCHOOL READINESS

Recent research such as that highlighted previously, as well as the efforts of early childhood education advocates, have raised both policy makers' awareness of school readiness as an important issue and interest in prekindergarten programs as a possible solution to persistent school readiness gaps. Most recent efforts to improve access to high-quality prekindergarten programs have taken place at the state level. According to National Institute for Early Education Research data, more than 1 million U.S. children now attend state-funded prekindergarten programs, which are offered in 38 states, and interest in the idea of universal prekindergarten has been growing steadily.

Another focus of more recent discussions about school readiness has been not only children's readiness for school but schools' readiness for children. The children who enter school in the United States are an increasingly diverse group. Roughly one in five children currently attending school in the United States is either an immigrant or the child of an immigrant, and this number is rapidly growing. Moreover, U.S. Census Bureau data show that nearly half of all children under 5 in the United States are from groups classified as racial or ethnic minorities. The FPG Child Development Institute, a group based at the University of North Carolina at Chapel Hill, focuses some of its work on examining how schools can be made more ready for children through such practices as addressing the specific learning needs of English-language learners, incorporating "culturally responsive practices" that take into account the diversity of children's ethnic and racial backgrounds, and providing early intervention for students who may be eligible for special services.

Other recent research on issues potentially related to school readiness has focused on such areas as neuroscience (studying the ways early experiences affect brain development and thus cognitive ability); health and wellness, including birth weight and maternal health; and differences in parenting practices (Rouse et al., 2005).

Given the growing diversity of the school-age population in the United States and the evidence that school readiness is strongly associated with success in later schooling (which is, in turn, associated with better future outcomes), school readiness is a concept with far-reaching implications both for the individual life course and for the composition of American society in years to come.

# SCHOOL TRACKING

Curriculum differentiation—the division of a domain of study into segments and/or the division of students into groups—is an important feature of schools in the United States. Tracking is one possible outcome of curriculum differentiation.

Aage Sørenson (1970) identified key dimensions of curriculum differentiation. Two dimensions—*horizontal* differentiation and *vertical* differentiation—concern the basis of the differentiation. Horizontal differentiation divides the curriculum into domains of study. For example, the division of foreign language study into German, French, and Spanish is horizontal differentiation. Vertical differentiation, however, reflects a division of students along lines relevant for learning, such as, for example, prior knowledge. The division of French into introductory (French I), intermediate (French II), and advanced (French III) provides an example of vertical differentiation. In vertical differentiation, students' performance in one course depends on their mastery in the previous course, a dependence reflecting the ordered nature of vertical differentiation.

Another key dimension of curriculum differentiation is *scope*, which reflects the extent to which students share the same peers over the school day. If scope is high, groups are segregated.

*Electivity*, which refers to the degree to which students' desires matter for their curricular placement, is another key dimension. *Mobility* and *selectivity* are two additional dimensions. Mobility concerns the amount of movement across curricular positions, and selectivity measures the degree of homogeneity within the curricular positions. These dimensions are important tools for understanding curriculum differentiation and, by extension, tracking.

## TRACKING: CLASSICAL DEFINITION AND HISTORICAL BASIS

Tracking has been defined in various ways. One restrictive view regards tracking as existing only when a formal process assigns students to explicit, overarching programs encompassing multiple subjects and years. Others define tracking as an association across disparate subjects, regardless of whether or not a formal program

assignment process exists. Others claim that an association of course-taking across time is tracking. And the least restrictive definition sees curriculum differentiation *itself* as tracking.

Matters were apparently more straightforward in an earlier epoch, one in which analysts suggest that *classical* tracking existed. Under classical tracking, students are formally assigned to overarching programs that determine the level of all of their academic courses.

Classical tracking was the aim of original tracking advocates who argued that the vast majority of students should be taught "followership," which would lead those students to uncritically parrot the views of their ostensible superiors (Finney, 1928). Further, these advocates contended that some students should be taught leadership, so that they could eventually, unapologetically, take power. In other words, these advocates sought *disparate socialization,* an aim that, they argued, required students to be consistently segregated.

These reformers defended classical tracking using early-20th-century theories of intelligence that asserted the existence of a generalized intelligence. In this view, differences in a person's ability across domains were trivial. Thus, one could identify the top students, provide them with exposure to challenging material in all domains, and avoid spending resources on those deemed constitutionally unable to grasp complex material.

Over time, classical tracking took root in the United States. During a period of high immigration and rising nativist fears, many reformers believed schools could "Americanize" immigrant youth (e.g., Kelley, 1903). In order for schools to do so, however, immigrant youth had to be forced into school. Compulsory schooling laws accomplished this aim, but produced another dilemma. Should schools teach a classical college preparatory curriculum of Latin and Greek to all students? Or should schools elaborate the curriculum to provide different types of training? Classical tracking was the eventual answer (Kliebard, 1995; Spring, 1972; Wrigley, 1982).

Consistent with this historical basis, evidence indicates that students in different tracks receive different amounts and kinds of resources. For example, lower-track classes are less likely to have experienced or capable teachers (Finley, 1984; Kelly, 2004). Further, consistent with the aim of differential socialization, courses of different tracks differ in multiple ways. Researchers have found that low-track classes require students to complete repetitive tasks based on simplified texts that are replete with lists to memorize, while, in contrast, high-track classes at the same school ask students to engage creatively using complex texts that demand students sift and synthesize the material (e.g., Oakes, 1985; Page, 1990).

Historically tracking appears to have been a major cleavage in students' experience. The best evidence suggests that, prior to 1965, most high schools assigned students to explicit, overarching programs that determined their academic course taking and thus governed the socialization to which they would be exposed. Classically, there were three broad tracks: college preparatory, general, and vocational. Students were assigned to one such program upon entering high school (e.g., Hollingshead, 1949; Alexander, Cook, & McDill, 1978), and students in a school spent most of their time with students in the same track.

## THE DECLINE OF CLASSICAL TRACKING

Under episodic pressure in the courts (e.g., Hayes, 1990), and in a 1960s context in which the claims of general intelligence were under attack, school districts began to alter their formal practices. Evidence suggests that the classical system of tracking began to erode in the late 1960s. Donald Moore and Suzanne Davenport (1988) studied four urban districts in 1965 and 1975, finding that all four had ended the assignment of students to overarching programs by 1975. Yet the districts maintained within-subject curriculum differentiation; students in the same grade could still take different levels of math, English, and so on. Districts formally decoupled course-taking *across* subjects, but maintained multiple levels of coursework within subjects. This change and stability allowed students to take different course levels in disparate subjects.

Evidence indicates that by the early 1980s most schools had moved similarly, dismantling the formal apparatus of cross-subject tracking (Oakes, 1981). By the early 1990s, 85% of schools lacked formal mechanisms of tracking (Carey, Farris, & Carpenter, 1994).

## THE AFTERMATH OF CLASSICAL TRACKING: MULTIPLE DEFINITIONS, MULTIPLE CONTROVERSIES

It is apparent that most schools have no formal process of overarching track assignment. Samuel Roundfield Lucas (1999) contended that an unremarked revolution in tracking had occurred, unremarked in that analysts acknowledged the change in school practice, but research methods did not keep pace with the change. Prior to the end of classical tracking, analysts routinely used students' self-reports or school personnel reports of students' track location (Gamoran & Berends, 1987). Indeed, scholars debated what discrepancies in the two measures signified (e.g., Rosenbaum, 1980 & 1981; Fennessey, et. al, 1981). However, the end of formal program assignment

made students' self-reports purely social-psychological measures (Lucas & Gamoran, 2002), and rendered the referent of school personnel reports even more opaque.

In that context, some maintain that curriculum differentiation *is* tracking, because as long as there is curriculum differentiation, students in the same school may be exposed to vastly different levels of rigor and types of socialization. Although some research has studied students' level of placement in individual subjects, this research is based on the inherent importance of those subjects, not on an explicit claim that curriculum differentiation is tracking. However, the view that curriculum differentiation is tracking has been the basis of proposals to end curriculum differentiation and instruct all students in heterogeneous classrooms. This policy proposal has often been called *detracking*, implying thereby that curriculum differentiation is tracking (e.g., Wheelock, 1992).

However, others resist the idea that curriculum differentiation is tracking, pointing to the original basis of tracking in a desire to make socialization consistent for any given student. In this view, the key issue concerns the degree to which courses are associated. Thus, some analysts contend that if students' level of course in one subject predicts their level of course in a disparate subject, this signals de facto tracking. When placement level in one subject predicts placement level in a disparate subject, the courses are associated (e.g., Lucas, 1999).

A great deal of research has been conducted under the assumption that students' academic programs are a collection of associated courses. Some of that research occurred prior to the end of classical tracking, and the questions given attention then have continued to be studied after the unremarked revolution. The research has concerned four principal questions:

1. What are the sources of tracking at the school-level?
2. What are the sources of the assignment of students to various levels of study?
3. What are the effects of students' track location? and
4. What is the source of any effects of students' track location?

## PREDICTORS OF SCHOOL-LEVEL TRACK STRUCTURE

The school-level factors that predict the existence or characteristics of tracking are important because any determinant of track structure is thus a determinant of the in-school environment students navigate. Learning the basis of that environment, therefore, is important for understanding the underlying basis of important aspects of adolescent experience and the context within which important life course transitions occur.

Maureen T. Hallinan (1994a, 1994b) maintains that tracking is a technical pedagogical device that allows students to receive education tailored to their prior preparation. In this view, tracking allows the construction of groups homogenous on prior achievement. In contrast, Jeannie Oakes (1994a, 1994b) contends that tracking inescapably involves segregation along lines of race, ethnicity, and class. Indeed, in this view the construction and maintenance of tracking is best understood as a means of buttressing such segregation after the end of de jure school segregation.

Research on detracking and on the factors predicting the strength of tracking systems addresses this debate. Ethnographic research on detracking shows that socioeconomically advantaged parents contest detracking until some advantages are preserved for their children (e.g., Wells & Serna, 1996). Yet if advantaged children receive advantageous positions, then both detracking reform and the technical pedagogical basis of tracking are both undermined.

Analysts find that the more race (Braddock, 1990) or class (Lucas, 1999) diversity, the higher scope—that is, the more pronounced de facto tracking is. Socio-demographic diversity is important even after the profile of student achievement is controlled in public (but not private) schools (Lucas & Berends, 2002). Further, the profile of students' achievement matters for track structure; the more highly correlated students' prior achievement is across domains, the higher the association in students' placements across subjects (Lucas & Berends, 2002). This result suggests a technical basis for some amount of de facto tracking. Still, the degree of de facto tracking appears driven, in part, by race and class diversity, consistent with the interest in segregation that provided the historical basis of the implementation of classical tracking.

## PREDICTORS OF STUDENT ASSIGNMENTS

Another key question asks what factors place students in different levels. If assignment is connected to factors other than prior achievement, the meritocratic basis of tracking is questioned, and one of the key technocratic rationales for tracking—its ability to produce groups homogenous on prior achievement so as to facilitate instruction—is undermined.

Research indicates that although measured achievement matters for placement, socioeconomic background matters as well (e.g., Gamoran & Mare, 1989; Mickelson, 2001; Jones, Vanfossen, & Ensminger, 1995). Ethnographic research reveals some of the ways social class enters the equation. Elizabeth Useem (1992) found that

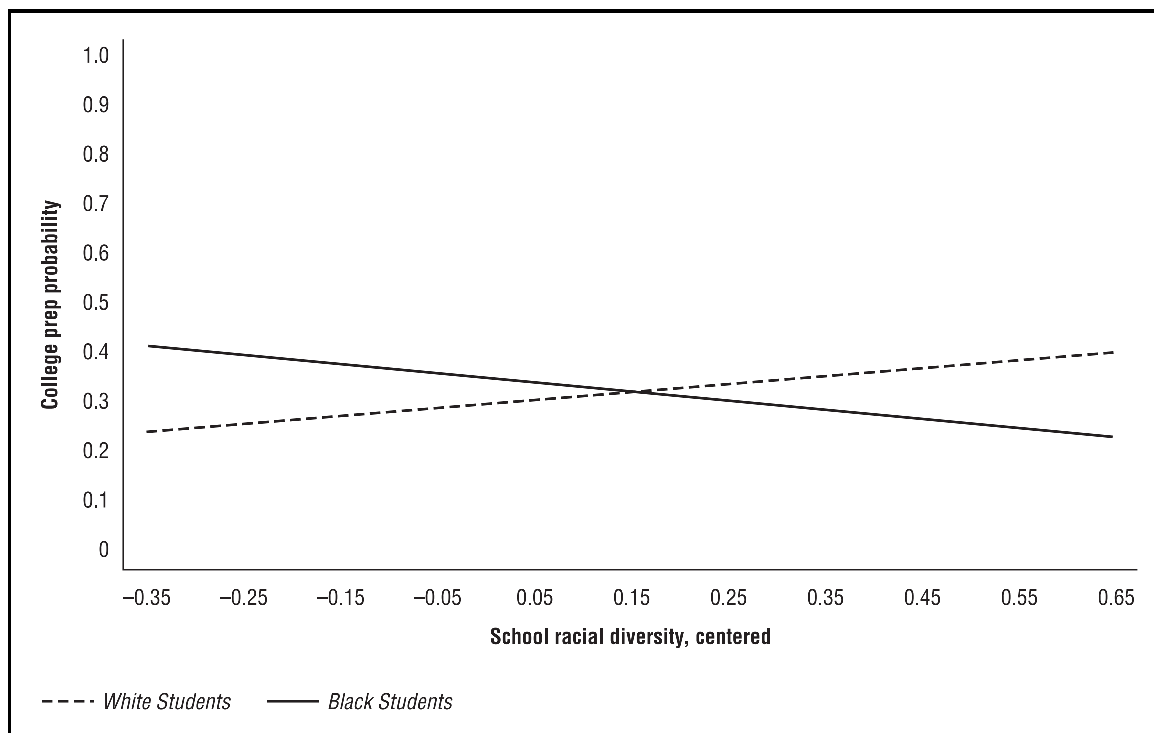

***Figure 1.*** *College prep probability by school diversity and student race.* CENGAGE LEARNING, GALE.

socioeconomically advantaged parents networked to obtain and distribute information amongst themselves, routinely intervened in placement decisions to assure high track placements for their children, and routinely acted to affect their children's course preferences.

The consensus concerning socioeconomic class and track location is not mirrored for race. Using nationally representative data, Oakes (1985) found that Black and Latino/a students were more likely to be found in vocational or remedial classes. Samuel Lucas and Adam Gamoran (2002), however, found a Latino/a disadvantage but no Black-White difference in college prep track assignment for 1980 sophomores, and parity for Blacks, Whites, and Latino/as amidst an advantage for Asians in their analysis of 1990 sophomores. Michael S. Garet and Brian DeLany (1988) found Blacks and Asians were more likely to be assigned to advanced mathematics classes than were Whites, whereas Roslyn Arlin Mickelson (2001) found Blacks disadvantaged in English class enrollment.

Evidence indicates that one explanation for the disparate findings is that schools differ appreciably in the relationship between race/ethnicity and curricular location (Lucas & Berends, 2007). That variation is not random: The more racially diverse the school, the less likely Blacks are, and the more likely Whites are, to enter college prep courses, even after test scores and parents' characteristics are controlled. Indeed, the differences resemble one-for-one substitution of Whites for Blacks in college prep courses as one compares more and less diverse schools (Lucas & Berends, 2007).

## EFFECT OF STUDENT ASSIGNMENTS

One oft-studied outcome is cognitive achievement. Research indicates an association between measured achievement and track location. Indeed, Gamoran (1987) found the achievement gap between college preparatory and non-college preparatory students exceeded the gap between high school graduates and drop-outs. One challenge in study effects of track location, however, flows from the research on track placement. That research, which finds social class, race, and other factors matter for track placement, implies that the students in any given track are not a random set of students. Thus, it could be that high track students would have higher test scores even if there were no tracking. Yet the difference between high-track and low-track student achievement appears to be caused by track placement, because when researchers control for the non-random assignment of

students to tracks, they still find that students in high tracks end up having higher achievement (Gamoran & Mare, 1989; Lucas & Gamoran, 2002).

Tracking could produce the effect on cognitive achievement by raising high-track students' achievement, lowering low-track students' achievement, or both. Alan C. Kerckhoff (1986) compared the outcome of British students of equal levels of achievement prior to their track assignment, and found that high-track students had high achievement growth while equivalent low-track students had less achievement growth. This pattern matches Thomas B. Hoffer's (1992) finding for middle school students in the United States. Hoffer (1992) compared not only high- and low-track students, but also schools with and without tracking. He found the usual advantage of high-track students compared to low-track students. However, comparing schools with and without tracking revealed that schools' overall level of achievement was virtually the same, because tracked schools improved the learning of high-track students but equally hindered the learning of low-track students.

Other outcomes have been studied as well. High-track students are less likely to drop out of school (Gamoran & Mare, 1989), more likely to receive encouragement for college (e.g., Hauser, Sewell, & Alwin, 1976), more likely to enter college (Rosenbaum, 1980), and have higher political efficacy (Paulsen, 1991) and academic engagement (Berends, 1995). General self-efficacy, however, appears unaffected once appropriate pre-track assignment controls are introduced (e.g., Wiatrowski, Hansell, Massey, & Wilson, 1982).

## THE SOURCE OF STUDENT ASSIGNMENT EFFECTS

Cognitive effects of track location exist and have been theorized in three ways. Effects may reflect an *instructional* basis, because lower tracks cover less content than do higher tracks (Gamoran, 1989). Effects may be *social,* because tracks provide different social contexts for students to explore and develop their selves and capabilities. Effects may be *institutional,* because tracking is a persistent organizational form and placements are arguably stable and public (Pallas, Entwistle, Alexander, & Stluka, 1994).

Evidence favors a role for instructional effects (Gamoran, 1989; Pallas, et al, 1994). Indeed, although tracking was originally motivated by the aim to teach students differently, some research suggests that low tracks would produce more achievement if they used the same approaches used in high-track classes (e.g., Gamoran, 1993). This is consistent with instruction as a key factor in producing track effects.

## FUTURE RESEARCH

Analysts have neglected some dimensions of curriculum differentiation. Electivity has been neglected, in part because students routinely report that they selected their courses when, in fact, researchers know that other factors, such as prerequisites and graduation requirements, play a large role in whether students will be allowed to take what they ostensibly desire (National Center for Education Statistics, 1981). No one has studied, using longitudinal ethnographic means, the coalescence of students' course-taking intentions and eventual behavior from before tracking to the end of high school. Until such research is conducted, carefully attending to students' unfolding preferences and the factors influencing those preferences, it will be difficult to reach any conclusions concerning electivity and tracking.

Almost every research effort would allow one to ascertain the selectivity of tracks. However, few researchers report this information. The little research that has reported on selectivity—the degree to which groups are homogenous—suggests tracks are heterogenous. Mickelson (2001) finds that while some students in the 30th to 39th percentile range are placed in advanced English, other students in the 90th to 99th percentile are placed in regular English. Many such placement inconsistencies existed, suggesting that tracks are often heterogenous on prior achievement.

Some research has studied mobility. One criticism of classical tracking is that it locked students into trajectories from which they could not escape. Early research on track mobility sustained this imagery, describing tracking as a tournament in which upward mobility was impossible (e.g., Rosenbaum, 1976 & 1978). But research after the unremarked revolution suggests that while downward mobility is far more common, a non-negligible amount of mobility is actually upward (Lucas, 1999), and patterns of mobility through the complex curriculum structure appear affected by race and class (Lucas & Good, 2001). Given the importance of mobility for the fairness and implications of tracking, and given the limited understanding we have based on the research completed to date, more research on track mobility would be desirable.

Tracking continues to affect the lives of students in schools throughout the United States. Tracking allows students to be exposed to different levels of cognitive demand and types of socialization. Track structures are most pronounced in racially and socioeconomically diverse schools. Assignment to courses is not meritocratic, as social class has been shown to matter, and race appears to matter as well. That race and class matter is likely consequential, because track location matters for a wide variety of cognitive, affective, and socioeconomic outcomes. The pathways

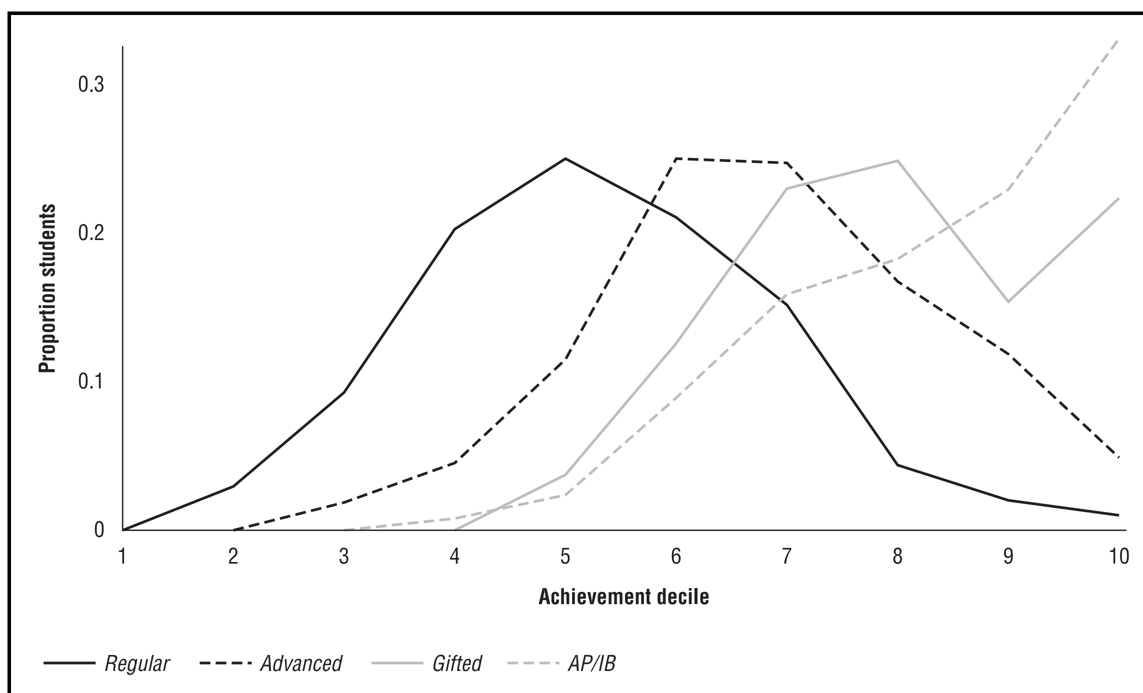

***Figure 2.*** *Distribution of prior achievement in four English courses.* CENGAGE LEARNING, GALE.

through which track effects are generated are contested, but instruction appears to be a key conduit for track effects.

# SCHOOL TRANSITIONS

Common features of virtually all individuals' educational careers are disruptions in organizational contexts, pedagogical approaches, and social relationships during school transitions. Most frequently, these transitions are planned or orchestrated as rites of passage from one level of schooling to the next made by student cohorts each year. Other changes in school enrollment are essentially random events occurring in individuals' lives, which often coincide with other transitions in residence and family status. Regardless of whether they are rites of passage or random events, school transitions involve changes in status and context that have myriad implications for individuals' developmental, social, and academic trajectories. This entry begins by describing the different types of school transitions and then outlines issues to be considered when trying to understand the opportunities and challenges that individuals encounter when changing schools. The entry closes with a discussion of the implications of school transitions for life course research.

## TYPES OF SCHOOL TRANSITIONS

Moves between schools can be generally grouped into two types: (a) school transitions marking completion of

a program of study and entry into the next stage of schooling and (b) school transfers due to changes in an individual's enrollment or assignment to a particular institution. The former are often called *normative school transitions* in that, annually, student cohorts follow similar patterns of movement between schools as guided by institutional policies and practices. In contrast, the latter are often called *nonnormative school transfers* in that students' movements between schools are unpredictable because they are predicated on individual circumstances, such as a family's move or disciplinary problems (Alexander, Entwisle, & Dauber, 1996). Although sometimes considered together in studies of changing schools, these two types of transitions are fundamentally different in the processes that individuals experience.

Normative school transitions are the most frequent changes in enrollment because they are required by the organizational structures of almost all educational systems. In most developed nations, school systems are organized into levels that can be roughly classified as lower elementary, upper elementary, middle, lower secondary (or junior high), and upper secondary (or senior high; Shavit & Blossfeld, 1993). In the United States, these levels are generally equivalent to kindergarten through third grade, fourth through sixth grade, seventh and eighth grades, ninth and tenth grades, and eleventh and twelfth grades, respectively. Although transitioning between levels reflects a change in program status, students do not necessarily have to enroll in a new school, depending on its grade configuration (e.g., kindergarten through tenth grades compared to a traditional 4-year high school). Although policies on school-leaving ages vary by state, school attendance is generally compulsory from ages 5 to 16 (roughly equivalent to kindergarten through tenth grade) in the United States. Some individuals also enroll in preschool prior to entering the early elementary grades, and others attend postsecondary schooling at colleges and universities. Regardless of the level, all normative transitions occur between academic years as dictated by the grade configurations and academic programs of the schools involved.

In contrast, nonnormative school transfers are generally unpredictable in that these decisions to change schools are the result of an individual's life circumstances. Most frequently, school transfers are prompted by residential moves that cross school attendance zones, whether from one side of the street to the other or across the country. However, many school transfers occur for other reasons, such as a consequence of schools' disciplinary and other administrative actions or a result of parents' exercise of school choice, such as transferring a child from a public to a parochial school (Swanson & Schneider, 1999). Generally, one or a small group of students transfer between two schools at a given time. Although many school transfers are made in the summer months, they can take place at any time during the school year and may occur with little warning or planning.

Although these two types of changes in school enrollment are distinct, the transition between levels of schooling can coincide with a decision to attend a different school than most of a student's cohort from the prior school. In these cases, the difficulties and opportunities encountered by students during school transitions may share many similarities with those of students transferring between schools during summer months. However, transfer students are usually changing schools at times when few of their classmates, at either their prior or new schools, would be contemplating similar shifts in schools. Thus, as discussed below, the contexts and challenges encountered by transfer students are different than those transitioning between levels of schooling because they tend to make their transition alone and at an unexpected time.

## CONTEXTS OF SCHOOL TRANSITIONS AND TRANSFERS

Regardless of whether a transition or a transfer, changing schools usually involves a student's entry into a new building, and it frequently features discontinuity in instructional techniques or approaches. The transition may also entail disruptions in one's teacher and peer networks. The frequency and predictability of students' changes in school enrollments create organizational and educational problems that vary in their intensity and duration. Schools' attempts to address these potential problems shape the structural, pedagogical, and social contexts of students' experiences during transitions and transfers.

Schools experience annual changes in enrollment, with varying proportions of students transitioning between grade levels and others transferring between schools. At one end of the spectrum, new students at schools spanning kindergarten through twelfth grades may be basically limited to a cohort of entering kindergarteners to replace the graduating senior class exiting the year before. At the other end, urban and rural schools serving transient populations may have rates of student mobility so high that the composition of classrooms can change dramatically during an academic year. To the extent that changes in enrollment are due to predictable arrivals of successive cohorts, school districts and systems can institutionalize the transition process by establishing policies and procedures to regulate the flow of students and information about them (MacIver & Epstein, 1991). In contrast, large numbers of transfer students can create chaotic environments for all students as schools must adjust their allocation of classroom and other resources

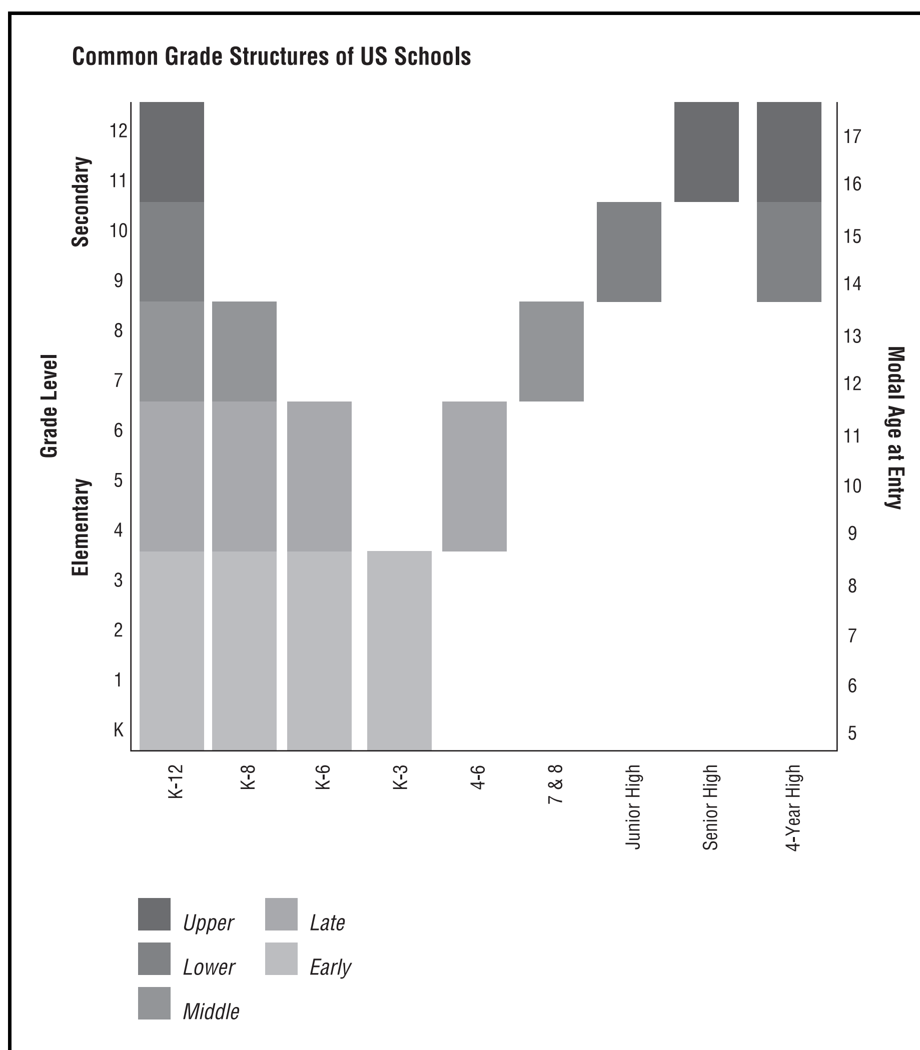

***Figure 1.*** *This figure outlines the major grade configurations in U.S. schools to highlight when transitions between levels of schooling are likely to occur.* CENGAGE LEARNING, GALE.

to accommodate their new classmates' needs (Ingersoll, Scamman, & Eckerling, 1989). Thus, from an organizational standpoint, managing the relatively predictable transition of successive cohorts is easier than assisting transfer students arriving under frequently chaotic circumstances.

One major source of organizational uncertainty is created by questions concerning new students' prior academic experiences and intellectual development. Most schools depend largely on official records and teacher recommendations accompanying new students in allocating them to classrooms and courses (Gamoran, 1992). Interpreting this information is easier when district feeder policies establish a consistent flow of students between schools, which facilitates the formation of both formal and informal relationships among school personnel (Schiller, 2005). For example, many school districts with schools linked by feeder patterns have personnel who meet to both exchange information about specific students and coordinate instructional practices and programs. Such meetings, however, become more problematic as the number of feeder schools increases and are almost impossible when a student transfers in from another district or state. In these situations, schools are more likely to establish internal assessments of prior academic progress to use in placing new students and provide more time in class for review of foundational curricular material (Riehl, Pallas, & Natriello, 1999). Despite schools' efforts to manage transition processes, however, students often encounter significant differences in instructional approaches and programs after changing schools that can disrupt their academic progress.

Changing schools usually requires students to also develop new relationships with peers, teachers, and other school personnel at the same time as they are encountering new academic environments. In addition to finding their way around a new building, new students usually must learn to negotiate the institutional procedures and social environments unique to each school (Eccles et al., 1993). Around the beginning of each academic year, most schools hold at least one orientation session to provide new students and their parents with information about policies they must follow and activities in which they may want to participate. Smaller numbers of schools establish mentoring programs or small learning communities to help new students connect with their teachers and form friendships with their peers. In contrast, transfer students, especially those entering during the middle of the school year, often receive little help in adjusting to the culture of their new school and integrating themselves into established friendship networks. Both members of incoming cohorts and transfer students are at risk of becoming socially isolated, yet they also have opportunities to identify with a new group of peers.

## RISK AND RESILIENCY DURING SCHOOL TRANSITIONS AND TRANSFERS

School transitions and transfers may precipitate changes in a student's academic success and social integration. The challenges and opportunities students encounter when entering a new school can dramatically affect their developmental trajectories in both negative and positive ways (Catterall, 1998). As noted earlier, most schools have programs to facilitate the integration of new students into their academic structures and improve the students' adjustment to a new social environment. However, an individual student's family circumstances, personality, and academic status also may influence how he or she is affected by the process of transitioning between schools.

Changing schools may disrupt a student's academic progress if the pedagogical approach—reflected in teaching style and curriculum—differs significantly between the two schools. Students transferring during the academic year are particularly likely to encounter severe discrepancies between what they were learning in the same class at each school (Lash & Kirkpatrick, 1994). Even within the same state or district, each class moves at a different pace and with varying emphases on particular topics based on the teachers' assessment of the students' strengths and weaknesses. These differences are particularly problematic for new students whose prior class was moving at a slower pace, as they will lack a similar foundation in basic concepts and skills compared to their new classmates.

Programs to coordinate curricula across feeder schools are intended to reduce differences in prior curriculum exposure among entering cohorts. However, these students must still deal with increasing conceptual complexity, more challenging tasks, and less personal attention from teachers with each transition between levels of schooling (Felner, Ginter, & Primavera, 1982). For example, students frequently first experience changing classrooms for some subjects when they enter middle school and do so for each class in high school. How successfully students adjust to new academic challenges and environments after either transfer or transition can have long-term consequences for their educational trajectories. A decrease in grades following a transition or transfer often signals that a student may be on a path to dropping out of school.

Similarly, newly arrived students are at risk of becoming socially isolated and alienated if their peer networks are significantly disrupted in the process of transitioning or transferring between schools. When entering a new school, transfer students are almost always required to build ties to peers who already have established relationships with longer-term classmates. Breaking into established social cliques can be particularly difficult when school transfers coincide with residential moves prompted by other life events, such as a change in parental marital status or a job loss (South & Haynie, 2004). Sometimes, however, school transfers are initiated by parents to distance their child from undesirable peer (or other) influences; such changes may not coincide with residential moves. In contrast, peer networks are likely to remain at least partially intact when cohorts transition between schools together. However, many students encounter difficulties adjusting to a new social status (i.e., being the youngest in a school instead of the oldest) and more diverse social groups when transitioning to larger schools. The larger pools of potential friends allow some previously marginalized individuals to redefine themselves as *normal* by identifying with new subcultures (Kinney, 1993). Individuals differ in their abilities to maintain or develop new connections to peers after entering a new school, which can also affect both their academic and social development.

## RESEARCH CHALLENGES AND FURTHER DIRECTIONS

Changing schools is a common feature of most individuals' educational careers, yet it is a complex process involving the interaction of institutional procedures and environments with students' readiness for the academic and social challenges they are likely to encounter.

Researchers are only beginning to understand why many students encounter difficulties that put them on the path to dropping out of school altogether (Roderick, 1993) whereas others find opportunities to blossom both academically and socially (Schiller, 1999). Investigators need to carefully specify the type or types of school transitions being studied to identify the particular processes and experiences that influence students' adjustment to new schools. For example, even if they remain in the same school, high school freshmen often experience similar changes in academic performance and social integration as those who transition into a 4-year high school (Weiss & Bearman, 2007). More studies following significant numbers of students through school transitions are needed to understand whether some changes in context—for example, from an urban to a suburban school—are more challenging for some students than others.

In addition, investigators need to consider what contributes to variation in how individuals are affected by school transitions. Changing schools may provide socially and academically struggling students with windows of opportunities for fresh starts, whereas more successful students may encounter more competition for positions in the elite groups. Studying school transfers can be particularly problematic because the difficulties students encounter may be due as much to the reason (e.g., a divorce or behavioral problems) for changing schools as to the transition process itself. Similarily, prior academic or social difficulties may become problematic again following school transitions and transfers. Disentangling these institutional and individual influences requires longitudinal study designs that allow a detailed examination of the transition process over time to determine what programs and interventions may work for which type of individuals.

# SCHOOL VIOLENCE

Schools are critical in the life course development of children and youth. Success in school is an important developmental outcome in its own right. School performance also has important implications for a range of adulthood outcomes including mental health, suicide, mortality, substance abuse, criminality, employment, and poverty. Research has shown that feeling safe at school is related to success, and even low levels of violence can have detrimental effects on student well-being. On a daily basis, however, many students fear being or are victims of school violence, which may involve either social victimization, such as harassment, social exclusion, and humiliation, or physical violence such as being threatened or physically assaulted.

The study of school violence is complex because such violence stems not only from a broad range of intertwined individual and environmental-level factors, including the social conditions in schools, but also from family and neighborhood factors. Starting in the 1990s, increasing efforts have been focused on the development of effective strategies to reduce and prevent violence in schools. These efforts have been motivated, in part, by a series of particularly violent events in schools such as the now infamous 1999 Columbine school shooting in Colorado, when 12 students and one teacher were killed and 23 students were wounded. Theorizing and research on school violence has moved in recent decades from an individual criminal justice orientation toward a more complex ecological and life course approach, which can be seen in the evolving definition of school violence and the theories informing its study.

## DEFINITIONS AND THEORIES OF SCHOOL VIOLENCE

School violence, like most social phenomena, is complex. For example, even defining what is and is not considered school violence is not straightforward. Conventional definitions of school violence have been framed by a criminal justice orientation—the use of force by one person toward another that results in harm to that person or their property—situated within the school, including the student's travel to and from school. Benbenishty and Astor (2005) offered an excellent example of such a definition: "any behavior intended to harm, physically or emotionally, persons in school and their property" (p. 8). *Harm* is in the perception of the harmed, and may encompass verbal, social, and physical forms of violence. Benbenishty and Astor also assert, however, that school violence is shaped by elements of wider social and cultural contexts, including neighborhood and family characteristics, and by "policies, practices, procedures, and social influences within the school setting as well as the impact of the variables external to the school" (p. 7).

Offering a broader definition of school violence, Henry (2000) argued that school violence is perpetrated not just by individuals, but by organizations and policies, and that it is not always by force, but may also involve the misuse of power. Further, the harm may be physical or emotional, but may also be in the areas of economics, opportunity, or equal access. Finally, Henry asserted, as Benbenishty and Astor suggested, that school violence is not limited to the school grounds, or travel to or from school, because that denies the interconnectedness of the school and community. Which definition is more accurate and more compelling? The current trend in research and theory is to use the more complex definition.

A broad range of theories has been applied to study school violence. Social disorganization theory is one traditional approach developed by sociologists Clifford R. Shaw and Henry D. McKay in response to the rapid changes in immigrant and ethnic minority communities in Chicago during the early 1900s. According to social disorganization theory, relationships are seen as organized when individuals actively engage in community institutions that foster social support and connectedness. As a criminology theory, social disorganization locates disorganizing forces within communities by attributing violence to a breakdown in community relationships and institutions. Social disorganization theory says little, however, about "organized" neighborhoods, for example rural and suburban communities, which statistically show school violence rates that are similar to urban schools in terms of teasing and bullying.

Ecological theory, developed by the psychologist Urie Bronfenbrenner, has seen increasing application to the study of school violence. Ecological theory emphasizes the multiple environments of youth, which include school, family, peers, neighborhood, the larger society, and the dynamic interplay of these settings over time. An increasing number of researchers who study school violence apply ecological theory to understand this web of environments and the many factors that contribute to violence in schools. An ecological approach fits well with the increasingly complex definitions of school violence that have emerged since the late 1990s and is especially useful when trying to develop comprehensive efforts to reduce and prevent school violence.

## STUDYING SCHOOL VIOLENCE

Although school violence has been the focus of much media attention in recent decades, actual school violence rates have not changed significantly since the 1980s. Overall trend data, however, tell only the surface of the story. As described above, school violence is a function of

the wider social context; therefore patterns vary with the characteristics of the students, school, and community. Four approaches typically are used in studying school violence: qualitative interview studies, analyses of school records, surveys of students and school staff, and after-the-fact analyses of violent events in schools such as multiple-victim school shootings.

Qualitative approaches have two advantages: Researchers may "discover" things that were not known, and they may construct "thick" descriptions of school violence issues. For example, in an interview study examining the connection between school violence and the community surrounding a New York City middle school, Mateu-Gelabert and Lune (2003) found that conflicts flow in both directions. The authors found that 18% of the violent events in the neighborhood started at school, while 21% of the violent events in the school started in the neighborhood.

Schools keep records, and such records offer data for the study of school violence. Cantor and Wright (2002) asked a nationally representative sample of school principals about violent events reported to the police and found that most violent events in schools are concentrated in certain schools, with 60% of the serious violence reported occurring in just 4% of the schools from which data were collected. The highest rates of violence occurred in urban schools with a high percentage of minority students and high rates of economic disadvantage. Such findings are consistent with the widespread belief that urban schools experience more violence. Cantor and Wright also found, however, that out of the 4% of schools whose records revealed the highest rates of serious violence a large percentage (36%) were in rural areas. School violence surveys also gather data from school staff such as principals. For example, Crosse, Burr, Cantor, Hagen, & Hantman (2002) surveyed 882 principals from across the United States and found that 72% of middle school principals reported physical fights between students in their schools. By contrast, only 11% of elementary school principals reported such fights, while the figure for high school principals was 56%. Such variation can be looked at from a life course perspective: What is known about children and youth developmentally that would explain such a pattern?

The most widely used approach to studying school violence is with surveys. Such research reveals that a significant percentage of students feel unsafe and report experiencing violence in schools. For example, in a survey of 7th, 9th, and 11th graders in a suburban school district, Cornell and Loper (1998) asked students about experiences of violence in the past 30 days, both "in school" and "out of school," with "in school" defined as the building and grounds and on the way to or from school. They found that 20% of students reported having been in a physical fight at school and 13% reported carrying a weapon to school for protection in the past 30 days. An important survey source of school violence patterns is the *Indicators of School Crime and Safety*, published annually starting in 1998 by the U.S. Departments of Education and Justice (Dinkes, Cataldi, Lin-Kelly, & Snyder, 2007). In this report, data collected for the period from 1992 to 2005 indicated a general decline from 10% to 4% of students aged 12 to 18 who reported being physically victimized during the previous 6 months. Rates varied by gender, however, with 10% of boys being threatened or injured compared to 6% for girls.

Although some survey studies have found that Whites experience lower rates of school violence than African Americans and Latinos, Chandler, Chapman, Rand, & Taylor (1998) found in a national sample of students that after accounting for the impact of socioeconomic conditions, African American students reported only slightly higher rates and Latino students slightly lower rates than White students. Such findings do suggest that some of the variation in school violence may be related to higher rates of poverty and historical patterns and experiences of inequality. Some authors have suggested that school violence increases when social problems—such as poverty, unemployment, drug abuse, crime, and child maltreatment—are left unaddressed. The following question emerges from these suggestions: How might such social conditions relate to violence in schools? One thing is clear: Despite variations in rates in local schools and communities, school violence is a pervasive problem affecting schools across the United States and around the world. Violence within specific schools, however, is linked to the social conditions of the surrounding neighborhoods and larger community.

Researchers also study school violence by retrospectively examining particularly violent events. Although school shootings garner high levels of media attention, violent deaths in schools are quite rare. Much more common are violent deaths of students outside school, although as discussed above community and school violence is connected. The year 1999, that of the infamous Columbine massacre, represented an average year for violent deaths, with a total of 33 murders committed at schools (Dinkes et al., 2007). This statistic suggests that the actual number of murders at schools occurring elsewhere, most typically urban schools, was low that year. Multiple-victim school shootings are unpredictable, but have been increasing in frequency, typically occur in suburban and rural communities, and are most often perpetrated by White males. Examinations of multiple-victim events in schools, such as Columbine or Red Lake (Minnesota) High School have revealed two clear patterns: The shooters were suffering from mental health

***Columbine Massacre.*** *Columbine High School security video shows Dylan Klebold and Eric Harris in the cafeteria.*
© REUTERS/CORBIS.

problems and had previously been victims of teasing, bullying, or social rejection (Leary, Kowalski, Smith, & Phillips, 2003). The question then becomes: How are more common types of school violence linked to more rare school shootings? An important consequence of high-visibility school shootings is that policymakers and educators have increased their attention to the widespread problem of more common types of school violence, leading to increased efforts and government funding for prevention and reduction efforts.

## PREVENTING AND REDUCING SCHOOL VIOLENCE

Just as the definitions, study methods, and patterns of school violence are varied and complex, so are efforts at reduction and prevention. Such efforts include procedures to make schools safer by keeping out weapons and aggressive students, initiatives to reduce teasing and bullying, the mapping of individual schools to identify where in those schools violence is most likely to occur, and, finally, comprehensive programs to change the social climate in a school.

In regard to the goal of keeping weapons and high-risk students out of schools, one such effort has been the proliferation of "zero-tolerance" policies. Such policies dictate that students who bring weapons to school will be expelled. This policy originated with U.S. Customs to combat drug smuggling in 1988. It was picked up by schools in a few states and then was made a federal law in 1994 with the passage of the Gun-Free Schools Act, which mandated that states punish students bringing guns (most states included all "weapons") to school with yearlong expulsions. By 1998, 91% of public schools had zero-tolerance policies, and as a result of such policies a total of 2,554 students were expelled for bringing a weapon to school during the 2001–2002 school year. There is little evidence, however, that these policies are effective, and they have been so rigidly enforced that students have been expelled for minor offenses, including bringing into a school such objects as a squirt gun, a 5-inch plastic axe as part of a Halloween costume, a rocket made out of a potato chip can, and nail clippers (Skiba, 2000). Skiba found these overreactions are not rare, whereas the serious infractions these policies were originally intended to address are rare.

Research has found that suspension and expulsion as a disciplinary strategy disproportionally affects poor and African American students. Such policies deny access to educational opportunities in the short- and mid-term, which can negatively impact academic progress. In the long run, such denial of access can negatively impact the educational trajectories of students, which can have lifelong consequences in terms of graduating from high school, employment opportunities, and a cascade of other negative adult outcomes as discussed above in the introduction. It is easy to see Henry's point made above—that school policies can do violence to students.

The Bully Prevention Program, developed by the Norwegian psychologist Dan Olweus, is an effective program designed to reduce teasing and bullying in schools. The program encompasses interventions focused on the school, classroom, and individual levels, including interventions for bullies and victims, and to elicit bystanders to intervene to help victims. The intervention process starts with a survey of students to assess the extent of the problem, followed by a schoolwide meeting that includes parents to discuss the results of that assessment survey and get everyone onboard with the need for change. Finally, the interventions are implemented, including clear rules in the school about teasing and bullying and classroom meetings to discuss these rules and ongoing problems.

Mapping the unsafe places in schools, including where and when students are more likely to become victims, was an important development in school violence prevention that emerged from the research of Rami Benbenishty and Ron A. Astor. These authors have also proposed an ecological approach to preventing school violence that takes into consideration the complex interplay between the school and the surrounding environment (Benbenishty, Astor, & Estrada, 2008). For example, they suggest that all schools complete comprehensive schoolwide assessments of violence, and they point out that the federal No Child Left Behind Act of 2001 calls for assessments of the level of safety in schools, the results of which are supposed to be made publicly available, although few

schools currently complete such assessments. The authors' comprehensive assessment strategy stresses the importance of gathering data from multiple informants—students, teachers, parents, and administrators—and they have developed strategies for how to best use the results to most effectively promote a successful change effort.

Another promising approach to reducing violence is to change the social climate in schools. The term *social climate* refers to the quality and nature of the interpersonal relationships that influence students' behavior and social functioning. This approach, adapted from a public health model, has three levels, termed *universal*, prevention efforts for all students; *selected*, for interventions delivered to students at risk; and *targeted*, for interventions for students who have been aggressive. Bowen, Powers, Woolley, and Bowen (2004), applying an ecological framework while identifying risk factors at the individual, family, peer group, school, and community levels, have described strategies to apply this three-level approach to reduce and prevent school violence. For example, an implementation could include: (a) a universal schoolwide program such as Responding in Peaceful and Positive Ways, which was developed by Albert D. Farrell to advance the social and conflict-resolution skills of all students; (b) a group-based intervention such as the Anger Coping Program, which was developed by John E. Lochman for students with some problematic behaviors; and (c) targeted interventions for students with ongoing problems with aggression such as Multisystemic Family Therapy, which was developed by Scott W. Henggeler.

## FUTURE DIRECTIONS

For schools to accomplish their central goal, nurturing the learning and growth of students, they must be and feel like safe places. Schools are most effective when students see the school as welcoming and supportive, and when students look forward to being there (Woolley, 2006). If school is a place where students are teased or bullied, or—even worse—stabbed, shot, or live in fear of a classmate going on a shooting rampage, then the central goal of learning is severely undermined.

With the downturn in reports of victimization in schools that occurred in the period encompassing the last years of the 20th century and the first years of the 21st, it appears that the increased efforts to study this problem and develop strategies to address it may be working. Nevertheless, researchers, policymakers, and school administrators have much work to do to achieve the goal of all students feeling safe at school. The development of more complex definitions and more life course and ecological orientations to this problem have been positive developments. Future research may seek to understand the commonalities found in school violence between schools in diverse settings in order to inform the development of more robust school violence intervention and prevention efforts.

## SCHOOL VOUCHERS

**SEE** Volume 1: *Policy, Education.*

## SEGREGATION, SCHOOL

Social science research in school segregation has both informed and been informed by legal consideration of segregated schools. In the 1954 *Brown v. Board of Education*, the U.S. Supreme Court declared racially segregated schools to be "inherently unequal" and therefore a violation of the Fourteenth Amendment of the U.S. Constitution. Although this ruling initially made very little change in the extent of school segregation in the 17 states that had laws requiring it (Orfield & Lee, 2007), it had an important effect on social scientists because of footnote 11, in which Chief Justice Earl Warren cited social science studies as part of his argument about why segregation was harmful. In particular, the decision and subsequent legal and policy actions to implement the decision created a fertile opportunity for social scientists to examine the extent of segregation (or desegregation), how school segregation related to other types of societal segregation, and the effect of judicial and policy actions, and to investigate the ways in which school segregation and desegregation affected students attending these schools.

### WHAT IT MEANS TO STUDY SEGREGATION

The meaning of segregation from a social science perspective is distinct from the legal definition, so it is important to clarify terminology. Social scientists define school segregation in terms of the distribution of students of different racial/ethnic groups, often measured at the school-building level. Social scientists measure segregation in a variety of ways: different dimensions of segregation (e.g., concentration, exposure, dissimilarity), different levels of analysis (within schools, between schools, between districts), and different groups (usually two groups: White–Black, White–Latino, and so on; Massey & Denton, 1988).

Further, for several decades, there has been a legal distinction between *de jure* segregation, which refers to segregation that occurs as a result of government law or policy, and *de facto* segregation, which occurs in the absence of such law or policy. In subsequent Supreme Court decisions about school desegregation, the Court ruled that unless there is de jure segregation, school districts are not required to—and even may not be able to voluntarily—take action to address the patterns of school segregation that exist (*Freeman v. Pitts*, 1992; *Parents Involved in Community Schools v. Seattle School District*, 2007).

One of the major causes of segregated schools in the absence of overt policies that segregate students is the segregated housing patterns in most communities across the country. There is an interdependent relation between housing and school segregation: Because schools often draw their students from the surrounding neighborhoods, schools will be segregated if neighborhoods are. At the same time, evidence suggests that in areas where there is not complete desegregation across the metropolitan area, communities with segregated schools have higher levels of residential segregation (Frankenberg, 2005).

It is also important to differentiate how K–12 school segregation is different from the higher education context. For the past several decades, discussions of racial diversity in higher education have focused on the design, legality, and effect of affirmative action policies. These policies differ considerably from school desegregation, most notably in that they affect only a fraction of students whereas school districts are required to educate all students who reside in their boundaries.

### BASIC TRENDS IN SCHOOL SEGREGATION RESEARCH

The most fundamental area of study is understanding the extent of school segregation. One of the foremost authorities in documenting school segregation trends has been Gary Orfield, a political scientist and founder of the Civil Rights Project. Using national-level data, Orfield and his colleagues have consistently documented segregation for, in particular, Black and Latino students at the national, regional, and state levels (e.g., Orfield & Lee, 2007). Some of his findings include:

1. Black student segregation fell dramatically in the South from the mid-1960s to the late 1980s;
2. Latino segregation has been increasing continuously since the late 1960s;

3. Black segregation has risen since the late 1980s, and Black students nationally are more segregated than they have been since before 1970, when many of the most extensive desegregation plans were implemented;
4. White students are the most isolated students of any racial/ethnic group.

In addition, there are very different percentages of students in intensely segregated minority schools (defined as schools in which 0% to 10% of students are White) by region of the country. Until very recently, Black students in the South were the most desegregated; Latino segregation in the West is high. Quite high percentages of Black and Latino students attend segregated minority schools in the Midwest and Northeast, which is likely a result of the many small school districts that divide students, often by racial background, in these regions' metropolitan areas.

Whereas Orfield's analysis aggregates school-level segregation measures to the state, regional, or national level, most case studies of segregation examine segregation within a particular school district. In general, much of this research dates from the time when school desegregation plans were being implemented. These studies might use a conceptualization such as Orfield's intensely segregated schools to assess whether the number of students in such schools diminishes with the implementation of certain policies. In addition, social scientists may have used measures influenced by court decisions that relate to that school district. For example, in Charlotte, North Carolina, compliance with desegregation as required by the courts—who found Charlotte had illegally segregated students—was that every school had to have a percentage of Black students that was within 15 percentage points of the system-wide percentage (Mickelson, 2001). As a result, case studies of Charlotte often used this definition of segregation.

In addition to examining changes in segregation as desegregation policies were implemented, often under court or administrative supervision and primarily in the South, newer district-level studies examine desegregation after such policies are lifted (e.g., Mickelson, 2001; Orfield & Eaton, 1996). Policies can be ended once the court believes that the district has eliminated all traces of prior segregation policies or are "unitary" systems. However, these studies generally conclude that when race-conscious policies are abandoned there has been a return to segregation—sometimes quite rapidly—and associated educational inequality.

More recent studies suggest that district-level analyses may understate the extent of segregation, because these studies do not incorporate the substantial differences in racial composition among school districts. One estimate was that 70% of segregation was due to segregation among school districts (Clotfelter, 1998). Additionally, a Connecticut Supreme Court ruling found that the way in which school district boundaries in the case were drawn was unconstitutional because they were the major cause of segregation within the state (Eaton, 2007). Both legally and politically, designing policies to address cross-district segregation is challenging. Yet in the South, countywide districts encompassed much of the metropolitan areas and contributed to lower levels of school segregation (Frankenberg & Lee, 2002; Orfield, 2001).

## WHY SEGREGATION MATTERS

The initial argument made in *Brown* about the "harms" of segregation focused largely on potential psychological costs to young people: Those who attend segregated minority schools are harmed in terms of their self-image, whereas those who are the "segregators" or who attended segregated White schools were also found to have a false sense of superiority. In addition, two Supreme Court decisions that paved the way for *Brown* by desegregating higher education relied on sociological evidence about the importance of access to professional networks as part of a graduate education. Since the mid-1950s, research on segregation has confirmed and extended these reasons as to how segregated schools deny their students equal opportunity. This can be divided into three categories: (a) the relation of segregated schools to important educational inputs, (b) cognitive outcomes for students, and (c) democratic outcomes for students.

In 1954 Harry Ashmore released a major study of schooling in the South that documented the persisting inequalities between the funding of "Negro schools" and White schools. Although the gap had closed, in some states schools with White students had three times the funding that schools educating Black students received. The relation between segregation and resource inequality is evident in several major ways. First, minority schools tend to have teachers with lower qualifications and fewer years of experience, both of which relate to lower student achievement. In addition, these schools have higher teacher turnover, particularly among White teachers who comprise the vast majority of the teaching force. Second, because of the relation between poverty and race, segregated minority schools are overwhelmingly likely to have a majority of low-income students (Orfield & Lee, 2007). This is important because research since the 1966 Coleman Report finds that being in classrooms with middle-class students has a powerful effect on student learning. Finally, segregated minority, high-poverty schools generally offer fewer advanced courses and other

college preparation opportunities (Solorzano & Ornelas, 2002). These schools may also have facilities that are inferior to schools serving more White and middle-class students.

**Cognitive Student Outcomes** More research has been focused on understanding the short-term effects on students who attend segregated schools, although recently there has been a shift to also examine long-term student outcomes as well. The bulk of research on short-term effects has examined how student achievement in segregated schools compares to that in desegregated schools. Some of the earlier studies found mixed or inconclusive results on student achievement—usually measured by test scores sometimes after only a year of partially implemented desegregation—although the general consensus is that there are at least modest benefits for Black students' achievement in desegregated schools. There was less focus earlier on the achievement of Latino students, due, at least in part, to the fact that most of the students "desegregated" were in the South, where there were few Latino students at the time. Most of the rationales for desegregation focused on the unequal opportunity for minority students, with less attention on White students. The few studies that have examined White student achievement concluded that as long as desegregated schools remained majority White, the achievement of Whites was not harmed.

With the development of new statistical techniques, more methodologically rigorous research has confirmed that minority students' achievement in segregated minority schools is lower (Hanushek, Kain, & Rivkin, 2006). Further, attending segregated schools is likely to result in lower track placement (Mickelson, 2001). Segregated minority schools have lower graduation rates. In fact, after controlling for other factors that might relate to lower graduation rates, the percentage of minority students in a school was a significant predictor of graduation rates (Swanson, 2004). In addition, attending racially isolated K–12 schools makes students less likely to attend and persist in higher education, even after controlling for factors such as students' standardized test scores (Camburn, 1990). High school and college diplomas are increasingly important for employment opportunities, which affect both the individuals who fail to attain these degrees as well as communities who will have a less-educated employment base.

**Noncognitive Student Outcomes** Much of the attention, particularly in legal opinions, assessing whether there are benefits to desegregated schools has focused on cognitive outcomes. However, evidence about noncognitive benefits of desegregated schools—psychological, sociological, and democratic—is more robust than that of cognitive outcomes.

In terms of psychological outcomes, several important findings have emerged in prior studies. First, desegregated schools help students to develop cross-racial understanding, which relates to reduced stereotypes and bias (Killen & McKown, 2005). Further, students are more likely to understand racial exclusion is harmful (Killen, Crystal, & Ruck, 2007). Importantly, these gains can only be realized as a result of intergroup contact—which is limited in segregated schools—and the benefits are most significant at early ages before the formation of stereotypes (Hawley, 2007). These outcomes are particularly important because the development of racial stereotypes can affect decisions students make as adults, such as their interracial tolerance and their willingness to live and work in mixed-race settings. In addition, racial stereotypes can affect the achievement of students who perceive themselves as the object of such stereotypes as compared to students who are unaware of stereotypes (Steele & Aronson, 1995).

One of the early arguments for desegregation was the access to networks that minority students lacked in segregated schools. This was particularly evident in the *Sweatt v. Painter* (1950) and *McLaurin v. Oklahoma* (1950) Supreme Court decisions, in which the justices noted that without access to professional colleagues and the reputation of graduate schools, future professional opportunities were likely to be limited for minority students. Likewise, in elementary and secondary schools in particular, networks can be important in helping students think about attending college and know what preparation is important. In addition, the reputation and alumni connections that high schools have with selective colleges and employers are valuable benefits for students who attend such schools. When minority students lack access to such networks because they attend poorly resourced, segregated minority schools, their postgraduate opportunities are more limited solely as a result of the school they attended.

More recent literature has described a democratic or perpetuating effect of attending desegregated schools. As opposed to the other benefits described previously, these accrue to students of all racial backgrounds that attend racially diverse schools. Studies examining the "perpetuation effects" of desegregated schools suggest that Black students who attend desegregated schools are more likely than their peers who attend segregated minority schools to live and work in desegregated environments as adults (Wells & Crain, 1994). This pattern reflects two mechanisms: First, attending diverse, majority White schools allows students to overcome their fears of such institutions, and second, they have access to information about diverse opportunities. Research also suggests that students of all racial/ethnic backgrounds attending diverse high schools are more likely to report that they would feel

comfortable living and working in desegregated settings later in life and may have more civic engagement than peers attending segregated schools (e.g., Yun & Kurlaender, 2004). In addition, communities with more thoroughly desegregated schools are likely to experience more integrated neighborhoods. All of these findings point to the conclusion that desegregated schools are more likely to result in desegregated experiences for both students and communities, which are important preparation for citizenship in a pluralistic, multiracial society.

**Structuring Desegregation** Nearly all the research discussed thus far has focused on segregation at the school level. Although desegregation is important, one expert panel noted that it is only when two (or more) racial groups of students are in a school that the actual process of desegregation, sometimes called *integration*, begins (Hawley et al., 1983). Within-school structures and practices matter, however, as to whether these benefits of desegregated schools accrue to students. In 1954, Harvard psychologist Gordon Allport published *The Nature of Prejudice.* In it, he described his theory of intergroup contact and specified four conditions (equal status for all groups, common goals, no competition among groups, and authority sanction for intergroup contact) that were necessary to fully realize the benefits of contact with people of other groups. A meta-analysis of five decades of research supports the importance of intergroup contact in reducing stereotypes and finds that gains are stronger when the conditions are met (Pettigrew & Tropp, 2006).

Despite the importance of intergroup contact, structures inside schools often segregate students *within* schools even if they are desegregated at the school level (Mickelson, 2001). In addition to preventing interracial exposure, such within-school segregation often disproportionately exposes minority students to novice teachers (Clotfelter, Ladd, & Vigdor, 2005) and contributes to a persistent racial achievement gap (Burris & Welner, 2007). In the early 1970s, the federal government passed a desegregation assistance law to help retrain teachers for desegregated schools and to conduct research to understand what strategies worked best in diverse schools. There is considerably less research focus on how to best structure desegregated schools despite the growing racial complexity of the student enrollment (see Frankenberg & Orfield, 2007).

## FUTURE OF SEGREGATION AND SEGREGATION RESEARCH

School segregation research is likely to be shaped by two significant trends: demographic and legal changes. The country is rapidly diversifying, and, by the middle of the 21st century, public schools will have a non-White majority student body, a reality that has already occurred in 10 states (Orfield & Lee, 2007). In many states there are racially changing, complex school contexts (Frankenberg, in press). These new school contexts require research to help teachers and administrators understand how to structure schools in ways that will enhance the learning and social outcomes for all students.

In addition, in 2007 the Supreme Court (in *Parents Involved in Community Schools v. Seattle School District No.1* and *Meredith v. Jefferson County Board of Education*) ruled that commonly used student assignment plans designed to achieve racial integration were illegal. This decision portends a number of important avenues for investigation. First, educators and administrators must understand the possible consequences of abandoning race-conscious voluntary plans. Second, it is important to understand where there are successful race-neutral plans, under what conditions these plans are successful, and how they could be replicated. Third, given the skepticism by Supreme Court justices about the importance of racially diverse schools and the harms of segregated schools, there continues to be the need to research—and compellingly communicate research findings—on these topics.

Thus, whereas research will continue to be informed by social reality (e.g., the persisting high levels of segregation in major urban centers), it is quite likely that the study of school segregation will continue to be influenced by legal and policy decisions to understand their consequences and help inform future policies.

# SELF-ESTEEM

Few concepts in the social and behavioral sciences have excited as much interest and spawned as many major research programs dedicated to defining its antecedents and consequences as has self-esteem. This concept is regarded by many social theorists and researchers as a central construct in explanations of human social behavior, over the life course and as a concept that must be attended to in the design and implementation of planned social interventions that are dedicated to the amelioration of individual and societal outcomes (Kaplan, 1986; Kernis, 2006; Mecca, Smelser, & Vasconcellos, 1989).

## DEFINITION AND MEASUREMENT OF SELF-ESTEEM

In spite of the central position accorded to self-esteem in theories and research about human social behavior, there are widely divergent positions regarding how to define this concept. Definitions of self-esteem usually involve one or more of four classes of self-referent responses: self-cognition, self-evaluation, self-feeling, and self-enhancing or self-protective mechanisms. *Self-cognition* refers to processes whereby the person conceives of, perceives, or otherwise thinks about him or herself. *Self-evaluation* refers to the process of judging one's self to be close to or distant from more or less salient personal values. *Self-feeling* refers to the more or less positive/negative affective (emotional) responses that are evoked by the ways in which the person thinks about and evaluates him or herself. *Self-enhancing* and *self-protective mechanisms* refer to the person's responses that allow the individual to think about him or herself in more favorable terms, to evaluate and feel more positively about him or herself, and to forestall negative thoughts, evaluations, and feelings about him or herself. Recognizing the conceptual and empirical interrelations among these classes of self-oriented responses, self-esteem is defined here in terms of all four classes: Self-esteem refers to the more or less

intense emotional responses that are evoked by self-conceptions and self-evaluations of being close to or distant from relatively important self-values and that motivate responses that are intended and may function to improve positive self-esteem or self-concepts, -evaluations, and -feelings.

Self-esteem may refer to one's momentary situation or to characteristic responses that transcend time and situations for the individual. In the latter case, regardless of the momentary situation, the person generally or chronically tends to conceive of and evaluate him or herself in terms of positively (or negatively) valued qualities, behaviors, and circumstances and to respond with positive (or negative) self-feelings. The stability of level of self-esteem may be accounted for by the stability of life's circumstances (the person continues to evoke rejecting responses from significant others in response to stable socially disvalued qualities), internalized attitudes, or, perhaps, genetic influences. Such stable, characteristic, or chronic levels are often referred to in terms of trait self-esteem.

In the case of momentary (state) or current self-esteem, level of self-esteem is variable and depends on the current circumstances in which the individual finds him or herself. In one social situation the person's attributes and behaviors might evoke accepting responses from significant others that stimulate positive self-conceptions, self-evaluations, and self-feelings and motivate attempts to reproduce these circumstances, and the same or other attributes in other social situations might evoke rejecting responses and concomitant negative self-conceptions, self-evaluations, and self-feelings that motivate responses that might forestall such experiences (e.g., avoidance of those who offered rejecting responses). Trait (characteristic, general) self-esteem and state (momentary, current) self-esteem are mutually influential. Individuals with low trait self-esteem may respond differently to current self-devaluing circumstances than individuals with high trait self-esteem. If a person feels like he or she has had a successful life, a momentary failure would be less traumatic.

Trait or state self-esteem may be based on more or less global (e.g., a worthy person) or specific (e.g., a good student) self-evaluations. A positive global self-evaluation generally is believed to be the most important basis for high self-esteem (Kaplan, 1986).

Defining self-esteem as a trait rather than a state, or in more general rather than specific terms, has implications for measuring self-esteem. The methodologies must be able to permit conclusions regarding cross-time and trans-situational versus current and situational-specific self-conceptions, self-evaluation, and concomitant self-feelings (how does one usually feel about one's self versus how does one feel about one's self now in this situation) and between more general versus more specific self-conceptions, self-evaluations, and concomitant self-feelings (I am a person of worth versus I am a good student). Further, because traditional self-report measures of self-esteem are vulnerable to distortions motivated by the need to perceive one's self in positive terms or to appear to others as if one perceives one's self in such terms, attention has been turned to the measurement of self-esteem in terms of nonconscious/automatic ways that presumably circumvent such enhancement-motivated distortions.

Such implicit, or "true" self-referent responses might be gauged by asking people to respond to stimuli that are associated with, but do not directly reflect, significant aspects of the self (Koole & Pelham, 2003). Unfortunately, measures of implicit self-esteem are more easily measured in experimental laboratory studies than in large-scale in-community studies. Such studies require alternative methods to determine that responses to self-evaluative scales are valid indicators of the individual's true feelings about him or herself. Among the self-report scales that are frequently used in research on self-esteem is Rosenberg's (1965) Self-Esteem Scale.

## SOCIAL ANTECEDENTS OF SELF-ESTEEM

The need for self-esteem is a fundamental human motive that is grounded in even more basic needs related to human survival and the interdependent social relationships that facilitate such survival (Kaplan, 1986). The need for self-esteem is experienced as the distressful emotions that are evoked when people perceive threats to their self-values. Such threats arise developmentally or contemporaneously when individuals anticipate, recall, or currently experience the failure to achieve important goals, evoke positive evaluations from significant others, or in general fail to approximate the self-evaluative criteria according to which they judge themselves to be worthy.

The self-values that comprise the hierarchically and situationally organized criteria for positive/negative self-evaluation may include the ability to perform tasks (contributing to a sense of competence), the ability to influence the environment (perhaps manifested as a sense of autonomy), likeability (perhaps manifested in the evocation of positive responses from significant others), leadership (reflected in the ability to influence others to adopt one's goals), or any number of other criteria. These values are hierarchically organized in the sense that if one could only approximate one value at the cost of failing to approximate another value, precedence would be given to the value that contributed more to one's overall sense of self-esteem. The values are situationally organized in the sense that different values are relevant to different situational contexts. On the battlefield, values relating to

loyalty to one's comrades or acting courageously might be salient. In the family, values relating to the ability to give and receive love and to care for those who are dependent might be salient whereas the battlefield-related criteria might be irrelevant. The experiences that contribute to one's negative (positive) self-feelings and, hence, to the need for self-esteem include past developmental circumstances and the current situation.

Other people provide important information to the individual that keys into the person's self-evaluation. Although it is not otherwise apparent as to how successful we are in meeting our self-evaluatively relevant goals, other people provide clues to how well we are doing in this regard. People may offer expression of approval or disapproval by virtue of their evaluation of our performance. Further, our own perception of what we accomplish may be measured against our perceptions of what others like us have accomplished. That is, others provide a normative standard against which we evaluate our own achievements. Other people's responses to us are important to our self-evaluation also insofar as evoking positive responses is intrinsically valued as a criterion for self-evaluation. That is, we think well of ourselves if others like and respect us. One of the criteria for high self-esteem is the self-perception of being liked and respected by others who are highly regarded by us.

It is in the context of emotionally significant interpersonal relationships that individuals develop characteristic levels of self-esteem and contemporaneously respond to what are perceived as threats to one's self-esteem. In the context of relations with parents, siblings, friends, children, spouses, and romantic partners, these interpersonal transactions assume great significance for how one perceives, evaluates, and feels about one's self.

Parenting style, for example, has a profound impact on children's level of self-esteem (DeHart, Pelham, & Tennen, 2006). Young adult children who had more nurturing parents tend to have higher implicit self-esteem. Experiences in secondary social institutions as well contribute to level of self-esteem. Individuals who identify with a positive religious identity tend to display higher self-esteem (Keyes & Reitzes, 2007), particularly during certain life transitions such as retirement, when a religious identity may serve to replace an important loss of some other identity (i.e., worker). Within medicine, better functional health (the ability to perform various activities) anticipates greater levels of self-esteem over a 2-year period (Reitzes & Mutran, 2006); and the success of the therapeutic experience is expected when the patient is able to perceive that the therapist truly places a high value on the patient's worth (Beutler et al., 2004).

In the workplace, a study of abusive supervisory patterns on subordinate's self-esteem (Burton & Hoobler, 2006) confirmed that individuals in the abusive supervision condition manifested lower levels of self-esteem than individuals in a neutral supervision condition. Finally, the relevance of political values is apparent from the observation that for those whose beliefs suggest that socioeconomic status reflects talent and effort, the achievement of higher levels of socioeconomic status is more likely to contribute to one's self-esteem than for those who believe that socioeconomic status is merely a reflection of one's initial placement in a social structure and does not reflect one way or the other on a person's merit (Malka & Miller, 2007).

Experiences of failure/rejection or success/acceptance will affect level of self-esteem depending on the effectiveness of the person's self-enhancing or self-protective responses to the experiences. These mechanisms include increased efforts directed toward achieving valued attributes or performing valued behaviors, distorting one's self-perceptions in a positive direction, changing one's values to give higher priority to those that are achievable and lower priority to those values that are more difficult to achieve, and directly counteracting negative self-feelings by repressing or suppressing them or through the use of mood-enhancing substances. Under some conditions, deviant behaviors that symbolize rejection of the society that engendered low self-esteem serve to decrease self-rejecting attitudes (Kaplan, 1975, 1980). Feelings of being rejected may be reduced by hostility toward the rejecting partners (Murray, Holmes, MacDonald, & Ellsworth, 1998), in effect discrediting the source of the rejection. Overly positive perceptions of acceptance in the context of peer relationships is effective in increasing feelings of self-worth, whether examining a normative sample or a peer-rejected group of grade school students (Kistner, David, & Repper, 2007).

A common mechanism that is employed in the face of probable failure to approximate one's self-evaluatively relevant goals is self-handicapping (Rhodewalt & Tragakis, 2002). This mechanism involves self-imposing barriers to success that would provide self-justification for excuses for failure. By not exerting effort, one can blame one's failure on the lack of effort rather than on any limitations on one's own ability. However, individuals who base their self-esteem on particular conventional values will ordinarily devote greater effort to achieving those values.

## SOCIAL CONSEQUENCES OF LOW SELF-ESTEEM

Threats to a person's self-esteem have important positive and negative consequences for the functioning of interpersonal relationships and group memberships. For those who identify with a group, devaluation of the group will lead to

increased in-group bias and a subsequent increase in social self-esteem. For individuals whose position in the group is insecure (neophytes, those who are ostracized or peripheral) a common reaction is increased conformity, or at least increased impression management of conforming to group norms (Jetten, Hornsey, & Adarves-Yorno, 2006). Lower status group members are more likely to present themselves as conforming than higher prestige group members, particularly when they are addressing an in-group audience and when they perceive their responses as being made public.

In some groups, paradoxically, conformity may demand the appearance of independence or being a rebel. In such groups, also, one would expect those most in need of group acceptance (that is, new, rejected, or peripheral members) to be most likely to make public displays of being nonconformists. Of course it is to be expected that conformity as a mechanism would be utilized only when the individual feels committed to the group and expects conformity to result in desirable rewards (including recognition) and when no alternatives are offered that lead one to anticipate more self-enhancing outcomes. Absent these contingencies, the loss of motivation to conform to the group and the disposition to seek alternative (perhaps deviant) response patterns becomes a real possibility. These principles play out in a variety of ways in interpersonal and group contexts.

In romantic relationships, low self-esteem on the part of one of the partners may have destructive implications with regard to the maintenance of the relationship. These individuals disbelieve that their partners hold positive attitudes toward them and frequently impute negative attitudes, a self-protective device by low self-esteem individuals that permits them to reject others before they themselves are rejected. Although low self-esteem individuals' partners may initially have positive attitudes toward them, because of their oversensitivity to rejection and their self-defensive responses to expectations of rejection, these individuals create the rejecting attitudes that previously did not in fact exist.

The mechanism of conformity to group norms as an adaptation to self-threatening circumstances has important implications for intergroup behavior because it often takes the form of public displays of derogation or deleterious action against groups that are regarded as competitors or otherwise in conflict with one's own group. It is the individual who has a tenuous relationship with the group rather than the longstanding member that feels the need to derogate outgroups as a mechanism for achieving acceptance within the group (Noel, Wann, & Branscombe, 1995).

As low self-esteem persons associate their self-derogation with participation in the conventional socio-normative system, it becomes increasingly likely that individuals will withdraw from participation in conventional social institutions and rather will adopt deviant patterns that offer alternative sources of self-esteem (Kaplan, 1975, 1980, 1986; Kaplan & Johnson, 2001). For example, lower levels of self-esteem during the university years predicted lower levels of work involvement and satisfaction and higher levels of unemployment, weariness, and negative attitudes toward (along with reduced accomplishment at) work (Salmela-Aro & Nurmi, 2007). In the educational realm, studies of adolescents followed into adulthood demonstrate that low self-esteem during adolescence is associated with a greater probability of dropping out of school, and, of course, being less likely to attend a university, findings that are significant because they are frequently observed after controlling for the effects of socioeconomic status, depression, and IQ, among other variables. At the same time, long-term studies confirm that adolescents characterized by low self-esteem predicted higher levels of criminal behavior during adulthood.

To some extent the loss of motivation, and perhaps ability, to conform to conventional role obligations might be accounted for in part by the association of low self-esteem with poor physical and mental health outcomes. For example, over a 2-year period, low self-esteem was associated with decreases in functional health (i.e., the ability to perform various tasks; Reitzes & Mutran, 2006).

## LIFE COURSE AND SELF-ESTEEM

The empirical literature clearly suggests that the level, stability, and even capacity for self-esteem is contingent on stage in the life course and its concomitants. Level of self-esteem has been observed to change over the life course. The level of self-approval is relatively high during early childhood but is somewhat lower during middle and late childhood. The level apparently declines during the transitional period between childhood and adolescence. During adulthood, level of self-esteem seems to increase during the latter part of the third decade of life (the 20s) and in the 50s and 60s. However, self-esteem appears to decrease among adults ages 70 or older (Tevendale & DuBois, 2006). More specifically, global self-esteem tends to decrease during adolescence and gradually increase during the third decade of life (between 20 and 30; Kling, Hyde, Showers, & Buswell, 1999). A follow-up of individuals between the ages of 16 and 26 over a 20-year period reported an average increase of self-esteem (Roberts & Bengtson, 1996). Individuals with lower self-esteem ages 18 to 25 manifested a greater increase in self-esteem over this period (Galambos, Barker, & Krahn, 2006). Improvements in self-esteem correlated with receiving greater social support and experiencing less unemployment.

Amount of change/stability in self-esteem, as opposed to change in level of self-esteem, also varies throughout the life course. Amount of change (low stability) tends to be relatively great during childhood. However, stability tends to increase between adolescence and adulthood and decreases between the adult years and old age (Trzesniewski, Donnellan, & Robins, 2003).

The developmental basis for a global sense of high or low self-esteem appears to emerge at an earlier age (3 years) when children begin to use self-referent words "I" and "me" in sentences suggesting that they have particular competencies such as knowing their letters or being a "big boy/girl." Implicit in these statements is the sense that these competencies have evaluative significance. However, very young children do not have a self-conscious concept of global self-esteem that they can verbalize. Nevertheless, a sense of high or low self-esteem becomes manifest in behaviors. Thus, among children ages 4 through 7, children with high and low self-esteem were said to be distinguished by whether or not they showed exploration, confidence, curiosity, and so on (Harter, 1999). Around the age of 8, however, children appear to be able to reflect on themselves as being globally more or less self-accepting. It is around this age that it is possible to conceive of one's self and to communicate a self-conception that is less than positive. The ability to form such global self-evaluations is facilitated by the development at this age of the capacity to compare one's self to a self-evaluative standard and to take the role of another person and perceive one's self from the other person's point of view.

Influences on low or high self-esteem are associated with stage in the life course. Some social changes that are predictably likely to occur at particular stages in the life course may influence level of self-esteem. Thus, the transition from elementary school to middle school appears to adversely affect self-esteem (Seidman et al., 1994). Whether this decrease in self-esteem associated with transition is due to the disruption of normal adaptive/coping/defense mechanisms or increased expectations on the individual that the individual has problems fulfilling or is accounted for by other correlates of the transition remains to be determined. In any case, stage of the life course does appear to moderate level of self-esteem and must, of necessity, be considered in any attempt to fully understand the nature, antecedents, and consequences of processes related to self-esteem.

## SEX EDUCATION/ ABSTINENCE EDUCATION

People learn about their sexuality throughout their lives and from a multitude of sources, including peers, family, religious institutions, online sources, commercial advertising, self-help books, television, and popular music and films. Despite the varied sources and moments at which people glean lessons about sex and sexuality, researchers, educators, policy makers, and community members concerned with sex education routinely focus on school-based instruction for adolescents. This focus often forecloses attention to lifelong learning about sexuality. Sexuality exists in all stages of the life course, and sex education thus has the potential to be a lifelong pursuit.

Most school-based sex education in the United States promotes a narrow conception of not only *when* people learn about sex and sexuality but also *what* they need to learn. Sex education—both policy and practice—routinely approaches sexual health as an issue of reproductive anatomy, disease and pregnancy prevention, and sexual abstinence. The narrow scope of sex education has a long legacy entrenched in moral panics, social purity movements, and disease prevention. This focus obscures other issues that many consider central to sexual well-being, including mental and emotional health, spiritual growth, and a sense of sexual agency.

At the beginning of the 21st century, the debate over sex education in the United States is particularly contentious. Proponents of abstinence-only sex education argue for instruction that insists on the value of abstaining from sexual activity outside of heterosexual marriage. Such definitions of sexual well-being deny lesbian, gay, and bisexual people and other sexual nonconformists access to information that promotes their health. Those advocating comprehensive sex education argue that schools must provide young people with lessons about pregnancy and disease prevention; lesbian, gay, and bisexuality; abortion; and masturbation to address the reality that many people are sexually active outside marriage. Conflicts over school-based sex education are about much more than whether and what young people should learn about sex and sexuality in school; rather, these debates address fundamental issues about gender norms, family formations, sexual possibilities, and life trajectories.

### SEX EDUCATION IN THE 20TH CENTURY

Sex education emerged as a public concern in the United States in the late 1800s, when the YMCA, YWCA, and American Purity Alliance, organizations based on Judeo-Christian principles, hosted sex-related panels and lectures. In the early 1900s, U.S. educators and advocates formed organizations to address sexual morality and hygiene, including the American Society of Sanitary and Moral Prophylaxis (founded in 1905), the American Federation for Sex Hygiene (1910), and the American Social Hygiene Association (1914). These groups focused on the dangers of "social evil" especially within the context of venereal diseases. During World War I, policy makers grew concerned that soldiers would return from overseas with venereal diseases such as syphilis and gonorrhea and thus endanger U.S. morality and well-being. In response, organizations such as the American Social Hygiene Association ran a social marketing campaign that brought moral and physical fitness together with the aim of preventing sexually transmitted infections (STIs). During this period, medical information about sexually transmitted diseases (STD) improved and popular media about sexuality increased. As sexuality information escalated in public spaces, parents and teachers worried about adolescents' access to this information. Regulating sex education within schools promised to control how youth talked about sex. Therefore, by the end of the 1920s, consensus was emerging that sex education was primarily schools'—and not families—responsibility (Rosow and Persell, 1980).

***Abstinence.*** *A billboard in downtown Baltimore promotes teen abstinence.* AP IMAGES.

In 1964 the Sexuality Information and Education Council of the United States (SIECUS) formed to promote access to sexual health information. SIECUS founder Mary Calderone explained, "We put sexuality into the field of health rather than the field of morals" (Irvine, 2002, p. 27). SIECUS departed from earlier hygiene groups that combined sexuality and morality rather than sexuality and health. SIECUS continues to be a national organization invested in advocacy for sexual health, sexual rights, the defense of comprehensive sex education, the promotion of sexual pleasure, and the eradication of sexual guilt.

The emergence of the HIV/AIDS epidemic in the 1980s strengthened the link between sexuality and health and had a broad and significant impact on sex education. HIV heightened the fear that lives were at stake in the debate over sex education. For comprehensive-education supporters, HIV provided further evidence that young people needed to be equipped with the tools to fight sexually transmitted diseases. For abstinence-only supporters, HIV affirmed that sexual expression is appropriate and safe only within monogamous, faithful, heterosexual marriage (Irvine, 2002).

## CONTEMPORARY DEBATES OVER COMPREHENSIVE AND ABSTINENCE-ONLY SEX EDUCATION

The fight over abstinence-only sex education was well underway before the emergence of the HIV epidemic. In 1978 Senator Edward Kennedy (Democrat-Massachusetts) sponsored the Adolescent Health Services Act, which aimed to address a perceived epidemic of teen pregnancies by funding comprehensive sex education, contraceptive services, and other family planning and reproductive services. Objecting to the Adolescent Health Services Act and to broad shifts in gender and sexual norms, conservatives argued that federal funding should promote sexual abstinence among young people, not suggest that they might engage in sexual activity safely.

Congress passed the Adolescent Family Life Act (AFLA) in 1981. AFLA, also known as the "chastity law," codified and funded a standard of sexual abstinence. The legislation promoted regulation and conventional modesty among youth by funding exclusively abstinence-only education and denying funding to state and local programs that discussed, counseled, or provided abortion.

The 1996 Personal Responsibility and Work Opportunity Reconciliation Act (what many know as "welfare reform") included an amendment that required that programs receiving federal funding adhere to an eight-point definition of "abstinence education" as instruction that asserts mutually faithful, monogamous marriage as "the expected standard of sexual activity" for all people.

All of this legislation contributed to a sustained federal effort to fund education that reasserts conventional gender and sexual norms and morality. In the 1990s and 2000s, conservatives have been unabashed in their aim to reassert heterosexual marriage as fundamental to a healthy society and to establish a taken-for-granted idea that sexual abstinence is the most, if not only, appropriate choice for young people outside of heterosexual marriage. This "common sense" emerged despite consistent support for comprehensive sex education that presents abstinence as one of many ways to prevent sexually transmitted infections and pregnancies and which discusses the benefits, failure rates, and side effects of contraceptive methods. Such instruction usually affirms the value of sexual abstinence in pregnancy and disease prevention. However, comprehensive sex education also argues that, because some youth are sexually active before leaving high school and before marriage and that non-heterosexual youth are invisible in education that relies on marriage, schools must provide sex education that equips them to engage in consensual and safe sexual activity.

## SEX EDUCATION IN CONTEXT: CULTURE, CURRICULA, AND CLASSROOMS

Debates and controversies over sex education are about much more than whether, when, and what young people should learn in school about sex and sexuality, and the effects of sex education extend well beyond whether students learn how to prevent pregnancies and disease. Community struggles over sex education policy in the United States reflect, resist, and affirm broad social conflict. Sex educators offer lessons that aim to protect young people from harm but that may have little effect. Further, day-to-day practices in sex education classrooms reflect and reproduce persistent social inequalities such as gender norms, family structures, and sexual expectations.

## SEXUAL SENSIBILITIES: SEX EDUCATION AND SHIFTING SOCIAL NORMS

Varying contexts of family values, cultural proscriptions of adolescent sexuality, and religion all have a significant impact on sex education, adolescents' ability to navigate their sexuality, and the role of sexuality in the life course. Amy Schalet's research (2004) on the construction of adolescent sexuality in the Netherlands and the United States reveals the significant role of culture in sexual health. Schalet found that Dutch parents normalize and accept adolescent sexuality whereas U.S. parents dramatize, deny, and fear adolescent sexuality. While Dutch parents see adolescents as sexual agents capable of healthy sexual decision-making and loving relationships, Americans distrust adolescents' ability to navigate sexuality and deny their ability to foster love-based relationships. The U.S practice of denying adolescent sexuality makes it harder for adolescents to gain access to contraceptives, abortion, and relevant sex education material. Young people in the United States also find it difficult to act on healthy sexual choices.

This culture of denial and proscription is also evident in adult talk about young people's sexuality and sex education. Janice Irvine (2002) researched the role of emotions in the politics of sex education debates to unravel the power of emotion and language in the culture wars of sexuality. Irvine realizes that *how* people talk about sex has significant implications on sexual culture. These adult-driven debates ignore adolescents' voices; messages of fear illicit strong emotional responses that further compel abstinence-only support while masking the benefits of comprehensive sex education.

## INSTRUCTIONAL IMPACT: EVALUATION RESEARCH AND SEX EDUCATION

Despite proponents' claims that abstinence-only sex education contributes to individual, familial, and social well-being, reports consistently confirm that no studies meeting scientific standards have demonstrated that abstinence-only education reduces teen pregnancies or delays first intercourse (Kirby, 2001). Indeed, few systematic evaluations exist of sex education, broadly defined, and, in particular, of abstinence-only sex education. Those evaluations that are available indicate that participating in abstinence-only programs does not increase the likelihood that youth will abstain from engaging in sex or delay sexual initiation. Some research suggests that many young people who participate in abstinence-only education and who take "virginity pledges" eventually do become sexually active before marriage, are less likely to use condoms at first intercourse, and thus are ultimately at greater risk of contracting an STI.

This finding contradicts the widespread belief that talking with youth about sex education will increase their interest in having sex. Indeed, research shows that participants in comprehensive sex education wait longer to have sex, have fewer sex partners, and use condoms and other contraceptive methods at significantly higher numbers as compared to students not in comprehensive sex

## VIRGINITY PLEDGE

Virginity pledges are promises to remain sexually abstinent until marriage. Pledgers tend to be school-aged, evangelical Christians, and from conventional families. Many—though not all—pledgers promise abstinence through formal organizations such as The Silver Ring Thing and True Love Waits. At the turn of the 21st century, virginity pledging, like abstinence-only sex education, contributes to a broad movement to reassert conventional gender and sexual norms.

Definitions of virginity are elusive, often making it unclear precisely what a pledger is committing to. Some believe that engaging in penile-vaginal intercourse constitutes the loss of one's virginity; for others, remaining abstinent may mean avoiding kissing, oral sex, or anal sex. Some assert the possibility of "secondary virginity," in which a person pledges to no longer engage in sexual activity and to remain abstinent until marriage.

Pledgers may postpone sex, but, having had little instruction in disease and pregnancy prevention, they are less likely to use a condom during their first sexual experiences. Identity appears important to pledging's effectiveness: Pledgers successfully delay sexual activity as long as committing to abstinence remains nonnormative among their peers—too many or too few pledging peers results in a less socially significant and therefore less effective pledge.

education. The curricula most effective in reducing teen pregnancies focus on contraceptive use and sexual behavior while also highlighting abstinence as the safest choice to avoid pregnancies and STIs (Kirby, 2001).

These and other findings in the evaluation research have become increasingly politicized. Critics of abstinence-only policies have called on the federal government (a) to desist funding for curricula that contain medical and scientific inaccuracies and (b) to conduct rigorous scientific evaluations of the curricula's effectiveness. These calls grew only louder in 2006, when the nonpartisan Government Accountability Office (GAO) released a report on abstinence education, conducted at the request of Democratic members of the House of Representatives and Senate. According to the GAO, the U.S. Department of Health and Human Services had not required grantees to review their curricula for scientific accuracy or to conduct scientifically sound evaluations of their programs' effectiveness in meeting their own goal of promoting sexual abstinence among young people. A 2004 report sponsored by Representative Henry Waxman (Democrat-California) demonstrated that abstinence-only curricula contain scientific errors (including false information about contraceptives and the risks of abortion), distort distinctions between religion and science, and provide stereotypical depictions of girls' and boys' behavior.

As of late 2007, approximately one quarter of all states have refused federal funding for sex education that requires abstinence-only curricula. This is a dramatic change from 2006, when only four states rejected this funding.

### INSIDE THE CLASSROOM: SEX EDUCATION AND THE REPRODUCTION OF SOCIAL INEQUALITY

While states' refusal of abstinence-only funding is a significant development in the debate over sex education, legislative and administrative decisions are only brief moments in a process of curricular negotiation and contestation. Abstinence-only and comprehensive curricula are never regimes of absolute control. Teachers adapt administration priorities to meet their own instructional aims, and once inside the classroom, negotiations continue as students receive, resist, and revise their teachers' lessons.

Much of the research on sex education focuses on hidden lessons on gender and female sexuality. In one of the earliest and still most influential publications on sex education, Michelle Fine (1988) argued that discourses of female victimization and (im)morality dominated school-based sex education. Fine pointed to a "missing discourse" that recognizes girls' and young women's sexual desires and pleasures. This discourse emerges in whispers from students, but teachers and the formal curriculum routinely mute talk of female sexuality as a site of agency and pleasure, contributing to the broad educational, intellectual, and political disempowerment of girls and women.

This muting continues in the wake of U.S. abstinence-only legislation. Jessica Fields found that whereas abstinence-only lessons may be the formal mandate in sex education courses, multiple curricula abound in a single class meeting. Formal, hidden, and evaded lessons compete for students' attention, and all help to determine the sex education students receive. These lessons are consistently inflected with social differences and inequalities. For example, teachers affirm sexist understandings of sexuality when they present lessons that officially promote open sexual communication while also casting boys and men

as sexual aggressors and assigning girls and women responsibility for maintaining sexual boundaries. Often, teachers are complicit in perpetuating racist and able-ist depictions of bodies and sexuality when they present exclusively white, able-bodied, and idealized images of sex organs and anatomies.

### SEX EDUCATION'S FUTURE AND POTENTIAL

Building on the work of Michelle Fine, feminist researchers have explored the "whisper" of desire in sex education, finding in these whispers not only the hint of female sexual agency, but also the potential for transformative sex education, and a call for broad social change. Sometimes those whispers occur outside the classroom—in school-based health clinics, in online chat rooms, or over dinner with a trusted adult, for example. Other times those whispers occur inside the classroom during, for example, a discussion of orgasms, clitorises, or heterosexual intercourse. In these moments, the discourse of desire and the challenge to social inequality so often missing from sex education interrupts the prevailing talk about female sexuality as victimization, violence, and individual morality. In these moments, sex education becomes more than an opportunity to teach the skills and norms expected of young people as they move toward adulthood. Instead, sex education becomes a site in which young women and others can struggle against disadvantage and come to a sense of entitlement. This sensibility is crucial to a range of conventional health outcomes—for example, avoiding unwanted pregnancies, STIs, and sexual coercion. It is also entangled with the political, intellectual, and social entitlement that is central to people thriving throughout the life course.

Researchers, advocates, and educators with a critical perspective on sexuality, education, and youth pursue inquiry that "suspends the 'givens' of adolescent sexuality" (McClelland and Fine 2008, p. 67). These givens include the commonsense assumptions that abstinence is the most desirable outcome in young people's sexual lives; that young people are naturally and best heterosexual; that girls are passive in their heterosexual relationships; that boys are inevitably sexually aggressive; that sex education's promise and effects lie primarily in preventing pregnancies and disease and in delaying sexual initiation; and that learning about sex and sexuality ends once we leave adolescence.

Intersections of religion, public policy, school-based education, and media all inform youth and adults of the potential benefits and harms of sexuality. Locating sex education in classrooms that uncritically promote gender and sexuality conventions limits sex education's potential. Sex education represents an opportunity to promote understandings of sexuality as a lifelong process; affirm lesbian, gay, bisexual, and heterosexualities; and acknowledge that individuals learn about sex and sexuality across institutions and across their lifetimes.

## SEXUAL ACTIVITY, ADOLESCENT

"It started with a chair," says Juno in the opening line of the 2007 movie of the same name. As quickly becomes apparent, "it" refers to sex between two teenagers that in this case leads to pregnancy, birth, and finally an

awakening of what love is all about. In contrast, a very different sequence of life course events is laid out in the traditional children's jump rope rhyme: "first comes love, then comes marriage, then comes a baby in a baby carriage." The chain of events portrayed in Juno, however, in which marriage is not even mentioned, is the one that comes closest to typifying adolescent sexual behavior at the turn of the 21st century. It is also the sequence that continues to worry parents and policy makers alike.

## TRENDS IN ADOLESCENT SEXUAL BEHAVIORS

A range of excellent Web sites provide facts and figures pertaining to adolescent sexual behavior, including statistics on pregnancy, birth rates, contraception and sexually transmitted infections (STIs) (for example, www.cdc.gov/nchs; www.childtrends.org; www.guttmacher.org). Since the early 1970s many aspects of adolescent sexual behavior have undergone marked changes; an understanding of the historical trends helps to put current teen activities in context.

Beginning in the late 1960s and continuing throughout the 1980s, increasing proportions of teenagers had nonmarital sexual intercourse. This trend reversed during the late 1990s and into the early 21st century, however. Comparisons of data from the 1988 and 2002 National Surveys of Family Growth (NSFG) show that, whereas 60% of 15- to 19-year-old males in 1988 reported having had intercourse, by 2002 this had dropped to 46%. Girls showed a decrease over the same time period, from 51% to 46%. American teens also appear to be waiting longer to have sex. Whereas in 1995 19% of girls and 21% of boys said they had had sex by age 15, in 2002 the corresponding percentages were 13% and 15% (Abma, Martinez, Mosher, and Dawson, 2004).

Adolescents have always had sex, so why should current figures be of concern, especially given their downward trend? Despite the declines, close to half of American teens report having had sexual intercourse at least once, and roughly 1 in 7 initiated sex prior to age fifteen. Alongside moral disquiet that adolescent sexual behavior overwhelmingly occurs outside of marriage, risk of pregnancy and STIs also lie at the forefront of societal worries.

Looking at the glass half full, a steady drop in teen pregnancy rates from a high point in 1991 has paralleled declines in sexual intercourse among teenagers in the United States. So has the teen birth rate, which in 1991 stood at 62 births per 1000 15- to 19-year-old American girls, but by 2004 had dropped by one third to 41 births per 1000. Although social conservatives have credited much of the drop in teen pregnancy rates to abstinence education programs, the numbers show that improved contraception has been the principal player (Santelli, Lindberg, Finer, and Singh, 2007). Data from the 1995 and 2002 rounds of the NSFG placed the percentages of 15- to 19-year-old males who used contraceptives the most recent time they had sex at 82% in 1995 and 91% in 2002. Comparable figures for girls were 71% and 83%. Teens are increasingly using condoms, which provide the best protection from STIs, and the birth control pill and injectable hormonal methods such as Depo-Provera to prevent pregnancy. The number of adolescents who used two or more methods simultaneously over this time period also more than doubled, from 11% to 26%, reflecting a desire to protect against both pregnancy and STIs. Contraceptive use at first sex has also become more common. This is important because youth who use contraceptives at first sex are more likely to use them when they have sex later than are youth who do not, and consistent contraception is key to preventing pregnancy and STIs.

The same glass may also be seen as half empty, however, as close to one-third of American girls get pregnant by age 20—a figure that stands at just over 50% for Latina teens. More than four-fifths of teen pregnancies are unplanned and just under half of unintended teen pregnancies end in abortion. Of those teen pregnancies that are carried to term, the proportion of teen births that occur within marriage decreased from just under half in 1982 to less than 1 in 5 in 2002 as fewer unmarried pregnant teens chose to marry prior to giving birth, if at all. Further, despite significant declines in teen sex, pregnancy, abortions and births since 1991, U.S. teen pregnancy rates, birth rates, abortion rates, and rates of STIs remain among the highest in the industrialized world (Singh and Darroch, 2000; Darroch, Singh, and Frost, 2003). Although levels of adolescent sexual activity do not vary much across comparable developed countries such as Canada, Great Britain, France, Sweden, and the United States, American teens are more likely than their foreign counterparts to have sexual intercourse before their 15th birthday and to have two or more sexual partners in a year. They are also less likely to use contraceptives, especially the pill and other long-acting reversible hormonal methods that are the most effective at preventing pregnancy.

Youths who delay sexual initiation are less likely to regret the timing of their first sexual experience, and are less likely to be involved in coercive sexual relationships. Approximately 10% of first sexual encounters that occur prior to age 20 are reported by young women as involuntary or forced; for those who first have sex before age 15, the percentage is higher still. Early initiation of sex is also especially worrisome because young teens are less likely to use contraception at first sex and to use contraceptives

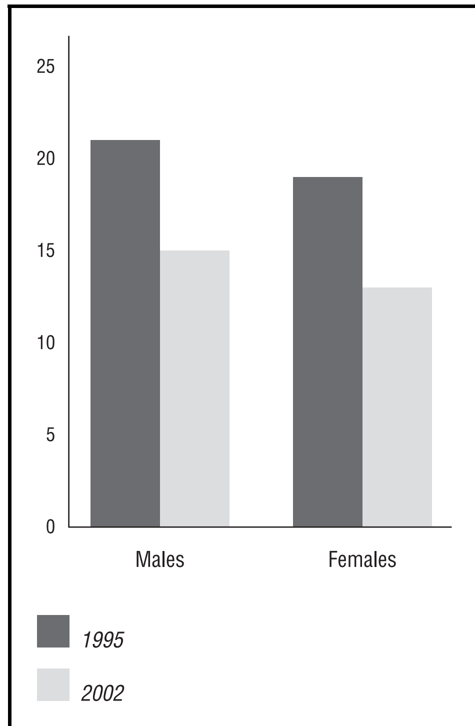

***Figure 1.*** *Percent of teens having had sex by age 15 years.* CENGAGE LEARNING, GALE.

consistently throughout their first relationship (Ryan et al., 2003). Although most teens who have had sex report none or only one sexual partner in the past year, close to 10% report four or more. Having more partners also is associated with a lower likelihood of contraception and a higher likelihood of acquiring an STI. According to figures published by Child Trends in 2006, young people between 15 and 24 years old account for almost half of all newly acquired STIs in the United States. Figures released by the Centers for Disease Control in 2008 show that at least 1 in 4 teenage girls had an STI.

Why might American teens have sex at an earlier age, have more partners, and use contraception less consistently than teens in other developed countries? A number of reasons have been proposed, including more negative societal attitudes toward teenage sexual relationships, more restricted access to contraceptives, and higher costs associated with reproductive health services. The Alan Guttmacher Institute notes that countries with low levels of adolescent pregnancy, childbearing, and STIs are not only characterized by a greater acceptance of teenage sexual relationships but also provide more comprehensive and balanced information about sexuality, and the prevention of pregnancy and STIs within these relationships.

## WHAT DO PEOPLE MEAN BY "SEX"?

At a White House press conference on January 26, 1998, President Bill Clinton denied allegations of prior sexual relations with White House intern Monica Lewinsky, stating: "I did not have sexual relations with that woman." In the sense that sexual relations means male-female intercourse, President Clinton did not lie. However, sexual relations can include behaviors other than intercourse; adolescents in the early 21st century are engaging in both oral and anal sex, sometimes while clinging to the belief that by avoiding intercourse in favor of these behaviors, they officially remain virgins (Remez, 2000). Data from the NSFG show that in 2002, 16% of teens between the ages of 15 and 17 years who had not yet had sexual intercourse had engaged in oral sex.

What teens do or do not consider to be sex is also a subject that has received publicity as a result of research on virginity pledges by Peter Bearman and Hannah Brückner (2001, 2005). Approximately 1 in 10 teens in the United States takes a virginity pledge that is designed to curb adolescent sexual activity (Maynard, 2005). While it appears that taking the pledge delays the initiation of sexual intercourse for some teens, pledgers who remain virgins are more likely to have anal and oral sex. Adolescents view oral sex as less threatening to their values and beliefs, and perceive it to have fewer health, social, and emotional consequences than vaginal sex (Halpern-Felsher, Cornell, Kropp, and Tschann, 2005). However, although both oral and anal sex remove the potential for pregnancy, these activities can put teens at high risk for STIs.

## WHY DO TEENS HAVE SEX?

Much research over the past few decades has tried to work out why some teens will have sex while others will refrain, and why among sexually active teens, some will use contraception and others will not. To identify both risk and protective factors, many of these studies have used data from large surveys such as the National Longitudinal Survey of Adolescent Health (Add Health), the 1979 and 1997 National Longitudinal Surveys of Youth (NLSY79 and NLSY97), the NSFG, and the Youth Risk Behavior Survey (YRBS), supplemented with information gleaned from questionnaires targeted at more specific subpopulations of adolescents.

There is no simple answer to the question: What predicts adolescent sexual activity? Myriad structural and contextual influences play a role. For example, African-American youth initiate sexual activity at earlier ages than do European-American or Latino/a youths, and features of the neighborhood environment have been highlighted to account for this racial difference: neighborhood poverty as a factor that elevates the risk of early sexual initiation, and neighborhood social cohesion and social

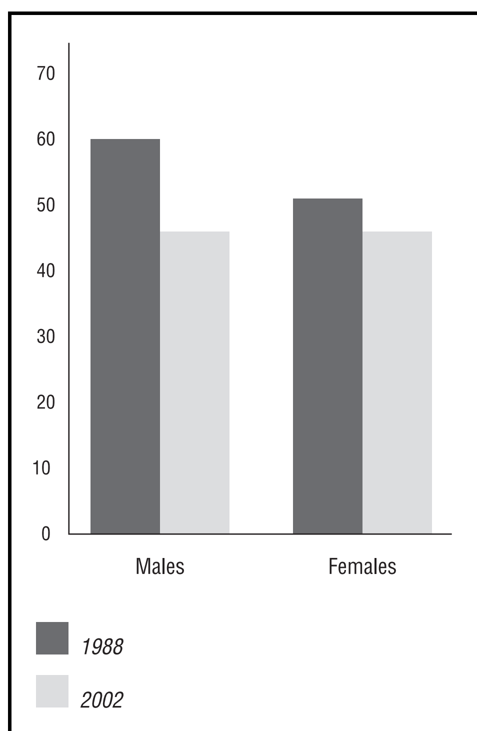

***Figure 2.*** *Percent 15–19 year olds who have had sexual intercourse.* CENGAGE LEARNING, GALE.

control that helps delay sexual onset (Browning, Leventhal, and Brooks-Gunn, 2004). Television, movies, music, magazines and the Internet all expose teens to sexual imagery, but rarely depict realistic consequences of risky sexual activities. Although relatively few studies have looked at the effect of media exposure on adolescent sexual knowledge, attitudes, and behaviors, findings generally suggest that greater exposure to sexual content within the media is associated with higher estimates of the extent to which friends are sexually active, and more and earlier sexual behavior among adolescents themselves.

Emphasis has been placed on the role of peers, and studies have found that friends' sexual behaviors, perceptions of friends' behaviors and attitudes, and the degree to which adolescents are involved with their friends all influence adolescent sexual behaviors. For example, in 2006 Renee Sieving and colleagues from the University of Minnesota found that sexually inexperienced kids in 9th to 11th grades had greater odds of having intercourse in the following 18 months when a higher proportion of their friends were sexually active. Youths who believed that they would gain their friends' respect if they were to have sex also had higher odds of initiating intercourse.

Numerous studies also demonstrate the importance of both family structure and parental processes for adolescent sexual behavior. For example, youth who grow up in intact two-parent homes are more likely to delay sexual initiation and to have fewer sexual partners than adolescents in single parent and stepfamily homes. Why? Parental supervision may be higher in two-parent families, reducing the amount of time that a teen can spend at home without a parent, and hence their opportunity to have sex. Parental monitoring also conveys to children that they matter. A 2007 study by Chadwick Menning and colleagues that finds that the more involved adolescent males are with their stepfathers the less likely they are to have sex. This finding also underscores the importance of close family relationships (Menning, Holtzman, and Kapinus, 2007). Further, even if teens cite their peers and the media as primary sources of sexual information and influences on their sexual behavior, parents can play a critical intervening role. Although having sexually active peers tends to accelerate sexual initiation, parental responsiveness to adolescents during discussions about sex can decrease risk-taking behaviors, and can buffer the negative influences of peers (Fasula and Miller, 2006). Conversely, peer effects may be stronger when parental bonds are strained (Jaccard, Blanton, and Dodge, 2005).

Reflecting different theoretical perspectives and disciplinary approaches, other research has been more qualitative in nature, using information from semi-structured, one-on-one interviews that allow teens to more easily tell their own stories surrounding their sexual experiences, and to reflect on how and why they made the decisions they did—choices that do not always appear to be in their best interests. Qualitative studies are a reminder that curiosity plays an important role, and that adolescents, like adults, have sexual desires. Such studies also underscore the importance of understanding the social contexts within which adolescents act. For example, how does the quality of a relationship or perception of romance define the context for sexual decision making? Although a teen may well understand the importance of using contraception to reduce health and social risks, their decision to actually use a condom might instead come down to whether they believe this choice might improve or harm their relationship.

In-depth interviews with inner-city Black adolescents uncovered some important gender differences in the ways in which youth approach sexual relationships (Andrinopoulos, Kerrigan, and Ellen, 2006). Whereas young men reported that sexual relationships helped them feel wanted and that they could gain social status among their peers when they had multiple partners, young women desired monogamous romantic partners for emotional intimacy, although most also reported having had nonmonogamous partners. Understanding contextual factors

such as a lack of socioeconomic opportunities for young men, or an imbalanced sex ratio as a result of the incarceration of many young men, is crucial for comprehending the types of sexual relationships that youth engage in, as the nature of the relationship can then affect the sexual activities engaged in within the relationship, and the contraceptive decisions they make (Kaestle and Halpern, 2005).

A 2005 study of adolescent sexual decision making by Tricia Michels and colleagues from the University of California provides evidence that at least some young adolescents set a priori boundaries for how far they are willing to go with a particular partner at a given time (Michels, Kropp, Eyre, and Halpern-Felsher, 2005). The limits that teens mentally set for themselves are influenced by their own personal characteristics and the nature of the relationship they are in. Study participants also acknowledged that the lines they drew now might be crossed in the future as they matured, their relationship changed, or they became more sexually experienced. Their findings also suggested a dynamic, self-regulating process of decision making as teens (especially girls) reflected on their behaviors and how they felt about them, and then either reaffirmed or reappraised where their boundaries lay.

Results from both quantitative and qualitative research methods therefore highlight a range of both personal and contextual factors that play an important role in why teens behave in the ways they do, and help to construct our overall understanding of adolescent sexual behaviors block by block. Adolescents are not only influenced by the social contexts within which they operate, but, as the life course perspective underscores, the decisions they make and pathways they take are influenced by the trajectories of their past. As Lisa Lieberman states in her essay on early predictors of sexual behavior (2006), "the seeds of sexual risk-taking are sown early in adolescence."

Adolescence is a stage in the life course marked by significant developmental growth, and as youth mature physically, emotionally, and socially, they are tempted to explore various sexual behaviors. Further, within their unique social contexts that provide both boundaries and opportunities for sexual activity, adolescents appear to consider both costs such as guilt, embarrassment, and risk of perceived negative outcomes along with benefits such as physical pleasure, social status, and intimacy when making their sexual and contraceptive decisions (Deptula, Henry, Shoeny, and Slavic, 2006). The vast array of factors that play a part in teen decision making are complex and interrelated and each can influence the weight that teens ascribe to the risks and advantages that they perceive. For example, teens who attend religious services frequently might attribute high levels of guilt to premarital sexual activity; youth with lofty academic plans might perceive the risk of pregnancy as especially damaging; and adolescents who are themselves children of adolescent parents might place a much lower significance on avoiding pregnancy.

## LOOKING TO THE FUTURE

Although it is no longer accepted that a young girl's life script is mostly written should she, like Juno, get pregnant while still a teenager, the decisions that adolescents make concerning their sexual and contraceptive behaviors still have consequences for the ways in which their life course trajectories will unfold, the futures of the next generation, and costs for society in terms of public assistance, or health care for teens and their children. It is unrealistic to expect all teens to remain virgins until marriage, but interventions that promote the value of responsible behaviors, delay sexual initiation, encourage the consistent use of contraceptives that protect against both pregnancy and STIs when teens do decide to become sexually active, and recognize that even "virgins" engage in potentially risky sexual behaviors are important ones to endorse. One can learn from the successes and failures of other countries, and should involve parents, teachers, and other adult role models as active participants in our programs. Finally, and perhaps most importantly adults must keep the lines of communication open and listen to the voices of adolescents themselves as they attempt to navigate the complex transition from child to young adult within a constantly changing culture.

# SIBLING RELATIONSHIPS, CHILDHOOD AND ADOLESCENCE

Within the family realm, siblings potentially affect each other in myriad ways. Psychologists generally study the quality of relationships and interpersonal dynamics of sibling relationships (see Cicirelli, 1995; Dunn, 1985). Sociologists, on the other hand, tend to focus on the structure of sibling relationships. Growing up with brothers and sisters in a family is associated with a variety of behavioral outcomes from school accomplishments to misconduct (Blake, 1989; Downey, 1995; Steelman, Powell, Werum, & Carter, 2002). Siblings, as members of the family primary group, can and do affect one another over the life course. Envision a family with more than one child at home. As a child matures any sibling may be a confidante or a rival, an ally or foe, a coresident or occasional housemate. Scholarly study of the role that siblings play in child development ironically commands considerable scholarly attention at the precise moment in history when birth rates in most industrialized societies are dropping. Indeed, the famous "only one child" policy in China epitomizes a worldwide trend. Knowledge about whether and how siblings matter thus is ever more compelling.

Virtually every scholar recognizes that the family is the most enduring influential small group to which individuals will ever belong. Families ordinarily affect their members across the life cycle. Because contemporary families are in the midst of significant and sometimes unforeseen changes, experts express concern that children may be adversely affected by such transformations. Growing up in a home with siblings helps shape a child's growth in both positive and negative ways. We focus on the consequences of sibling structure features insofar as this is where most scholarly attention is directed. The most investigated outcome in which siblings may play a role is educational achievement.

## CHARACTERISTICS OF SIBLING RELATIONSHIP RESEARCH

Much of what we suspect about the impact of siblings comes from study of the four characteristics that comprise the sibling matrix: sibship size, birth order, space intervals, and sex composition (Steelman, 1985). Sibship size is simply the number of brothers and sisters within the family. Birth order is an individual's rank in the age hierarchy of the sibling group, for instance, firstborn, second-born, and so forth. Child spacing is the time interval that separates consecutive or adjacent siblings. Sex composition captures whether a child is reared in a

## BIRTH ORDER

Popular interest in birth order is as high as ever, and, in 2007, the highly prestigious journal *Science* presented new data that suggested the superiority of the eldest child in academics. Renewed interest in birth order followed the publication of Frank J. Sulloway's 1996 book *Born to Rebel: Birth Order, Family Dynamics, and Creative Lives*. For his data, Sulloway asked academic experts to identify famous scientists and other academic luminaries over the past 500 years. He considered those most referenced as those who essentially leapfrogged over their contemporaries in terms of discovery, innovation, and philosophy and identified their birth orders by bibliographic and other archival sources. He observed that although first-borns are more likely than later-borns to become scientists, the latter group more likely spearheaded transformative ways of thinking. Nicolaus Copernicus, Charles Darwin, and Galileo Galilei, all later-born children, exemplify Sulloway's reasoning. Although his study is often criticized for methodological flaws, it pushes the link between birth order and intelligence back to the front burner. Whether future research will corroborate Sulloway's thesis is uncertain, but his bestselling book almost single-handedly reignited the flame of interest in it.

sibling group composed of same sex or opposite sex siblings. These sibling group characteristics mold the conditions under which children and their siblings' lives develop.

### PERSPECTIVES ON CHILD DEVELOPMENT

There are two well-known rival views of how the sibling group as a set affects child socialization. The first is Robert Zajonc and Gregory Markus's (1975) confluence model, which maintains that firstborn and children from small families excel in academic outcomes compared to their counterparts. It purports that a child's intelligence is affected by the dynamic intellectual climate to which he or she is exposed during maturation. The confluence model explains the joint consequences of the number of siblings and birth order on intelligence. The model, moreover, applies to the effects of child spacing, sex composition, and parental absence. At the time the model was fashionable, conventional wisdom was that children in large families and at later birth orders were at an intellectual disadvantage relative to their counterparts. Follow this logic: Suppose that one considers just raw intelligence, not adjusted for age (the standard IQ test). The intellectual atmosphere is the average of the intellectual levels of all family members divided by the number of people in the household. Thus, as the sibling group expands in the number of children (ordinarily less intellectually stimulating), the weaker the intellectual climate to which any given child is exposed. Note also that child spacing should logically matter. The further children are spaced, the greater the odds that both an older child and a much younger newborn sibling experience a similar intellectually stimulating environment.

Even sex composition of the family can be tied to intellectual development, given sex differences. Boys traditionally outperform girls in math and girls outperform boys in English. Families populated with more boys should accordingly benefit from higher intellectual stimulation in the subjects of math and science whereas the presence of girls should enhance reading and language arts (Steelman, 1985). Despite its elegance, the confluence model has not received consistent empirical support and indeed is quite often disconfirmed. Nonetheless, to date no one has provided a definitive test of the model.

Another perspective, the resource dilution model, is embraced by many social scientists for its elegance (Downey, 1995, 2001). Put simply, the amount of resources available to any child is diminished by the number of siblings with whom he or she must compete. Resources cover a gamut of things that children may require to advance academically and in other realms. They encompass social capital or the extent to which parents spend time with children and have ties with important figures in the school system. Financial resources are very important, especially for adolescents who may require parental assistance as they plan to go to college. Educational materials such as encyclopedias or computers in the home are also pivotal. Finally, the educational attainment of parents and siblings (their human capital) may affect a developing child. The greater the number of siblings, the less resources that parents can divest to their children, whether they are social, intellectual, cultural, or economic. Under resource dilution principles, birth order does not make a difference but the number of siblings and the spacing between them does. As the family grows by adding children, there should be fewer resources to allocate to any given child. If parents space children widely, then they have time to recover from financial and other obligations before the next child arrives.

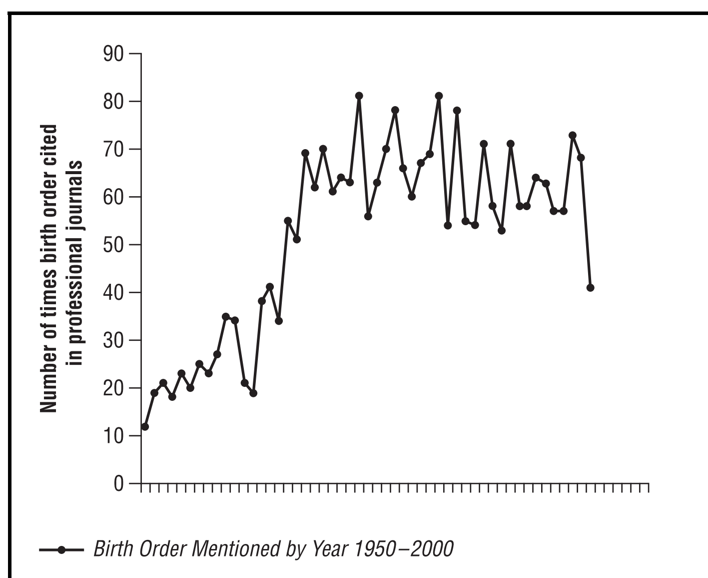

***Table 1.*** *Scholarly research that includes birth order.* CENGAGE LEARNING, GALE.

Despite vast evidence to support the resource dilution hypothesis, scholars remain uncertain about whether or not children's development is negatively affected under all conditions. Whereas the number of siblings is usually found to be a detriment to children and adolescents when it comes to educational progress, there are noteworthy exceptions in which family size has either no impact or a positive one (Guo & Van Wey, 1999; Steelman et al., 2002). Under conditions in which families have abundant resources, the size of the sibling group may not count so much. Nonetheless, the majority of studies suggest that sibship size dampens educational progress. On other outcomes such as teamwork and sociability that remain less studied, the number of siblings may be beneficial (Steelman et al., 2002). Indeed the literature on siblings is often critiqued for its overwhelming concentration on just those outcomes that typically favor small families over large ones, such as educational advancement. It might be more than coincidence that as the birth rate has declined, the proportion of students going to college has generally increased.

Whether one takes a confluence model or a resource dilution perspective, as the number of siblings increases the amount of educationally lucrative resources that any given child can depend on relative to their counterparts seemingly decreases after other interrelated variables are statistically controlled (Downey, 1995; Steelman, 1985). Correspondingly, the number of siblings is almost invariably considered in attempts to understand where and when children and adolescents are privileged or are shortchanged as they mature. It is noteworthy that the number of siblings has become a standard factor included in models of status attainment. Such models attempt to understand how family dynamics over time work to either encourage or discourage educational and occupational successes.

Birth order intersects with the interests of life course scholars because firstborn children are the sole ones who at least for some interval enjoy uninterrupted time with parents and, as such, may or may not profit from their position in the age rankings (see Conley, 2004). Correspondingly, later-born children more likely arrive at the time in the life course when parents reach their earnings peak and, because they are last, may profit from mentoring by older siblings.

Another sibling structure variable that meshes nicely with resource dilution and confluence model is child spacing. Brian Powell and Lala Carr Steelman (1993) observe that the more closely spaced consecutively born children are, the less likely parents can prepare for college and other advantages to pass on to their children. Nonetheless, there also may be payoffs to close spacing, such as greater opportunities to interact with brothers and sisters as age mates in ways that in no small measure shape interests, hobbies, and who children pick as friends. Siblings may also form coalitions with each other to challenge parental authority. Nonetheless, a widely spaced child may profit in a different way. Depending on birth order position, large age differences between siblings may set the stage for either giving or receiving help in school and other activities. As an example, the older sibling may help mentor the younger sibling in

school activities and in so doing learn more himself or herself. Additionally, wider spacing allows parents to recover from financing older children's training just in time to assist their younger children.

Not surprisingly, many contemporary child advice books actually encourage families to consider such spacing strategies to benefit their children. Given the constraints of the childbearing years for women and the often accidental pregnancy, parents surely cannot completely control when they have children how their children will be spaced, nor can parents control the genders of the children they bear. All male or all female sibling groups may experience a lifelong difference in the way that parents rear them—the former focusing more on "masculine" domains, the latter on "feminine" ones. Still, there is no consistent support for any gender composition effect, and scholars remain baffled by these discrepancies observed across a number of studies (Conley, 2000; Steelman et al., 2002).

Notably, siblings may matter for different reasons as they mature. Social scientists have begun to broaden research on the sibling group to include alternatives to the traditional nuclear family. Specifically, scholars in the 21st century are concentrating on the addition or subtraction of biological siblings, half-siblings, step-siblings, or a combination of these that alter the overall character of the sibling group over time (Tillman, 2007; Zill, 1996). To a great extent the child's experiences are linked both to their siblings and their parents, who decide or accidentally are responsible for the structure of the sibling group. Birth order continues to tantalize laypeople despite the fact that many claims of early researchers that firstborns are superior to their later-born counterparts in terms of intellect have been seriously challenged. Most commonly, but not always, observed is that as the number of siblings increases, educational and occupational opportunities decline. So studies of educational and occupational attainment routinely include the number of siblings as a predictor but are much less likely to include birth order.

## FUTURE RESEARCH

Research about siblings should and probably will move in many exciting and needed directions. For example, scholars need to collect direct behavioral observations of siblings as they interact. Such a study clearly would animate if and how siblings make a difference in each other's lives. A major flaw in existing sibling influence research is the lack of data from whole families. Whereas the earliest studies of siblings more or less presumed the presence of both biological parents, the need to expand research to encompass alternatives family forms that in turn affect the character of the sibling group is now acknowledged. Step-, half-siblings, or siblings that may be in the custody of another parent may have different effects than do siblings who always live with one another (McLanahan & Sandefur, 1994; Zill, 1996). Across the life course young children and adolescents may experience the entrance or exit of siblings as parents divorce and remarry at high rates. To comprehend family dynamics requires investigating families across time.

Note also that the way in which children are arranged may infringe on the extent and manner in which parents may invest in and treat children. In contrast to living with both biological parents, children who abide with single parents, stepparents, and cohabiting partners are becoming more common. These variations also affect the character of the sibling group and pose a daunting challenge to researchers concerned with understanding sibling influence. Children who do not grow up with both biological parents are much more likely to live with step- and/or half-siblings and to experience fluctuations in the siblings with whom they reside. Consequently, contemporary research about the impact of siblings ordinarily must take into consideration types of families in which sibling groups are embedded. Co-resident siblings, for example, tend to take a negative toll on academic achievement during adolescence and early adulthood (Blake, 1989; Downey, 1995, 2001; Steelman et al., 2002) as does close spacing between siblings. It is unclear if non-coresident siblings have a similar impact. Young children may have to share parental attention with closely born siblings, often found in blended families, so much so that it has deleterious consequences for them. As adolescents approach independence, how economic resources are distributed in families with multiple types of siblings may even more profoundly affect educational expectations than is ordinarily observed in traditional nuclear families (Steelman et al., 2002).

In the early 21st century, scholars have begun to recognize how family change in the sibling group may have various consequences for children across the life cycle. A sibling can mean many different things in contemporary society. It is a status that may or may not include residential and nonresidential half- and step-siblings, as well as other relatives reared as veritable siblings such as cousins, foster children, or even the children of older siblings. All of these represent outstanding challenges to define what a sibling is. Grappling with this issue, although not easy, is a necessary step in future research.

Another direction involves evolutionary theory, which urges scholars to view siblings through a different prism. These theories posit that although siblings have a genetic connection with one another (they share 50% of their genes), their greatest gene share is with oneself. Proponents of an evolutionary psychology position

would argue that genetic connectedness prods children to protect their siblings against external threats. Concern for the welfare of brothers and sisters emanates from the innate tendency to protect one's genetic heritage. Paradoxically, it also accounts for sibling rivalry. The genes that a person most wants to protect are his or her own. Hence siblings compete with each other to garner familial resources to advance an even larger portion (100%) of their genes into the next generation. Evolutionary theories also explain why biological siblings should be more vested than step-siblings (whose genes do not coincide with the other sibling) and why identical twins are the most protective of each other among the various types of siblings.

Future research on siblings must also move away from reliance on snapshot data of children taken at one point in time toward the examination of the role of siblings as they interact across the life span. So far sibling research is just not complete enough to capture the full essence of family life. Moreover, the need to collect and analyze data on whole families over the life cycle cannot be understated. More studies that analyze longitudinal data are warranted and may help reconcile the many inconsistencies already documented. Through these techniques researchers can assess the growing family forms and understand changes in the sibling group that occur through divorce, remarriage, and single-parent families. Finally, sibling research should devote more attention to outcomes other than those such as educational success that typically favor small families. The extent to which children cooperate and share, for example, could be a by-product of maturation in a large family. If scholars move in the recommended directions reviewed above, then a greater appreciation of the extent to which siblings affect one another across the life cycle could become a reality.

## SINGLE PARENT FAMILIES

**SEE** Volume 1: *Family and Household Structure, Childhood and Adolescence.*

## SOCIAL CAPITAL

*Social capital* refers to social relationships that have the capacity to enhance the achievement of one's goals. Social relationships are viewed as investments, whether the investment is conscious or unconscious. The fundamental insight of the idea of social capital is that life chances are influenced by the social resources available through social networks. This fundamental insight, coupled with the generality of the definition, has contributed to social capital's widespread appeal across a variety of research

areas, including research on child and adolescent development. Social capital is believed to aid in the achievement of both individual goals, such as educational attainment and achievement, and collective goals, such as safe neighborhoods that promote healthy psychosocial development.

## ORIGINS AND CONCEPTUAL DEVELOPMENT OF THE SOCIAL CAPITAL

The theoretical roots of social capital can be traced to the work of sociologists Pierre Bourdieu (1930–2002) and James Coleman (1926–1995) during the late 1980s. Bourdieu (1986) introduced social capital as a part of his larger project aimed at understanding the social reproduction of inequality, or how social class is passed from one generation to the next. He defined social capital as "the aggregate of the actual or potential resources which are linked to the possession of a durable network of more or less institutionalized relationships of mutual acquaintance and recognition" (1986, p. 248). The amount of social capital to which an individual has access depends on both the quantity of his or her connections and the amount of capital (e.g., financial, human, or cultural) that each network member possesses. Hence, membership in various social groups (such as gender, race, and social class) provides differential access to social capital. Bourdieu portrayed the accumulation of social capital as the result of conscious and unconscious long-term investment strategies designed to establish or maintain relationships of perceived obligations that can be accessed on some future occasion. The solidarity and resources provided by the social capital of the dominant class enable it to maintain its position.

Coleman's purpose in introducing social capital was to bridge the gap between sociological and economic explanations of social action by showing how explanations based on rational action could fit into a framework that also emphasized the importance of social context. Coleman wrote that social capital is a "variety of entities with two elements in common: They all consist of some aspect of social structures, and they facilitate certain actions of actors—whether persons or corporate actors—within structures" (1988, p. S98).

According to Coleman, social relationships can provide three major types of resources. The first, obligations and expectations, occurs when a person can count on their favors being returned. The reciprocity that allows one to collect "credit slips" for future use depends on the trustworthiness of the social environment. Information is the second type of resource. For instance, social relations are important sources of information about job openings and how to apply to college. The third type of resource is norms and effective sanctions. Coleman argued, for example, that strong and enforceable pro-school norms within a community facilitate the job of schools and teachers. A social network with a high level of closure, when a group's members are highly interconnected and not very connected to persons outside of the group, can more effectively maintain compliance to norms because members can act collectively to restrain undesirable behavior. In the context of child development, Coleman argued that *intergenerational closure*, when parents know the parents of their children's friends, is particularly important. Because intergenerational closure enhances communication among parents, it facilitates norm enforcement and parental control over their children's behavior.

Bourdieu and Coleman's definitions share important similarities. Both identify social capital as the resources that exist in social relationships rather than as something that is tangibly possessed by individuals. In addition, in both definitions it is clear that investment in interpersonal relationships is what creates social capital. However, the Bourdieu and Coleman formulations differ in important ways. Consistent with their different purposes in introducing the concept, they diverged on the phenomena that they used social capital to explain. Bourdieu used it to explain the reproduction of inequality. In contrast, Coleman used the concept in a more general sense to explain a wider range of outcomes, from dropping out of high school to the successful organization of social movements, and did not emphasize the nature of groups that act in ways to concentrate resources within their boundaries. Also, while both theorists viewed social capital as something that can exist in collectivities, there is a crucial difference in their formulations at this level. In his discussion of social capital at the group level, Bourdieu refers to homogeneous groups that have a unified set of interests. Coleman's discussion suggests that social capital can serve as a public good in large groups, such as neighborhoods, that have a number of subgroups within them. His work on social capital did not consider inequality in access to social capital within such aggregates.

While Bourdieu's and Coleman's work on social capital has been highly influential, it was political scientist Robert Putnam's (b. 1941) work on social capital that galvanized its appeal across almost every social scientific discipline and even into popular discourse. Putnam drew from Coleman's work on the nature of social capital as a public good and defined social capital as "features of social organization, such as trust, norms and networks, that can improve the efficiency of society by facilitating coordinated actions" (1993, p. 167). He argued, for example, that regional levels of social capital account for why the identical local government structure functions so much better in the regions of northern Italy than in

the regions of southern Italy (1993). He has also attributed the decline in American political engagement, as reflected by voter turnout, to a decline in social capital (2000).

Coleman and Putnam's definitions of social capital are so broad that they have resulted in a proliferation of social phenomena labeled as social capital, leading some commentators—Charles Kadushin (2004) and Alejandro Portes (1998), for example—to question the utility of the concept. Despite this concern, the use of social capital continues to flourish. As Putnam (2000) notes, social capital is not just one thing, much like physical capital is not just one thing. It is useful to consider that there are different forms of social capital without extending the "notion of social capital beyond its theoretical roots in social relations and social networks" (Lin, 2001, p. 28). While there is no shortage of alternative definitions of social capital, research on child and adolescent development has tended to follow Coleman's framework by focusing on norm enhancing social relationships or, to a lesser extent, Bourdieu's ideas by focusing on the role of social capital in social reproduction.

## RESEARCH ON SOCIAL CAPITAL AND CHILD AND ADOLESCENT DEVELOPMENT

Multiple social contexts, including the family, friendship network, school, and community, are important in the lives of children; as such, adolescents and most social capital research on children's outcomes has focused on one or more of these contexts. Following Coleman, early research on social capital and child development focused on parent-child relationships. With some exceptions, research generally finds that living in a two-parent family, having fewer siblings, parental monitoring, discussion of school with parents, and parental expectations that that their child will go to college are associated with lower chances of dropping out of high school, higher chances of attending college, higher grades, and higher achievement on test scores. (For a comprehensive review of social capital studies in the area of education through 2001, see Sandra Dika's and Kusum Singh's *Applications of Social Capital in Educational Literature* [2002].) Research on the effects of parent involvement in school has found inconsistent results; some studies find positive associations with school achievement, whereas others find negative associations, likely because problems in school often prompt parent involvement.

Social capital research has also examined other important relationships. Friends can influence each other's academic outcomes in several ways. First, they act as agents of socialization through which pro-school norms can be encouraged and enforced, which can translate into more successful academic outcomes. Having academically successful friends provides an adolescent with access to educational resources. In addition, friends can act as role models. R. Crosnoe, S. Cavanagh, and G. H. Elder. (2003) observed that having friends with a higher grade point average and higher school attachment decreases having trouble at school.

Still other research has focused on school and community social capital. R. D. Stanton-Salazar and S. M. Dornbusch (1995) argued that schools can provide important social resources for low-income students by providing guidance in the college application process, for example. Furthermore, a good relationship between the family and the school enhances the likelihood of obtaining valuable resources at the school. Y. M. Sun (1999) found that in communities with higher levels of adolescent participation in religious activities and sports groups and where parents belong to more organizations, standardized tests scores were higher. In addition, higher community levels of intergenerational closure and being able to work together were related to higher achievement on test scores. Not only did these forms of community social capital enhance educational achievement, but they also explained a part of the association between neighborhood poverty and lower educational achievement.

Although most examinations of social capital concentrate on its positive effects, it can easily have negative consequences as well. Coleman (1988) himself recognized that a form of social capital that is useful for one desired end might be disadvantageous to the achievement of another goal. For example, community norms that

discourage delinquency might also hinder creativity. In addition, not all social networks are characterized by prosocial norms. Moreover, some relationships might not provide helpful social support. For example, in a sample of African-American parents, M. O. Caughy, P. J. O'Campo, and C. Muntaner (2003) found that in poor neighborhoods, knowing many neighbors was associated with more behavioral problems among their children. In nonpoor neighborhoods, having neighborhood ties was associated with fewer child behavioral problems. Similarly, in a study of poor families, F. F. Furstenberg (1993) found that in the most disadvantaged and disordered neighborhoods, avoiding neighbors and activating ties to resources outside of the neighborhood proved to be a more successful parenting strategy than forging close ties with neighbors.

An important insight to take from these findings is that the value of social capital may depend on the situation. For example, is social capital more important and therefore effective for disadvantaged youths than for middle-class and affluent youths because it may offset the lack of other types of resources? Or, does social capital exacerbate inequality by being more effective for already advantaged youths? In one study, parental access to time and financial assistance from friends was associated with higher educational attainment for the offspring of high-income families, but not low-income families, suggesting that lower-income families are less able to access help that provided educational resources (Hofferth, Boisjoly, & Duncan, 1998). D. H. Kim and B. S. Schneider (2005) found the effects of college visits and matching educational expectations by the student and parent on attendance at a selective 4-year college or university were larger when parents had higher levels of education. In contrast, parental participation in college and financial aid programs at the high school pays off more for children of lower educated parents, which is consistent with Stanton-Salazar's and Dornbusch's (1995) argument that school resources are particularly important for working and lower-class families. Sun (1999) found that the negative effects of high levels of nontraditional families in the community on school achievement can be partially offset by high levels of parent participation in organizations and intergenerational closure, suggesting that community social capital can mitigate disadvantageous neighborhood circumstances. Future research will undoubtedly continue to examine the contexts in which social capital is more and less useful.

## GAPS IN CURRENT KNOWLEDGE

Two decades of research on social capital have produced significant and important findings, but there is still more to learn. First, much of the research on social capital and child development has focused on educational outcomes. With some notable exceptions, relatively less is known about whether and how social capital influences outcomes such as social adjustment, behavioral problems, violence, and psychosocial resources such as an internal locus of control. S. De Coster, K. Heimer, and S. M. Wittrock (2006) found that intergenerational closure does not appear to curtail delinquent behavior. This is surprising in light of the association of intergenerational closure with a host of educational outcomes that is purportedly explained by the ability of parents to enforce norms, and, accordingly, more research is needed to understand the mechanisms that explain the relationship between closure and school outcomes.

Second, there is more to learn about the relative advantages of *bonding* versus *bridging* social capital. Bonding social capital is characterized by networks rich in strong and densely connected ties, usually of socially similar persons, whereas bridging social capital is characterized by dispersed networks that access disparate social worlds. In the context of education, bonding social capital might be beneficial because it is conducive to norm enforcement and the social support that adolescents need to be successful. Yet as S. L. Morgan and A. B. Sørensen (1999) argue, bridging social capital might be beneficial because it accesses diverse pools of information that create greater opportunities for learning. Rather than one form of social capital being generally more advantageous than the other, it may be the case that bonding social capital is more important for some types of educational outcomes, such as grades and school retention, whereas bridging social capital may be more advantageous to outcomes such as going to college because it is more likely to provide beneficial information. Thus far, research has not been able to adequately assess this debate.

Finally, as the field moves forward, measures will continue to be refined in ways that more closely tap the conceptual definitions. Certainly, much progress has already been made. Early research on social capital relied heavily on proxies, or very indirect and approximate measures, for social capital such as two-parent families, number of siblings, and number of residential moves. While these factors may influence the availability of family and community social capital, there are other factors, such as unmeasured aspects of socioeconomic status or family background, that could account for their relationships with better child outcomes. Many of the later studies on social capital and adolescent outcomes were based on data from the National Educational Longitudinal Study, a survey that includes several somewhat better measures of social capital, but is still limited in its information about social networks. A more recent survey, the National Longitudinal Study of Adolescent Health,

has made it possible to measure the content and structure of school-based adolescent friendship networks.

However, there are still aspects of social capital that cannot be adequately measured with a widely available survey. For example, no survey has collected information about adolescent relationships outside of the immediate family and the school. In addition, the parental social networks are likely quite important in terms of the information they can provide about parenting techniques and the educational system, for example, and yet little information exists on them. Collecting more detailed and direct measures of social capital will allow researchers to address important issues, such as the relative benefits of bridging and bonding social capital, as well as to better understand the contexts in which various forms of social capital are more or less useful.

# SOCIAL DEVELOPMENT

Peer relations are a critical aspect of youngsters' social development (Hartup, 1996). Children and adolescents place considerable importance on their peer relations and are influenced strongly by the attitudes and behaviors of their peers. Peers also provide a source of emotional support that rivals and, during adolescence, even exceeds support from parents.

Studying the development of peer relations in childhood and adolescence is essential for understanding the foundations of youths' friendships and romantic relationships into adulthood and across the lifespan. Children and adolescents who encounter serious difficulties in their peer relations early on are at risk for the development of later interpersonal and psychological difficulties, including delinquency, marital problems, substance use, and depression. Thus, efforts to understand and promote positive peer relations in youth is an important mental health goal. This entry describes the types of peer relations that are important for children and adolescents. Theory and measurement issues also are described.

## CHILDREN'S PEER RELATIONS

During elementary school, children typically spend most of the day in self-contained classrooms with a specific group of classmates. In this context, children's peer status—or degree of acceptance from the peer group (i.e., classmates)—is a salient aspect of their peer

relations. Peer acceptance provides children with a sense of belonging and inclusion.

Children's social status has been defined by the degree to which they are accepted by their peers. Specifically, social status groups are determined by ratings of peer acceptance (liking) and peer rejection (disliking) as follows: popular (high on liking, low on disliking), rejected (low on liking, high on disliking), neglected (low on liking and disliking), and controversial (high on liking and disliking). Popular children often have positive social skills and personal competencies, whereas rejected children display a number of interpersonal, emotional, and academic difficulties, such as aggressive, disruptive, and inattentive behaviors and feelings of loneliness (Coie, Dodge, & Kupersmidt, 1990).

In addition to peer acceptance, peer friendships (close supportive ties with one or more peers) provide children with a sense of intimacy, companionship, and self-esteem. Children's close friendships typically are with same-sex peers and vary in terms of quantity and quality. Most children have a close friend in school, although girls are more likely to have a best friend than are boys and to have more peers whom they rate as close friends. Common positive qualities of children's friendships include sharing activities, affection, receiving help, trust, and sharing. Intimacy and emotional support also are evident in children's friendships and increase during adolescence (La Greca & Prinstein, 1999). Friendships also have negative aspects, such as conflict and betrayal, although most children report more positive than negative qualities in their close friendships.

### ADOLESCENTS' PEER RELATIONS

As children make the transition to middle school, their peer networks expand considerably. Most adolescents have a peer network that includes their best friends, other close friends, larger friendship groups or cliques, peer crowds, and often romantic relationships (Furman, 1989; Urberg, Degirmencioglu, Tolson, & Halliday-Scher, 1995).

**Peer Crowds** Adolescents interact with a large number of peers and need to find their place in the larger social system. In this context peer crowds can be viewed as an outgrowth of the social status groups observed among children (La Greca & Prinstein, 1999). Peer crowds are distinct from smaller friendship cliques in that they are much larger, and peer crowd members may not know or be friends with one another.

Peer crowds reflect adolescents' peer status and reputation as well as the primary attitudes and behaviors by which adolescents are known to their peers. Although peer crowds and their labels vary, the most common crowds are jocks (or athletes), populars (or elites, preps, hot shots), brains (or nerds), burnouts (or druggies, dirts), alternatives (or nonconformists, goths, freaks), loners, and special-interest groups (e.g., dance, music; Brown, 1990; La Greca, Prinstein, & Fetter, 2001).

Peer crowds provide opportunities for social activities, friendships, and romantic relationships and provide a sense of belonging and identity. This is particularly important in middle school because peer crowds may help younger adolescents define their identity and reputation and provide norms for behavior and "fitting in." The importance of peer crowds peaks in high school, followed by a decline as adolescents focus their attention on close friends and romantic relationships. At the same time, peer crowds are evident among college-age youth and gay men, suggesting that crowd membership can be salient even into young adulthood (Urberg et al., 1995).

**Friendships** Adolescents spend more time talking to peers than they spend in any other activity. In the current technological age, adolescents' use of mobile phones and text messaging to connect with friends is widespread. Adolescents' interactions with friends occur primarily in the context of dyadic interactions with close friends or romantic partners and in friendship cliques.

Cliques are friendship-based groupings that may vary in size (usually from five to eight members), density (the degree to which each member regards others in the clique as friends), and tightness (the degree to which cliques are open or closed to outsiders). Cliques are the primary basis for adolescents' interactions with peers, and an adolescent's best friends are likely to participate in the same clique or group (Urberg et al., 1995). As adolescents begin to date, same-sex cliques may transition to mixed-sex groups. Over time cliques often are replaced by adolescents' interactions with close friends, romantic partners, or smaller friendship-based groups (La Greca & Prinstein, 1999).

Adolescents' close friendships have many of the same qualities as children's friendships (companionship, trust, and so on) but are characterized by intimacy, that is, the sharing of personal, private thoughts and feelings and knowledge of intimate details about friends. As with children, adolescent girls report having more close friends than do boys and report more intimacy in those relationships. However, adolescent boys have more open friendship groups than girls do and are more willing than girls to let others join ongoing interactions. During adolescence having close "other-sex" friends also becomes common and may set the stage for the development of romantic relationships.

The quality of adolescents' close friendships is linked with psychological adaptation. For example, adolescents

who report more positive qualities in their best friendships also report less social anxiety than do their peers. Moreover, high levels of negative interactions in adolescents' close friendships are related to greater social anxiety and depressive symptoms.

## SOCIALIZATION VERSUS SELECTION

As discussed above, peer relations serve many important developmental functions, providing support, a sense of belonging, opportunities for social interaction, and a means of developing identity. The literature on peer relations is compatible with the theory of homophily. Homophily (Kandel, 1978) posits that individuals with similar interests and characteristics tend to cluster together and seek one another out (selection). Further, peers reward and reinforce similar attitudes and behaviors among group members (socialization).

Children often gravitate toward others who are similar to themselves; this is consistent with selection theory. In fact, children select friends on the basis of similarities in observable characteristics such as sex, race, and preference for engaging in certain activities rather than on less observable factors such as personality, attitudes, and self-esteem. Friendships typically occur among youth of the same age and gender, although this changes in adolescence (Aboud & Mendelson, 1996).

Socialization is also important in children's peer relationships. For example, low-achieving 5th-, 6th-, and 7th-graders who affiliate with higher-achieving friends perform better academically than do those who affiliate with low-achieving peers. Thus, although children gravitate toward similar peers to form friendships, those friendships also socialize children and influence their behaviors and development.

Selection and socialization processes also are relevant for adolescents (Aboud & Mendelson, 1996). For example, adolescents may affiliate with certain peer crowds because of perceived similarities of interests, behaviors, or skills, reflecting a selection process. Smart adolescents may affiliate with the brains; athletes may affiliate with the jocks. However, socialization also may occur as adolescents feel real or perceived pressure to conform to or comply with the attitudes and behaviors that are prevalent in their peer crowd. For example, adolescents affiliating with the burnouts may feel pressure to drink or smoke; adolescents affiliating with the brains may be encouraged to take academic work seriously. Research also suggests that adolescents' aspiration to belong to a particular crowd may lead them to engage in behaviors they believe to be typical of that crowd (Brown, 2004).

Selection and socialization processes also occur within adolescents' friendships. Like children, adolescents gravitate toward others who share similar qualities, interests, and personal characteristics, although selection does not fully explain the formation and maintenance of adolescents' friendships. Socialization processes in friendships are also important and may influence adolescents' academic achievement. Although selection and socialization processes are difficult to disentangle, they provide a framework for understanding the importance of adolescents' friendships and peer crowds.

## MEASUREMENT ISSUES

Peer relationships are challenging to study because they can be temporary and dynamic. Longitudinal studies are particularly revealing because they may capture the shifting nature of peer relationships and help clarify selection and socialization processes. Overall, self-report measures are used widely to capture youths' reports of close friendships and membership in a peer crowd; however, peer nominations, observations of group/dyadic interactions, and ethnographic observations also are important (Brown, 2004).

In assessing peer relationships, it is important to consider youngsters' ethnic/cultural background to understand the larger context in which relationships develop. Friendships may be defined and valued differently in different cultures; friendship selection also may vary by culture (Brown, 2004). In fact, research suggests that African American adolescents select friends on the basis of ethnic identity rather than academic orientation or substance use, whereas the opposite pattern may be prevalent for Asian and European American adolescents (Hamm, 2000). This may be because social concerns, such as racism, are more widely experienced by African American teens, making their ethnicity/race a more salient attribute for friendship selection than is the case for other adolescents. As another example, the high value placed on academic achievement in the Asian American culture may foster adolescent friendships that develop around academic pursuits.

Peer nominations are the most common method of assessing children's peer acceptance and friendships (Coie et al., 1990). Peer nominations require each child within a classroom or group to nominate up to three peers that he or she "likes the most" and "dislikes the most" (or "likes the least"), used for evaluating peer acceptance/rejection, or to nominate up to three "best friends," used for evaluating mutual friendships. Those nominations are used to categorize children into popular, rejected, neglected, and controversial social status groups to identify mutual friendships. Teachers' and parents' reports of peer acceptance and rejection may be useful when peer nominations are not possible. Peer networks, or mapping out patterns of relationships within the context of a school or other setting, are also commonly used

in research to examine how adolescents form friendships and romantic relationships. Examining these networks facilitates the understanding of how adolescents transmit ideas, values, and also disease among their peers. In addition, self-report measures such as the Friendship Quality Questionnaire (Parker & Asher, 1993) have been used to evaluate the number and quality of children's close friendships. Overall, it is best to obtain several measures by using multiple approaches.

Although peer nominations are used widely with children, they are employed less with adolescents, whose peer networks are larger and are not limited to a particular school or classroom. Further, it is important to assess multiple relationships among adolescents, such as close same-sex and other-sex friendships and romantic relationships. Self-report measures such as the Network of Relationships Inventory (Furman & Buhrmester, 1985) have been used to assess the number and quality of adolescents' friendships and romantic relationships.

Although some investigators have obtained peers' perceptions of crowd affiliations (Sussman et al., 1990), self-report measures are used most commonly to assess adolescents' peer crowd affiliations. Measures such as the Peer Crowd Questionnaire (La Greca & Harrison, 2005; La Greca et al., 2001) describe and label each of the common peer crowds (e.g., jocks, populars, brains) and ask adolescents if those crowds are present in their school and, if so, what they are called. Adolescents then select the crowd they identify with most closely. Adolescents also may rate their degree of identification with each peer crowd (using a Likert scale) to obtain scores for multiple peer crowds. Sometimes additional items may be added, depending on the particular research questions. For example, adolescents have been asked how peers would classify them, which peer crowds they would like to belong to most, and the peer crowd affiliations of their three best friends or romantic partner. Overall, measures assessing peer crowd affiliation have been found to be reliable, have good construct validity and interrater reliability, and show good correspondence between adolescents' self-identification and peers' assignment to crowds.

## FUTURE RESEARCH

Peer relations play a significant role in the social and emotional development of children and adolescents and provide an important source of social support. The quality and type of friendships change as children develop into adolescents. Future research might address cultural variations in peer relationships as well as the role of changing technology, such as the Internet and cell phones, on these relationships. Because friendships and peer relationships are so crucial for the social and emotional development of children and adolescents and have implications for interpersonal functioning across the lifespan, efforts to understand and promote competence in youngsters' peer relationships should be an important target of developmental research, school and public policy, and mental health promotion and intervention.

SEE Volume 1: *Bullying and Peer Victimization; Friendship, Childhood and Adolescence; Peer Groups and Crowds.*

# SOCIALIZATION

The concept of and approaches to socialization have a long history in sociology, psychology, and anthropology. Although life course sociologist Glen H. Elder Jr. (1994) has argued that socialization has declined as a research paradigm and become part of other paradigms, especially the life course perspective, theory and research on childhood and adolescent socialization in the 1980s and 1990s have revitalized the field. These new approaches stress the importance of the agency of children and youth. To say children have agency means they are active participants in their own socialization rather than being simply shaped or molded by adults. Such approaches also focus on how children collectively produce "peer cultures," which play a key role in their life trajectories and transitions as they become active members of adult culture. There has also been a convergence in theories of human development and socialization that is complementary to important theory and research on the life course (Corsaro & Fingerson, 2003).

## THEORETICAL APPROACHES TO HUMAN DEVELOPMENT AND SOCIALIZATION

Theories of human development in psychology are primarily concerned with the individual child's acquisition of skills and knowledge and general adaptation to the environment. Sociologists, by contrast, normally use the term *socialization* when discussing human development. Their definitions of socialization highlight the ways in which the individual learns to fit into society. Some sociologists give more agency to children than others, but all emphasize interaction and collective processes when discussing socialization and argue that it is a lifelong process. Gerald Handel, Spencer Cahill, and Frederick Elkin (2007) defined socialization as "*the processes by which we learn and adapt to the ways of a given society or social group so as to adequately participate in it*" (pp. 2–3).

In the 1980s and 1990s, important changes occurred in the conceptualization of human development and socialization in psychology and sociology. In general, these changes involved more of a focus on agency in the socialization process, more concern for the importance of social context, and agreement that experiences beyond the early years in the family (especially interactions and experiences with peers) are in need of careful theoretical development and empirical research.

## RECENT TRENDS IN PSYCHOLOGICAL THEORIES OF HUMAN DEVELOPMENT

As noted earlier, psychologists use the term *human development* rather than *socialization*. Psychological theories of human development vary regarding (a) their perception of individuals as active or passive; (b) the importance they place on biological factors, the social environment, and social interaction; and (c) their conception of the nature of development or change. Three theoretical approaches have important implications for sociological approaches to socialization because they recognize the importance of the collective activities and processes of children and youth in social context and over time.

**Cognitive Developmental Theory** Since the early 1990s, work in cognitive development theory as centered around refinements and extensions of Jean Piaget's (1950) theory of intellectual development, which advocates an active view of the child who constructs his or her own place in the social and physical world. Several theorists argue that early interpretations of Piaget's work concentrate on the details of stages in cognitive development at the expense of an understanding of the theory they were intended to illustrate. Geoffrey Tesson and James Youniss (1995) argued that although Piaget described a series of stages of cognitive development he believed all children progress through, he did see these stages as the central focus of his theory. In his later work Piaget investigated the interrelationship between the logical and the social qualities of thinking. Tesson and Youniss argued that Piagetian

intellectual operations enable children to make sense of the world as a set of possibilities for action, and thereby they can build a framework within which these possibilities may be envisioned. Thus Piaget attributes agency to children. Piaget also believed that children's peer relations were more conducive to the development of intellectual operations than the authoritative relations with adults, which primarily involved parental constraint over children, rather than a mutually influential and equal relationship.

**Systems Theories of Human Development** An excellent example of dynamic systems theory can be seen in the work of Esther Thelen and Linda Smith (1998), who criticized studies of human development that strive to discover invariants, that is, the programs, stages, structures, representations, schemas, and so on that underlie performance at different ages. Thelen and Smith argued that this approach uses the metaphor of a machine and that "knowledge is like the unchanging 'innards' of the machine, and performance subserves the more permanent structure" (p. 568).

Thelen and Smith (1998) offered instead the image of a mountain stream to capture the nature of development. They noted that there are patterns in a fast-moving mountain stream: Water flows smoothly in some places, but nearby there may be a small whirlpool or turbulent eddy, whereas in other parts of the stream there may be waves or spray. These patterns may occur for hours or even days, but after a storm or a long dry spell, new patterns may emerge. The mountain stream metaphor captures development as something formed or constructed by its own history and systemwide activity. In this approach there is a direct focus on processes, and outcomes are important primarily as part of further developing processes. The key strength of Thelen and Smith's systems approach is that it captures the complexity of real-life human behavior in physical, social, and cultural time and context.

**Sociocultural Theories** Sociocultural theorists refine and extend central concepts in the work of the Russian psychologist Lev Vygotsky (1978). According to Vygotsky, human activity is inherently mediational in that it is carried on with language and other cultural tools. A significant portion of children's everyday mediated activities take place in the zone of proximal development: "the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers" (p. 86).

Building on Vygotsky's (1978) work, Barbara Rogoff (1996) argued that changes or transitions in children's lives can be best examined by asking how children's involvements in the activities of their community change, rather than by focusing on change as resulting from individual activity. To capture the nature of children's involvements or changing participation in sociocultural activities, Rogoff suggested they be studied on three different planes of analysis: the community, the interpersonal, and the individual. In line with this view of change, Rogoff introduced the notion of "participatory appropriation" by which she means that "any event in the present is an extension of previous events and is directed toward goals that have not yet been accomplished" (p. 155). Thus, previous experiences in collectively produced and shared activities are not merely stored in memory as schema, plans, goals, and such and called up in the present; rather, the individual's previous participation contributes to and prepares or primes the event at hand by having prepared it.

Rogoff (1996) demonstrated this concept in a study of preadolescent girls' participation in the sale and delivery of Girl Scout cookies. The mothers of the girls initially managed and directed the interrelated tasks involved in this activity such as taking orders, calculating prices, and actually delivering the cookies. Over the course of time, however, the girls became more centrally involved and in some cases actually took over tasks (such as calculating prices) and played key roles (such as giving their mothers driving directions) as the mothers helped the girls deliver the cookies.

## SOCIOLOGICAL THEORIES OF SOCIALIZATION AND THE SOCIOLOGY OF CHILDHOOD

As noted earlier, when discussing human development, sociologists normally use the term *socialization*. Since the 1980s, however, there has been a movement to refine or even replace this term in sociology because it has an individualistic and forward-looking connotation that is inescapable (Corsaro, 2005; Thorne, 1993). Some offer instead interpretive-reproductive theories that present a new sociology of children and childhood in which children's own cultures are the focus of research, not the adults they will become. These new approaches are refinements of earlier theoretical work on socialization in sociology.

**Macro-Level Approaches to Socialization** The major spokesperson of the macro-level view of socialization is the functionalist theorist Talcott Parsons, who envisioned society as an intricate network of interdependent and interpenetrating roles and consensual values. Parsons and Robert Bales (1955) likened the child to "a pebble 'thrown' by the fact of birth into the social 'pond'" (pp. 36–37). The initial point of entry—the family—feels the first effects of this "pebble," and as the child matures the effects are seen as a succession of widening waves that radiate to other parts of the social system. In a cyclical process of dealing with problems and through

formal training to follow social norms, the child eventually internalizes the society. The influence of functionalist theorists has waned given their overconcentration on outcomes of socialization, deterministic views of society, and underestimation of the agency of social actors.

A recent and innovative macro-perspective of childhood can be seen in the work of Jens Qvortrup (1991), whose approach was based on three central assumptions: (a) Childhood constitutes a particular structural form, (b) childhood is exposed to the same societal forces as adulthood, and (c) children are themselves co-constructors of childhood and society. By childhood as a social form, Qvortrup means it is a category or a part of society such as social class, gender, and age groups. In this sense children are incumbents of their childhoods. Because childhood is interrelated with other structural categories, the structural arrangements of these categories and changes in these arrangements affect the nature of childhood. In modern societies, for example, changes in social structural arrangements of categories such as gender, work, family, and social class have resulted in many mothers working outside the home and their children both taking on more household work and spending more of their time in institutional settings, such as day-care centers and after-school programs, that did not exist in the past.

At a more intermediate level, analysis of socialization processes can be seen in work on social structure and personality and the life course. This work often escapes the deterministic nature of traditional macro-theories by documenting how specific features of social structure affect interaction in various contexts of socialization. For example, Elder (1994) argued that transitions in the life course are always embedded in trajectories that give them a distinct form and meaning. The life course approach, thus, overcomes the static nature of cross-sectional studies and captures the complexity of socialization across generations and key historical periods.

**Interactionist Approaches to Socialization** Interactionist approaches stem primarily from the social philosophy of George Herbert Mead (1934). Mead saw the genesis of self-consciousness as starting with the child's attempts to step outside him or herself by imitating others and reaching completion when the child, through participation in games with rules, acquires the ability to take on the organized social attitudes of the group. In Mead's stages in the genesis of self, however, children acquire more than a sense of self; they also appropriate conceptions of social structure and acquire a collective identity.

Surprisingly there has been little research by symbolic interactionists on early socialization. In one exception, Norman Denzin (1977) studied early childhood and argued that socialization "from the standpoint of symbolic interactionism, represents a fluid, shifting relationship between persons attempting to fit their lines of action together into some workable, interactive relationship" (p. 2). From this perspective, Denzin studied the worlds of childhood in the preschool and family. In the family, for example, Denzin documented how parents incorporated their young children into shared discourse by responding to their gestures and vocalizations as meaningful communications. However, there has been no real research tradition or theoretical innovation on children and childhood from Denzin's work.

Other symbolic interactionists have been more persistent in theoretical and empirical work on preadolescents. Gary Fine (1987), for example, studied Little League baseball and identified how, over the course of a season, boys through their collective activities taught each other about morals, emotional expression and control, and language routines only indirectly related to the sport. Patricia Adler and Peter Adler (1998) identified clear status groups and cliques among elementary school children and how the clique dynamics varied across groups. Somewhat surprisingly, the members of the popular clique were visible but not always well liked, and the competition within the group worked against close friendships.

**Interpretive Approaches to Children's Socialization and the New Sociology of Childhood** Central to the interpretive view of socialization is the appreciation of the importance of collective, communal activity—how children negotiate, share, and create culture with adults and each other. In line with these assumptions regarding interpretive collective activity, William Corsaro (2005) offered the notion of *interpretive reproduction*. The term *interpretive* captures innovative and creative aspects of children's participation in society. Children produce and participate in their own unique peer cultures by creatively appropriating information from the adult world to address their own peer concerns. The term *reproduction* captures the idea that children do not simply internalize society and culture but also actively contribute to cultural production and change. The term also implies that children are, by their very participation in society, constrained by the existing social structure and by social reproduction.

Interpretive reproduction views children's evolving membership in their culture as reproductive rather than linear. According to the reproductive view, children and youth strive to interpret or make sense of the adult culture, and in the process they come to produce their own peer cultures (Corsaro, 2005; Eder, 1995). Appropriation of aspects of the adult world is creative in that it both extends or elaborates peer culture (transforms

information from the adult world to meet the concerns of the peer world) and simultaneously contributes to the reproduction of the adult culture.

Corsaro (2003) pointed to children's dramatic role play as an instructive example of interpretive reproduction. In role play, children do not simply imitate the adult model but appropriate and embellish it to meet the interests, values, and concerns of their peer cultures. Corsaro documented complex differences in the dramatic role play of the upper-middle class compared to that of economically disadvantaged preschool children. The upper middle class children created an ice cream store in their private preschool where they portrayed themselves as owners of the store, invented a type of ice cream that would not melt in the hot sun, and decided to donate some of the money from their store to help sick kids pay their hospital bills.

The economically disadvantaged kids (attending a Head Start center) created a role-play event in which they pretended to be their mothers having a telephone conversation about the difficulties of parenting in poverty. They discussed how their children wanted them to take them to the store when there were no large grocery stores in the neighborhood and to the park. The girls talked about the difficulties of transportation to faraway stores and safe parks when the local bus system was slow and demanded transferring from one bus to another to get to the desired destination—a problem few middle-class families face. Although the complexities of both role-play events were impressive in regard to the children's cognitive and communicative skills, it was clear that the predispositions of the middle-class children were optimistic and confident, whereas those of the economically disadvantaged children displayed a sobering recognition of their challenging futures.

# SOCIALIZATION, GENDER

Individuals must learn the *culture* of the society in which they live—the ways of life, beliefs, values, behaviors, and symbols—to have the shared knowledge necessary to interact with others meaningfully. Using a life course perspective, culture is acquired through the ongoing process of socialization during which people first learn broad elements of the culture such as values and beliefs

from the family and continue to learn the expectations and appropriate behaviors associated with particular social settings such as school and work from peers and coworkers. However, the socialization experience is not the same for everyone and the specific information transmitted to individuals through socialization can differ according to their race, socioeconomic status, and gender.

## DEFINING SOCIALIZATION

The contemporary notion of socialization is a combination of ideas from psychology, sociology, anthropology, and human development. Some of these academic orientations, such as sociology, have traditionally emphasized the actions of external groups in the socialization process and stress the perpetuation of culture from one generation to another through social institutions such as the family, educational system, religion, and government. Other orientations, such as psychology, emphasize the individual's reaction to the information received through socialization. At this individual level, socialization leads to three outcomes. First, people internalize the values of their society that define what is good and desirable. Secondly, *social norms*, the rules that guide behavior, are learned. And third, people learn appropriate *roles*: the patterns of behavior attached to recognized positions in society such as son, daughter, husband, wife, or boss.

These dissimilar emphases on either the external processes or internal outcomes have actually served to make socialization an increasingly generic and ambiguous conception. So many different processes have been discussed under the heading of socialization that the concept has been critiqued for lacking a concise and authoritative meaning. Noting this ambiguity, socialization can generally be defined as both the external procedures by which the beliefs and appropriate behaviors of a society are conveyed to individuals and the internal processes resulting in the internalization of societal values, norms, and roles.

## SOCIALIZATION AND GENDER

Gender is a very important component in the socialization process. Throughout the entire life course, people experience differential treatment and expectations depending on their sex. Boys and girls are encouraged by their parents, teachers, and friends to exhibit the behaviors and traits traditionally considered to be gender-appropriate. Eventually, individuals develop self-concepts based on the social meaning associated with their sex.

Whereas *sex* is usually used to describe the biological distinction between males and females determined by sex organs and genes, *gender* refers to a cultural distinction having to do with the attributes and traits thought to be related to each sex. A child's sex develops in the womb before birth, but gender is learned in a social context. Depending on the level of analysis, gender can involve both *gender roles*: society's notion of appropriate masculine or feminine behavior and attitudes, and *gender identity*: individuals' subjective feelings of themselves as male or female.

Gender roles are passed down from one generation to another through socialization and many of the attributes and behaviors considered to be innately male or female are largely determined by the society in which one lives. All societies have *gender stereotypes*: widely held sets of beliefs regarding the personal traits of men and women (Williams & Best, 1990). In U.S. society, males are commonly ascribed instrumental traits and are considered to be assertive, aggressive, independent, competent, and logical, whereas females are characterized as passive, warm, caring, submissive, and emotional.

Gender stereotypes can vary between societies depending on if perceived differences between the sexes are emphasized or minimized. Margaret Mead (1963) conducted a classic and pioneering study illustrating cultural variations in gender roles with three tribes in New Guinea. Among the members of the Arapesh tribe, both men and women exhibit qualities that U.S. society would define as being traditionally feminine: warmth, cooperation, and nurturance. In the Mundugumor tribe, both sexes have the traditionally masculine characteristics of anger and aggression and in the Tchambuli tribe, traditional gender roles are reversed with females being dominant and males being submissive and emotional. Even though the accuracy of some of Mead's conclusions have been questioned, her early research has inspired studies to focus on the social definitions of gender-appropriate behavior.

Just as gender stereotypes can differ between societies, variability can also exist within the same society depending on factors such as sex, race, and social class. Past research has found that boys have stronger gender-stereotypical views than girls as children and are more likely to conform to their gender role. African-American adults have been found to endorse greater gender equality than whites. Additionally, middle-class adults have more flexible gender-stereotypical views than individuals from the working class (for a more in-depth discussion of gender and a review of research findings, see Wharton, 2005).

## MAJOR THEORETICAL APPROACHES TO STUDYING SOCIALIZATION

*Socialization* is a concept that bridges the gap between social experience and the development of individual personality. Three major theoretical approaches exist for

studying socialization. Scholars with more social orientations have drawn largely from structural functionalism to highlight the structural dimensions and processes related to how people are socialized by other individuals and social groups. Structural functionalist approaches generally hold that societies are composed of complex social structures, such as families, the government, and the economy that function interdependently to promote stability and ensure continuation of the society (i.e., Parsons, 1951). The purpose of socialization is to transmit components of culture to new generations and to train individuals for their social roles. Therefore, conforming to the norms of society is necessary for the stability and the effective functioning of society.

Conversely, scholars with more individualistic orientations have used symbolic interaction theories to emphasize personal experiences in the socialization process and how social values and norms become part of identity. Symbolic interaction approaches focus much more on the individual and assume that people actively construct their own realities and self-concepts through interactions with others in specific social settings (i.e., Mead, 1962 [1934]). The self, therefore, develops through social activity and socialization. Symbolic interactionism stresses that socialization is a dynamic interactive process in which individuals adapt information to their specific needs (for an accessible overview of both theories see Ritzer & Goodman, 2004).

A third, developmental approach to studying socialization encompasses numerous different theories such as psychoanalytic, social learning, and cognitive development to explain how early social experiences influence personality. The theories included in this approach are the most focused on individual processes. The psychodynamic theory of Sigmund Freud (1856–1939)—and the extensions by Erik Erikson (1902–1994), Harry Stack Sullivan (1892–1949), and Alfred Adler (1870–1937)—address how the components of personality form and illustrate the specific mechanisms used to internalize social norms and expectations. Additionally, the constructivist theories of Jean Piaget (1896–1980) and Lev Vygotsky (1896–1934) deal with how individuals develop higher mental functioning by actively engaging their environment and interacting with others. Many of these theories have greatly informed the study of socialization and have been used to explain the development of gender identity; however, they are too varied to be adequately discussed at length in this entry (for more information see Miller, 2002).

## AGENTS AND PROCESSES OF SOCIALIZATION

Numerous social experiences and interactions with others have the potential to affect beliefs and behaviors. However, certain groups in a society are much more influential than others. These *agents of socialization* are those groups that teach the important social norms and values that eventually become part of individual self-concept, including what is considered to be gender-appropriate behavior.

Agents socialize individuals through numerous processes. At the societal level, the *processes of socialization* are activities and actions of external groups that transmit societal norms and values to an individual such as direct instruction, modeling the appropriate behavior, rewarding proper behavior, and discouraging unacceptable behavior. However, socialization processes can also be analyzed at the individual level and can include individuals' behavioral responses and internal reactions to the socialization they receive such as attending to the instruction, imitating, remembering the lesson, and accepting or rejecting the value.

**The Family** The family is widely considered to be the most important agent of socialization. Because parents are more likely to follow what is considered to be appropriate parental roles for the culture in which they live, families serve to transmit the values of the society as a whole through their parental practices (Arnett, 1995). Additionally, each family is characterized by a specific ethnicity, income level, social class, religious belief, and political orientation that help to determine how children will be raised.

Differential treatment by parents can establish different expectations for behavior and teach young children much about gender. However, a review of the research conducted in North America has found that the only consistent difference in parental treatment between boys and girls is the encouragement of sex-typed play activities such as offering dolls to girls and balls to boys (Lytton & Romney, 1991). Of course, any differences in treatment between boys and girls in a specific family could also depend on factors such as the race and social class of the parents as well as the parents' ideas about appropriate gender roles.

**School and Work** Schools are formally responsible for teaching children the knowledge and skills needed to participate in society. However, the belief system of the larger society greatly influences the structure and culture of schools. Aside from academic lessons, schools also teach the norms, values, and socially appropriate behaviors of the society. Children learn numerous unintended lessons through this *hidden curriculum*. For instance, because students are counted as tardy if they are not in class by a certain time, they learn that punctuality is important. Additionally, the competitive nature of

activities such as spelling bees, science fairs, and extracurricular sporting events teach children to value success.

Teachers also continue the instruction about gender-appropriate behavior that children first receive from their parents. Boys are given more attention and praise than girls (Sadker & Sadker, 1994). Additionally, teachers are more likely to praise boys for their knowledge, but praise girls for obedience and following the rules. These differences in treatment further reinforce separate expectations for boys and girls and establish different standards of acceptable behavior.

In adulthood, the work setting replaces school. Instead of a teacher, most people work under the authority of a boss and hard work is rewarded with money instead of grades. Workers learn to adopt a strong work ethic and can eventually see their job as an important part of their identity.

**The Peer Group** A peer group is a collection of individuals who regularly interact, share similar interests, and are approximately the same age. For younger children, peer groups normally include nearby neighborhood playmates. Later, peer groups are composed of more distant acquaintances as preteens and adolescents make friends in school and join peer groups according to similar interests and concerns about social status. Whereas relationships with family members remain important, the significance of peers increases during the school years and become especially significant during adolescence.

Unlike the family or the school, the peer group provides children with a much more interactive context in which the meaning of gender is learned and reinforced. However, peers generally expect conformity to gender stereotypes and discourage others from nonappropriate behavior. Eleanor Maccoby (1998) details how boys and girls segregate themselves into same-sex play groups at an early age and learn different styles of interaction. Boys are more physical, competitive, and physically aggressive. Girls play in smaller groups, tend to be more cooperative, engage in taking turns during play, and express greater self-disclosure to each other. The different styles of interaction reinforced by each group help further socialize boys to be more independent and dominant whereas girls learn the importance of maintaining relationships.

**Mass Media** The mass media are different forms of communication directed to a very large audience and includes television, movies, radio, magazines, and the Internet. Public exposure to the mass media is considerable and has been increasing since the beginning of the 20th century due largely to technological innovations in the middle and latter parts of that century (such as the wide sales of televisions after World War II, ca. 1946–1955), and the development of the World-Wide Web). Even if not intended by the producers, numerous messages presented by the media can teach values, beliefs, and ideologies.

Studies suggest that gender role perceptions and attitudes are affected by television programs and commercials that generally portray men in positions of authority and women as subordinate. Erving Goffman (1979) found that in magazine and newspaper advertisements, men were positioned in front of women or pictured as being taller than women whereas women were more likely to be in positions of subordination such as lying down or being seated on the floor. More recent research has supported Goffman's findings (i.e., Cortese, 1999), and even newer forms of media continue this traditional portrayal of men and women. For example, video games under-represent female characters and often portray them as sex objects.

**Cohort Differences in Socialization** Societies can be conceptualized as collections of various stratified groups based on factors such as gender, race, and socioeconomic status. However, societies are also composed of a number of *cohorts*: groups of people born during approximately the same time period. Values and beliefs can differ among cohorts depending on the socialization they received at a specific time. But as individuals in a cohort grow older, they also share a unique set of historical life experiences that have the potential to alter the initial beliefs and values learned through socialization (Settersten & Martin, 2002). This is especially true when the effects of a particularly important generation-defining historic event are experienced (e.g., the Great Depression in the 1930s, World War II with U.S. involvement from 1941–1945, or the counterculture movement of the 1960s). In turn, the new values and beliefs of the cohort will be transmitted to the next generation through socialization.

For example, a woman born in the 1920s would have experienced very different gender socialization than a woman born in the 1970s. Whereas significant differences in gender socialization could be expected depending on variables such as social class and race, many women born in the late 1920s would have probably been told that a woman's place was in the home, would have been discouraged from seeking employment, and would have been expected to get married and have children. Yet in their late teen years, this cohort would have experienced America's entrance into World War II during the early 1940s and witnessed the large numbers of women who contributed to the wartime effort by working in previously male-dominated professions. As a result of living through and possibly even participating in these events,

some members of this cohort may have changed their ideas about the capabilities of women and subsequently taught their children an expanded notion of the appropriate behaviors and attitudes for women.

The children of this late 1920s cohort would have been born after World War II (the so-called Baby Boom). In turn, this new cohort would have experienced the Vietnam War and the counterculture movement. The gender role socialization that the Baby Boom generation provided to their children would probably be significantly affected by the women's movement of the 1960s and the resulting legislative changes banning sexual discrimination such as Title IX (outlawing sexual discrimination in any educational program or activity that receives federal funds). Additionally, the children of the Baby Boomers, born beginning around the mid-1970s (Generation X), would witness more and more of their mothers seeking employment outside of the house. Seeing this expansion of the homemaker role for women could have an influence on the messages about gender that this generation provides to their children. This greatly abbreviated review of the major historical events occurring over just three generations illustrates how radically different gender socialization could be for an individual born in 1930 and a member of Generation X born in the 1970s.

## FUTURE DIRECTIONS

A review of the main theoretical approaches to socialization and previous research findings illustrate socialization as a multifaceted process. Gender socialization, in particular, is especially complex given the potential influence of numerous social and temporal variables. Trends in socialization research indicate that scholars are noting the influence of societal change on socialization patterns and are envisioning individuals as more active agents in their own socialization. Future research can be expected to continue along these trajectories with more of a focus on the individual and the effects of social change.

Societies are not static and at least some degree of change is inevitable. Whereas many theorists and researchers have stated the importance of the family as an agent of socialization, the nature of the traditional family is changing. Numerous couples divorce, more children are being born into cohabitating unions, more mothers are working, and more single women are the heads of their own households. Future research could investigate if witnessing these changes in the traditional homemaking compared with breadwinning roles is related to children's notions about the appropriate gender roles of men and women. Additionally, research could also explore if witnessing these changes affect girls and boys similarly.

Research can also be expected to continue focusing on individuals as more active participants in their own socialization. With increasingly interactive forms of media such as the Internet and with so many entertainment choices offered by the multitude of channels on cable and satellite television, people can choose media that supports their already established notions of appropriate gender roles. Future research may explore the processes and mechanisms involved in how people choose the media they consume instead of the effects of the media on individual conceptions of gender.

## SOCIALIZATION, RACE

*Socialization* is the lifelong process through which norms and expectations are transmitted among people in order to create stability in society through consensus. Agents of socialization can be individuals, groups, or institutions. These agents are constrained by cultural conditions and political forces such that socialization generally supports the status quo. In a certain sense then, socialization is conservative in nature because deviance from the status quo is discouraged. The content of socialization messages transmitted relates directly to the developmental stages (e.g., child, youth, adolescent, young adult, or adult), roles (e.g., son, teacher, student, mother, professor, or politician), and ascribed and achieved statuses (e.g., race, gender, or socioeconomic status) of individuals being socialized.

*Race socialization* is the lifelong process through which the social meaning and consequences of race and racism are transmitted (Brown, Tanner-Smith, et. al, 2007). Through this process, individuals learn about physical differences, history and heritage, identity politics, and/or prejudice and discrimination (Chesire, 2001; Hughes, Rodriguez, Smith, et. al, 2006; Lesane-Brown, 2006). Children and adolescents of color are the central focus in the literature because families of color are the agents of race socialization predominantly studied. More specifically, most studies focus on Black families. This is so because race socialization research started with attempts to explain how Black children could form and maintain positive self-concepts despite their in-groups' marginalized status in the U.S. racial hierarchy (Hughes et al, 2006). Familial race socialization continues to be deemed essential for the healthy development of Black children because it initiates a watershed experience after which Black children develop racial identity and become conscious regarding the nature of racial intolerance. Racial identity and consciousness are necessary for success in contexts such as the United States, where non-white physical features remain an impediment to social and upward mobility. Along those same lines, recognition that the lives of other U.S. racial minority groups are similarly shaped by racial hierarchy began during the 1990s (Hughes et al, 2006). In response, scholars began asking whether racial minorities other than Blacks socialize their children regarding race and racism (Aboud, 1988; Brown et al, 2007).

Parents raising White children teach them about race and racism too, yet are virtually neglected in discussions regarding the race socialization process because Whites define the norm. In addition, the goals of White families' teachings may differ from the goals of parents raising children of color. One study suggests that in White families the main objective of race socialization is to promote White children's tolerance of diversity (Katz & Kofkin, 1997). In contrast, another study finds that most White parents are indifferent toward socializing their children regarding interracial relations (Hamm, 2001). Although it probably has differential meaning within non-White and white families, race socialization occurs in all families rearing children and thus is universal.

### TERMINOLOGY

Hughes, Rodriguez, Smith, Johnson, Stevenson, and Spicer (2006) suggest using the term *ethnic-racial socialization* when referring to the broad research literature. Unfortunately, some scholars use the term *ethnic socialization* when referring to, for example, *both* Blacks and African Americans, confounding race with ethnicity. In response, the present authors prefer the term *race socialization* when describing socialization processes involving U.S. racial group members of various ethnicities (e.g., Whites, Blacks, Hispanics, Asians, Native Americans, or multiracial individuals) and *ethnic socialization* when describing U.S. ethnic groups of various races (e.g., Irish Americans, Cuban Americans, Jamaican Americans, Jews, Mexican Americans, Japanese Americans, or Hopi Indians). Clearly race socialization and ethnic socialization might overlap, but in some cases one is present without the other. For reasons of clarity and parsimony, the authors use the term *race socialization* throughout the remainder of this entry.

### WHY SOCIALIZE CHILDREN TO RACE

Brown, Tanner-Smith, Lesane-Brown, and Ezell (2007) theorize that there are three reasons families tend to socialize young children to race and racism: (a) the context in which the child lives exposes him or her to diversity; (b) some families are facile at communicating with children regardless of topic; and (c) the child is being prepared for membership in a marginalized racial minority group. An additional reason is that: (d) families desire to pass down traditions and customs. The first reason suggests that everyday life exposes the child to opportunities to learn about racial diversity. Indeed, research indicates that children, some as young as six months, recognize and react to differences in physical features (Katz & Kofkin, 1997). Second, in families where warmth characterizes interactions, children feel loved and probably discuss many topics with family members, race and racism among them (Aboud, 1988). The third reason is that race socialization prepares children of color to live successfully in an often hostile context (Lesane-Brown, 2006). The fourth reason deals with preservation of collective memory as some families

***Lunchtime.*** *Muslim schoolchildren select from traditional Middle Eastern foods.* © GIDEON MENDEL/CORBIS.

pass in-group traditions and customs down to the next generation (Chesire, 2001).

## THEORETICAL APPROACHES

There are five theoretical approaches that may be helpful for understanding the meaning and significance of the race socialization process: (a) social cognitive learning theory, (b) the life course perspective, (c) ecological theory, (d) racial identity theory, and (e) the social capital perspective. Connections among these theories are reflected in the centrality each assigns to meaning-making during interpersonal and group interactions.

*Social cognitive learning theory* is useful for understanding ways families teach children about race and racism. Broadly, this theory predicts how children come to think and behave in normative fashion at particular developmental stages, asserting that socially acceptable behaviors are learned through discussions, observation, modeling, vicarious reinforcement, and imitation of significant others (Bandura, 1977). Through these mechanisms, children learn about race and racism, and how to respond in race-related situations. For example, Chesire (2001) describes common practices (e.g., listening, telling, watching, and observation) related to transmission of cultural knowledge among American Indian women and their families. Children play an active role in this process because they must actively attend to their parents' messages, encode what they are hearing or observing, reject or store this new information in memory, and then retrieve this information at some later time (Bandura, 1977).

*Life course perspective* (Alwin, 1995; Elder, 1994) is useful because it describes how individuals' lives are shaped by social change. This perspective links agency, social conflict and change, individual development, and biography across various life domains including work, family, and health. In terms of the race socialization process, the life course perspective suggests that family communication about race and racism are contoured by historical time. The perspective acknowledges that parents' race socialization practices must adapt to fluctuations in cultural conditions and political forces in anticipation of when their children will come of age. Consequently, messages transmitted to one generation of children may be different than those transmitted to another generation (Brown & Lesane-Brown, 2006).

*Ecological systems theory* (Bronfenbrenner, 1979) defines several concentrically and temporally arranged levels of the environment (i.e., microsystem, mesosystem, exosystem, macrosystem, and chronosystem) that simultaneously interact to influence social development. Positioned at the center of these levels of the environment is a child who is influenced by and proactively influences the surrounding environment. In part, these environments determine when, how, and why parents racially socialize their children (Lesane & Brown, 2006). Ecological systems theory represents the causative layering of levels. More specifically, the theory addresses how multiple levels and socializing agents interrelate to influence individuals, and is truly social psychological in formulation (i.e., suggesting reciprocity between macro and micro levels).

*Racial identity theory* (Katz & Kofkin, 1997) views race socialization as the requisite precursor to development of racial identity. Racial identity represents a sense of attachment to a collective and imagined community of similar others. The sense of attachment provides purpose and an inter-subjective definition of the situation. Scholars theorize that race socialization is therefore psychologically affirming to children of color because it concretizes their emergent self-schemas—defined as organized, affective, coherent, and integrated generalizations about self and relationship of self to others in the in-group and out-group (Oyserman, et. al, 2003).

*Social capital perspective* (Putnam, 2000) defines social capital as an intangible resource that facilitates certain outcomes for actors within a social structure or an intangible resource that creates value through meaningful social relations within a social network. Scholars have neglected how the race socialization process creates two forms of social capital. First, race socialization encourages "bridging" social capital, formed of inclusive networks that encompass people across diverse social cleavages (e.g., region, socioeconomic status, or historical time) including members of one's racial group (Katz & Kofkin, 1997; Putnam, 2000). Second and simultaneously, race socialization encourages "bonding" social capital because it reinforces exclusive identities and homogeneous groups, framing racial identity as distinct from other identities (Oyserman et al, 2003).

## EMPIRICAL RESEARCH

Most race socialization research focuses on the *content* of parental messages transmitted (Hughes et al, 2006). In these studies the research question has typically been: What are the specific things that parents say to teach their children about race and racism? Message content is usually divided into four broad categories: (a) racial pride and teachings about cultural heritage, traditions, and values; (b) awareness of and preparation for racism and discrimination; (c) equality and coexistence among racial groups; and (d) the importance of life skills, citizenship, and individualism.

*Prevalence* assesses the proportion of parents that transmit race socialization messages. Research indicates that a larger proportion of parents raising non-White children practice race socialization as compared to the proportion of parents raising White children (Brown et al., 2007).

*Frequency,* which includes information such as persistence and accumulation that is obscured in studies of prevalence alone, assesses how routinely race socialization occurs. The frequency in which parents transmit race socialization messages may vary depending upon the content of the message. For instance, child and adolescent studies conducted since the 1980s have found that Black parents transmit messages regarding racial pride and heritage, and equality among racial groups more frequently than any other message (Hughes et al., 2006).

Several *predictors*—related to the child (e.g., age, gender, and race), parent (e.g., gender, education, income, marital status, discrimination experience, relationship with child, and racial identity), and situation (e.g., child school characteristics, neighborhood demographics, and region of residence)—are associated with whether (prevalence) and how often (frequency) parents transmit race socialization messages as well as the content of messages transmitted. For example, a nationally representative study comparing preschool-aged children found that families living in the West and families rearing American Indian children are likely to frequently teach children about their ethnic/racial heritage (Brown et al, 2007). Historical time is also emerging as an important situational predictor of race socialization, in the sense that appropriate race socialization depends upon cultural conditions and political forces (Brown & Lesane-Brown, 2006).

Regarding *outcomes,* several studies support the hypothesis that receiving race socialization messages in general and receiving group membership and pride messages in particular promote affirming racial identity structures, protection from internalizing negative racial stereotypes, positive academic orientations and outcomes, and positive psychosocial outcomes (Lesane-Brown, Brown, Caldwell, et. al, 2005). In addition, race socialization may act as a buffer against perceived experiences of discrimination. In contrast, messages emphasizing awareness of and preparation for racism and discrimination transmitted to children of color show inconsistent effects. Some studies suggest such messages are associated with positive psychosocial and academic outcomes, whereas others suggest these messages lead to negative academic outcomes, poor psychosocial functioning, and

distrust of individuals outside one's racial group (Lesane-Brown, 2006). Little is known regarding implications of receiving messages that emphasize equality among racial groups or that deemphasize race and racism while touting individualism.

## MEASUREMENT

Disagreement exists about what constitutes a reliable and valid measure of race socialization (Lesane-Brown et al, 2005). Some measures use open-ended questions to assess message content, whereas others use close-ended questions. Some measures are considered multidimensional and scalable, whereas others are not (Lesane-Brown et al, 2005). Some measures include few message content categories, whereas others include several.

Throughout the 1980s to late-2000s, race socialization measures that assess message content and frequency have dominated the literature, but there is progress toward more comprehensive assessment. In fact, Lesane-Brown, Brown, Caldwell, and Sellers (2005) developed an inventory that moves the field in that direction. In addition to capturing message content and frequency, their inventory, the Comprehensive Race Socialization Inventory (CRSI), examines neglected components of the race socialization process such as: onset and recency, the most useful message, multiple sources (i.e., agents of socialization), anticipatory socialization messages, and socializing behaviors.

## FUTURE DIRECTIONS

The United States is becoming a more diverse and arguably more divided nation. Long-standing divisions relate to immigration, region of residence, religion, socioeconomic disparity, language, political orientation, and so on. What is interesting about these divisions is the extent to which they are racialized and to which individuals claiming specific racial backgrounds tend to represent particular positions. Given this, it is no wonder the race socialization process intrigues many scholars. To improve scholarship on the topic, it is particularly important to understand the history of race socialization research and where current research trends are headed. If one anthropomorphizes the race socialization literature, then she is currently an adolescent, experiencing excitement, amazing growth, and turmoil.

The following suggestions are offered to help facilitate her transition from adolescence to young adulthood. First, the race socialization literature needs studies that examine dynamism in the race socialization process (e.g., demonstrating whether message content is internalized or rejected). Second, because parents are but one of numerous socialization agents at work over the life course, scholars must examine how messages from multiple sources (including family, friends, the media, schools, or religious organizations) interact with one another to shape paradigms of children, youth, adolescents, young adults, and adults (Lesane-Brown et al, 2005). Third, long-term longitudinal, life course–inspired research designs are needed to reveal how early-life race socialization experiences link to older adults' conceptions regarding race and racism. Fourth, because there is little consensus regarding measurement of race socialization, studies that incorporate multiple measures and compare results are to be welcomed. In addition, rather than relying solely on self-report measures, scholars should employ multi-method approaches (such as use of observational measures, diaries, or vignettes) to investigate the race socialization process. Finally, more multi-generational studies of families are needed. These are particularly informative in terms of triangulating perspectives of socialization agents with those that they are intending to socialize.

# SOCIOECONOMIC INEQUALITY IN EDUCATION

Family background is consistently found to be related to educational outcomes such as grades, test scores, school dropout, and educational-degree attainment. Researchers often study the relationship between socioeconomic status (SES) and education. The term *socioeconomic status* often is used to describe the hierarchical arrangement of individuals and families on the basis of the social and economic factors that are rewarded in society. Although there is no consensus about the best way to measure SES in empirical studies, individual or family SES often is measured by three attributes: parents' income, education, and occupation. Studies using these individual-level measures of SES find that students from higher socioeconomic backgrounds tend to have higher test scores, lower rates of school dropout, and higher rates of postsecondary school enrollment and completion. Research on socioeconomic inequality also emphasizes the characteristics of a child's school and/or neighborhood, suggesting that it is not just the SES of individuals that matters but also the average socioeconomic level of all the individuals in the community. Schools with lower percentages of students eligible for free or reduced-price lunches have higher proportions of high school graduates, as do schools in districts with lower poverty rates. Because education matters for individuals' life chances, socioeconomic disparity in educational outcomes is a topic of concern to researchers and educators. In sum, family SES during childhood affects education, which in turn affects later SES as well as other life course outcomes.

This entry describes general trends in the relationship between SES and educational outcomes in the United States, then discusses the processes of social stratification in education, highlighting key mechanisms in the family and schools that reproduce social and economic disparities in schooling. It concludes with a brief discussion of current and future research on socioeconomic inequality in education.

## TRENDS IN SOCIOECONOMIC INEQUALITY IN EDUCATION

The Coleman Report (Coleman et al., 1966) remains one of the most influential studies on educational inequality. One of its key findings is that family background has a greater influence on student academic achievement than do school resources; it is the characteristics of students and their families, not those of schools, that account for differences in students' test scores. Sociologists interested in social stratification have examined the ways in which family SES is transmitted.

Peter Blau and Otis Duncan's (1967) *The American Occupational Structure* marked the beginning of the predominance of research on status attainment in sociological studies of social stratification. Using data on adult males in the United States in the early 1960s, those researchers found that a father's education and occupation positively influence his son's educational attainment and occupational status. Although those authors found direct effects on both outcomes, the relationship between family background and a son's occupational status was mediated by the son's educational attainment. This means that although most men end up in occupations that are similar to those of their fathers, education is the main pathway for those from lower-SES backgrounds to move into occupations that place them in higher social strata than their parents. After Blau and Duncan, researchers studying status attainment processes documented the relationship between family SES and educational and occupational attainment.

Although traditional models of status attainment have been successful in documenting and describing the relationship between social origins and individuals' educational and occupational attainment, the Wisconsin model of status attainment developed by William Sewell, Archibald Haller, and Alejandro Portes in1969 takes a more social psychological approach by including cognitive ability, educational aspirations, and the influence of significant others in the process of educational attainment. This model is distinguished from prior status attainment models by its concern with mediating factors and understanding of the way family background affects

the attainment process. Though the Wisconsin study has been replicated and refined by others, the results of later studies generally support the original findings.

Socioeconomic inequality in educational achievement and attainment has persisted over time and across countries and is expected to continue to do so in the future (Gamoran, 2001). More recent studies have confirmed the persistence of the relationship between socioeconomic background and academic achievement over time. In Karl White's (1982) analysis of various studies that examine the relation between SES and academic achievement, a moderate correlation ($r$ = .343) between SES and student academic achievement was found in studies conducted before the 1980s. Selcuk Sirin (2005) conducted a similar analysis of studies done between 1990 and 2000 and found that the average correlation between SES and academic achievement remained moderate ($r$ = 0.299).

This persistent effect of family SES on educational outcomes has larger implications for many other life course outcomes and the reproduction of social and economic inequality. Academic achievement and educational attainment are important determinants of later social and economic success. Educational attainment is positively related to labor force participation, occupational prestige, income, and wealth in adulthood. Not only are SES differences reproduced in terms of later educational, financial, and occupational outcomes, initial SES differences in education can lead to later inequality in adult well-being. Education has been shown to have positive effects on both physical and mental health, and these relationships mediate some of the association between initial SES and health.

Figure 1 shows that the percentage of individuals reporting to be in good or excellent physical health increases with educational attainment. In addition, individuals with higher levels of educational attainment demonstrate more knowledge of current events and higher levels of political participation. Many of these relationships are not due only to differences in social origin; the studies described here have shown that after accounting for differences in family background, the effects of education on later social and economic outcomes still exist.

Having identified the role of education in maintaining the privileged status of those in higher social strata as well as its role in making it possible for those from lower strata to be upwardly mobile, researchers turned to the task of understanding how family SES affects academic achievement and educational attainment. This research has demonstrated that differences in financial resources, parental involvement, social and cultural capital, and school organization and quality all contribute to socioeconomic differences in educational achievement and attainment.

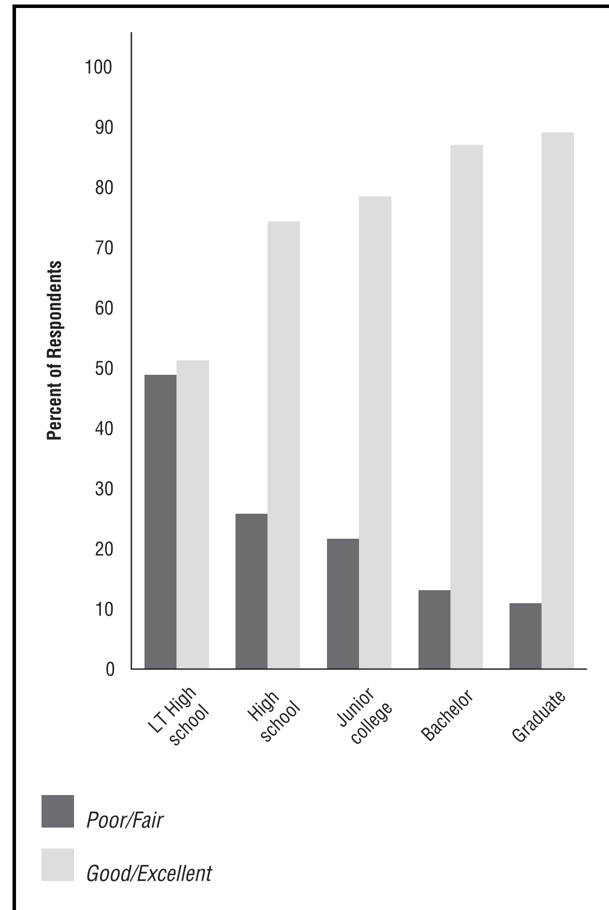

***Figure 1.*** *Self–reported health condition by educational degree attainment, 2006 General Social Survey.* CENGAGE LEARNING, GALE.

## PROCESSES OF SOCIAL STRATIFICATION IN EDUCATION

In the most basic sense, higher-SES parents have resources—human, financial, social, and cultural capital—that translate into advantages for their children in the educational system. One of the most obvious ways in which family SES matters for children's educational outcomes is the tangible resources money can provide. Children from higher-SES families have greater access to resources that enhance academic achievement: books, computers, tutors, trips to libraries and/or museums, and involvement in extracurricular activities. These families also have access to reliable transportation and flexible schedules that make it possible for their children to attend enrichment activities (Lareau, 2003).

**Learning in the Summer Months** Resource advantage also is reflected in opportunities for learning during the summer months, when school is not in session. Research by Barbara Heyns (1978) and Doris Entwisle, Karl Alexander, and Linda Olsen (1997) has attributed much of the disparity in scores on achievement tests between high- and low-SES children to the summer learning gap. Children with disadvantaged socioeconomic backgrounds make smaller increases in achievement during the summer than do their high-SES peers. This, combined with a slower rate of learning during the school year, leads to a widening gap in achievement over time. Some of the differences in summer learning have been attributed to differences in summer activities that are related to cognitive development, such as trips to the library, attendance in summer school, and even summer vacations. Research by David Burkham, Douglas Ready, Valerie Lee, and Laura LoGerfo (2004), however, showed that even controlling for these activities, the summer learning gap between high- and low-SES youth remains. Therefore, future research should focus not only on the frequency of participation in summer activities but also on the nature of activities that can foster higher levels of achievement.

**Parental Involvement and Child Rearing** The availability of those resources also allows higher-SES parents to be more involved in their children's schooling. According to Annette Lareau (1987, 2003), although both middle-class and working-class parents value education and want their children to do well academically, the two groups employ different strategies to help their children in this area. Middle-class parents are more involved in their children's education. They engage in supplemental activities at home, maintain established relationships with teachers and administrators, and are more comfortable intervening on behalf of their children. Working-class parents, in contrast, are more distanced from their children's experiences at school, relying on the schools to educate their children. The interactions they have with school personnel often are marked by a sense of distrust, powerlessness, and ineffectiveness.

Aside from these differences in direct involvement in school activities, there are social class differences in child rearing. Middle-class culture views parenting as requiring a conscious effort to develop children's skills and talents. To that end middle-class parents undertake a process of "concerted cultivation" (Lareau, 2003), emphasizing involvement in extracurricular activities, independence, and developing children's social and intellectual skills through reasoning and discussion. Working-class culture, in contrast, is more focused on what Lareau called the "accomplishment of natural growth." Parents are more concerned with providing children with the necessities—food, clothing, shelter, safety—and believe that children will develop naturally if those needs are met. Working-class parents stress obedience, are less likely to engage in discussion or negotiation with their children, and expect their children to organize their own time.

Because the actions of middle-class parents are valued by schools, middle-class children reap the benefits of their parents' efforts in the form of higher levels of comfort in school and other formal settings and better academic performance. Taken together, the financial, human, and cultural capital that middle-class parents have at their disposal allows them to prepare their children better for academic success throughout their educational careers.

**Social Capital** Children's life chances also are influenced by their access to social capital. James Coleman (1990) defined social capital as resources that accrue to individuals as a result of their relationships with others (their social networks). Coleman (1990) argued that when parents know their children's friends' parents (intergenerational closure), they are in a better position to work in tandem with the other parents to monitor and evaluate their children's behavior because information, norms, and values can be shared through the network. Having parents whose social networks are characterized by higher levels of intergenerational closure leads to better educational outcomes for children. In addition, connections to others provide parents with information and other resources that they can use to improve their children's lives, including their educational experiences. For example, in an in-depth study of social class differences in family life, Lareau (2003) found that middle-class parents have social network connections that provide them with information they can use to help their children navigate the education system. Because social networks are stratified by social class, parents of children in lower strata are less likely to have connections that provide the same kinds of advantages.

**Tracking and School Sector** Although the studies cited above describe processes within the home, the nature and organization of schooling also contribute to socioeconomic differences in educational outcomes. For example, school tracking is considered one of the most important mechanisms in the social reproduction process. Tracking originated in efforts to allow teachers to modify their methods of instruction to suit the abilities of their students. However, Maureen Hallinan (1994) found that track assignment is influenced by a variety of factors other than academic ability, such as resource limitations, organizational constraints, parental influence, and teacher recommendations. Because of these factors, more advantaged families may be better able to manipulate the

***Poverty.*** *Uniontown Elementary School Principal Ora Cummings helps first grade students read at the school in Uniontown, AL. Their desire to learn is not dulled by the fact that recent U.S. Census estimates show that more than one in three of the students in the mostly black Perry County school system, which includes Uniontown, live below the poverty level.* AP IMAGES.

system in their favor, resulting in the overrepresentation of lower-SES students in lower tracks and/or ability groups (Oakes, 1985). This is consequential for socioeconomic inequality in eventual educational attainment because students in college preparatory tracks (also referred to as regular, advanced, or honors course levels) receive more and better academic instruction and have teachers with better skills who present them with more complex material and "high-status" knowledge. In light of the fact that lower tracks provide poorer-quality education, have less qualified teachers with lower expectations, and socialize youth differently, tracking systematically limits the educational opportunities of disadvantaged students.

School sector is another factor in the way SES affects educational outcomes. Public schools are managed by a public entity, generally the state, whereas private schools are not, although they sometimes are affiliated with and/or run by religious organizations. Private schools often require students to go through an extensive application process and charge tuition fees, making them much less accessible to disadvantaged families. Socioeconomic differences in access to private schools are important because attending private school is associated with several positive educational outcomes, including student achievement, retention, and college attendance, although the causal effects of private school attendance have been debated. According to Caroline Persell, Sophia Catsambis, and Peter Cookson (1992), students who attend private schools not only are more likely to attend college but also are more likely to go on to elite private colleges and highly selective public universities. Elite private schools have connections to admissions offices at selective private colleges, making it easier for students to gain admission to those schools. With the increased importance placed on the selectivity of the college/university for one's life chances, the ability to gain admission to selective colleges and universities will be very beneficial for advantaged students and their families, allowing them to maintain their privileged position.

**Access to Resources** The mechanisms through which SES influences education extend beyond an individual and his or her family. As Coleman et al. (1966) demonstrated,

the family backgrounds of a student's schoolmates also influence academic achievement. In a study of high school students in Louisiana, Stephen Caldas and Carl Bankston (1997) found that the social status of schoolmates' families has a significant effect on academic achievement and that this effect is only slightly smaller than that of a student's own family background. Other research suggests that socioeconomic inequality in education also is due to unequal resources at the school level. Because a large proportion of school funding is linked to local property taxes, there is considerable variation in per-pupil expenditures across school districts. Thus, students who live in areas with lower property values often attend schools with less funding. This disparity in funding is reflected in the quality of the schools. Although some research has suggested that school resources and spending do not have as large an effect on student achievement and later income inequality as does family background, other research has shown that unequal spending has led to disparate outcomes in academic achievement. For instance, Dennis Condron and Vincent Roscigno (2003) found that schools with higher per-pupil expenditures are in better physical condition and have a higher degree of classroom order, factors that are associated with higher student attendance rates, higher teacher quality, and higher average test scores.

## CURRENT AND FUTURE RESEARCH ON SOCIOECONOMIC INEQUALITY IN EDUCATION

The studies described above focus primarily on socioeconomic inequality in primary and/or secondary education. However, as more individuals participate in postsecondary schooling, more research has been devoted to socioeconomic inequalities in higher education. Social reproduction theorists such as Pierre Bourdieu and Jean-Claude Passeron (1977) view the continued existence of socioeconomic inequality in education as resulting from the fact that privileged members of society use education to maintain their status and thus pass that privilege on to their children. Thus, as one level of education expands to become accessible to those in the lower strata, the threshold of inequality shifts upward. Most recently, the emphasis has shifted to postsecondary education, and those in the higher social strata have been able to maintain their advantage with higher rates of college attendance and completion. Recent institutional initiatives enacted by several public and private universities (e.g., the University of North Carolina, Brown University, and Stanford University) have attempted to reduce and in some cases eliminate financial barriers to higher education for lower-income and middle-class families. For example, in February 2008 Brown University announced that it would eliminate loans for students whose families earn less than $100,000, and Stanford University approved a plan to waive tuition for students with family incomes under $100,000. Although these initiatives are intended to increase access to education, the effects of these efforts remain to be seen.

College access and enrollment has long been a concern, but research has shifted to studying access to and enrollment in different types of higher education (two-year vs. four-year, private vs. public) and college trajectories. Therefore, it is not only a matter of whether individuals attend college but also how they do so. Postsecondary perceptions and experiences vary by social class. For instance, Robert Bozick and Stephanie DeLuca (2005) found that low-income students are more likely than their higher-SES peers to delay college entry, resulting in a lower likelihood of college completion. Sara Goldrick-Rab (2006) found that college students with lower socioeconomic backgrounds are more likely to experience interrupted pathways through college, which prevent or delay degree completion. Bozick (2007) found that college students with fewer economic resources are more likely to be enrolled only part-time to keep tuition costs down or work to afford college expenses. This can lead to only a partial investment in or disengagement from school, which can lead to dropping out.

In addition to a greater focus on higher education, with the current emphasis on standards and accountability, researchers increasingly have focused on how education policies and reform such as No Child Left Behind (NCLB) alleviate or exacerbate socioeconomic differences in education. Although the explicit goals of reforms such as NCLB are to combat differences in education caused by family background, it remains to be seen whether they have been successful in doing so. Pamela Walters (2001) suggested that although educational reforms have increased educational attainment among disadvantaged groups, they have not closed or reduced social class gaps in education. The same might be true for NCLB. High standards and testing are intended to make school more difficult. This may result in higher rates of dropout, and researchers also are interested in how the effects of accountability and high-stakes testing on academic outcomes such as achievement and school dropout vary by SES.

Another educational reform that is associated with socioeconomic inequality is the school choice movement. Parents, educators, policy makers, and communities are interested in providing alternatives to large public schools. Charter schools allow parents and students to choose schools that better suit their needs. Although charter schools often are geared toward racial/ethnic minority groups or those of lower SES, as with the standards and accountability movement, it is not known whether they really are increasing levels of

academic achievement and if there are social and economic differences in which families choose and attend these schools.

Although most gender differences in educational achievement and attainment have been eliminated and racial/ethnic differences are declining, SES continues to exert a stable moderate to strong influence on educational outcomes. Those from higher social strata are in an advantaged position in terms of financial resources and social and cultural capital and are able to use their resources to pass on that advantage to their children. This relationship between SES and educational outcomes has been shown to occur in a variety of settings, particularly in families, schools, and communities, and is evident at all levels of education (primary, secondary, and postsecondary). Education will also continue to mediate the effect of SES on later life outcomes such as occupation and income, political involvement, and physical and mental health. As Adam Gamoran (2001) noted, family background is likely to continue to influence children's educational achievement and attainment, making it an area of continued interest and importance for researchers, educators, and policy makers.

# SPECIAL EDUCATION

**SEE** Volume 1: *Learning Disability; School Tracking.*

# SPORTS AND ATHLETICS

A primary goal of life course sociology is to document the way in which institutions and interpersonal interactions within those institutions influence peoples' lives. For the study of childhood and adolescence, this focus often leads scholars to highlight the influence of traditional institutions such as the family, education, and religion. Yet research shows that sport is another significant field for understanding development from childhood to adulthood. Although the extent to which it achieves this goal is debated, sport is framed as a domain of activity with the potential to shape a broad range of characteristics and values, such as teamwork, following rules, and discipline, that are central to the development of a prosocial child and future adult.

## SPORT VERSUS INFORMAL PLAY

Although seemingly obvious, clarifying what is meant by the term *sport* is necessary to understanding how it contributes to youth development. This definition often is made by distinguishing sport from what it is not—informal play.

Informal play is a free-flowing activity structured through the mutual agreement of the participants. Norms may exist, but they derive from the interaction of the participants and are open to modification. Sport, on the other hand, is defined as "institutionalized competitive activities that involve rigorous physical exertion" (Coakley, 2001, p. 20). The key distinctions between sport and play are: Sport inherently involves physical activities, sport is based on a goal of competitively establishing a clear winner and loser, and the rules and boundaries of sport are codified in institutions with regulatory powers. Unlike informal play, sport is an institution, meaning it exists without the presence or action of any particular participants. Sports are formalized with written and enforced rules and guidelines. The objective of sports always is predetermined (e.g., to get a basketball through a hoop the most times), minimizing the ability for participants to construct their own goals or outcomes.

For the purpose of understanding the place of sports in youth development, demarcating exactly which activities are sport and which are play is not nearly as important as studying how the interaction with and between participants and adults constructs activities to be more like one or the other. Gary Fine's (1987) study of Little League baseball showed that the balance between sport and play was a source of tension among adults and youth. Coaches and parents stressed the importance of Little League being "fun" and "enjoyable" while concurrently calling for "structure" and "rules" to teach the children important life lessons. Even within the same league, coaches took very different approaches to practice and games. For example, one coach allowed players to play any position they wanted and did not discipline players for playing makeshift games in the dugout. For the youth on this team, baseball would seem very much like informal play. Other coaches, however, held rigorously structured practices that emphasized learning uniform techniques with the ultimate goal of winning each game. Studying the impacts of these two models is a prime area for research in sports participation as it speaks directly to broader issues of learning and human development.

## WHO GETS TO PLAY?

Beyond concerns about what the qualities of sports are and what they should be, there are pragmatic issues concerning how the current system of athletic participation plays out in the lives of youth. The majority of research in this area focuses on organized athletic participation, with primary emphasis on participation in school-sponsored sports teams. One of the unique aspects of studying sports participation, in contrast to involvement in other institutions such as education or the family, is that not all youth are equally likely to be involved. Thus, to understand the impact of being involved in sports, it is necessary to account for the factors that may affect the chances that one will participate in the first place.

A major element influencing the likelihood that a youth will participate in organized sports is one's physical stature. Although very few sports have physiological requirements, most have de facto ideal types, such as being tall in basketball or being petite in female gymnastics. Children may see these ideal types as necessary conditions for participation, and if they do not perceive themselves as fitting the mold, they may be less likely to try out for a team. At more competitive levels, youth who do not match the preferred physical types may be less likely to make the team even if they do try out, either because of stereotypical biases on the part of coaches or because of real physical limitations.

In addition to pure physical structure, cognitive and personality traits may lead certain youth to be more likely to participate in sports or in particular types of sports. For example, children who are more social and extroverted may be drawn more toward participating in sports in general and team sports more specifically than comparatively more introverted or shy children. Similarly, youth who are aggressive may enjoy contact sports such as football or wrestling, and children with high levels of hand–eye motor coordination will find success in sports that reward this ability, such as tennis or baseball. Sociologists of sports, however, recognize that none of these

***Little League Baseball.*** *Little league players celebrate after a victory. There is a debate over whether sports have a positive influence on development or increase propensities toward anti–social and delinquent behaviors.* AP IMAGES.

patterns naturally occur; rather, sports are designed in such a way as to reward certain attributes over others. However, given the reality of the current sporting system, certain inherent physical and cognitive traits will continue to influence young people's likelihood of participation.

Social and structural factors also contribute to the ability of a child or adolescent to be involved in athletics and the likelihood of such involvement as well. One of the most prominent of these factors is a child's family's socioeconomic standing. Youth in families on the lower end of this hierarchy are more likely to live in poorer neighborhoods, which are less likely to have the economic and physical resources to fund organized athletic leagues (Pedersen & Seidman, 2005). Moreover, the move toward private athletic participation, such as club teams, requires families to invest more to keep children involved. From buying equipment and paying for specialized camps to taking time off for trips to tournaments, the cost of playing organized sports has continued to rise, further inhibiting youth with fewer economic resources from participating.

Perhaps one of the most polarizing attributes surrounding sports participation is gender. Title IX, passed in 1972, was intended to provide proportionate opportunities and funding to women in all public institutions. Surprisingly, most of the research and controversy in this area has focused on opportunities for female athletes at the collegiate level, with much less attention paid to equality in secondary education. Although evidence shows that the number of females participating at all levels has increased since the passage of Title IX, their numbers still do not equal their representation of the population in high schools (National Women's Law Center, 2007). Furthermore, high schools, unlike colleges, are not federally required to even report on their achievement of Title IX requirements, creating a lack of accountability and enforcement of the goals of Title IX at this level of participation. Because of this dearth of attention and emphasis, one of the most needed avenues for future research is to examine the way in which Title IX has affected—or not affected—the athletic experience for female children and adolescents.

## SPORT'S IMPACT ON YOUTH

Without question the most researched and contested topic concerning sports and youth is the debate over whether sports have a positive influence on development or increase propensities toward antisocial and delinquent behaviors. Many researchers hold that participation in athletics helps young children learn important life lessons, such as understanding the consequences of decisions, learning from constructive criticism, and accepting failure. More directly, sports are thought to promote prosocial skills and positive affect. Children who play sports learn how to work with others toward a common goal, gain respect for and acceptance of rules and punishments, and develop an increased sense of self-worth. In support of these claims, James McHale et al. (2005) found that sports participants had higher levels of self-esteem and were rated as more sociable by their teachers than nonparticipants.

For adolescents, research tends to focus more on sports' ability to minimize deviant behavior and increase academic performance. Travis Hirschi's (1969) social control theory posits that adolescents who are more attached to norm-enforcing institutions and people are less likely to commit deviant acts than those who are less attached. According to this perspective, sports are posited to limit deviance for several reasons. First, the majority of adolescents who play sports do so for school-sponsored teams, which have requirements for participation. Acting in deviant ways, such as committing crimes, skipping school, or failing in the classroom, would violate these regulations and result in a dismissal from the team, stripping the adolescent of a valued opportunity. Not surprisingly, the majority of research has shown that athletes are less likely to drop out of high school (Mahoney & Cairns, 1997) and, on average, achieve higher grades than nonparticipants (Eccles, Barber, Stone, & Hunt, 2003).

Second, participating in sports requires an extensive time commitment, which reduces the time available to be involved in deviant activities. Third, sports introduce adolescents to positive adult role models and mentors who can directly influence adolescents' choices as well as serve as another psychological control measure (i.e., a valued tie that may be broken by participating in deviant activities). Finally, as for younger children, sports are thought to engender a certain moral framework that disapproves of deviant behaviors.

Despite evidence demonstrating the positive influence of sports, many scholars argue that sports have detrimental consequences for all youth, participants and nonparticipants alike. Three primary areas in which sports are thought to have the most negative impacts are creating and supporting harmful status hierarchies in schools, maintaining and promoting gender inequality, and increasing delinquent behavior and encouraging substance use.

Donna Eder's (1995) ethnographic study of junior high students showed how the limited nature of athletic participation combined with the increased visibility of those who make school-sponsored teams led to status stratification in schools. Students who played sports, especially football for boys and cheerleading for girls, were attributed the highest status in the school, whereas those who were not on teams were socially marginalized. Frequently this stratification increased bullying, both physical and verbal, of the lower-status students, contributing to issues of self-esteem and depression among these students. Eder also contended that school officials were more lenient with the higher-status athletes, which only increased their status and facilitated their negative behaviors.

In addition to producing status hierarchies, sports have been identified as a significant source in the creation and maintenance of traditional gender stratification. Michael Messner (2002) claimed that sports are structured in a way that legitimizes and promotes male dominance. From the time youth begin playing sports, teams are segregated by gender, and even at very young ages children can see a highly unequal distribution of power and resources. Positions of authority in both male and female leagues are virtually all filled by men, and male teams receive disproportionate funding and resources (Eitzen, 2003). Beyond the structural segregation of gender, numerous studies have demonstrated that sports are a site of hegemonic masculine socialization. Often femininity is invoked as a threat and put-down by male coaches. For example, in his observations of a preschool soccer team, Messner found that when the boys were not paying attention the coach would suggest that he would bring "in the Barbies to play them." Similarly, Fine (1987) observed numerous Little League baseball coaches chastise their teams for "playing like a bunch of girls." This type of language teaches children not only that boys and girls are different but also that boys are supposed to be tough and aggressive, that weakness and failure is a feminine quality, and that by and large males are superior to females.

The emphasis placed on stereotypical masculine characteristics in sports also has been linked to increased violence and aggression on the part of participants. Robert Hughes and Jay Coakley (1991) argued that involvement in sports creates *positive deviance*, meaning that athletes' commitment to the values and norms of sports actually increase the likelihood of deviant behavior. For example, participants in particular sports may come to think that violence is an acceptable means to solve problems. Coaches often use contests of aggression as a way to settle within-team disputes, and in certain sports (e.g., hockey), fighting is a tolerated aspect of the game itself. These alternative norms result in socially unacceptable behavior outside of sports. This theory is supported by Derek Kreager's (2007) analysis of a nationally representative sample of adolescents, in which he found that participants in contact sports were more likely to get into physical fights with peers than were nonparticipants, whereas involvement in noncontact sports, such as baseball or tennis, showed no influence on fighting.

The theory of positive deviance helps explain further the seemingly paradoxical finding that students involved in athletics drink alcohol more and use particular drugs more frequently than do nonparticipants (Hoffman, 2006). The idea that one must win at all costs quite clearly encourages athletes' higher use of steroids, and the value of pushing oneself to the extreme could explain collegiate athletes' higher rates of binge drinking. Additionally, unquestioning devotion to the team may lead high school athletes to be more influenced by fellow athletes who drink. Athletics themselves therefore may imbue adolescents with values that make them more inclined to commit deviant acts, as well as providing a social peer environment that supports these behaviors. Still some studies have found no differences between participant and nonparticipant levels of delinquency (e.g., see Miller, Melnick, Barnes, Sabo, & Farrell, 2007, for a review of mixed findings). Thus, despite the numerous studies that have examined this connection, the relationship between athletic participation and deviant behaviors is an area in which further research is needed.

## CONCLUSION

For those interested in education policy, the question concerns the role of sports as an institution given these consequences. Some research points to the mere presence

or inherent nature of sport as problematic, but most scholars conclude that it is the organization of formalized sports programs that leads to negative social consequences. For example, one study found that a program designed to teach Little League baseball coaches positive-reinforcement instruction strategies resulted in an increase in the players' feelings of self-worth over the course of the season (Barnett, Smoll, & Smith, 1992). As noted, the theories underlying arguments both for and against sports participation rest on the idea that youth learn particular values in sports. Thus, life course scholars must continue to study exactly what values and behaviors are being transmitted in the current system of sports as well as designing structures to help promote prosocial characteristics. Although the debate over whether sports are "good" or "bad" seems endless, the question of how sports could be designed in ways to promote gender empowerment, norms of nonviolence, and equality seems to be quite open and worthy of greater study.

## I. OVERVIEW AND INTRODUCTION

In the United States, education is a system that has a collection of interrelated parts working together to produce some intended outcome—in this case, a well-trained, well-rounded youth who can contribute to the nation's economy and civic institutions. Like most systems, the American educational system originated in a simple form—the one-room, multigrade schoolhouse comes to mind—but slowly diversified into an increasingly complex form, typified by the large, diverse, departmentalized high schools of the modern era. Perhaps the most striking example of this diversification is the gradual reorganization of public education into the three distinct stages of schooling—elementary, middle, and high school—described in the following entries.

These stages emerged through a constellation of sociohistorical forces, including (a) an increasing supply of students because of population growth and the abolition of child labor laws, which meant children were available to attend school during the day; (b) demands introduced by the restructuring of the labor market; and (c) evolving ideas about the developmental needs of children and adolescents. Thus, the challenge of effectively educating increasing numbers of students with widening age ranges in developmentally appropriate ways to supply labor for the industrial (and then post-industrial) economy required that the educational system be divided into more manageable, age-homogenous subsystems.

Elementary schools are typically smaller than middle or high schools. Children move across classes in groups, with nonspecialized classes and few extracurricular activities. This more personalized, generalized approach to education is considered appropriate to the developmental status of young children. High schools emerged to answer concerns about the need to tailor education to adolescents. Larger, with more differentiated curricula and an increase of choice in coursework and activities, these schools are less about fostering learning in a supportive environment and more about preparing students in practical ways to enter adult roles. Middle schools (also referred to as junior high schools) emerged somewhat later as a bridge between these two models of education. Growing too old for the protective, common curriculum of elementary school but not yet socially or psychologically mature for the impersonal, individualized structure of high school, young people in or around the pubertal transition are educated in schools that are supposed to represent a middle ground in size, instruction, and course and activity offerings.

Progress through these stages is cumulative. What is learned in one stage influences what is taught and learned in the next. In this way, achievement trajectories diverge and demographic inequalities compound across stages. This cumulative nature undermines the ability of the system to serve as a vehicle for social mobility for historically disadvantaged groups because children from these groups tend to enter the system with less developed skills and, as a consequence, lose ground over time. In theory, transitions between stages could be turning points, allowing some students to start fresh or change directions. In reality, however, transitions are more likely to be points of disruption that increase performance disparities. Policies to manage transitions and to counteract the cumulative nature of education in general, therefore, are important to making the system work more effectively and better serve society.

## II. ELEMENTARY SCHOOL

Walking into any elementary school in the United States, one sees brightly colored pictures on the walls, frequently the work of students. Stars, writing samples, photographs, and science projects adorn the bulletin boards, and children move quickly and not always quietly through the halls. Classrooms look much they way they did in the mid-20th century, which is not surprising because many schools were built in the 1950s and 1960s to accommodate the large baby boom cohort. In the early 21st century, schools are more diverse ethnically and racially. Unfortunately, children living in poverty still generally attend underresourced schools with less qualified teachers, whereas children from more affluent homes attend schools with computers, libraries, and a stable and well-qualified teaching staff. Nevertheless, the structure of elementary schools is very similar throughout the United States (Stigler & Hiebert, 1999).

### ORGANIZATION OF SCHOOLS

Within a school district, typically headed by a superintendent, each elementary school has a principal and, frequently, an assistant principal. The principal is considered the educational leader of the school and is responsible for all aspects of the students' education, including who their teacher is going to be and which curriculum will be used. The principal is also the lead disciplinarian. Most principals take the achievement of their students very seriously and work hard to make sure every child gets a good education. This level of accountability is mandated in the No Child Left Behind (NCLB) Act of 2001, which holds districts and schools, and thus superintendents and principals, responsible for

students' achievement. This represents an important change in policy away from using school resources as a measure of quality (input) and toward a focus on student learning (outcomes; Cohen, Raudenbush, & Ball, 2003).

For the most part, children attend elementary school from kindergarten through fifth or sixth grade. Although research suggests that a kindergarten through 8th grade model may be associated with stronger student achievement overall, this organization is not as popular. Sometimes children will share classrooms with children one grade level above or below (e.g., a class might be composed of first and second graders), but this is usually a way to stretch resources. Typically students begin kindergarten when they are 6 years old and are required to stay in school until the age of 16 to 18, depending on the specific state's law.

In contrast to middle and secondary (or high) schools, elementary schools are organized to be more protective and nurturing of young children. Generally schools are smaller and children have one teacher throughout the day (although they may change for math or reading). Classes are kept relatively small, and the quality of the teacher–child relationship is an important predictor of students' academic success.

Class size varies from state to state and even from district to district. Most children will attend classes that have between 20 and 30 children. Some states, such as California, Tennessee, and Florida, have mandated class size reductions in the early grades, based on research conducted within the Tennessee school systems. This research shows that in classes of fewer than 17 students, children, especially children living in poverty, generally learned better than did children in larger classes. Most classes include both boys and girls.

A highly qualified teacher is the heart of the U.S. educational system. Indeed, the NCLB Act requires that all students be taught by highly qualified teachers. Unfortunately, deciding what "highly qualified" means is not clear. Qualifications that are typically associated with being a capable teacher do not always predict how well students will learn. For example, years of experience, having a formal teaching credential, and years of education are not consistently associated with students' achievement (Morrison, Bachman, & Connor, 2005). Research does show, however, that when teachers are warm and care about their students, are highly knowledgeable about the subject they teach, and are masterful classroom managers so that children spend most of their day in meaningful activities, children learn more and are happier.

Increasingly, the content of instruction is dictated by state standards. Leading up to the passage of the NCLB Act, states were required to develop rigorous standards for what students were expected to learn at each grade level. These standards vary from state to state. There are no national standards, which is a feature that is fairly unique to the United States among the major countries of the world. Many countries, such as England and Korea, have national standards. Individual state standards (which are available on the World Wide Web) include content for reading, language arts, writing, science, social studies, mathematics, and other subjects. The topics and expectations are frequently provided by grade or by early versus late elementary grades (e.g., kindergarten through second vs. third through fifth). Updating these state standards can be a highly contentious process as stakeholders argue about what should and should not be included. For example, when Florida updated its math and science standards in the winter of 2008, there was controversy as to whether the scientific theory of evolution should be part of the science standards.

A number of states, including California, Texas, and Florida, provide a short list of acceptable curricula in each of the subject areas. Schools and districts may select curricula only from the approved list. In many states, however, the curriculum is a district- and sometimes school-level decision. Increasingly, states, districts, and schools are requiring that the curricula be founded on solid research. Part of the reason for this is that under the NCLB Act, districts, schools, and teachers are held accountable for whether their students learn or not, based on the results of mandated tests and a number of other indicators. By insisting on research-based curriculums, teachers hope to have more effective teaching materials at their fingertips.

Another result of the NCLB Act's focus on student outcomes is more frequent formal assessment of students' reading, math, and science skills. The benefits of this policy are highly contested, but most likely such tests will become a permanent part of the elementary school experience. Fortunately, more effective ways to judge students' learning are being developed. For example, value-added scores recognize that a large part of how students perform on tests is related to the skills with which they entered school (Morrison et al., 2005). If children begin 1st grade with weak reading scores, at the end of the year—even if they make very good progress—they will still not achieve scores that are as high as students who began first grade with very strong reading skills. Value-added scores do not penalize schools where many children begin the year with weak reading and math skills—for example at schools where many students come from families living in poverty. Rather, these scores

focus on children's progress from the beginning to the end of the school year and take this into account when judging school and district performance.

## HISTORICAL ROOTS OF THE ELEMENTARY SCHOOL MODEL

The roots of the elementary school model that prevails in the United States in the early 21st century can be traced back to the Revolutionary War. Although the colonial settlers founded schools and instituted mandatory education and charity schools, these schools followed European traditions (Jeynes, 2007). With the onset of the Revolutionary War, the founding fathers, and Thomas Jefferson in particular, believed that a new nation deserved a new way of educating their children. Sons no longer attended Oxford and Cambridge but rather went to Harvard, Princeton, or Yale. Many children were schooled at home or in church schools. Prior to the revolution, the education of children was a local endeavor and varied depending on the town and how much the citizens and churches valued education. Most schooling focused on literacy so that children could read the Bible.

With political independence came an increasing focus on the importance of education and the belief that schools improved children intellectually and morally. Private schools flourished. In 1789, the year George Washington became president, Massachusetts passed the Massachusetts Education Act. Towns of 200 or more citizens were required to educate all children (boys and girls) at public expense through elementary school. This act implemented equal education for girls and formed the foundation of American schools. Many of these schools were church-run charity schools, which some credit with establishing many of the characteristics of contemporary U.S. elementary education, including the professionalization of teaching, a focus on developing moral character, and the implicit belief that education can help children escape poverty and become good citizens. These early schools provided the blueprints for the U.S. public education system of the early 21st century.

## CURRENT EDUCATIONAL CHALLENGES

In many respects, the U.S. public school system is a model for providing high-quality free K–12 education

to all children. However, the system can be improved and, indeed, faces significant challenges that have important implications for the future. These include closing the achievement gap, individualizing instruction, and monitoring students' response to interventions so that all children receive an effective education that prepares them for the demands of the modern world.

**Closing the Achievement Gap** Finding ways to close the achievement gap between children who are poor and their more affluent peers is one of the most important goals of the policy and research endeavors of the early 21st century (Jencks & Phillips, 1998). How can instruction be made more effective, especially for the nation's most vulnerable children? Converging evidence is showing that high-quality early intervention, although important (Reynolds, Temple, Robertson, & Mann, 2002), is not an inoculation against academic underachievement. Instead, the impact of instruction across grades appears to be additive and cumulative. This means that students are left further behind in math and reading each year they receive ineffective instruction. It has been argued that closing the achievement gap would do more to promote social justice than any other policy (Morrison et al., 2005). Much of the NCLB Act was designed to do this. States and schools must report achievement test data by ethnic group and poverty levels and must show that all students' performances are improving. Moreover, a move to outcomes rather than resources to hold schools accountable may, in the long run, help close the achievement gap (Cohen et al., 2003). With this in mind, accumulating research on new instructional strategies is presented next: individualized instruction and response to intervention.

**Individualizing Instruction/Response to Intervention** The amount and type of literacy instruction children receive in the classroom consistently and systematically predicts literacy growth. Increasingly, research studies have moved away from the "either/or" days of the reading wars (phonics vs. whole language; Ravitch, 2001). Research shows a combination of methods incorporating code-focused strategies with more holistic and meaning-focused strategies is more effective in supporting students' literacy skill growth (Connor, Morrison, Fishman, Schatschneider, & Underwood, 2007; National Reading Panel, 2000). Code-focused strategies are those that are designed to help children learn that letters and sounds go together and combine to make words. Code-focused skills include the alphabet, phonological awareness, phonics, and letter and word fluency. Meaning-focused strategies are designed to teach children how to extract and construct meaning from text. Activities include reading aloud together, discussion, comprehension strategies, and writing. Generally, as long as interventions are sustained, intensive, and balanced with at least some time spent in explicit code-focused instruction (especially for children with weaker skills), educational differences across interventions that differ in pedagogical theory are small.

New research is finding that instruction that is tailored to the individual needs of children is more effective than high-quality instruction that is not individualized (Connor et al., 2007). Using software that computed recommended amounts of code- and meaning-focused instruction for first graders based on their vocabulary and reading test scores, many teachers were able to individualize reading instruction. The software recommended substantial amounts of time in teacher-managed code-focused instruction (e.g., phonics) for children who were struggling with reading. For children who were strong readers, however, the software recommended more time in independent meaning-focused instruction (e.g., reading books, writing). The more precisely the teachers provided the recommended amounts of each type of instruction, the stronger was their students' reading skill growth. Further, when teachers fully individualized instruction, they were able to close the achievement gap between children with strong and weak vocabulary skills (Connor et al., 2007). This finding was encouraging because children living in poverty often start school with weaker vocabulary skills compared to their more affluent peers.

Another way to individualize instruction for those children who are truly struggling to learn to read is *response to intervention*. There is a vital need for effective early identification and interventions for students who struggle to learn reading and mathematics. Remediating these problems becomes increasingly difficult over time. Once students fall behind, even the most powerful remedial interventions are often unable to help them (Torgesen, 2005). On average, children who have weak reading skills at the end of second grade almost never acquire average reading skills by the end of elementary school.

## THE ROLE ELEMENTARY SCHOOLS PLAY IN THE LIVES OF STUDENTS AND IN SOCIETY AS A WHOLE

School and classroom environments are among the strongest influences on children's early life experiences. Thus, children who attend good schools have a lifelong advantage over children who attend underresourced and ineffective schools. Effective schools share common characteristics (Taylor & Pearson, 2002; Wharton-McDonald, Pressley, & Hampston, 1998), including a safe and orderly environment, strong leadership, high expectations for student achievement, an emphasis on academics, uninterrupted

time devoted to literacy and mathematics instruction, the use of assessment to evaluate student progress and guide instruction, and good classroom management.

The climate of the classroom and the social and emotional support provided by effective teachers is important. Children generally learn better and develop important social skills in classrooms that provide high levels of social and emotional support as well as instructional support. These learning environments appear to be especially important for children who have weaker social skills in kindergarten. Students' interest in learning, or *engagement*, and their motivation to learn also contribute to their success in school. Thus the more teachers understand about how to engage and motivate their students to learn while spending time in meaningful instruction activities that take into account children's skills, the more effective classrooms and schools will be.

Effective schools are important for students because early success builds a foundation for a lifetime of achievement. Children who achieve well in school become contributing members of society (Shonkoff & Phillips, 2000; Snow, Burns, & Griffin, 1998). At the same time, school failure is costly for students and society alike. For example, children who cannot read well are more likely to be retained a grade, to enter special education, and to drop out of school, and ultimately are more likely to enter prison and be unemployed. Elementary schools serve a crucial role in American democracy.

## III. MIDDLE SCHOOL

Middle schools play an important role in American society. Because early adolescence is a time of rapid cognitive, emotional, and social change, middle schools need to be places that promote this growth while fostering a sense of belonging. Contemporary research offers a clear understanding of the importance of teacher caring and a sense of belonging for students' academic and social well-being, especially at the middle school level. Yet many middle schools are currently not organized to promote belonging and a sense of community.

### THE HISTORY AND ORGANIZATION OF MIDDLE SCHOOLS

Initially, the middle school concept was developed to deal with the multiple changes and wide range of maturing students undergo between the sixth and eighth

grades. Middle schools replaced junior high schools that typically covered seventh through ninth grades, as well as the kindergarten through eighth grade model. Educators emphasized project-based learning within teams of 2 to 5 teachers. The advantage of project-based learning for this age group is that students can work on different aspects of the same project, reflecting their different levels of development. The initial concept also emphasized learning communities where students gained a sense of belonging by participating in decisions about topics of study and the social operation of the classroom.

The ways in which most middle schools are organized does not correspond with this initial concept. Rather than team-based instruction, most schools are organized with students taking courses from different teachers. According to Anthony Jackson and Gayle Davis, authors of *Turning Points 2000: Educating Adolescents in the 21st Century* (2000), the most common form of curriculum organization is tracking, which assigns students to different classes based on their actual or perceived capacity to learn. In this way middle schools—like the junior high schools that preceded them—are really "mini" high schools, lacking an organization that meets the special needs of this age group.

Educators continue to seek organizational changes in line with the initial middle school concept. When they describe aspects of effective schools, they continue to emphasize the importance of small learning units, team teaching, and other aspects that contribute to a sense of community and belonging. Jackson and Davis cite evidence from numerous studies showing that small schools lead to better educational outcomes and advocate dividing students in large schools into "houses." While they recommend houses numbering no larger than 250 students, there is evidence of especially positive student outcomes with houses of 120 students or fewer. The houses should be diverse—reflecting the ability levels, ethnicities, and social classes of the school population—given the problems that have been identified with dividing students on the basis of perceived or actual ability.

Entwined with the concept of houses is the concept of team teaching, which groups teachers covering the core subjects of math, science, social studies, and language arts. Ideally, these teams of teachers would stay together for a minimum of 5 years. Still other organizational aspects of effective schools include keeping students with the same team of teachers for more than one grade and using differentiated curriculum, which varies both by content and process according to different levels of readiness, interest, and learning styles.

## THE ROLE OF MIDDLE SCHOOL AND SENSE OF BELONGING

Middle schools have social value as well as academic value for early adolescents. Schools are most successful when students see their schools as communities and experience a sense of belonging. This may happen naturally in rural areas where middle schools are often the focus of community life. It also occurs in affluent suburban areas that have the resources to create exemplary schools with low teacher-student ratios. In other cases, administrators and teachers have adopted the model of smaller houses with project-based learning to create definable learning communities.

Research on middle schools has focused on students' sense of belonging, drawing upon the theories of John Dewey (1859–1952) and Lev Vygotsky (1896–1934). Both theorists view education as a social process that is most successful when students are part of meaningful groups. There is now considerable evidence that teacher support, peer support, and a sense of belonging are important for students academically.

Students who perceive that their teachers support them have higher expectations for academic success, value education more, and often have higher academic motivation than do other students. Furthermore, when teachers were perceived as supportive, as promoting interaction with peers, and as promoting mutual respect among students, students showed an increase in motivation and engagement. However, when teachers were perceived as promoting academic comparisons and competition with other students, students experienced a decrease in motivation and engagement.

Other studies reveal the ways in which teacher caring influences students' social and emotional welfare. One study found that teacher caring was linked to students' goals for altruistic behavior and social responsibility. In another study, the school was shown to have more impact on students' emotional distress and acts of violence than the family at the middle school level (Resnick et al., 1997). In her review of research on a sense of school belonging, Karen Osterman (2000) notes that while an experience of belonging is important at all age levels, it is especially important during middle school.

Given the importance of teacher and peer support at this age level, some studies have examined the degree to which different students feel supported by their teachers and peers. While a sense of belonging led to positive outcomes for all students, African-American and Hispanic students in low-income schools have much less sense of belonging in school than do White students in middle-income schools (Goodenow & Grady, 1993). Even though peer support is often important for a male student's academic well-being, males in one study had more negative relationships with classmates (Wentzel & Caldwell, 1997). Osterman (2000) reports that secondary schools, on average, are less supportive than elementary schools. She indicates that tracking adds to this

trend, with students in lower tracks expressing much lower levels of perceived teacher caring and support.

## PEER CULTURES WITHIN MIDDLE SCHOOL

Although not studied as extensively as school belonging, another theme in the research on middle schools is the study of peer culture. In their 1995 book, *School Talk: Gender and Adolescent Peer Culture*, Donna Eder, Catherine Evans, and Stephen Parker found that students in the middle school they studied defined popularity as being well-known by other students and not necessarily as being well-liked. Because of the limited number of extracurricular activities, cheerleading and certain male sports became very important for gaining visibility in this school. The large size of this school (more than 750 students), combined with the limited opportunities for visibility, meant that many students reported feeling like social failures. While high schools also provide students with some visibility through extracurricular activities, the fact that high schools offer a much wider range of activities means many more students find ways to become socially connected with their peers than do middle school students.

Other research suggests that high-status groups, such as preps, achieve prestige because they reproduce mainstream values. In their study of cheerleading and school board policy, Pamela Bettis and Natalie Adams (2003) found that a school's policy to reduce race and social class bias in the composition of its cheerleading squads failed to be effective 5 years after being implemented. They found that cheerleaders tend to be selected on the basis of their petite appearance and ability to mask feelings with a smile, characteristics that were more common in the middle-class and White student culture.

Eder and her colleagues (1995) also found that the social isolates in the school they studied were frequent victims of bullying. Because students often take out their social anxieties on the most vulnerable students in the school, those who lacked a friendship group were targets of most of the bullying. While these students were initially isolated, in part, because of their appearance, lower intelligence, or atypical gender behavior, it was even more difficult for them to enter a peer group once they became the target of bullying.

Much of the research on peer culture focusing on peer harassment indicates that bullying occurs most often between the sixth and eighth grades. While there is little variance across urban or rural settings, the targets of harassment vary depending on the racial composition of the school. Sandra Graham (2004) found that the majority ethnic groups were perceived to be the aggressors (in this case, blacks and Hispanics), whereas the minority ethnic groups were perceived to be the victims (in this case, other racial groups as well as Whites). As in her other research, the bullies in this study had high social standing, while the victims reported more loneliness and more social anxiety than non-victims. Interestingly, when classrooms were ethnically balanced, students felt less lonely and less socially anxious.

The research on peer status and peer harassment cannot be explored fully here, but it is important to consider aspects of the middle school environment that could contribute to an emphasis on social rankings and bullying, such as the limited number of extracurricular opportunities leading to visibility for a few students in many schools. Also, when adults rank and label students through tracking assignments, they could be inadvertently promoting the ranking and labeling of students by each other. These larger organizational aspects can have a strong impact on peer culture as well as classroom factors such as those mentioned above.

## DIRECTIONS FOR FUTURE RESEARCH

Middle school researchers know more about social psychological processes, such as the influence of a sense of belonging, than the influence of peer and teacher cultures on middle school students. Studies, such as the one on cheerleading policy, are a reminder that unless policy decisions take students' culture into account, they will meet with limited success (Bettis & Adams, 2003). Had the policy makers paid attention to the way cheerleading selection was shaped by middle-class and White peer culture, they might have crafted a more effective policy for limiting biases in selection. Currently most studies of peer culture are at the high school and elementary level, so that little is known about how peer cultures vary depending on the backgrounds of students and the organization of the school.

There is even less research on teacher culture at the middle school level. Some researchers have suggested that teachers may react to negative elements in peer culture by assuming that adolescents are naturally unkind. More research is needed to better understand the nature of teacher culture in diverse school settings.

Also needed is a better understanding of the impact of organizational changes beyond the classroom. Studies of the process and outcomes of school changes, such as James Rourke's *Breaking Ranks in the Middle* (2006), will benefit the understanding of these broader influences. In particular more research is needed comparing the influence of organizing students in diverse houses as compared to homogenous tracks, as well as comparing schools with intramural activities to those with extracurricular activities in terms of their influence on peer rankings and

bullying. It is likely that by providing more students with opportunities for visibility and participation through intramural activities, students might focus less on peer status and isolates might have an easier time joining peer groups.

The impact of middle school teacher training is another subject deserving of attention. Currently most states do not require specialized preparation at this level, using instead the elementary versus secondary model. This may explain, in part, why many middle schools are structured like high schools, as most middle school teachers are trained along with high school teachers, with many using middle schools as their starting point on the career ladder.

Given the needs identified with this age group, middle school training might best employ what has been called a suppositional, as opposed to a propositional, approach to teaching. In this approach teachers are encouraged to invite student input as part of exploring a topic that might go in many directions. Teacher training should also include knowledge about organizational and cultural influences on students' experiences along with cognitive and psychological ones. By comparing teachers with specialized middle school training versus those with secondary training, one can better assess the impact of specialized training on teachers' and students' experiences.

In summary, middle schools were designed to address the special needs of and wide range of maturity in students between sixth and eighth grade. Unfortunately, many schools in the early 21st century are organized more like high schools, with the common use of curriculum tracking and the focus on extramural versus intramural activities. This may be due, in part, to the lack of specialized training for the middle school level. It may also be due to a lack of awareness of the cultural and organizational influences within middle schools. Until there is a better understanding of all the organizational and cultural factors at play, schools are not likely to foster the sense of belonging that research shows is so important at this period in the life course.

## IV. HIGH SCHOOL

In the United States, high school is undoubtedly one of the most important institutions in an individual's life course. The high school plays two primary roles in the lives of students and society, the importance of which cannot be overestimated. The first role of the high school is that of sorting and selecting students for differentiated life tracks and opportunities. The second role is that of socializing students to community norms, roles, and behaviors. The ways in which students experience these processes holds profound implications for college-going, access to middle-class jobs, and quality of life more generally.

### HISTORY AND ORGANIZATIONAL STRUCTURE

The American high school has its roots in the nation's earliest years. The high school developed in response to economic stimulus and cultural inspiration. An increasingly diversified, industrial economy, coupled with urbanization and modernization, created the need for specialized and advanced forms of training. At the same time, early educational reformers—responsible for putting a system in place that largely remains in the 21st century—found their philosophical footing in four

cultural currents. As much as economic demand, the American high school was born from the social needs of early citizens, with the public (common) school system fueled by four primary cultural facts: the democratization of politics; the struggle to maintain social equality; changes in conceptions of the individual and society; and the rise of nationalism (Cremin, 1951). Educational founders and reformers, working from within government bureaucracies, felt confident that a public, specialized school system would meet demand for labor, guard against the creation of a caste system, and prepare youth for civic participation. Universal schooling would also Americanize increasing numbers of immigrants arriving in the 1830s and 1840s on matters pertaining to the primary roles and values of the new nation.

Early reformers such as Horace Mann (1796–1859) agreed that education should be free and available to all and that a curriculum should include essentials for everyday living, including reading, writing, spelling, and arithmetic, as well as instruction on moral adequacy and responsible citizenship. Free public education was first put into legislation following a report to the Philadelphia legislature in 1829, which stated that "all children, regardless of means, should have access to a liberal and scientific education." The same bill called for the establishment of high schools, based on a union of agricultural and mechanical instruction with literary and scientific instruction (Cremin, 1951).

Early high schools followed the village model, and were largely structured and run by local authorities. As cities and towns grew, and with increasing migration to urban centers in the mid- 19th century, high schools underwent important structural and governance changes. Tension emerged between a model of local governance and bureaucratic control. A struggle between community control and professionalism was waged openly until later in the century when two important trends took the country by force. As the industrial revolution advanced, the distinction between work and home, and the character of interactions, changed appreciably. Simultaneously, with the expansion of science, individuals relied less on folk knowledge and public schools lifted up rationalism and science-based expertise. These trends favored professionalism and the systematizing of U.S. high schools, both in terms of curricular decisions and with its embrace of corporate, centralized governance. Schools developed different tracks and specializations, and high schools began to occupy an increasingly important position in the life course, as knowledge gained ground on culture and social pedigree. This period of time came to be known as the Progressive Era (1890–1920), which was associated with efficiency, expertise, and the public service of disinterested elites. It was also an era that resonates strongly with contemporary educational reforms.

In the 20th century, high schools experienced massive expansion and growth and went through various structural reforms. In general, high schools became larger and more complex, and more sophisticated and ambitious in their goals with increased course offerings and specializations. This offered, in some part, changing notions of intelligence, and the emergence of psychometrics. Furthermore, with time, schools played an increasingly important role in students' lives, due in part to the passage of child labor laws, in addition to increasing demands from employers for certified credentials—a holdover from the Progressive Era. As schools began to matter more, the system of sorting and selection, as well as principal teaching philosophies developed dramatically. The latter part of the 20th century through the present day is defined most notably by its increasing expansion, adoption of desegregation laws in the 1960s and 1970s, and a decline in vocational training in favor of liberal education in the service of the emerging national standard of college for all.

## STRATIFICATION AND SOCIALIZATION FUNCTIONS

Since its foundation, the high school has been a selective institution. During its earliest years only selected populations (primarily White males) were considered to be candidates, despite its availability "to all" per law. When high school attendance became compulsory in the 20th century, sorting and selection processes occurred within the schools. In spite of early Americans' resistance to a caste system of economic and social stratification, the United States has developed a distinct class system where some individuals occupy privileged positions and others remain at the bottom of the class ladder. Contrary to the position of social Darwinists, social hierarchies do not happen naturally but rather are built and maintained by a series of social institutions.

Writing in the mid-20th century, Harvard sociologist Pitirim Sorokin (1889–1968) summarized, "Within a stratified society, there seems to exist not only channels of vertical circulation, but also a kind of a 'sieve' within these channels which sifts the individuals and places them within society" (Sorokin, 1959 [1927], p. 182). Taking his cues from Max Weber's (1864–1920) classic writings on the interchange between modern democracy, bureaucracy, and education, Sorokin equates this "sieve" with social institutions such as the church, the army, the family, professional organizations, and, importantly, the school. In scholarship that examines the sorting functions of education, there is a tension among scholars about whether schools serve to advance social mobility or reinforce existing social hierarchies. This debate is discussed below.

***High School Fashion Show.*** *High School students standing in a hallway wait to participate in a fashion show. High School socializes students to community norms, roles, and behaviors.* © ARISTIDE ECONOMOPOULOS/STAR LEDGER/CORBIS.

In addition to its sorting and selecting role, the high school is one of the most important socializing institutions in the individual life course. Writing in the latter part of the 19th century, Émile Durkheim (1858–1917) was among the first to acknowledge this role: "The aim of education, is, precisely, the socialization of the human being; the process of education, therefore, gives us in a nutshell the historical fashion in which the social being is constituted" (Durkheim, 1982 [1895], p. 6). Schools are not merely places where students sit, isolated from each other, in dialogue with words on a page. On the contrary, schools are complex social sites where students interact with teachers, and, not insignificantly, with their peers, during a very formative developmental period. To dismiss the social elements of the high school experience is to come away with an incomplete understanding of its role in the lives of students and society.

Adding significantly to knowledge on schools as sites of social activity, where certain behaviors are learned, rewarded, and sanctioned, was sociologist James Coleman (1926–1995). Writing first in 1961, Coleman published *The Adolescent Society*, which documented the importance of peer relationships for student learning. Later in the decade, Coleman led a research team to assess the impact of desegregation in schools. The subsequent report, *Equality of Educational Opportunity* (1966), commonly known as *The Coleman Report*, focused again on peer effects. The Coleman Report stirred up the world of educational research with an examination of desegregation. Most notable of his findings was the assertion that White schools were outperforming Black schools, even with equal funding. For Coleman, the difference in student achievement between and within high schools was influenced by students' communities, particularly by the cultural and social capital of parents and caregivers, and the degree to which parents and communities maintained meaningful contact and intergenerational social closure—a concept Coleman defined as social capital.

Another high profile finding in his study was that Black students benefited from being in integrated schools. Coleman's work led to the introduction of school busing policies, which were intended to diminish the lingering impact of school segregation, rooted in

residential segregation. Following a decade of research on White flight and busing in the 1970s, during which Coleman retracted his commitment to busing policies, he launched yet another major strand of inquiry that compared student achievement in Catholic, private, and public high schools. Holding economic and racial status constant, Coleman concluded that students in Catholic high schools outperformed their peers in public schools. He attributed the advantages to greater parent engagement, better school discipline, and a strong sense of school community.

The importance of the high school as a socializing institution is being increasingly taken up by social scientists that have grown increasingly concerned with violence and disorder in schools, as well as with increasing incarceration rates of young adults that the public has associated with school inadequacies (e.g., 73% of adults believing that poor quality of schools is a critical or very important feature of increasing crime [Gallup, 1994, p. 184–185]). In particular, sociologists of education have argued that public school capacity to socialize youths requires the moral authority of school actors, which has been undermined both by adversarial legal challenges to school disciplinary practices as well as by policies that have limited educator's professional discretion by requiring mandatory zero-tolerance punishments (Arum, 2003).

## RESEARCH DIRECTIONS

Within research on the U.S. high school, there is broad consensus about its importance in the life course. Students' high school experiences and performance have profound implications for quality of life and opportunity. Apart from this general agreement, however, researchers tend to fall into two different camps about how high schools impact student life chances. One group tends to view high schools as truly democratic places where students gain access to social mobility, and where special examinations allow for talented, hardworking students to rise to the top, regardless of social background. This is not to say that schools produce equality; on the contrary, according to Sorokin, "even in the most democratic school, open to everybody, if it performs the task properly, is a machinery of 'aristocratization' and stratification of society, not of 'leveling' and 'democratization'(Sorokin, 1959 [1927], pp. 189–190.). However, while the winners in this system constitute a new privileged stratum, schools themselves do not hinder social mobility (Weber, 1946). Other researchers, however, have shown that rather than promote social mobility, high schools themselves actually work to maintain and reinforce social hierarchy. Exemplary of research in this trend is Adam Gamoran's 1992 study, *Is Ability Grouping Equitable?*, where he demonstrates that the common high school practice of ability grouping reinforces divisions that contribute to inequality through the separation of students from different racial, ethnic, and social backgrounds.

In line with Coleman's examination of school environment and peer effects, contemporary research on high schools is largely focused on the relationship between schools and communities. Unlike previous work, however, current research takes a closer look at what is meant by a school community. At present and going forward, researchers are working to identify and define the political, institutional, and network dimensions of school-community relationships. In particular, scholarship on schools is emerging in the neo-institutional tradition. Leaders in this field argue that schools are embedded not only in local communities, but are also situated in larger organizational communities, or what neo-institutional scholars refer to as *organizational fields*. Organizational fields include organizations directly related to schools, such as regulating bodies, union organizations, and professional schools, or that share similar structural attributes, such as other schools in the same school district. Researchers are currently working to demonstrate how these organizational relationships affect school institutional practices and subsequently are thus implicated in the shaping of life course trajectories of individuals. The field of institutions and individuals subject to such studies is vast: 3,303,000 U.S. high school students are on track to graduate in the 2007–2008 school year, 2,988,000 from public schools and 315,000 from private schools. These numbers are consistent with steady growth over time in percentages of the adult population completing high school. The percentage of the American adult population (ages 25 years and over) who have completed high school (including both diplomas and high-school equivalency exams) climbed from 82% to 86% from 1998 to 2008.

## SUICIDE, ADOLESCENCE

### DEFINING SUICIDE AND SUICIDALITY

Suicide refers to causing one's own death. This act may be pro-active or "positive," when one actively takes one's own life, or "negative," when one does not take actions to save one's own life when in danger. Distinctions are also made between direct and indirect suicide. *Direct suicide* refers to actions that one knows will almost certainly lead to death, while *indirect* refers to actions that one may knowingly take that could potentially lead to death, such as in entering a very risky situation like using potentially lethal drugs.

Scholars of suicide emphasize that suicidal behavior involves a continuum. At one end is *suicidal ideation,* which is talking or thinking about ending one's life. The next point on the continuum is developing a plan for how one would do this, followed by an attempt to kill oneself, generally referred to as a "suicide attempt." The final point of the continuum is an actual completed suicide. The term *suicidality* is sometimes used to refer to the entire continuum and also is used to describe attitudes and behaviors that may indicate that a person is at risk of committing suicide.

When the general public and scholars discuss teen suicide, they generally refer to the teenage years, from 13 to 19. However, because government data are almost always reported in 5-year age ranges, statistical reports of teen suicide usually involve the age range of 15 to 19 and, occasionally, 10 to 14 years of age.

### VARIATIONS IN TEEN SUICIDE

Teens are not at equal risk of suicide. Studies throughout the years have noted differences by developmental status or age; by demographic characteristics, especially race and gender; and over historical time periods. Rates also vary between countries. International variations in suicide rates of teens generally mirror cross-cultural variations in suicide rates of adults.

**Developmental Trends** Suicide rates are higher for older teens than for younger teens. For instance, in 2005 suicide rates for youth age 15 to 19 in the United States were 12.1 per 100,000 for males and 3.0 per 100,000 for females. For 10- to 14-year-olds, the rates were 1.9 for males and 0.7 for females (Sourcebook of Criminal Justice Statistics Online, 2007). Changes that accompany adolescence, often involving concerns with body changes, emotions, and evolving sexuality, are associated with these developmental differences in suicide rates. Studies also indicate that factors related to the risk of suicide may vary developmentally, with some risk factors having a more powerful influence on suicide attempts in the younger teen years than the older teen years.

**Demographic Variations** Demographic variables are strongly related to completed suicides and suicide attempts. As noted above, completed suicides are much

higher for males than for females. This pattern appears at all age ranges and cross-culturally. In contrast, non-fatal suicide attempts are more common among females than among males. Data from the Centers for Disease Control, for a representative sample of students in grades nine through twelve in 2005, indicate that 10.8% of females and 6.0% of males reported one or more attempts of suicide in the year preceding the survey (CDC, 2006).

Pronounced differences exist between race/ethnic groups in suicide deaths and attempts. Suicide rates are higher for Whites than for Blacks at all age groups and for both sex groups. For instance, for 15- to 19-year-olds, the rates for Whites are usually about twice as high as those for Blacks (13.2 per 100,000 versus 7.2 for males, 3.1 versus 1.4 for females in 2005) (Sourcebook, 2007). Given smaller population sizes, the data for other race and ethnic groups are somewhat less reliable. Consistently, however, American Indian/Alaskan Native young people have rates that are much higher than those of other race or ethnic groups. In addition, data from surveys of adolescents indicate that gay, lesbian, and bisexual teens and young adults have higher rates of both suicide ideation and suicide attempts than heterosexual teens (Silenzo, Pena, Duberstein, Cerel & Knox, 2007).

**Historical Trends** Suicide rates have fluctuated over historical time for people in all age groups. Within the United States, rates are often higher during times of economic distress, such as the era of the Great Depression in the 1930s. Changes in rates of suicide for teens have often paralleled the changes for the total population. For instance, the suicide rate for 55- to 59-year-olds in 1930 was 38.2 per 100,000, but by 1960 was substantially lower at 23.6. The rates for teens also declined, although not as dramatically: from 4.4 per 100,000 in 1930 to 3.6 per 100,000 in 1960. Life course scholars and demographers refer to changing patterns over time as a "history" or "period" effect.

For many years the suicide rates for adults were substantially higher than the rates for teens, reaching their highest levels at older ages, usually among men ages 65 and older. Life course scholars use the term *age effects* to describe these differences between age groups. The dramatic differences between the ages in the risk of suicide was noted by the earliest observers of suicide rates, the "moral statisticians" of 19th-century Europe, and were long thought to be immutable.

This traditional pattern of age effects changed quite dramatically, however, in recent decades. For instance, in 1930, suicide rates for adults in their late 50s were more than eight times as high as those for teens 15 to 19. By 1960 the ratio had declined slightly, to 6.6. But by 1995, adults in this age group had suicide rates that were only 1.2 times as high as teens. This resulted from both a substantial decline over time in the rates of adults (to 12.9/100,000 for 55- to 59-year-olds in 1995) and a very sharp rise in the rates of teens (to 10.5/100,000 for 15- to 19-year-olds in that year). These changing ratios between youth and adult suicide have persisted through the start of the new millennium. Some scholars suggest that these changes reflect birth cohort effects, patterns of suicide that differ between groups of people born in different eras. They suggest that more recent birth cohorts are much more prone to suicide at younger ages than were earlier cohorts (Stockard & O'Brien, 2002a, 2002b).

## THEORETICAL EXPLANATIONS OF TEEN SUICIDE

Explanations of teen suicide are found in both psychological and sociological literature.

**Psychological Explanations** An important influence on all psychological explanations of suicide, both teen and adult, has been the work of Sigmund Freud, who wrote from the late 19th century through the 1930s. Many of these writings focused on aggressive urges and motivations, but, during his lifetime, Freud's views on the sources of aggression and suicide changed. In his earlier writings Freud suggested that suicide involved aggression turned inward, toward one's self, an action that is more likely to happen when an individual is anxious and fears punishment by others (Freud, 1957/1917). In his later years Freud rejected this formulation and suggested that aggression, including that against oneself, reflected a "death instinct" rather than simply a reaction against frustration (Freud, 1955/1920). One of the most notable scholars to follow in Freud's footsteps was Karl Menninger, also a psychoanalyst. Menninger suggested that every act of suicide includes three elements: hate, or the wish to kill; guilt, or the wish to be killed; and hopelessness, or the wish to die. Like Freud, he concluded that suicide is "disguised murder," motivated by an unconscious wish to kill another (Menninger 1938, p. 55).

Other scholars, especially those influenced by empirical psychology and tenets of learning theory, built upon Freud's earlier analyses, dismissing the notion of a "death instinct." The most influential work in this tradition is the frustration-aggression hypothesis developed by John Dollard and his colleagues in the late 1930s. They originally contended that "aggression is always a consequence of frustration" (Dollard, Miller, Doob, Mowrer et al. 1939, p. 27), but later modified the hypothesis to state that aggression can be one of a number of responses to frustration (Miller, Sears, Mowrer, Doob et al, 1941).

Following the early Freudian tradition, they suggested that the usual target of one's aggression would be the perceived source of the frustration, but that at times the aggression could be displaced onto others, including oneself. Thus, like previous scholars, they generally saw suicide as displaced homicide, but also suggested that suicide could occur when the self was seen as the source of frustration. Their analysis strongly influenced the work of later clinicians, as well as several sociologists.

Common to the work of all of the scholars working within this broadly defined Freudian heritage is a concern with the strength of the superego or conscience. A strong superego can impel individuals to check and control aggressive intentions toward others. At the same time, an excessively strong superego may prompt individuals to turn aggressive actions against the self. While few contemporary social scientists use an explicitly Freudian, or even neo-Freudian, approach, many are concerned with the circumstances related to the development of the conscience and self-control. In addition, some sociological work on lethal violence that appeared in the mid-20th century often built, at least implicitly, upon the neo-Freudian assumption that suicide (and homicide) are related to frustration, but translated this understanding into a macrolevel analysis of rates (Whitt, 1994).

**Sociological Writings** Psychological explanations of suicide focus on characteristics of individuals and, at times, their relations with others, generally trying to understand why one individual rather than another might choose to end his or her life. In contrast, sociological explanations focus on characteristics of societies and sub-populations of societies and the reason that some groups have higher rates of suicide than others.

The most important contributor to sociological analyses of suicide was Emile Durkheim, a French scholar writing in the late 19th and early 20th centuries and now considered one of the founders of the discipline. His book *Le Suicide*, published in 1897, has long been considered a classic contribution. Durkheim delineated four different types of self-destructive behavior, and contended that each type of suicide was related, in different ways, to varying amounts of social regulation and integration. He gave relatively little attention to two of these categories, altruistic and fatalistic suicides, which he suggested reflected reactions to very high levels of integration and regulation. Altruistic suicide may involve killing one's self for the good of society, whereas fatalistic suicide occurs when one sees no hope in the future, such as in the case of slaves who are confined by societal rules. The bulk of his writings and statistical analyses, as well as those of later generations of sociologists, concentrated on the impact of too little social integration and regulation and increases in what Durkheim termed egoistic and anomic suicide.

Despite Durkheim's lengthy attempts to distinguish these two varieties of suicide, sociologists have long noted that his distinctions are both conceptually confusing and inconsistent. Most contemporary discussions tend to blur the distinction and focus on the two underlying causal variables posited by Durkheim, generally suggesting that they are strongly related. *Social integration* refers to the ties of individuals to the society, and the strength of one's relationships with others. *Social regulation* refers to social control that a group holds over its members. The basic hypothesis stemming from this work is that suicide rates will be higher among populations that have weaker ties with others within the society (lower levels of integration) and/or are subject to less social control (lower levels of regulation). Empirical analyses of suicide have consistently supported Durkheim's contention that suicide rates are higher in situations with lower levels of social integration and regulation. For example, parents and married persons have lower suicide rates than childless persons and unmarried persons, given their presumably higher levels of social integration.

Durkheim gave very little attention to the issue of youthful suicide, apart from noting its rarity. In perhaps his only reference to youthful suicide, he cites the analyses of Henry Morselli, one of the moral statisticians. Morselli, using data from the mid-and late-19th century in Paris, London, Petersburg, Vienna, and Berlin, documented the very low incidence of suicide among children in general but a striking increase among youth within cities. As Morselli put it, "In fact, it is in the great centres that the number of suicides amongst the young rises so extraordinarily high" (Morselli 1975/1882, p. 222). Durkheim concurred with Morselli's conclusions and explained the high incidence of youthful suicide in these regions as stemming from social factors:

> It must be remembered that the child too is influenced by social causes which may drive him to suicide. Even in this case their influence appears in the variations of child-suicide according to social environment. They are most numerous in large cities. Nowhere else does social life commence so early for the child.... Introduced earlier and more completely than others to the current of civilization, he undergoes its effects more completely and earlier. This also causes the number of child-suicides to grow with pitiful regularity in civilized lands. (Durkheim 1951, p. 101)

In one of the few sociological analyses to examine teen suicide, Peter Bearman (1991) describes how the anomic situation of modern society may affect young

people. He notes that the "teen today is often a member of two separate societies, the family of origin and the peer group" (p. 517). The teen is integrated into these two "societies," but these social worlds are usually independent of one another and produce conflicting social demands. "The normative dissonance experienced by the teen is the same as anomie," according to Bearman.

**Explaining Cohort Effects** Sociological work on teen suicide has used a Durkheimian perspective and focused on the late-20th-century changes in the age distribution of suicide that were noted above. These scholars have examined ways in which social regulation and integration vary across birth cohorts and can account for the upswing in teen suicide relative to that of adults. Supported by a variety of complex statistical models, their results demonstrate the importance of cohort variations in family structure and relative size, both of which they take to reflect the integration and regulation that young people receive. Cohorts born in the 1980s and 1990s have higher suicide rates relative to adults because they have experienced less integration and regulation through their childhood years (Stockard & O'Brien, 2002a, 2002b).

Using cross-cultural data, researchers also have shown that the impact of cohort effects can vary from one social context to another. In the late 20th and early 21st centuries many modern societies have had similar risks of low levels of integration and regulation for their youth, stemming from changing family structures and numbers of youth relative to adults. Yet only some of these societies have experienced the dramatic upturn in teen suicides relative to adults that occurred in the United States and other nations. Research suggests that an important protective element is social policies that provide greater support to families and children. Teens in societies with these traditions have been much less likely to experience higher rates of suicide (Stockard & O'Brien, 2002a; Stockard, 2003).

## FUTURE DIRECTIONS FOR THE STUDY OF TEEN SUICIDE

Undoubtedly, the most striking development in the area of teen suicide is the dramatic increase of youthful rates relative to adult rates. This issue is much more than scholarly in nature, for the deaths that the increased rates reflect have no doubt brought enormous emotional pain to many people and produced substantial losses in human and social capital for communities throughout the nation.

One of the most important areas for future research on teen suicide will be continued study of the relative rates of youth and adults. To what extent will the narrowed gap between teen and adult rates persist into the future? Do the factors that the recent cohort-related analyses have uncovered continue to predict the age-period variations in suicide?

Prevention efforts will, of course, continue to be very important. Much prevention work concentrates on mental health efforts. These efforts often involve suicide prevention campaigns, mental health treatment for individuals who appear at risk, and training for adults working with youth to help them identify danger signals. Some scholars refer to these efforts as "downstream" policies, those that try to address issues of suicidality after they have already appeared. While these efforts are, of course, absolutely necessary and important, it is also possible to focus change efforts "upstream" and address factors more distally related to suicide risk, such as those identified in the analyses of cohort effects. Using this perspective, upstream approaches to diminishing teen suicide could focus on promoting social integration and regulation for teens through methods such as greater support for families and youth throughout childhood and for the society as a whole (Stockard, 2003).

## THEORIES OF DEVIANCE

*Crime*, *deviance*, and *delinquency* are often used interchangeably. However, these terms refer to different behaviors. *Crime* refers to an act or a failure to act that is a violation of criminal law. *Delinquency* is a crime that only juveniles can commit. *Deviance* refers to violating social standards or norms about what is collectively considered conventional behavior. Deviance is often antisocial behavior that is typically condemned by the general public. Scholars who study theories that explain why youths commit different acts, whether these acts are truly criminal or merely deviant, overlap. In other words, a theory that explains deviance usually explains crime and delinquency as well. Several contemporary theories that explain why youth commit crime and deviance fall under three broad categories: psychological, sociological, and biological theories of deviance.

Psychological and sociological theories are by far the most commonly used to explain deviance and crime. Whereas psychological theories tend to focus on individual-level factors such as mental health and intelligence as influences on youthful deviance, sociological theories emphasize the role of the social structure and social processes that may impact a youth's life chances. For instance, sociological theories focus on race/ethnicity, gender, sexuality, and social class as the backdrop for understanding why an individual might commit a crime or deviant act. Few theories in the early 21st century are purely sociological or purely psychological. Instead, most of the tested theories of deviance emphasize a social-psychological approach, or a blended approach to understanding why people commit deviance.

Although the specific hypotheses generated by different social-psychological theories vary, these perspectives do share some common themes that may predict the social environments that generate youthful deviance. These themes include:

1. living in an impoverished area,
2. having poor quality relationships with parent(s), which are characterized by inconsistent discipline, abuse, and/or lack of parental affection,
3. poor academic performance, attendance problems, and/or dropping out of school,
4. access to deviant peers or parents who reinforce deviant behaviors (Giordano, Deines, & Cernkovich, 2006).

Four of the most influential social-psychological theories merit detailed discussion: differential association theory, social control theory, labeling theory, and life-course perspective. Differential association theory has the most longevity and has influenced other theories of deviance for nearly a century. Social control theory has had the most powerful impact on policy makers' strategies for how to reduce juvenile delinquency. Although such strategies have failed to produce the results promised, the conservative nature of social control theory has helped it remain a popular explanation of deviant behavior. Labeling theory began a revolutionary way of looking at delinquency as a problem created and maintained by the juvenile justice system itself. No other theory of lawmaking has been as widely accepted or integrated into policy as labeling theory. Finally, the life-course perspective is a theoretical integration, borrowing the best from various theories and helping to explain deviant behavior over longer periods of the life span than any other theory covers.

## DIFFERENTIAL ASSOCIATION THEORY

Prior to the 1930s, most American theories of crime and deviance focused on biological causes, psychological malformations, or economic social conditions. Criminality was either an innate characteristic of an individual or crime was the product of abstract socioeconomic forces in an individual's life. Differential association was the first theory to challenge the existing positions by bridging sociological and psychological theories of behavior. Posited by Edwin H. Sutherland (1883–1950), differential association suggests that all crime and deviance are learned behaviors. Learning to commit crime occurs through associations or relationships with deviant peers or close family members. This theory was a revolutionary idea for its time and has come to be one of the most longstanding and valued theories of crime and deviance.

Differential association theory suggests that individuals learn to become criminal through interactions with immediate family and peers. Sutherland (1947) detailed this process of social learning of deviant behavior in nine postulates:

1. Criminal behavior is learned.
2. Criminal behavior is learned in interaction with other persons in a process of communication.
3. The principal part of the learning of criminal behavior occurs within intimate personal groups.
4. When criminal behavior is learned, the learning includes (a) techniques of committing the crime, which are sometimes very complicated, sometimes very simple; (b) the specific direction of motives, drives, rationalizations, and attitudes.
5. The specific direction of the motives and drives is learned from definitions of the legal codes as favorable or unfavorable.
6. A person becomes delinquent because of an excess of definitions and associations favorable to violation of law over definitions and associations unfavorable to violation of law. This is the principle of differential association.
7. Differential association may vary in frequency, duration, priority, and intensity. This means that associations with criminal behavior and also associations with anticriminal behavior vary in those respects.
8. The process of learning criminal behavior by association with criminal and anticriminal patterns involves all of the mechanisms that are involved in any other learning.
9. While criminal behavior is an expression of general needs and values, it is not explained by those general needs and values since noncriminal behavior is an expression of the same needs and values. Thieves generally steal in order to secure money, but likewise honest laborers work in order to secure money. The attempts to explain criminal behavior by general drives and values such as the money motive have been, and must continue to be, futile, since they explain lawful behavior as completely as they explain criminal behavior. They are similar to respiration, which is necessary for any behavior, but which does not differentiate criminal from noncriminal behavior. (pp. 6–7)

These postulates are generally understood by scholars to mean that criminal behavior is learned from deviant peers and close family members through talking about criminality. Not only must the how-to's of crime be learned by individuals, the norms, rationales, definitions, and attitudes that reinforce the deviant behavior also must be learned. It is these definitions that individuals make based on their associations with deviant peers and family that allow them to commit deviant acts.

From the 1930s through 1947, Sutherland revised this theory several times. Since 1947, however, differential association theory has remained relatively unchanged and has been extensively tested and criticized by scholars. Most research that evaluates differential association has focused on juvenile delinquency, partly because delinquency is considered a group phenomenon in which peer influences are probably the strongest (Vold, Bernard, & Snipes, 2002).

No academic studies have found that delinquency is caused by transmitting definitions and techniques of crime through delinquent peers and family members. However, several researchers have found some support

***Teen Violence.*** *James Watson at the end of his sentencing hearing where he was sentenced to 9 to 12 months for the beating death of Shane Farrell in New Smyrna, FL.* AP IMAGES.

for the general spirit of Sutherland's differential association. For example, Ross L. Matsueda (1982, 1988) found that delinquent youth are more likely to have delinquent peers than are nondeviant youth. Matsueda (1988) also found that just having delinquent peers is not enough to increase risk of deviance. Youth must also have learned definitions favorable to committing crime. In the late 1990s, better statistical techniques and data allowed differential association to be further tested. Costello and Vowell (1999) reanalyzed Matsueda's results with more sophisticated statistical models, and his initial findings were not as strongly supported.

Other studies have shown some support for differential association. For instance, Jang (1999) found that there are direct effects of delinquent peers and school on delinquency in that having delinquent peers is related to committing more delinquency. This relationship, however, is age-limited. The effects of delinquent peers on one's own delinquency tend to increase from early to middle adolescence, reach a peak at the age of mid-13 to mid-15, and then decline. In addition, Battin, Hill, Abbot, Catalano, and Hawkins (1998) tested differential association theory focusing on gangs. The findings showed that the strongest and most consistent factor that predicts delinquency is prior delinquency. However, associating with peers who engage in delinquency plays a strong role in predicting delinquency as well.

Despite the fact that there is mixed support for differential association, most scholars who study deviance, delinquency, and crime still pay close attention to the issues that Sutherland raised in the early twentieth century. Ronald L. Akers (1998) and others added to the original tenets of differential association by integrating specific psychological learning processes such as operant conditioning. These additions are generally called *social learning theories* as they specify the process of actual learning better than Sutherland's original work. Most testing of social learning theories have shown evidence for the ideas proposed in differential association such as delinquent peer association and learning criminal behavior from close relationships with peers and family.

The influence of differential association extends far beyond social learning theories. The original concepts of delinquent peers or close family members are tested in most major theoretical tests of delinquency in the 21st century, even if the central purpose is not to test differential association. No other criminological theory has been as influential or as enduring.

## SOCIAL CONTROL THEORY

Differential association is readily comparable to the next theory of deviance: social control theory. Both theories focus on explaining juvenile offenses more than adult crime, and both theories consider similar influences, but the order in which the influences act vary across the two theories. For differential association theory, an individual first has deviant peer and/or family associations. Next, the individual learns to become a criminal from those peers and family associations. Finally, the individual commits the criminal or deviant act. Conversely, social control theory is based on the assumption that deviant peers are more of a byproduct of being a deviant. In colloquial terms, "birds of a feather flock together": Like-minded, deviant juveniles congregate because they share a common interest in deviance (Glueck & Glueck, 1950, p. 164). According to most social control theorists, first an individual commits a criminal act; the individual then finds other deviants or criminals to associate with after already committing deviance.

More important than peers, however, is the role of social conformity in this theory. In 1957 Jackson Toby argued all young people have "stakes in conformity," meaning that juveniles are aware they might lose something by breaking the law. Toby's ideas on social

conformity were expanded and are now most often associated with the work of Travis Hirschi (1969), which begins with some unique assumptions compared with other theories of deviance. First, social control theories focus on the question: Why do people conform? The answer according to this perspective is because social control prevents individuals from committing crimes.

According to Hirschi (1969), there is no specific criminal motivation, but instead all individuals have a natural motivation to commit crime. Hirschi argued that deviance results from an individual having a weak or broken bond to society. Society in social control theory is specified for youth as family, school, church, and other conventional activities. Hirschi proposed that four primary bonds to society are what prevent juveniles from committing deviant acts. These bonds are: attachment, commitment, involvement, and belief (Hirschi, 1969).

*Attachment* refers to affectional ties that a youth has toward others, predominantly parents. Attachment is the building block necessary for all humans to internalize values and norms and thus be socially controlled (Vold et al., 2002). Unlike differential association theory, an individual can have affectional ties to deviant family members or peers and not commit deviance. Attachment to anyone should foster conforming behaviors in people.

The next social bond, *commitment*, refers to the level of investment individuals have in conventional society and in their personal long-term goals. The more an individual feels invested in schools and future careers, the less likely that individual will commit any deviant behaviors that may threaten society. *Involvement* is the actual tangible activities individuals participate in to show their commitment to the social structure. Moreover, involvement in conventional activities such as sports, extracurricular school activities, or religious activities leaves little or no time for deviant activities. The last bond, *belief*, refers to how much individuals believe in the legitimacy of the social structures around them. Hirschi (1969) argued that if individuals believe that they should obey the law and rules of society, they usually will.

Many scholars have tested Hirschi's (1969) social control theory over the past 40 years. Most research shows support for two of the four bonds: attachment and commitment (Costello & Vowell, 1999). There is no empirical evidence showing that belief and involvement are related to delinquency, as social control theory predicts. In the original study Hirschi conducted during the 1960s to develop social control theory, he could not find support for involvement. Many studies have found the opposite to be true: Heavy involvement in conventional activities, including extracurricular sports and having a part-time job, predict delinquency (Begg, Langley, Moffitt, & Marshall, 1996; Ploeger, 1997). Moreover, tests that focus on the belief bond also have not supported social control theory (Marcos, Bahr, & Johnson, 1986; Massey & Krohn, 1986). Once delinquent peers are accounted for in these tests of social control, the impact of all four bonds decreases (Empey, Stafford, & Hay, 1999).

From the time social control theory emerged through the mid-1990s, it was an extremely popular explanation of deviance with policy makers. The policy implications of social control are fairly easy to implement and were appealing to the designers of tough-minded crime policies. The idea is to provide more opportunities to conventionally bond to legitimate social structures for young people. However, many of the programs implemented in the name of social control theory did not reduce deviant behavior among youth (Empey et al., 1999).

Social control theory has since waned in popularity partially because it is considered by many academic scholars to be too conservative (Greenberg, 1999). In addition, social control assumes an innate criminal nature of youth and adults that is disconcerting to some academics who believe that people are not inherently bad or criminal. Many scholars who study crime refer back to Sutherland's (1947) work on differential association in which he stated, "People are not inherently antisocial. If young people violate the law, it is because they have learned to do it" (p. 6).

### LABELING THEORY

The theories discussed so far have focused on explaining deviant and law-breaking behavior. The next theory, labeling theory, became popular in the 1960s and focuses on lawmaking. According to the labeling perspective, peers, social control, and the other factors previously discussed are not relevant to explaining the true problem with delinquency. This perspective contends that the most important factor to study when focusing on crime is the formal label a youth receives as a result of being caught committing a delinquent act. The actual deviant behavior is secondary in importance. The labeling theorists instead ask: Who applies a deviant or criminal label? What determines when and to whom that label is applied? (Vold et al., 2002). It is the label itself that causes further criminal behavior in a process called *deviance amplification*.

Labeling theorists begin with a set of assumptions about the social structures and the nature of people that are quite different from those used by social control and differential association theorists. Labeling theorists believe that society is characterized by social conflicts. The so-called "winners" in these social conflicts are the people who are in the most powerful positions in terms of social class, status, wealth, and power. This powerful group, the

elites, tends to have the most influence on laws about criminality and deviance. The elites tend to protect their own interests by defining lower-class behaviors as deviant or criminal. As a consequence, labeling theorists believe that laws and the persons involved in the legal system are responsible for generating crime by labeling the least powerful people as criminal (Empey et al., 1999).

Labeling theory emerged predominantly from the works of two theorists and over a 30-year period beginning in the 1930s (Vold et al., 2002). Frank Tannenbaum (1938) argued that when a child becomes enmeshed with the juvenile justice system, those experiences turn him or her from the occasional misbehaver to the active delinquent. Tannenbaum detailed how adult reactions become stronger and the perceptions of mischief become perceptions of evil. The child begins to accept the evil label by adults, further amplifying the problem.

Edwin Lemert (1951) added two additional concepts to labeling theory: primary and secondary deviance. Lemert argued that the first delinquent act may go undetected and unpunished, and this is common among youth from all social backgrounds (Empey et al., 1999). Those youths who commit deviant acts and are not caught, punished, or labeled usually desist their mischievous behaviors. However, juveniles who are caught are stigmatized by the label "delinquent." Usually the newly labeled delinquent is watched more closely and with stricter rules that may be too difficult to follow. Thus the youth will likely adapt to the new label by committing secondary deviance: additional crimes that result directly from the label.

Both Lemert (1951) and Tannenbaum (1938) believed that this labeling process was a gradual one that occurred over a period of time. A primary deviance would occur, followed by an initial labeling, the acquisition of a delinquent identity, and then secondary deviance. The deviance would be further amplified each time the youth was caught and relabeled by the formal juvenile justice system. Moreover, the labeling process would eventually lead to the juvenile accepting the label as a master status or a powerful label that may overshadow all other aspects of his or her identity. The master status as a delinquent would eventually lead to a life-long criminal career.

This process of deviance amplification following the acquisition of a formal deviant label does not affect all juvenile offenders equally. Howard Becker (1963) argued that juvenile justice administrators use labeling selectively. The least powerful youth in American society, such as the impoverished and racial and ethnic minorities, were more likely to be labeled as deviants than others.

By the 1960s and 1970s, when crime among youth was a top national concern for the first time, there was initial excitement about labeling theory. Empey and colleagues (1999) described the excitement: "Were it not for punitive reactions to mischievous children, entangling them in a self-fulfilling prophecy, there would be few career criminals" (p. 260). Labeling theorists outlined several reforms for the juvenile justice system to decriminalize, divert, and deinstitutionalize juvenile offenders to prevent the application of stigmatizing labels and summarily end deviance amplification. Many of these programs were implemented in the late 1960s and remain in existence at the beginning of the 21st century (Empey et al., 1999). However, the excitement over labeling theory faded quickly because of some theoretical problems.

The first problem is that scholars could find only limited support that the label was the problem causing deviance amplification. Although evaluations of labeling theory did find support for the idea that, once labeled, a youth was likely to commit more deviant acts, other factors were more important. In all of the tests of labeling theory, prior deviance was the largest predictor of secondary deviance, not the label (Empey et al., 1999).

One of the most influential tests of labeling theory was conducted by Smith and Paternoster (1990). These researchers found that juvenile offenders referred to juvenile courts were more likely to be referred again to the court for further offenses, which initially appeared to be consistent with labeling theory. However, a closer inspection of the data showed that it was not the juvenile court referral that caused the additional delinquency; rather, the juveniles who were referred to court were considered to be higher risk than those not referred because of the seriousness of prior convictions, the lack of capable guardianship in their homes, and other socioeconomic factors.

Labeling theory has not been abandoned outright, despite the scholarly evidence against it. Instead, labeling theory has been revamped by such academics as John Braithwaite (1989), who posits a theory of reintegrative shaming in lieu of the stigmatizing labels. In general, Braithwaite's theory has received some support and is an area in which the basic legacy of labeling theory is still used by scholars and policy makers in the early 21st century. However, labeling theory does not appear to be well supported independent of other socioeconomic factors that better predict youths' propensity toward deviant behavior.

## LIFE-COURSE PERSPECTIVES ON DEVIANCE

The life-course perspective provides one of the newer frameworks for understanding deviance and crime. In general, life-course perspectives contain theoretical tenets about how changes in an individual's life determine the probability of that person becoming a criminal or ending a criminal career. Life-course perspectives integrate social,

psychological, and environmental factors, which makes these theories more comprehensive and inclusive than other theories of crime. Researchers who study life-course perspectives typically follow a cohort or group of youths over a period of time, which allows scholars to document how changes in the life course affect youths' future opportunities and likelihood of committing deviant acts.

The term *perspective* is used instead of *theory* because one theoretical model does not unify the wide breadth of ideas that fall into this general category. Indeed, if one asked a sociologist and a psychologist about life-course theories of deviance, one may get surprisingly different answers. In general scholars who study life-course perspectives believe that a wide range of factors contribute to deviance at different points in an individual's life. Yet there is not a general agreement about which specific factors are most important to study. For these reasons, life-course perspectives should be divided into biosocial developmental issues and sociological issues.

**Biosocial Life-Course Theories** Biosocial theories suggest that some biological factors may predispose some youth to commit crime in addition to the social factors that are known to be related to crime. These biological factors usually capture some quality that inhibits normal biological development. For example, levels of hormones such as testosterone, physiological development indicators such as puberty onset, nutrition levels during formative years, or brain chemistry during different developmental ages have been linked to delinquent behavior.

***Biosocial life course: Pubertal development.*** One of the most important biosocial areas of study related to life-course perspectives focuses on pubertal development and deviance. In fact, researchers have long noted that the onset of puberty for boys often coincides with the onset of delinquency (Felson & Haynie, 2002). Scholars have tested whether or not that coincidence indicates that delinquency and puberty are related to each other. For boys, pubertal development may be as important as peers and school performance in predicting deviant behaviors. Felson and Haynie showed that puberty predicts violent crime, property crime, illicit substance use, and precocious sexual behavior. However, this study and others cannot accurately determine the exact social or biological mechanisms that make this relationship apparent.

The relationship between puberty and deviance is different for girls and boys. Girls who enter puberty earlier than average are more likely to engage in deviant behaviors than girls who begin puberty at an average or older age. Girls who attend coeducational or mixed-sex schools are even more likely to be affected by early puberty, as boys tend to have an aggravating effect on girls' deviance (Caspi, Lynam, Moffitt, & Silva, 1993).

***Biosocial life course: Neurological development.*** The widely known research of Terrie Moffitt (1993) is often credited for beginning a new and distinct discussion of life-course perspective and deviance. Moffitt created a taxonomy, or classification system, for two distinct types of offenders: adolescence-limited deviance and life-course persistent deviance. The first group, adolescence-limited, contains the majority of youthful offenders. These juveniles commit delinquent acts during their teen years and quickly end their criminal careers before adulthood. The offenders who fall into this group are for the most part normal youth who do not commit serious crimes.

Life-course persistent offenders, on the other hand, are far more problematic deviants. Moffitt (1993) suggested that individuals who have an early age of onset, or in other words begin committing antisocial acts during early childhood, will continue through adulthood committing more serious crimes than the other group. She argued that a neuropsychological impairment is the root cause of delinquency. Neuropsychological refers to "anatomical structures and physiological processes within the nervous system [that] influence psychological characteristics such as temperament, behavioral development, cognitive abilities, or all three" (Moffitt, 1993, p. 681). These impairments can be inherited or caused by maternal alcohol or drug use while in utero, poor prenatal nutrition, brain injury, or exposure to toxins such as lead. Moffitt, Lynam, and Silva (1994) argued that neuropsychological impairments lead to poor verbal skills and low self-control, which in turn causes delinquency.

Moffitt's (1993) theory has been the subject of many scholarly debates and research. The age of onset of criminal activities as well as desistance are the two factors that have been examined most frequently. Although Moffitt's own tests and other psychological research have shown some support for her theory (Donnellan, Ge, & Wenk, 2000), sociological studies show very limited support without factoring in sociological variables. For instance, one study found that, irrespective of the age of onset, criminal trajectories tended to specialize (Piquero, Paternoster, Mazerolle, Brame, & Dean, 1999). This finding suggests that there is no clear difference between adolescent-limited and life-course persistent offenders. Others found that parental and school reactions to deviant behavior are associated with long-term changes in children's behavior (Simons, Johnson, Conger, & Elder, 1998). Thus, social factors during development are more important in determining delinquency trajectories than neuropsychological traits.

The mixed support for this theory may reflect the variety of perspectives of the researchers who are interested in Moffitt's (1993) taxonomy. Sociologists are unlikely to believe in the more deterministic elements of her work, whereas psychologists may not be as willing to accept some

of the social factors Moffitt addresses. Because Moffitt's (1993) theory is relatively new, future studies are sure to elaborate and refine her original work. Sociological studies of the life course are already working on refining her psychological ideas in the contexts of the social world.

**Sociological Life-Course Theories** Although not necessarily in agreement with Moffitt's (1993) pivotal work, sociological life-course researchers acknowledge the many contributions of her work. The most widely cited sociological life-course work has been conducted by Robert Sampson and John Laub (1993, 2005). Sampson and Laub's studies of juvenile delinquency through adult criminality begin with a direct discussion of Moffitt's work.

In a 2005 publication, Sampson and Laub outlined why they agree and disagree with Moffitt's ideas. Sampson and Laub moved away from biosocial determinism in favor of a sociological explanation of why people begin, persist, and desist their criminal careers or trajectories. They also see criminal careers as well as the life course as dynamic. Changes that happen during individuals' lives were more important to Sampson and Laub than any early childhood or neonatal factors that Moffitt emphasized.

Sampson and Laub (1993) presented an age-graded theory of informal social control. They argued that adolescents tend to not commit deviant acts when informal social controls are working. If a youth is properly supervised by fair and loving parents, that child is not likely to engage in deviance. Conversely, a lack of informal social controls, including poor parenting, low supervision, erratic or harsh discipline, and weak ties to schools, are all linked to predicting juvenile delinquency. Sampson and Laub's ideas were based in part on the tenets of Hirschi's (1969) social control theory, discussed earlier.

Sampson and Laub (1993) also maintained that informal social controls change over the life course. As adolescence ends and adulthood begins, social controls also change. Social capital now becomes an important form of social control. The more social capital individuals have, the less likely they are to commit a deviant act that will threaten their social capital. The most important forms of social capital according to this theory are marriage and job stability. Thus, securing adult milestones such as employment and marriage are linked to the ending of adolescent crime because individuals do not want to risk losing these social gains.

Adolescents can fail to make a positive transition to adulthood if their lives are marked by negative turning points or milestones. Sampson and Laub (1993) argued that prolonged incarceration, heavy drinking, and subsequent job instability during the transition to young adulthood will exacerbate criminal careers.

Numerous theoretical tests of Sampson and Laub's work (1993) that show support for their version of life-course theory have been published in criminology and sociology journals. Nagin, Farrington, and Moffitt (1995) studied Moffitt's (1993) adolescence-limited offenders along with life-course persistent offenders under Sampson and Laub's age-graded model of social control. This study followed offenders until age 32. The results show that adolescent-limited offenders do cease most serious types of crimes throughout adulthood. These offenders committed only minor infractions between the ages of 18 and 32, such as petty theft from employers and minor substance use. They also tended to have greater job stability and less family disruption than the chronic offenders in the study. The adolescence-limited offenders were careful to avoid committing crimes with a high risk of conviction that might jeopardize their work. These offenders did not engage in spousal abuse that might harm familial relationships. Thus, the theory of adolescence-limited offenders "aging out" of crime because of functioning informal social controls is well supported.

Several other tests show support for Sampson and Laub's (1993) theory in regard to adult criminal behavior. One study found that for adult convicted felons, living with a wife is associated with lower levels of offending, whereas living with a girlfriend is associated with higher levels of offending (Horney, Osgood, & Marshall, 1995). Another found that social capital is more important in terms of preventing adults from offending than threat of legal punishment (Nagin & Paternoster, 1994). Individuals in this study who were more concerned about losing their social capital also ranked high on scales measuring forethought and other negative consequences of criminal behavior.

**Future Directions of Life-course Perspectives** Whether sociological, psychological, or biosocial, it is clear that life-course perspectives will remain at the forefront of theories of deviance. Many life-course theoretical questions remain unanswered in part because of data limitations; there just are not enough longitudinal studies that follow children through adulthood to test all the competing theories of deviance. As data become more plentiful, theoretical development in this perspective is likely to continue to integrate the ideas of multiple disciplines.

# THOMAS, W. I.

***1863–1947***

William Isaac Thomas was one of the most prolific and progressive sociologists of the early 20th century. The son

***W. I. Thomas.*** **COURTESY OF THE AMERICAN SOCIOLOGICAL ASSOCIATION.**

of a Protestant minister, Thomas was born in Virginia. He received his B.A. at the University of Tennessee and went on to hold teaching positions at several academic institutions, including the University of Chicago where he completed his Ph.D. in sociology. Thomas has made significant contributions to the field of sociology and the study of the life course in particular. He is best known for the *Thomas theorem*, which states, "If men define situations as real, they are real in their consequences" (Thomas & Thomas, 1928, p. 572). The book in which the theorem first appears, *The Child in America*, was coauthored by a graduate student, Dorothy Swaine (1899–1977), Thomas's second wife.

The Thomas theorem was likely inspired by his exposure to German philosophy and phenomenology—Thomas was an avid reader of German philosophy and studied in Germany for a year. The theorem can be interpreted in different ways. If one were to emphasize its phenomenological roots, the Thomas theorem means that reality is always subjective, contextual, and constructed via social interaction. In this context, the plural noun *men* connotes the collective endeavor that underlines the social construction of reality (i.e., definitions of situations are arrived at collectively and are mediated by culture and history). By contrast, a positivistic reading of the Thomas theorem suggests a type of personal or collective delusion; the individual erroneously defines a situation as real even in the face of objective evidence to the contrary. In this vein, Robert Merton (1957) links the Thomas theorem to "self-fulfilling prophecies" and suggests that a "false" definition of a situation could become real if collectively shared. So, for example, the belief that the stock market is about to crash could cause an otherwise robust economy to fall into a recession. In a sense, a positivistic interpretation of the theorem implies that people sometimes fall in a sort of collective trance that causes them to believe a falsehood and act toward it as if it were true.

A close examination of Thomas's work suggests that he took a position somewhere between extreme objectivism and subjectivism. Indeed, the paragraph immediately following the theorem in *The Child in America* reads as follows: "The total situation will always contain more and less subjective factors, and the behavior reaction can be studied only in connection with the whole context, i.e., the situation as it exists in verifiable, objective terms, and as it has seemed to exist in terms of the interested persons" (1928, p. 572). Also, it is unlikely that Thomas intended for the theorem to apply to a limited class of human interactions (e.g., explaining how errors in judgment occur on a mass scale). Rather, as indicated in the excerpt below, the theorem simply articulates his previous research on what he believed to be a universal law of human interaction and personality.

> the human personality is both a continually producing factor and a continually produced result of social evolution, and this double relation expresses itself in every elementary social fact; there can be for social science no change of social reality which is not the common effect of pre-existing social values and individual attitudes acting upon them. (Thomas & Znaniecki, 1918, p. 5)

The phrase "every elementary social fact" is particularly significant in this context. It implies that it is not just a certain class of social facts (i.e., false perceptions) that fall under the Thomas theorem, but the theorem is a fundamental principle that applies to a wide range of social actions. In the case of the economic example, the Thomas theorem could also point to more foundational questions, such as how people come to define economic prosperity in terms of competitive trade among large corporations.

Interestingly, Thomas attributes the origins of this unique methodology to a happy accident, which is cited in Paul Baker's 1973 essay on Thomas:

> It was, I believe, in connection with *The Polish Peasant* that I became identified with "life history"

> and the method of documentation. . . . I trace the origin of my interest in the document to a long letter picked up on a rainy day in the alley behind my house, a letter from a girl who was taking a training course in a hospital, to her father concerning family relationships and discords. It occurred to me at the time that one would learn a great deal if one had a great many letters of this kind. (p. 250)

Since its publication, *The Polish Peasant* has been criticized for its negative portrayal of Polish immigrants and for generalizations that did not necessarily grow out of the empirical data at hand. Despite these shortcomings, *The Polish Peasant* remains a seminal study that showed (a) identity is not an innate, stable trait but a fluid and malleable social form; and (b) individual identity is mediated by the broader social forces of culture and history. Thomas and Znaniecki's (1918) focus on how the individual fares in society over time continues to be the central theme of the study of the life course and social psychology in general.

*The Polish Peasant* and Thomas's other works challenged gender and ethnic stereotypes of marginal identities. For example, in *Sex and Society*, Thomas (1907) states that "the psychological differences of sex seem to be largely due, not to differences of average capacity, nor to difference in type of mental activity, but to differences in the social influences brought to bear on the developing individual from early infancy to adult years" (p. 438). Thomas was similarly critical of what is now referred to as objectification of women:

> Woman was still further degraded by the development of property and its control by man, together with the habit of treating her as a piece of property, whose value was enhanced if its purity were assured and demonstrable. As a result of this situation man's chief concern in women became an interest in securing the finest specimens for his own use, in guarding them with jealous care from contact with other men, and in making them together with the ornaments they wore, signs of his wealth and social standing. (pp. 460–461)

Thomas's views on ethnic minorities were equally progressive. For example, in *Old World Traits Transplanted*, he and his coauthors warn against "demanding from the immigrant a quick and complete Americanization through the suppression and repudiation of all the signs that distinguish him from us" (1921, p. 281). They go on to note that the demand for the "destruction of memories" for immigrants is an oppressive totalitarian impulse shared by conservative Americans and radical Communists. In this sense, Thomas's reverence for memory and its role in identity formation is another hallmark in the study of the life course.

Thomas's professional career was eclipsed by a sex scandal in 1918. The 55-year-old Thomas was arrested along with a 24-year-old woman who was married to a U.S. Army officer serving in France. The couple was charged with registering under a false name at a hotel and later tried at the Chicago's Morals Court for disorderly conduct and other charges. It is rumored that Thomas's personal politics, his radical views on gender relations, and his wife's leadership of the Woman's Peace Party played a role in the Federal Bureau of Investigation's aggressive approach to his case. Thomas and the woman with whom he was having an affair were eventually cleared of the charges. Nonetheless, Thomas was dismissed from his position at the University of Chicago. Additionally, as a result of the scandal, the Carnegie Foundation, which was funding Thomas's research on immigration at the time, insisted that his name be removed from a forthcoming publication. That manuscript, *Old World Traits Transplanted*, instead gave writing credit to Robert Park (1864–1944) and Herbert Miller (1875–1951), both of whom contributed only minor parts to the book.

## TRANSITION TO MARRIAGE

At the turn of the 21st century Americans were entering first marriages at later ages than at any other time in the previous hundred years. Combined with increasing rates of

cohabitation and a growing proportion of births occurring to unmarried mothers, this suggests a diminished role for marriage in the lives of many young adults. However, it is important to study the transition to marriage for a number of reasons. Demographers estimate that the vast majority of Americans will marry, and most people continue to report that they value marriage highly. Marriage tends to be more stable than other types of intimate unions and confers greater legal rights and protections than does nonmarital cohabitation. Marriage also is associated with positive outcomes such as improved economic well-being, reduced risk-taking behaviors, and relatively higher levels of child well-being. The timing of the transition to marriage is important, with very early marriages associated with some negative outcomes. With a focus on the experience of young adults, this entry reviews trends and differentials in the transition to marriage, patterns of family formation outside marriage, and existing knowledge about the association between marriage and the well-being of adults and children.

## SHIFTING PATTERNS OF MARRIAGE ENTRY

The timing of the transition to marriage has changed considerably over recent decades. Although ages at first marriage decreased during the 1950s, they increased rapidly in the decades that followed. In 2006 the median age at first marriage in the United States reached 27.5 years for men and 25.5 years for women (U.S. Census Bureau, 2007), the latest marriage ages at any time in the previous century. These trends have reshaped the family lives of young adults dramatically. Whereas 64% of women age 20 to 24 had ever been married in 1970, the same was true of only 31% in 2000. Among men age 20 to 24, roughly 55% had ever been married in 1970, compared with only 21% in 2000 (U.S. Census Bureau, 1991, 2008). Similar patterns of marriage delay also are observed in many other industrialized countries. Average ages at first marriage throughout much of Western Europe are as high as or higher than those observed in the United States (Kiernan, 2000).

However, at least in the United States these patterns seem to be more about marriage delay than about eschewing marriage altogether. Demographers estimate that nearly 90% of recent cohorts of U.S. women will marry (Goldstein & Kenney, 2001). The vast majority of U.S. high school seniors surveyed in the late 1990s reported that having a good marriage and a happy family life was extremely important (Thornton & Young-DeMarco, 2001). The importance of marriage in the United States also is reflected in a strong social movement demanding marriage rights for same-sex couples and in the sometimes heated and emotional debate about the nature of marriage that this movement has generated (Hull, 2006). However, the fraction of people expected to marry is lower in many European countries than in the United States, perhaps indicating the relatively lower salience of marriage in these countries. For example, fully 40% of Swedish women born in 1965 are expected to be never married at age 50, as are roughly 30% of such women in Norway, Finland, and France (Prioux, 2006).

## FAMILIES FORMED OUTSIDE MARRIAGE

Although young adults in the United States are less likely to marry than they were in the past, many are choosing to live with a romantic partner. In the last two decades of the 20th century and the first decade of the 21st rates of nonmarital cohabitation (living with a partner outside marriage) increased substantially. Whereas only 11% of first marriages formed between 1965 and 1974 were preceded by cohabitation, the same was true of 56% of first marriages formed in the early 1990s (Bumpass & Lu, 2000, Bumpass & Sweet, 1989). At the beginning of the 21st century, nearly one-third of all current unions among women age 19 to 24 were nonmarital cohabitations and 38% of these young women had ever cohabited (Bumpass & Lu, 2000). High levels of nonmarital cohabitation also are observed in many other parts of the world, including regions of Northern and Western Europe as well as many Central American and Caribbean nations (Fussell & Palloni, 2004, Kiernan, 2000). For example, 83% of women are expected to enter a nonmarital cohabitation before age 45 in France, as are roughly two-thirds of women in Sweden (Heuveline & Timberlake, 2004).

Nonmarital cohabitation in the United States tends to be relatively short-lived, with half of these unions lasting no more than about one year and only 1 in 10 lasting five years or longer (Bumpass & Lu, 2000). Roughly half of U.S. cohabiting unions eventually end in marriage (Bumpass & Lu, 2000). Cohabitation tends to be most common among those with relatively less education, although it is widespread among all educational groups. For example, 59% of women with less than 12 years of schooling had ever cohabited in the mid-1990s, compared with 37% of women with at least 4 years of college (Bumpass & Lu, 2000).Cohabitation also tends to be relatively more common among individuals from economically disadvantaged families and those who lived apart from at least one parent during childhood (Bumpass & Sweet, 1989). Although reasons for cohabitation are varied, individuals with relatively fewer economic resources may feel less able to afford the perceived economic responsibilities associated with marriage.

In addition to losing its dominance as a setting for intimate relationships, marriage has lost some of its dominance as a setting for childbearing. Roughly 37% of all births in the United States in 2005 were to unmarried

mothers, compared with 11% in 1970 (Martin, Hamilton, Sutton, Ventura, MeNacker, Kirmeyer, et al., 2007, Ventura & Bachrach, 2000). The fraction of births occurring outside marriage is even greater among relatively younger women, representing more than half of all births to women age 20 to 24 and more than 80% of births to women under age 20 (Martin et al., 2007). These trends are driven by a number of factors, including declining rates of marriage in young adulthood, increased rates of childbearing among unmarried women, and declining rates of childbearing among married women. Also, women are considerably less likely to marry in response to a pregnancy than they were in the past. In the early 1950s more than half of all women age 15 to 29 married before a first premaritally conceived birth in the United States, compared with less than one-quarter in the early 1990s (Ventura & Bachrach, 2000).

Delayed entry into marriage, combined with a loosening of the connections between marriage and life course events such as entry into committed romantic relationships, entry into parenthood, school completion, and leaving the parental home, has led a number of scholars to argue that marriage has become less important as a marker of the transition to adulthood (Corijn & Klijzing, 2001, Furstenberg, Kennedy, McLoyd, Rumbaut, & Settersten, 2004). One study finds that whereas well over 90% of Americans believe that completing one's education, achieving financial independence, and working full-time are at least somewhat important to being considered an adult, only 55% say the same thing about marriage (Furstenberg et al., 2004). Other studies indicate that people in their teens and twenties place less emphasis on marriage and greater emphasis on qualities such as "accepting responsibility for one's self" and "making independent decisions" in self-identifying as adults (Arnett, 2000, p. 473). Contemporary cohorts of young people arguably tend to view marriage and parenthood as life choices rather than prerequisites for becoming an adult (Furstenberg et al., 2004).

The last decades of the 20th century and the first decade of the 21st brought delayed entry into marriage, growth in the proportion of young adults living with an unmarried partner, and an increase in the proportion of births occurring to unmarried parents. Although marriage is less dominant than it once was over the organization of family life, many family scholars argue that it remains important in American society. Sociologist Andrew Cherlin argues that marriage "has been transformed from a familial and community institution to an individualized choice-based achievement" (Cherlin 2004, p. 858). Recent shifts in marriage patterns likely result from a complex and deeply intertwined set of social and economic factors, many of which have deep historical roots. These include shifts in the labor market and educational opportunities of women and men, changing attitudes toward sex and childbearing outside marriage, improved control over the link between sex and reproduction, and growth in the importance individuals place on personal fulfillment. The fact that many people view school attendance and marriage as incompatible provides a nice twist on the life course theme of "linked lives." Although recent patterns of transition into marriage are well documented, there is less agreement about what marriage will look like in the future. The likely course of future change in marriage patterns is an important area of study and debate among social scientists.

## DIFFERENTIALS IN EARLY ADULTHOOD MARRIAGE

A number of background factors are associated with the likelihood of becoming married before age 25. For example, there are substantial racial and ethnic differences in the likelihood of early marriage. Although 63% of White women and 61% of Hispanic women had transitioned to marriage by age 25 in 1995, the same was true of only 37% of non-Hispanic Black women and 44% of non-Hispanic Asian women (Bramlett & Mosher, 2002). Race differences in marriage extend into the later life course, with over 90% of recent cohorts of White women expected to ever marry, compared with roughly two-thirds of recent cohorts of Black women (Goldstein & Kenney, 2001).

Religion and region of residence also are associated with differences in early adulthood marriage patterns. Women who have no religious affiliation or who report that religion is not important to them are less likely than others to marry by age 25. Women in the Northeast are less likely to marry by age 25 than are women in other regions of the country. Although regional variation in the proportion ever married largely levels off by age 30, differentials by religiosity persist into older age groups (Bramlett & Mosher, 2002). Several of the same factors that predict a greater overall probability of marriage during one's lifetime are associated with a reduced probability of marrying during the early adult years: A number of studies demonstrate that people with relatively higher levels of education are more likely to marry over the course of their lives than are those with relatively less schooling, yet having completed more years of education is associated with a reduced probability of marrying by age 25. Estimates suggest that whereas roughly two-thirds of women with no more than a high school degree marry by age 25, the same is true of only half of women with relatively more schooling.

Variation in patterns of family formation across social class and racial/ethnic groups has been of particular interest to social scientists. Although better-educated women increasingly delay both marriage and parenthood, less-educated

women delay marriage but not parenthood (Ellwood & Jencks, 2004). Black Americans are both less likely to marry than non-Hispanic Whites and more likely to bear children outside marriage. These patterns lead to considerable differences in the context in which children are born, with a much larger proportion of births occurring within marriage among Whites and the most educated than among Blacks and the least educated. The causal factors underlying social class and racial/ethnic differences in patterns of family formation, however, are not well understood. Sociologists William J. Wilson and Kathryn Neckerman (1987) argue that high rates of unemployment and incarceration among men in poor urban areas reduces the number of attractive male marriage partners. Yet most studies find only a relatively modest contribution of the availability of "marriageable" men to group differences in marriage patterns. Variation across groups in attitudes toward marriage is similarly unable to fully explain racial and socioeconomic gaps in marriage behavior (Edin & Kefalas, 2005; Ellwood & Jencks, 2004). The search for alterative explanations for these patterns remains an important area of future research.

## MARRIAGE, HEALTH, AND WELL-BEING

Marriage is associated with a number of beneficial outcomes for men and women, including higher family income, improved health, and reduced risk-taking behavior (Waite, 1995). Although most children fare well regardless of the structure of their families, growing up with two biological parents who are married to each other rather than with a single parent or two cohabiting parents is associated with relatively higher child well-being (Amato, 2005). Scholars disagree, however, about the extent to which marriage causes these positive outcomes as opposed to people with higher preexisting levels of health, resources, and well-being being more likely to marry in the first place. Also, relatively little is known about whether these potential benefits of marriage extend to individuals who marry during the earliest years of adulthood. Attempts to answer this question are complicated by the fact that individuals who marry early in life tend to come from relatively more disadvantaged backgrounds than individuals who delay marriage. Marriage before age 20 also is associated with other negative outcomes for individuals, including a higher risk of experiencing a subsequent divorce than is the case for individuals who marry relatively later in life (Martin & Bumpass, 1989). Many explanations have been offered to explain this relationship. For example, relatively young people may be less able to predict what kind of partner would make the most compatible long-term match or may have fewer economic or emotional resources to draw on in support of their marriages.

In considering the potential benefits of marriage in the contemporary United States it is important to keep in mind that marriage brings certain rights and legal protections that are less easily available or not available to unmarried couples. Laws give special recognition to married couples in a number of domains, including their emotional attachment, parental status, and economic organization and resources (Hull, 2006). For example, the Family and Medical Leave Act gives spouses but not unmarried partners the right to take time off from work to care for a partner with a serious health condition. Married individuals generally can receive health insurance and other benefits through a spouse's employer and are subject to special rules governing inheritance and taxation. In court proceedings married partners receive protection from testifying against a spouse. Such legal and economic differences in the status of married versus unmarried couples have received considerable attention in debates about the extension of marriage rights to same-sex couples.

## FUTURE DIRECTIONS

Although Americans increasingly are delaying the transition to marriage, most young people eventually marry and the desire to marry is widespread. However, young adults have more latitude in choosing what kinds of romantic partnerships to enter, when to enter those relationships, and the relationship context in which to bear and raise children. Although scholars know a considerable amount about patterns of marriage, much remains to be learned. For example, causal factors underlying differences in marriage patterns across educational and racial/ethnic groups are not well understood. Also, although marriage is associated with many positive outcomes, the processes underlying those outcomes are not well understood. How much of the relatively greater physical, emotional, and socioeconomic well-being of married versus unmarried people can be attributed to causal effects of marriage per se and how much is due to preexisting differences between people who enter marriage versus those who do not? Also, the extent to which any potential benefits of marriage extend to young adults is unclear.

There is much disagreement about the likely direction of change in future patterns of marriage. Will age at first marriage continue to increase over time? Will there be a meaningful reduction in the proportion of individuals who marry over the course of their lives? Answers to these questions are an important focus of ongoing efforts to understand the meaning and nature of marriage in the 21st century.

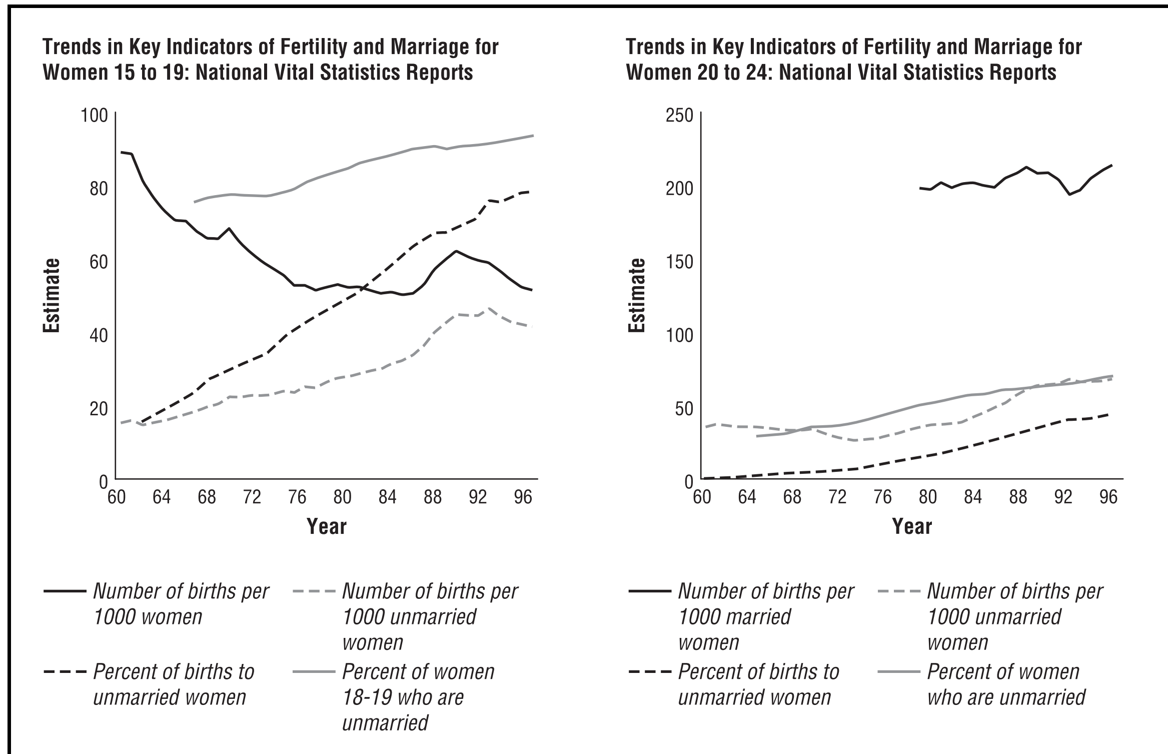
# TRANSITION TO PARENTHOOD

The transition to parenthood is typically defined as the event of becoming a biological mother or father. Early transitions to parenthood in the United States have been a topic of concern to scholars, policy makers, and the general public since the early 1970s. This concern has been fueled by the growing proportion of young mothers who are single and by the putative consequences of early and single childbearing. For instance, women who have a birth during their teens are more likely than their counterparts who postpone childbearing to drop out of high school or become dependant on welfare. Although early parenthood is a relative concept, considerable attention has been paid to transitions during the teen years (i.e., 15 to 19). Basic trends in adolescent and young adult transitions to parenthood, the causes and consequences of these trends, and directions for future research are discussed here.

## HISTORICAL TRENDS

One of the more noted trends in the transition to parenthood is its postponement. As evidence of this, the proportion of women who have their first child before the age of 25 has decreased since the 1960s, whereas the proportion of women who have their first child beyond the age of 25 has increased. The postponement of childbearing has been concentrated mainly among women with college degrees



***Trends in Key Indicators of Fertility and Marriage.*** CENGAGE LEARNING, GALE.

and reflects increases in their returns to higher education. Delayed childbearing on the part of more educated women has led to a divergence between educational groups in rates of early childbearing. In spite of this divergence, scholars documenting trends in early parenthood have focused mainly on the dramatic increase in the fraction of early births occurring to unmarried women.

Among women of all reproductive ages, changes in the proportion of births to unmarried women, termed the *nonmarital fertility ratio*, have been driven by declines in the proportion of women marrying, increases in nonmarital birthrates, and decreases in marital birthrates. Trends in these statistics, which are presented in Figure 1, are more frequently and fully documented for teen women than for woman of other ages, and they are rarely presented for men. The proportion of births occurring to unmarried teen women increased from 0.148 to 0.785 between 1960 and 1998. During this same period, the proportion of teen women who were unmarried increased from 0.719 to 0.936. Whereas the birthrate for married teen women (calculated as the number of births per 1,000 married women ages 18 to 19) declined from 530.6 to 322.1, the birthrate for unmarried teen women (the number of births per 1,000 unmarried women ages 15 to 19) increased from 15.3 to 41.5. The nonmarital birth ratio for women ages 20 to 24 (presented in Figure 2) also increased considerably between 1960 and 1998 (i.e., from 4.8 to 47.7) but remained considerably lower than the ratio for teen women throughout this time period; the nonmarital birth ratio for teen women increased from 0.148 to 0.785.

Demographers attribute substantially more of the increase in nonmarital fertility ratio to changes in marriage than to changes in fertility. Although pregnancy rates among unmarried women have declined since the 1960s, the proportion of younger women who are single has increased considerably. Delays in marriage have dramatically increased women's exposure to the risk of having a nonmarital pregnancy. Furthermore, women are decreasingly likely to marry in response to a nonmarital conception. Consequently, birthrates among unmarried women have increased over time. Changes in marriage have been more dramatic for Black women than for White women and have driven relatively more of their increase in the nonmarital birth ratio. Changes in the measurement of race and ethnicity make it difficult to document and analyze changes in the nonmarital fertility ratio for Hispanic women.

Although the birthrates for unmarried teen women have increased, birthrates for teen women as a whole have fallen considerably since the 1960s (with some fluctuation over time). For instance, the teen birthrate declined from 89.1 to 51.1 (births per 1,000 women) between 1960 and 1998. Until the early 1990s, Blacks had the highest teen

***Mobile Pregnancy Clinic.*** *Evelyn Flores holds her one-month-old daughter Hailey Interiano after their checkup at the mobile health clinic in Garland, TX. The clinic is just one way of helping teen mothers in Texas, which has the fifth-highest teen pregnancy rate in the nation.* AP IMAGES.

birthrates, followed by Hispanics and then by non-Hispanic Whites. Because of the large decline in teen birthrates among non-Hispanic Blacks during the 1990s, Hispanics have surpassed Blacks in their teen birthrates. As of 2000, rates for non-Hispanic Whites, non-Hispanic Blacks, and Hispanics were 32.6, 79.2, and 87.3 (births per 1,000 women), respectively.

Other developed countries have similarly experienced large declines in teen birthrates since the 1960s. Declining birthrates in developed countries have been attributed to increased education and increased knowledge of contraception and access to it. The decline in birthrates for teens in the United States has been considerably smaller than the decline observed in many other developed countries. Consequently, teen birthrates in the United States are high in comparison to those of Canada and European countries. The relatively higher birthrates among teens in the United States are only partly attributable to their greater socioeconomic disadvantage. Within all socioeconomic groups, U.S. youth tend to have higher teen birthrates than their counterparts from other developed countries. Nor are the higher birthrates on the part of U.S. teens attributable to greater levels of sexual activity. U.S. youth begin having sex around the same age as youth in other developed countries. U.S. youth are said to have higher teen birthrates because of other factors: a weaker consensus that childbearing is only an adult behavior, less accepting attitudes toward teen sex, less access to family planning services, and greater inequality.

A handful of studies have attempted to explain the decline in teen motherhood by examining the relative magnitude of changes in the "proximate determinants" of fertility (i.e., sexual activity, contraception, abortion, and pregnancy). Declines in teen birthrates during the late 1990s have been linked to declines in pregnancy. A small fraction of the decline in pregnancy rates has been attributed to increases in sexual abstinence, but a large share of the decline has been attributed to increases in contraceptive use. Researchers have yet to explain the decline in teen parenthood over a broader time frame.

## PERSPECTIVES

Explanations for the timing of transitions to parenthood are typically informed by rational choice perspectives.

According to these perspectives, individuals weigh the expected rewards of having a child against its anticipated costs (or disadvantages). Because women have historically been the primary caretakers of children and caretaking is time intensive, these perspectives highlight the opportunity costs of having children for women. Child rearing and childbearing interfere with the development of important educational and labor market experiences. In contrast, men have been more responsible for the financial support of children. The transition to fatherhood is likely to impede schooling (at younger ages) and increase men's participation in the labor force.

Studies of early parenthood focus not only on the role of opportunity costs but also on socialization, social control, stress, and risk preferences. Socialization perspectives emphasize the importance of adults and peers as role models for adolescent behavior, whereas social control perspectives highlight the importance of parental monitoring and supervision. Stress perspectives suggest that stresses accompanying major life events are critical to adolescent behavior to the extent that they change parenting practices or reduce an adolescent's sense of control. Deviance perspectives propose that a variety of risk-taking behaviors, including sexual behavior, are linked because of their dependence on a number of factors, including self-esteem, expectations about the future, and peer affiliations.

Studies have drawn on each of these perspectives to explain the influence of various factors on the risk of early motherhood. Although a growing number of studies are examining transitions to early fatherhood, studies typically focus on women because of concerns about men's representation in surveys and the reliability of their reports of fertility. Studies of early parenthood often highlight the role of a single variable or set of variables in measuring the various theoretical constructs. For example, growing up in a single-parent family is thought to be associated with lower levels of monitoring, a greater number of stressful life events, and more exposure to single motherhood.

Several patterns repeatedly emerge in studies of teen motherhood. Reflecting their higher birthrates, Black and Hispanic women are more likely than their White counterparts to become teen mothers; differences by race are explained only partly by family background variables. Women born to a teen mother are more likely to become teen mothers themselves than their counterparts born to an older mother, and women living with a single mother or a stepparent in adolescence are more likely to have a teen birth than their counterparts who live with two biological parents. Women are also more likely to become teen parents if they have parents who are less educated or economically advantaged, or if they themselves have lower academic achievement or aspirations. Women living in more disadvantaged communities (e.g., communities with larger percentages of impoverished families) are at greater risk of teen parenthood, regardless of their own characteristics. Women are more likely to have a teen birth if they reside in states with weaker child support enforcement, but their chances of having a teen birth increase only slightly, if at all, as the level of welfare benefits in their state increases. Yet women growing up in a household receiving Aid to Families with Dependent Children (AFDC) are much more likely to have a teen birth than women whose parents did not receive welfare. Finally, women are more likely to become teen mothers if they experience changes in family structure and income. Studies suggest that the influence of family background factors on teen parenthood does not differ markedly by cohort and is similar in other developed countries (e.g., England).

Rational choice perspectives assume that individuals with greater opportunities for advancement delay fertility in order to avoid incurring early parenthood. These perspectives suggest that the association between disadvantaged family background and the transition to parenthood will weaken or reverse at some point in the life course. Studies that examine how the influence of different variables on the transition to parenthood differs by age offer mixed evidence about if and when this turning point occurs. Some studies suggest that the association between background characteristics and fertility is stronger for teens than for young adults, whereas other studies fail to find any considerable differences.

## CONSEQUENCES

Early childbearing continues to be an issue of public concern not only as a consequence of increases in the nonmarital fertility ratio but also because it is associated with negative outcomes for mothers and children. To consider just a few examples, teen mothers are less likely than their counterparts without an early birth to complete high school and to marry, and the children of teen mothers are less likely than the children of older mothers to receive prenatal care. More recently, scholars have argued that some of the negative outcomes associated with early childbearing are not a consequence of having a teen birth but a reflection of conditions that existed prior to the birth. According to this argument, women whose life chances are more precarious are less motivated to avoid early parenthood in the first place; these women would have had comparable experiences even if they had postponed a birth. Such an argument emphasizes the selection of women with more precarious circumstances into early motherhood, rather than the influence of early motherhood on women. Studies have attempted to identify the causal influence of early childbearing through the use of statistical models (e.g., fixed effects or random effects) that take into account family characteristics that

are not directly measured by researchers and through the use of natural experiments, such as miscarriages, that reveal how women predisposed to early pregnancy fare when they delay childbearing. Taken together, the results of these studies suggest that some but not all of the negative outcomes associated with early childbearing are attributable to selection. Consequently, the experience of being a young mother has some negative influences on women. Researchers also suggest that the specific age at which women transition to parenthood is critical; becoming a teen mother at the age of 15 is more consequential than becoming a teen mother at 19.

## DIRECTIONS FOR FUTURE RESEARCH

Although social scientists' understanding of early childbearing has broadened considerably, several important issues remain to be addressed. Studies of early parenthood and the events that lead to it often fail to consider more than one type of factor, focusing exclusively on the effects of demographic, socioeconomic, or policy variables. For instance, some studies concerning the effects of policies fail to control for socioeconomic factors such as male and female wages. Studies also need to take into account within-group variation by measuring physical attributes such as pubertal development, physical attractiveness, and body size and enduring attributes such as cognitive ability.

Studies also need to consider the family processes by which different factors influence parenthood and its proximate determinants. For instance, studies examining the effects of family structure on such outcomes typically measure mechanisms such as parental monitoring only indirectly. Consequently, it is not clear how family processes mediate family structure, family changes, and the intergenerational association in the timing and circumstances of parenthood. Research is additionally needed on how social-psychological processes (e.g., attitudes) mediate the effects of different factors. Validating opportunity-cost perspectives, qualitative studies reveal that some youth view early parenthood positively because other avenues to success are restricted to them and because they do not expect to live very long. Studies that consider "nothing to lose" attitudes about the future (e.g., expectations about graduating from college or surviving into adulthood) have shown that factors such as neighborhood context influence the transition to parenthood through their influence on expectations about the future. More work in this tradition is needed.

Studies typically examine union dynamics and fertility in isolation, even though pregnancies and births occur within the context of some form of relationship. Studies need to examine how different factors influence the formation of romantic and sexual relationships, in addition to the timing and sequencing of behaviors within these relationships. Related to this, studies need to examine the consistency of influences on the proximate determinants of early births. For example, if a particular welfare policy has no effect on pregnancy and no effect on abortion, then it would be inconsistent to find that it has a significant effect on births. Similarly, if a policy reduces pregnancies and births but has no effect on abortion, then this is evidence that the pathway of influence is through either less sex or more use of contraception. This approach allows researchers to make inferences about the pathways of influence and identify the policy levers most effective in delaying parenthood.

Because previous studies have focused simply on teen or premarital childbearing, it is not clear whether factors associated with having an early birth are also associated with the relationship context of the birth. Statistics based on mothers of all ages reveal that the number of births that occur to cohabiting women is growing and substantial. Changes in the relationship context of teen births beg several questions. Among women who become teen mothers, do factors such as economic disadvantage reduce the chances of having a cohabiting birth, as opposed to a single or marital birth? Do consequences of having an early birth differ by its relationship context? To the extent that children in cohabiting relationships tend to experience subsequent changes in family structure, having a child within a cohabiting relationship may not necessarily be more beneficial than having a child while single.

Information that teen mothers report about fathers on birth certificates suggests that teen fatherhood is much less common than teen motherhood. It is estimated that only about a third of the partners of teen women are teens themselves, and about a fifth of them are 25 or older. Premarital births appear to have important consequences for men, and assessments of the quality of male birth reports conducted in the early 21st century identify aspects of surveys that improve these estimates.

## VOCATIONAL TRAINING AND EDUCATION

Vocational education, broadly speaking, is a type of course intended to train students for particular jobs. The extent to which an individual student is exposed to such courses can vary greatly, from a student taking a single vocational education course, to whole high schools being organized around vocational preparation. Most often, vocational education courses are intended to prepare students who are unlikely to attend college for the jobs they are likely to obtain. In so doing, vocational education attempts to retain students in high school by providing instruction that ''at-risk'' students see as useful and/or interesting. The rationale is that vocational involvement can benefit students by offering skills that will be of value in local labor markets. Although certainly plausible, certain fundamental questions remain unanswered. Who is placed into vocational education? Is the process relatively neutral, or are certain subgroups more likely to be vocationally steered despite actual achievement and expectation levels? And finally, do these processes play a part in creating labor market inequalities and concentration patterns by class, race, and/or gender?

### THE HISTORY OF VOCATIONAL EDUCATION AND RESULTING STRATIFICATION

Federal funding of vocational education predated more general educational funding by about 40 years and had as its primary intent student preparation for occupational roles through differential socialization. Consequently, class, gender, and racial disparities in occupational status have a history of being reproduced through vocational programs. The recreation of inequality was sometimes implicit, although at other moments was quite explicitly mandated. Congress, for instance, had two goals for vocational training in the 1930s: first, to create programs that reflected the local labor market segmentation in terms of race and gender and, second, to reduce unemployment by matching workers to available blue-collar jobs (Werum, 2002).

As part of this process, federal vocational programs placed top priority on agricultural job training. For example, in 1936, two-thirds of the funding for vocational education targeted the agriculture industry. This

focus provided the greatest benefits to southern agrarian elites who had their workforce trained at the federal government's expense. The marginalization of vocational training available to females resulted from this overemphasis on agriculture, an industry dominated by men. Both the Smith-Hughes Act of 1917 and the George-Ellzey Act of 1934 left underfunded vocational education intended for females by limiting such training to home economics courses. In short, there is a history of highly gendered policies dating back to the beginnings of the vocational education movement (Werum, 2002).

Whereas the history of vocational education consistently demonstrates disadvantages faced by females, the race-related history is mixed. Dating back to the Smith-Hughes Act of 1917, states' rights arguments emphasized state control of education and prevented equitable distribution of resources across racial groups. Such policy once again benefited southern agrarian elites, because states and local school boards had discretion over how federal dollars would be spent. Although Black high schools were finally established in the South, their primary intent was to train workers. For their part, Black southern leaders preferred an emphasis on liberal arts education, yet the available external funding placed serious constraints on the curriculum. Note that race and class divisions also shaped the type of vocational training females received: Whereas middle-class White females were trained to be "household managers," immigrant and Black females were prepared to be "household workers." On a related point, Black males typically trained for "substance" farming, whereas White males were taught "scientific" farming techniques.

Historical cases such as these illustrate the overarching influence of local labor market conditions and elite decision making on racial and gender patterns of participation in vocational education and, consequently, segregation and differential opportunity in local labor markets. Moreover, such cases suggest quite clearly that vocational education may mean very different things to different groups in the stratification hierarchy or, at the very least, may influence social groups in very distinct ways.

For example, in a qualitative study of vocational education students, Royster (2003) argues that getting a job is driven not by qualifications but by who knows about the job openings and who has the "weak ties" that help them secure the position. Despite coming from similar backgrounds and performing similarly in school, Whites in Royster's study experienced far greater occupational success than the Blacks she interviewed. Specifically, Whites earned higher wages and experienced less unemployment than Blacks. Moreover, Black men were more likely to find work outside the trades they trained for in high school. In short, Whites had much more productive social networks beyond school than Blacks. As a result, rather than a meritocratic sorting of workers into jobs, racial inequality was reproduced through the social networks of working-class Whites and their links to the vocational education system.

## BENEFITS, RISKS, AND COSTS OF VOCATIONAL PARTICIPATION

Considering the overall literature on vocational education, results suggest some contradictory patterns. Much of the research suggests that involvement in vocational education reduces the risk of dropping out of high school. Specifying this relationship, Rasinski and Pedlow (1998) argue that the protection from dropping out is generally indirect (working through performance), although the influence of certain types of vocational education (e.g., agricultural) may be more direct. Ainsworth and Roscigno (2005), by contrast, found that students taking large numbers of blue-collar vocational education classes were actually more likely to drop out of high school—a finding that calls into question the central reason vocational education exists.

Beyond high school persistence, other benefits have also been demonstrated. High school vocational education, for instance, has been linked to reductions in teen pregnancy among at-risk teenagers, reduced unemployment after high school, increases in one's earning potential, and the likelihood that one will work in a skilled position. Finally, some work suggests that graduates of vocational education programs are more satisfied with their jobs than are comparable students from other high school programs.

There nonetheless appear to be additional risks, if not costs, of vocational participation. For instance, students in vocational programs do not perform as well in basic academic skills such as mathematics, science, and reading compared to those enrolled in more general academic programs. When it comes to the school-to-work transition, Gamoran (1998) found that academic course work improved students' ability to find a job and enhanced occupational mobility relative to vocational course work. This benefit appears to increase over time. Consistent with this point, Rosenbaum (2001) suggested that most employers are more interested in basic academic skills and trainability rather than specific vocational skills. Along with such costs to occupational mobility, vocational training significantly reduces the chances of attending four-year college and limits opportunities for garnering a professional or managerial position (Ainsworth & Roscigno, 2005; Arum & Shavit, 1995).

## VOCATIONAL EDUCATION AS TRACKING

By placing students into college preparatory or vocational tracks, schools act to stratify students—a process that differentially prepares some students for college attendance and others for work. This type of tracking could be interpreted as unproblematic, particularly when the channeling it entails is assumed to be based solely on merit. This, however, may not be the reality. Instead, micropolitical evaluation, including the frequent and questionable use of ''neutral'' standardized tests, may act to reproduce inequality at almost every turn. Thus, students from advantaged families (in terms of class, race, and gender) are more likely to be placed in college preparatory tracks.

But how and why might differential tracking of groups occur? As high school students form goals and aspirations, the adults and peers in their lives easily influence them. If teachers and counselors disproportionately encourage certain students (e.g., minorities, the poor, those who have parents with less education) to enroll in vocational courses, these students may come to believe that they are neither suited for nor capable of success in college preparatory courses. Moreover, low-income and minority parents rarely challenge such school-level decision making, including tracking decisions, because they themselves were tracked in a similar manner, because they trust the judgments of educators, or because they are politically disengaged or feel powerless relative to the educational process. Alternatively, middle-class parents are intimately familiar with how the educational system works and often act to place their children in an advantaged position. Such processes play out both individualistically, as a parent successfully negotiates for his or her child's placement into an advanced class, or collectively, as a group of parents may lobby for curricular development in a particular direction. Questions surrounding the sorting of students into vocational courses or tracks is a relatively understudied topic in the vocational education literature and represents a fruitful avenue for future research.

## CONCLUSION

The literature suggests that higher status students avoid taking vocational education classes. Alternatively, disadvantaged students are funneled into vocational education classes, and this involvement increases the likelihood that they will drop out of high school and decreases the

chances they will attend college. In short, vocational education programs promote very real advantages and disadvantages in the schooling process. They shape which students persist into college and the types of jobs available to them in the local labor market following their exit from high school.

Despite the potential for inequality reproduction, some researchers continue to advocate vocational education as the best way to motivate students to behave and work hard in school. The assumption here is that incentives—in this case, incentives for eventual job placement—are necessary to motivate students (Rosenbaum, 2001). To be sure, this viewpoint is consistent with the original purpose of tracking: to encourage students to resign themselves to their appropriate position in society, to garner marketable skills, and to see their placement as just. This viewpoint, however, is based on an assumption of a fair and meritocratic educational sorting process. The literature on vocational education suggests that this assumption is questionable at best.

## YOUTH CULTURE

The study of youth culture and its formation is diffuse and expansive, charted across a variety of disciplines that include but are not limited to sociology, anthropology, psychology, education, history, literature, and cultural studies. Two central questions have directed the study of youth culture. What are the conditions for the emergence of a mass youth culture? In other words, what forces led to the formation, proliferation, and concentration of youth cultures as they are understood in the early 21st century? How can researchers define and identify a culture or cultures of youth as being distinct from the adult culture or cultures in a particular society?

### DEFINING YOUTH CULTURE

Images of punks, burnouts, mods and rockers, suburban wiggas, goths, cheerleaders, graffiti writers, teenyboppers, skater kids, beats, hippies, zootsuiters, b-boys, DIY kids, lesbian zine-writers, and ravers come to the fore when one thinks about what youth culture is and the groups that constitute it. However, the precise meanings of the terms *youth* and *culture* have been difficult to establish. In response to the ambiguous and historically shifting boundaries that mark age categories—distinct youth cultures are developing earlier in the life course, whereas transitional markers representing adulthood such as marriage increasingly are delayed—and the broad use of the word *culture*, much scholarly discussion has involved matters of definition.

Those who conduct youth studies recognize youth cultures as expressive, emerging in and through a set of shared practices and collective meanings and organized by young people as they navigate a range of material, historical, and ideological forces. In this regard there is both a symbolic basis and a material basis to youth culture. Youth culture constitutes itself as a peer group yet is not homogeneous. An endless proliferation of splintering groups can found among the ranks of contemporary youth. Cultures of youth may be identified in terms of symbolic resources (sneakers, cell phones, iPods, hair extensions, slang, and argot), rituals and practices (car cruising, car racing, body piercing and tattooing, surfing, graffiti writing), and scenes (streets, raves, parking lots, proms, schools, skate parks, arcades).

Generally, scholars agree that youth culture should be regarded as semiautonomous in nature. Youth culture is not something young people create in isolation from the

currents of the mainstream or dominant adult culture of a particular historical moment. Youth culture also is not fully independent of what often is referred to as parent culture, which typically is differentiated from the mainstream by race, ethnicity, and class. For example, the Brown Berets, a cohesive group of working-class Chicano and Chicana students in southern California in the late 1960s, positioned themselves against the White mainstream as they mobilized in support of Chicano studies in universities and improved educational opportunities for Chicano high school students and condemned the oppressive conditions responsible for racial profiling, violence, and poverty in their communities. At the same time they embraced an alternative language of identity from their parents, referring to themselves with proud defiance as Chicano instead of Hispanic. In doing that, they distinguished themselves from the mainstream culture and the parent culture simultaneously (Chávez, 1998).

Many scholars have investigated youth culture as an oppositional culture while recognizing that many of its defining features are not oppositional to the mainstream adult culture or the parent culture. Youth cultures can be part of the mainstream, originating from school-sanctioned activities (e.g., jocks) or being commercially developed (the MTV generation). Youth cultures can be defiant, embracing an ethos of irreverence and abandon, as concern about questions of mobility is suspended temporarily—as in the case of the college panty raids that weakened college administrators' role of being *in loco parentis* in the 1950s—yet also can be squarely mainstream in their orientation to the future.

## CONDITIONS FOR THE EMERGENCE OF YOUTH CULTURE

The changing economic and social reality of childhood and adolescence in North America in the late 1900s set in motion swift changes in the leisure activities of young adults, the spaces they occupied, their activities, and the collective and individual selves they imagined. In the process it created a situation ripe for the emergence of a semiautonomous youth culture. Though a burgeoning youth culture can be traced to the early 1800s with evidence of young groups of men gathering in public settings for festivals and parades, most scholars agree that a mass youth culture emerged in the later part of the 19th century and was firmly a part of the cultural landscape by the mid-20th century.

Most youth historians agree that a confluence of forces combined to form a mass youth culture. In the United States, where a distinct youth culture is most visible, the growing freedom and independence of youth from family life that followed urban and industrial expansion in a modern capitalist nation-state set the stage for increasing school attendance, the emergence of professional psychology, and public campaigns of youth advocacy that together played a role in shaping the boundaries of a mass youth culture.

High levels of age segregation are recognized as a necessary precondition for the emergence of a distinct youth culture. Institutions of mass socialization such as public schools conceived in terms of their potential as a socially integrative force served to cement a society that had been segmented by age. Before the 20th century, few youths attended high school; most worked, often beside adults, in factories and fields. The movement of youth into school meant that young people's lives played out in an institutional setting largely apart from adults, although there is some evidence of distinct youth cultures having taken shape through work before the mass ushering of youth into school. One example is the newsies, indigent boys in their early adolescence who sold newspapers on the streets of New York City, often lived in shared housing, and collectively organized for improved work conditions in the late 1800s.

The character and place of a semiautonomous youth culture was the subject of concern among educators, parents, and social reformers for most of the twentieth century. Youths' growing diversity with the mass influx of immigrants in the late 1800s and the shifting place of young people in a rapidly changing social landscape in the early 1900s fueled anxieties among a generation for whom the ability to supervise all aspects of young people's cultural life was increasingly beyond their grasp, giving rise to moral panics and widespread worry about youth deviance and delinquency.

Changes in the way young people had been culturally identified and constructed as a distinct age group also played a significant role in the formation of a mass youth culture. Beginning in the mid-nineteenth century, young people began to be seen by scholars for the first time as a cohort with distinctive habits and traits. By the 1930s the idea that adolescence is a distinct stage in the life course was entrenched in both the American cultural imagination and scholarly literature. At the threshold of adulthood, adolescence increasingly was treated as a tumultuous stage in the life course, a period of uncertainty and angst over the status and stability of the self. That characterization was influenced by the popularity of professional psychology, with its growing concern for adolescents' "normal" moral and psychological development and departures from that norm. The preoccupation with normal development, combined with widespread worry about youth delinquency and the fact that young adults' lives increasingly were dedicated to activities outside the home, led to concerted efforts to socialize young

people inside and outside school, paving the way for the development of a mass youth culture (Palladino, 1996).

A variety of organized nonschool activities for youths sprang up to ensure their development as morally sound citizens and guard against youth complacency and delinquency, such as President Franklin Delano Roosevelt's youth workers' program. By the mid-20th century, teen canteens, school dances, and sock hops were a mainstay of cultural life for young adults, although race, religion, class, and sex played an influential role in participation in those activities. William Graebner (1990) showed how the sock hop was an event largely attended by White middle-class girls and was intended to protect that group of teenagers from activities organized within working-class, Black, and male youth cultures. Its conservative undertones, especially the selection of music played, kept many young people whose musical tastes were rooted in the emerging youth subcultures and not in the adult-sanctioned youth culture away.

School-sanctioned activities such as proms, student government, and after-school sports in the post–World War II period were also central to an evolving mass youth culture. Shaped by an uneasy cold war climate at home, school-based activities, much like school itself, were organized to create a more cohesive, assimilated, and homogeneous youth cohort. Willingness to participate in mainstream youth cultural activities reflected one's patriotic duty and democratic commitment and also was seen as an expression of essential teenhood by the 1950s.

The expansion of a middle class, its growing prosperity after World War II, rapid suburbanization, and rising consumerism also helped transform the leisure lives of young people and establish a mass youth culture. The growing presence of a consumer market radically transformed the leisure activities of youth as teens, a group that for the first time had disposable income (their incomes were less likely to be directed to family needs and allowance became more common) and thus emerged as a distinct consumer category (Palladino, 1996). The leisure of young adults was reinvented radically around consumption as entire markets developed to produce and sell distinct teen commodities (Palladino, 1996), distinguishing this age group from others.

## THE PROLIFERATION OF CONTEMPORARY YOUTH CULTURES

Since the mid-1940s, leisure and consumption have been central means by which young adults constitute themselves as belonging to distinct cultures, distinguishing themselves not only from other age-based groups but also from one another. The consumer market has played a large role in the expansion of a mass youth culture and the proliferation and splintering of contemporary youth cultures. The consumer market has been a powerful force in organizing the social spaces and social activities of young people, appropriating signs and symbols that already register as repositories for youth culture and style. However, much research on youth culture, rather than seeing that culture as flowing from the market, has recognized that youth cultural groups use the objects offered by a consumer market for their own ends: to construct identities, express in-group solidarity, and define themselves apart from adults and other youth groups. For instance, Sarah Thornton (1996), in an investigation of ravers (those who participate in an underground dance scene emerging in the early 1990s, held in empty warehouses as an alternative to dance clubs), demonstrated how youth develop subcultural distinctions and symbolic boundaries to distinguish the hip from the unhip mainstream within club culture.

The focus on the creative means by which youth used objects and forms available through the mass market may be the legacy of the Centre for Contemporary Cultural Studies (CCCS) of Birmingham and its abiding interest in symbolic resistance by youth, especially young working-class men. CCCS scholars in the 1970s and 1980s attempted to understand the formation of oppositional youth cultures and subcultural styles as expressions of marginalized young people's oppressive structural location and the moral panics that developed around them (Hall & Jefferson, 1976; Hebdige, 1979). Blending ethnography and semiotics (a type of analysis concerned with understanding systems of signs and meanings) to reveal the contested nature of youth cultures, scholarly attention was given to young people's use of resources provided by a consumer market to establish subcultural boundaries and respond to the mainstream. Dick Hebdige's 1979 study of the mods, who used discarded market goods (clothes, records, clubs, hairstyles) as identity markers to craft an alternative youth culture that was defined against other youth cultures belonging to the mainstream, is an important example.

## CURRENT AND FUTURE DIRECTIONS FOR RESEARCH

Although a great deal of research on the formation of oppositional youth cultures has focused primarily on rituals of resistance formed through consumption, a much smaller group of youth scholars has focused on the ways in which collective forms of transformative social action have emerged within youth culture. Musical and (maga)zine-based movements such as the Riot Grrrls have served as important conduits for girls to resist commodification, forge an alternative gender and sexual

order, and articulate a feminist political agenda. Cultural jammers—young activists who protest the corporate control of everyday life—have been successful in disrupting the flow of information to the mass audience.

Far greater attention has been paid to the dynamic ways in which race, disability, ethnicity, sexuality, and gender have intersected in the formation of youth cultural groups in the last decades of the 20th century and the first decade of the 21st. Early youth cultural research focused almost exclusively on male youth cultures but with little attention to gender. The British scholar Angela McRobbie (1991) demonstrated that teenyboppers, who are by definition girls, consumed images of teen idols, courting them in the private space of their bedrooms, where the negotiation of feminine sexuality was a little less uncomfortable because girls were unlikely to have an audience there. In 2006 Amy Best examined how young Asian men struggle to assert their place as men among men and forge a pan-Asian identity in the underground import racing scenes in California against efforts by young men aligned with American muscle cars to discredit them as feminine.

Researchers increasingly have acknowledged that the boundaries of contemporary youth culture occur within a social landscape that has been transformed by globalization, the acceleration of production and consumption in late capitalism, the hypermobility of communication systems, and increasingly sophisticated media. The explosion of the Internet and people's movement into a digital age as "citizen consumers," the expansion of global markets, and the proliferation of global and corporate mediascapes have influenced the complex and historically distinct formations recognized as contemporary youth cultures. Technologies have reordered the social organization, expressive forms, and in-group communication that help constitute distinct youth cultures. Those cultures play out in a virtual world where elaborate cyber networks are forged and new publics are conceived. Important examples include the social utility Facebook and the blogs and online forums dedicated to topics and issues that are resonant with members of youth cultures. This direction is likely to be pursued in future research.

An increasingly global economy and the steady stream of people, cultural ideas, and cultural objects across ever-shifting borders has produced many changes in American youth cultures, impelling scholars of youth studies to examine the formation of youth cultures in a global context. As commercial forms of European and American youth culture from MTV to *Beverly Hills 90210* have been transmitted along global mediascapes, distinct and often hybridized youth cultures have emerged in settings where young people rarely were seen as a group apart from adults, pointing out the idea that youth cultures are the products of historical and cultural change. Another example can be seen among second-generation American youth of the Indian diaspora who combine traditional forms of Bhangra dance with the sampling elements of American hip-hop to forge a distinct club culture and construct race and gender identities as they negotiate a highly commercial American youth culture on the one hand and the nostalgic constructions of a India frozen in time by the parent culture on the other hand (Maira, 2002). Global considerations are also likely to inform future research. Because the social experiences of being young are thought to influence life outcomes in adulthood, youth cultural participation is quite relevant to the narratives that prevail as scholars try to make sense of the life course and understand different life trajectories.

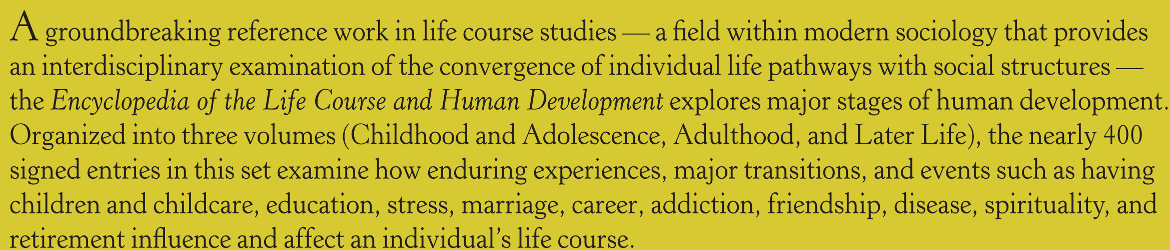
*Amy L. Best*



A groundbreaking reference work in life course studies — a field within modern sociology that provides an interdisciplinary examination of the convergence of individual life pathways with social structures — the *Encyclopedia of the Life Course and Human Development* explores major stages of human development. Organized into three volumes (Childhood and Adolescence, Adulthood, and Later Life), the nearly 400 signed entries in this set examine how enduring experiences, major transitions, and events such as having children and childcare, education, stress, marriage, career, addiction, friendship, disease, spirituality, and retirement influence and affect an individual's life course.

The 500 to 7,000 word entries are written by nationally renowned subject specialists and peer-reviewed by the editor-in-chief, Deborah Carr, and an editorial board of academic experts specializing in life course sociology and human development. Each article concludes with a bibliography pointing users to recent books, journal articles, board-approved Web sites, and proven classics to facilitate further research. The *Encyclopedia of the Life Course and Human Development* covers research methodologies and key data sources, and includes a glossary, thematic outline, annotated bibliography, and cumulative index. Individual entries are enhanced with graphs, charts, and tables, as well as photographs which complement, clarify, and add detail to the text. The set opens with a preface written by the editor-in-chief and each volume contains an introduction to that life stage written by a board member. By bringing together a wide range of information and perspectives on each of the three major stages of life, this set provides students with a basic research guide to life course studies and human development to use along side primary course materials. This set is also a useful reference tool for scholars and practitioners in the fields of life course sociology, developmental psychology, and gerontology.

The *Encyclopedia of the Life Course and Human Development* broadens Gale's collection of encyclopedias in the Macmillan Social Science Library, making it a companion to the *Psychology of Classroom Learning: An Encyclopedia*, the *Encyclopedia of Sex and Gender*, the *Encyclopedia of Race and Racism*, and the *International Encyclopedia of the Social Sciences*.

# *Introduction to Volume 2, Adulthood*

What was the moment when you felt that you were really an "adult"? This is a question that I ask students each year, when I teach my graduate seminar Sociology of the Life Course. Without fail, about two-thirds of the fifteen or so students in my class sheepishly respond, "I don't think I'm an adult yet." Each student—most of whom are in their early or mid-20s—then shares the reasons why they feel they're not quite an adult. "I don't own a home." "I'm still in school and don't really have a job." "I live with my boyfriend, but we're not married yet." "I don't have kids." "My parents still pay for my rent and car insurance."

This exercise reveals just how fuzzy the concept of adulthood is; while age 25 would clearly make one a legal adult, few 25-year-olds "feel" adult today. The life stage of adulthood encompasses three distinct and only partially overlapping components: legal, biological, and social. Consistent with this three-prong conceptualization, dictionary definitions of "adult" include: one who has attained maturity; one who is of legal age; and a fully grown, mature organism. Yet these three transitions rarely occur in tandem, thus contributing to the blurry boundaries demarcating adolescence, adulthood, and old age. For example, according to United States law, one becomes a legal adult at age 18. The biological transition to adulthood typically occurs around age 13, when girls and boys reach puberty. The social transition to adulthood is far less clear-cut, although it is typically conceptualized as the age at which one makes transitions into important social roles such as worker, spouse and parent.

Most Americans agree that a particular cluster of social roles signifies the entry to adulthood. Data from the 2002 General Social Survey (GSS), a large national survey of the United States population, revealed that 96% of Americans say financial independence and full-time work are the defining accomplishments of "adult" life, while 94% believe a young person isn't officially an adult until he or she is able to support a family. Yet national data also show that a surprisingly small proportion of young people have actually made such transitions even as late as age 30. The Census Bureau recently calculated the proportion of Americans who have accomplished all of the following transitions by age 30: left their parents' home, finished school, got married, had a child, and achieved financial independence. In the year 2000, just 46% of women and 31% of men had reached all five milestones. In 1960, by contrast, 77% of women and 65% of men had done so (Furstenberg, Kennedy, McLoyd, Rumbaut, & Settersten, 2004).

The entries in this volume provide answers to questions like what is adulthood, and how has adulthood changed over time. Just as importantly, though, the entries in this volume

show persuasively that there is not a universal conceptualization or experience of "adulthood." Adulthood comprises a series of distinctive stages, including early adulthood and midlife. The ways that individuals experience adulthood also vary widely by birth cohort, gender, social class, race, ethnicity, immigrant status, sexual orientation, and geographic region. Finally, one's experiences in adulthood are molded by early life experiences like one's family background, childhood physical and mental health, and educational attainment. One's adult experiences, in turn, set the stage for one's well-being in later life. The life course framework enables scholars to study adulthood using this critically important *whole lives* perspective.

## THE STAGES OF ADULTHOOD

Adulthood encompasses the age range of 18 to 64. Persons under age 18 are classified as youths, while the years of 65 and above are typically referred to as later life or old age. In 2000, persons ages 18–64 accounted for 62% of the 281.4 million Americans, while the 0–18 and 65+ populations accounted for 26 and 12% of all Americans, respectively (U.S. Census Bureau, 2001). While demographers define adulthood in terms of chronological age alone, the age range of 18–64 is incredibly broad and encompasses (at least) two distinctive adult stages: young adulthood, and midlife.

Young adulthood is typically conceptualized as ages 18–35, while midlife is typically conceptualized as ages 35–64. However, these boundaries are imprecise and are widely debated. Biologists often define life course stages using *physiological markers*. The transition to young adulthood, in this view, would be marked by puberty, or the point when children's bodies mature physically and are able to reproduce. The transition to midlife, by the same token, is defined in terms of the loss of or declines in reproductive capacity. According to this perspective, the "midlife" stage is demarcated by the transition to menopause for women and andropause or "male menopause" for men. Upon menopause, a woman is no longer physically capable of bearing children, while andropause is a time when men's physical vigor and virility starts to fade (although the very existence of andropause is hotly debated, as the encyclopedia entry reveals).

Other perspectives emphasize *psychological maturation* as the criteria for defining adult stages. Erik Erikson's (1950) classic model of adult development proposes that the transition between life course stages is contingent upon the successful and sequential resolution of a series of "crises." Young adults, defined by Erikson as persons ages 19 to 34, must resolve the crisis of intimacy versus isolation. Intimacy refers to one's ability to relate to another human being on a deep personal level. Before forming a committed romantic relationship or enduring friendship, however, one must develop a sense of their own identity. Young people who fail to achieve an intimate relationship with others are at risk of social and emotional isolation. The distinctive challenge of midlife (defined by Erikson as ages 40–65) is to resolve the conflict between generativity versus stagnation. A midlife adult is expected to avoid the lure of self-absorption and to instead become generative—working to preserve values and opportunities that will benefit succeeding generations.

A complementary perspective holds that an individual must accomplish a set of age-defined developmental tasks in order to make the successful progression through adult life course stages. Robert Havighurst (1971) wrote that the developmental tasks or prerequisites for successful maturation of young adults (defined as ages 18–30) included selecting a mate, learning to live with a partner, bearing and raising children, managing one's home, starting a career, taking on civic responsibilities, and establishing a circle of friends, acquaintances or coworkers. Midlife adults, defined by Havighurst as persons ages 30–60, were expected to raise their teenage children to become responsible and happy adults, to assume social and civic responsibility, to achieve and maintain satisfactory performance in one's career, to participate in rewarding leisure time activities, to develop a strong and understanding relationship with one's spouse, to accept and adjust to the physiological changes of middle age, and to adjust to the challenges experienced by one's aging parents.

Both Erikson and Havighurst proposed stage theories, which are based on the presumption that successful adult development requires the sequential completion of a series of tasks or challenges. Yet life course scholars argue that stage theories do not allow for individual-level innovation nor do they reflect the fact that social and historical context can affect whether, when, and in what order one experiences important role transitions, like marriage, childbearing, and first job. Thus, while life course scholars agree that adulthood should be defined in terms of the social roles one holds rather than one's chronological age, they grant more latitude in how and when adults experiences the stages of young adulthood and midlife.

## A LIFE COURSE LENS ON ADULTHOOD: ATTENTION TO DIVERSITY

Life course scholars typically conceptualize life course stages in terms of social roles, as Havighurst did, yet they do not tightly tie their definitions of "adulthood" to chronological age (Riley, Johnson, and Foner, 1972). Rather, they recognize that individual lives reflect the intersection of *biography and history*. As such, the ages at which one achieves particular social roles and statuses—and thus the timing of the transition to both young adulthood and midlife—vary widely across birth cohorts. As noted earlier, in the year 2000, just 46% of women and 31% of men had reached the five milestones believed to define "adulthood." In 1960, by contrast, 77% of women and 65% of men had done so (Furstenberg, Kennedy, McLoyd, Rumbaut, & Settersten, 2004).

Does this mean that younger cohorts of adults, those born in the 1960s, 1970s, and later are less mature than their parents or grandparents? Life course scholars believe the answer is "no." Rather, macrosocial factors including economic restructuring, educational expansion, the advent of effective birth control, and even the recent housing crisis have all contributed to what scholars call the "delayed transition to adulthood." Economic restructuring means that agricultural and manufacturing jobs have disappeared, and have given way to the expansion of the service economy; white-collar and professional jobs require bachelor's and master's degrees, so young people need to remain in school through their 20s and even 30s. Nonmarital cohabitation has become an increasingly acceptable living arrangement, so many young people cohabit with their romantic partner for years before officially tying the knot. The development of effective birth control means that young people can protect themselves against unwanted pregnancy—and the shot-gun, youthful marriages often triggered by such pregnancies. Skyrocketing housing costs mean that many young people can't afford to purchase their own homes, and often must share housing costs with roommates.

It's not just the transition to adulthood that has been delayed in recent years. The transition to midlife also has been delayed, at least if Havighurst's definition of midlife is used as criteria. One reason why the timing of the transition to midlife has been postponed is because this transition is tightly tied to the timing of young adulthood transitions. This pattern reflects the life course theme that the *timing of life events matters* for future transitions and trajectories. For example, life transitions typically viewed as the hallmark of midlife—such as achieving stability in one's career, and launching one's children into adulthood—are happening in one's 50s today, rather than one's 20s. As young people receive more education and enter the job market at later ages, they often do not reach their career peak until their 50s or later. Similarly, parents who have their first child while in their mid 30s do not reach the "empty nest" phase until at least their early 50s, when their 18-year-old child leaves for college. Yet some parents never achieve the empty nest phase, as their children remain in the family home because they cannot afford a place of their own.

Whether, when, and in what order adults experience important life course transitions also varies by social class, race, gender, cultural and geographic context, and immigrant status. For instance, young people from disadvantaged economic backgrounds often cannot afford college, and thus enter into full-time blue-collar or clerical occupations when they are in their late teens. They tend to marry earlier, and have children earlier. As such, they may experience the "empty nest" transition while in their late 30s, while their contemporaries who attended graduate school may be taking care of their newborn babies at that same age.

Social class also affects the timing of midlife and later life transitions. Persons living in economically depressed environments often experience the premature onset of health problems like high blood pressure, heart disease, and diabetes. These health conditions, in turn, can trigger an early transition to retirement or a disability-related departure from the paid work force.

Race also has a powerful effect on the transition to adulthood. Black women are far less likely than their White counterparts to ever marry, and also are more likely to bypass marriage en route to childbearing. For example, while 27% of White women ages 15 and over have never married, this figure is 42% for Black women. Nearly two-thirds of all births to Black women occur out of wedlock, while roughly 35% of White births are nonmarital. However, the meaning of "out of wedlock" birth has changed drastically in recent years, as roughly half of these babies are born to cohabiting couples (Mincieli, Manlove, McGarrett, Moore, & Ryan, 2007). An examination of racial differences in family transitions reveals the life course theme that individuals have *agency and guide their own life course*, within economic and structural constraints. Qualitative research by the sociologists Kathryn Edin and Maria Kefalas shows that young Black women in poor urban neighborhoods recognize that they have very low chances of marrying, and that they intentionally have children at young ages, and out of wedlock—as a way to bring meaning and family relationships into their lives.

## ADULTHOOD: THE BRIDGE BETWEEN CHILDHOOD AND LATER LIFE

Although the encyclopedia comprises the three freestanding volumes on childhood/adolescence, adulthood, and later life these three life course stages cannot be understood in isolation from one another. Childhood economic resources, parent-child relationships, the quality of one's schooling, and one's early physical and mental health set the stage for one's adult accomplishments. The broad range of experiences one has in adulthood—attending college, starting a first job, marrying and having children, progressing in one's career (or making major career changes), participating in social and religious activities, maintaining one's health, one's spending patterns, whether or not one relocates their home, and whether one is either a victim of or perpetrator of crime—all reflect, in part, the experiences one had during the formative years. For example, the life course theme of *linked lives* proposes that the fortunes of generations are closely linked. Children often go on to replicate their parents' experiences—either because they have been socialized to hold values and attitudes similar to their parents, or because they and their parents share the social characteristics—like social class or race—that provide either opportunities or constraints as one negotiates adult roles and transitions.

One's adulthood experiences also set the stage for whether one's later life years are marked by poverty, physical disability, cognitive decline, and social isolation—or financial stability, physical vigor, mental acuity, and social engagement. For example, the type of jobs one holds in adulthood may have long-term implications for late-life physical health and cognitive functioning. Physically grueling jobs, fast-paced jobs that place high demands on their workers yet offer them little control over their schedules, and part-time or seasonal jobs that do not offer health benefits all carry potential harmful consequences for health in later life. Interpersonal relationships and community activities also set the stage for successful or problematic aging; friendships, hobbies, family relationships, religion, and workplace relationships all protect against both physical and mental health declines in the long term.

Although the three life course stages are closely intertwined, and each sets the foundation for the successive stages, life course scholars argue strongly that the influences of early life events on adulthood are neither deterministic nor mechanistic. Rather, life course scholars are interested in documenting patterns of both *stability and change*. Resilience is an important theme in life course research, and the encyclopedia entries document those factors that can "undo" or reverse the effects of a particular adversity or resource that one had early in life. For instance, while social class is a strong determinant of college graduation, the strength of this relationship has varied throughout history. Young women from middle class homes

during the 1950s and 1960s often attended, but did not graduate, college because strong normative pressures during that time period encouraged early marriage (Goldin, 1990). African Americans, especially those from poor homes, had little chance of attending college during the early half of the 20th century, yet historical changes like the 1960s Civil Rights movement, public policy shifts like the establishment (yet ultimate weakening) of affirmative action programs, and normative shifts, where school teachers and guidance counselors offer encouragement to students of color, have contributed to the steady increase in the number of African Americans who earned bachelor's degrees in the late 20th and early 21st century. Although Blacks' rates of college attendance and graduation still lag far behind Whites, this gap—especially for women—has diminished over the past century (Hacker, 1992).

Taken together, the entries in this volume provide an exciting and thought-provoking glimpse in adulthood. We hope readers come away with an appreciation of the diverse ways that adulthood is experienced in both the United States and throughout the world. The life course lens reveals the ways that adults construct their own lives, yet the influences of time, place, and culture are inescapable.

## ABORTION

Induced abortion (henceforth referred to as abortion) is the voluntary termination of a pregnancy by removing an embryo or fetus from a woman's uterus. Abortion can be performed by either surgical or medical methods. In a surgical abortion, a woman undergoes a procedure called manual or vacuum aspiration that is performed by a trained physician. A medical abortion (or non-surgical abortion) is done early in pregnancy (through 9 weeks gestation) through use of a drug or combination of drugs that first causes the termination of the pregnancy and then causes the contents of the uterus to be expelled out of the body. In the United States, the drugs used for medical abortion (i.e., mifepristone, methotrexate, and misoprostol) must be prescribed by a registered physician. Although a woman usually experiences the actual termination of the pregnancy at home, a follow-up visit to a physician approximately 1 to 2 weeks after taking the medication is required to ensure that the abortion was complete.

It is estimated that over one-third of women in the United States has an abortion in their reproductive lifetime, making it a common life event and an important topic of study because abortion affects the lives of thousands of women each year. The decision to terminate a pregnancy or carry it to term has a significant impact on a woman's life course, physically, emotionally, and financially, and may influence her successful achievement of life goals.

### BRIEF HISTORY OF ABORTION IN THE UNITED STATES

Abortion was legal (and quite common) when the United States enacted the Constitution in 1776; but by the early 1900s, it was illegal in all states. In 1973, the United States Supreme Court cases of *Roe v. Wade* and *Doe v. Bolton* declared abortion to be a "fundamental right" rooted in a woman's constitutional right to privacy. In the 1980s and 1990s, the Court recognized the state's interest in "potential life," as evidenced in the cases of *Webster v. Reproductive Health Services* (1989) and *Planned Parenthood v. Casey* (1992), and gave individual states the right to regulate abortion as long as it did not put an "undue burden" on the woman. Since that time, states have introduced and passed several abortion laws that regulate and limit whether, when, and under what circumstances a woman may obtain an abortion (Guttmacher Institute, 2008). State-level laws regulating abortion range from mandatory 24-hour waiting periods, which require a woman to wait a full 24 hours between seeking and obtaining an abortion, information and counseling sessions that sometimes present inaccurate medical information, and restrictions or complete bans on state-level Medicaid funding for low-income women seeking an abortion.

Since 1977, the Hyde Amendment prevents any federal-level Medicaid funds from being used to pay for an abortion unless the pregnancy is the result of rape or incest, or if a woman's life is endangered. In practice, individual states are free to use state-based Medicaid funds to cover abortion, although many choose not to do so. Young women under the age of 18 are particularly affected by state-level restrictions, as many states have either parental consent or parental notification laws in place. These laws severely restrict young women's access to abortion, often resulting in later term abortions or forcing young women to have a child before they are emotionally, financially, or physically prepared to do so.

## THE PREVALENCE AND DISTRIBUTION OF ABORTION

Each year, more than 6 million women in the United States—one in every 10 women of reproductive age (between 15 and 44)—become pregnant, and almost half of those pregnancies are unintentional (Finer & Henshaw, 2006). Approximately 48% of unintended pregnancies end in abortion and, as a result, two out of every 100 women aged 15 to 44 have an abortion each year (Finer & Henshaw, 2005). In 2005, 1.21 million pregnancies were terminated by abortion, making abortion one of the most common surgical procedures in the United States (Jones et al., 2008a). The abortion rate, defined as the number of abortions per 1,000 women of reproductive age in a given year, was 19.4 in 2005, which represents a 9% decline over the previous 5 years and was the lowest rate since 1974. The abortion ratio, defined as the number of abortions per 1,000 live births, indicates that 22% of pregnancies (excluding those ending in miscarriages) ended in abortion in 2005 (Jones et al., 2008a). Almost 90% of abortions are performed in the first trimester of pregnancy (i.e., under 12 weeks of gestation) and 6 in 10 abortions are performed within 8 weeks gestation (Strauss et al., 2007). The proportion of abortions performed very early in pregnancy (at 6 weeks or before) increased from 14% in 1992 to 28% in 2004, most likely due to increased access and use of medical abortion, which the U.S. Food and Drug Administration approved for early abortions in 2000. In 2005, medical abortion accounted for 13% of all abortions, an increase from 6% in 2001 (Jones et al., 2008a).

Not all women in the United States are equally likely to obtain an abortion, however. Hispanic and Black women have abortion rates that are 2 and 3 times higher than the rates of White women, respectively (Strauss et al., 2007). The ethnic disparity in abortion rates reflects the fact that Black women and Latinas have higher rates of unintended pregnancy, and that Black women are more likely to resolve an unintended pregnancy through abortion (Guttmacher Institute, 2005). Black and Hispanic women also are at greater risk of poverty than White women, and poverty increases one's likelihood both of having an unintended pregnancy and of resolving the pregnancy through an abortion. Between 1996 and 2000, abortion rates for nearly all subgroups of women fell, yet rates among poor and low-income women increased. Women below the federal poverty level have abortion rates almost 4 times those of higher-income women (Jones et al., 2002).

The likelihood of having an abortion also varies over the life course, reflecting both biological factors (such as one's physical capacity to reproduce) and social factors (such as one's marital and parental statuses). Many people assume unintended pregnancy and abortion are issues confronted by young women or teenagers only, but the majority of women (56%) having abortions are in their 20s, followed by 30- to 34-year-olds (26%), and then 15- to 19-year-olds (16%) (Strauss et al., 2007). Abortion numbers and rates decline with age because fecundity (i.e., the ability to conceive) declines, use of contraceptive sterilization increases, and more women are married—which makes it easier to use contraceptives effectively and to carry an unintended pregnancy to term. Approximately 86% of abortions occur among unmarried women, including both never-married and formerly married women (Strauss et al., 2007). The proportion of unintended pregnancies terminated by abortion ranges from 67% among formerly married women and 57% among never-married women to 27% among currently married women (Finer & Henshaw, 2006). A commonly held myth is that women have abortions before they begin childbearing, but an estimated 6 in 10 women seeking an abortion are already mothers. Approximately half of women seeking an abortion have already had at least one prior abortion (Jones et al., 2002).

When U.S. women having abortions are asked their religious affiliation, 43% say they are Protestant and 27% say they are Catholic (Jones et al, 2002). Statistically speaking, approximately 51% of women between 18 and 44 in the United States identify themselves as Protestant and 28% as Catholics, which means that the abortion rates for these two groups are lower than that of women reporting other religious affiliations (Guttmacher Institute, 2008). Twenty-two percent of women seeking abortions report no religious affiliation and 8% report "other" affiliations, which may include Jews, Muslims, Buddhists, and Mormons, as well as other smaller religious groups (Jones et al, 2002). In the general population, only 16% of women between 18 and 44 report that they have no religious affiliation and 5% report other affiliations indicating that these two groups have abortion rates that are higher than that of Protestant and Catholic women.

Women's reasons for terminating a pregnancy vary, although over 70% of women report doing so out of concern for or responsibility to other people or because they cannot afford a baby at that time (Jones et al., 2008b). Other common reasons are related to an interruption of school or career, not wanting to be a single mother, or having already completed childbearing. These reasons underscore the important role of abortion in a woman's life course. For a young woman, an unwanted or mistimed birth may prevent her from pursuing her educational or career goals. For an older woman, an unwanted or mistimed birth may directly affect her ability to provide for children that she already has.

## SHORT- AND LONG-TERM CONSEQUENCES

Abortion is a very safe surgical procedure when performed by a trained medical professional and under sanitary conditions. The risk of death associated with safe abortion is low and the risk of major complications is less than 1% (Grimes, 2006). The earlier in a pregnancy an abortion is performed, the safer the procedure; when an abortion is performed under 12 weeks gestation, the risk of death is 0.4 per 100,000 abortions, but that number dramatically increases to 8.9 deaths per 100,000 abortions when an abortion is performed at 21 weeks gestation or beyond (Bartlett et al., 2004). Fortunately, fewer than 2% of abortions are performed after 20 weeks gestation. The most common causes of abortion-related death are infection and hemorrhage, accounting for over 50% of deaths (Bartlett et al., 2004). On average, eight women each year die in the United States from induced abortion, compared with about 280 who die from pregnancy and childbirth, excluding abortion and ectopic pregnancy.

Since the early 1980s, researchers have investigated the long-term effects of voluntarily terminating a pregnancy. Most research evidence indicates that abortion is safe and carries little or no risk of fertility-related problems, cancer, or psychiatric disorders (Boonstra et al., 2006). Studies indicate that vacuum aspiration—the method most commonly used during first trimester abortions—poses virtually no long-term risks of future fertility-related problems, such as infertility, ectopic pregnancy, spontaneous abortion, or congenital malformation (Hogue et al., 1999). In 1996, a meta-analysis of several studies suggested that there was a significant positive association between abortion and breast cancer; but since then, several reviews by experts concluded that there is not a statistically significant association. In 2003, the National Institute of Health (NIH) declared that the evidence shows that "induced abortion is not associated with an increase in breast cancer risk."

One of the most contested and controversial abortion-related issues is the association between abortion and women's mental health. Opponents of abortion have claimed that abortion is bad for women's mental health and leads to negative psychological outcomes such as depression and anxiety. In 1987, at the request of President Ronald Reagan (1911–2004), Surgeon General C. Everett Koop (b. 1916) reviewed the evidence linking abortion to negative mental health outcomes and stated that he could not come to a conclusion because of the serious methodological flaws of the studies, but that he perceived psychological problems related to abortion to be "miniscule from a public health perspective" (Koop, 1989). Since that time, numerous studies have attempted to link abortion to a range of conditions, including psychiatric treatment, depression, anxiety, substance abuse, and death (Fergusson et al., 2006). Many studies, however, have serious methodological flaws (e.g., failure to take into account important preexisting psychological conditions and other important life factors) that make it impossible to infer any type of causal relationship (Boonstra et al., 2006).

Several well-designed research studies and reviews have found no significant association between abortion and women's long-term mental health (Bradshaw & Slade, 2003). Some of the most conclusive evidence comes from a large-scale, prospective cohort study of 13,000 women in the United Kingdom, which compared women who terminated a pregnancy to women who carried the pregnancy to term. The findings indicate no difference in the psychiatric outcomes between the two groups of women. (Gilchrist et al., 1995).

Although researchers have not found strong evidence linking abortion and women's long-term mental health, opponents of abortion have successfully created the concept of a "postabortion syndrome," suggesting that women who have abortions suffer from symptoms similar to combat veterans and victims of natural disasters, rape, and child abuse (Speckhard & Rue, 1992). As of 2008, postabortion syndrome is neither supported by empirical evidence, nor is it recognized by the American Psychological Association or the American Psychiatric Association. Nevertheless, many antiabortion researchers (and lay people) continue to attribute negative postabortion emotions to the single act of having an abortion instead of taking into consideration the multitude of factors that may affect a woman's emotional adjustment after an abortion, including social stigma, the unintended pregnancy itself, preexisting mental health conditions, and other life circumstances.

The decision to have an abortion is difficult and complex. It occurs in the often-stressful context of experiencing an unintended pregnancy. Sociological research indicates that perceived social support is directly related to feelings of well-being and may reduce or buffer against adverse consequences of a stressful life event (Major et al., 1990). Perceived social support is defined as information or actions (real or potential) leading individuals to believe that they are cared for, valued, or in a position to receive help when they need it. Several studies have found a positive relationship between perceived social support (from partner, family, and friends) and postabortion well-being; women who perceive their family and friends to be supportive of their decision consistently rate higher on measures of well-being than women who perceive their friends and family to be less than supportive (Major et al., 1997). Perceived social support may be particularly

important for successful adjustment to abortion because of the strong moral sanctions against abortion in U.S. society. Family members' and friends' attitudes about abortion (as well as those of the general public) have the potential to influence a woman's perceptions of stigmatization, which may influence disclosure about abortion and access to social support.

Some women may feel guilt, shame, or embarrassment after having an abortion, but it is not yet understood whether these feelings are rooted in personal conflict about the abortion or in concerns about how others view her decision (i.e., feeling stigmatized by the abortion). The social stigma associated with abortion, much like stigma attached to other moral issues or behaviors, can have distressing consequences. For women, the stigmatization associated with abortion can confuse or delay an already challenging decision-making process, it can cause unnecessary guilt or remorse, and it can lead to feelings of alienation and isolation.

## THE IMPACT OF ABORTION POLICY

Abortion is safe and legal in the United States and it is estimated that one out of every three American women will have at least one abortion in their reproductive lifetime. Despite the legal status and common occurrence, abortion remains extremely politicized with people defining themselves as either pro-choice or pro-life, positions that are often aligned with identifying oneself as a Democrat or Republican. Pro-choice individuals and reproductive rights advocates maintain that women have a fundamental right to decide to carry a pregnancy to term and that the government should not control a woman's right to choose. By contrast, opponents of abortion (often termed *pro-lifers*) usually believe that life begins at conception and that abortion is murder, and thus an immoral and illegal act. Given the controversial nature of abortion, it is sometimes portrayed as a statistically rare and potentially distressing event that requires excessive restrictions and regulations. This depiction can create a hostile environment that fosters judgment and criticism about women who choose to terminate an unwanted pregnancy, and may directly impact the life course of a woman who prefers to terminate an unintended pregnancy but does not have financial, geographic, or social resources to do so.

Having an abortion may also significantly influence a person's life course depending on their own lived experiences. The ability to decide when and how many children to have is crucial to achieving life goals and abortion policies that severely limit whether, when, and under what circumstances a woman may obtain an abortion have the potential to alter a woman or couple's personal, educational, and career goals. Highly restrictive policies that limit access to abortion (geographically and financially) may be particularly injurious to women with the fewest economic resources. Limited access to abortion may force women to carry unintended pregnancies to term, which makes it extremely difficult for women to rise out of poverty and make a better life for themselves and their families.

Conducting rigorous and scientifically objective research on abortion is difficult for several reasons: underreporting of abortion on surveys and questionnaires; stigmatization of the issue that prevents people from talking about it openly; and biased research intended to strengthen arguments in defense of one particular side of the abortion debate. Nonetheless, well-designed abortion research is critical to understanding the role and impact of abortion in women's lives.

SEE Volume 2: *Adoptive Parents.*

## ADOPTIVE PARENTS

Adoption is the transfer of parental rights and obligations to a person or persons other than the biological parents of a child. Ancient records, including those from Babylonia and China, show that the practice of adoption has existed in various forms throughout history. It has been utilized for reasons as diverse as ensuring family lineage and inheritance, strengthening political and military alliances, and promoting children's well-being. Although adults are sometimes adopted, the vast majority of adoptions today are of minor children for the purpose of family formation.

### ADOPTIVE FAMILIES

Adoptive parents assume parental rights and responsibilities for a person who is not their biological offspring. In formal adoption, the parental rights of biological parents are legally severed and the courts oversee an official transfer of parental rights to the adoptive parents. Approximately 127,000 children were formally adopted in the United States during 2000–2001. Census 2000, the first U.S. census to collect data specifically on adopted children, found that there are more than 2.1 million adopted children in the United States, more than 1.6 million of whom were under age 18. According to some estimates, 2 to 4% of American families have an adopted child.

Married couples are the largest percentage of adopters, although adoption rates among unmarried couples and single people are increasing. Adoptive parents are generally older and have been married longer than biological parents. Rates of adoption of unrelated children are higher among Whites than African Americans or, particularly, Hispanics. They are also higher among those with higher levels of education and income. Adoptions of children already related to the adoptive parents before the adoption, however, appear to be higher among persons of color and those with lower levels of education and income. The overall rate of adoption among African Americans is historically higher than that of Whites.

The most common form of adoption (more than 40% of all domestic adoptions) is stepparent adoption. Under the law, a stepparent adoption occurs when the partner of one of the child's biological parents legally replaces the other biological parent as the second parent to the child. The most common scenario is when a biological parent remarries, although cohabiting heterosexual or same-sex partners may qualify in some cases.

Single adults, primarily women, are increasingly becoming adoptive parents. Although studies report outcomes among these adoptions that are comparable with two-parent adoptions, single-parent adopters may still encounter a preference for couple adopters among agency staff or biological mothers seeking to place a child for

adoption. One result is that these single adopters may face lengthy waits or end up adopting children who may present particular parenting challenges, such as older, special-needs children. Some single adopters who desire a young child, and who have the financial means to do so, adopt internationally to shorten the wait and increase the likelihood of finding such a child.

Gay and lesbian couples are another kind of adoptive parent. No clear data exist about the number of gay and lesbian adoptive parents, but a small but growing research literature addresses their experiences and family well-being. Evidence suggests these adoptions are as successful in terms of forming well-adjusted, supportive families as adoptive families in general. However, gay and lesbian adoption seekers may still experience resistance by some adoption agency staff, statutory restrictions, or negative public perceptions.

In recent decades, rates of international adoption—that is, adoptions of children born outside the United States—have increased significantly. More than 13% of the adopted children recorded by the 2000 Census were adopted from other countries. The number of immigrant visas issued by the U.S. State Department for international adoptions tripled between 1990 and the mid-2000s. Prior to the 1990s, the majority of international adoptions by U.S. parents were of Asian children, largely from South Korea. By 2008 China, Guatemala, and Russia provided the largest number of children adopted internationally by American parents.

International adoptions have increased in popularity among Americans seeking to adopt infants, to avoid often lengthy waits for children in the United States and to minimize the possibility that birthparents will try to reclaim their child. Age restrictions for adoptive parents vary among countries and may provide more options than some U.S. agencies. Although many countries allow singles to adopt (particularly women), some do not allow same-sex couples to do so. International adoptions can also be expensive relative to domestic adoption, with costs sometimes ranging into the tens of thousands of dollars. In addition to any agency fees and travel costs for the child, adoptive parents may be required to make one or more trips to the country from which their child is being adopted. Children adopted internationally may also have health concerns related to lengthy stays in orphanages, traumas, or illnesses such as HIV/AIDS that add expenses. Whereas most children adopted internationally do well, preadoption experiences such as institutionalization may lead to long-term emotional and behavioral problems or learning deficits. Accordingly, adoptive parents are advised to address potential problems with appropriate pre- and post-adoption support.

## ADOPTIVE PARENTS AND THE FAMILY LIFE COURSE

"Adoption is not a one-time event, but a life-long experience" (Palacios, 2006, p. 496). As such, Palacios adds, researchers and practitioners are increasingly taking a family life-course perspective in addressing adoptive families. The circumstances, composition, and experiences of these families vary widely. Some common themes of research on adoptive parents, however, can be identified.

Researchers have long been interested in the decisions, motivations, and preparations to adopt. Most parents adopt because of their love for children and their desire to parent. For some, the decision to adopt is made only after a diagnosis of infertility or failed attempts to become pregnant using assisted reproductive technologies. Adoptive parents experience the scrutiny of investigations and home studies to establish parental suitability as well as the potentially lengthy wait, financial costs, and uncertainties involved in adoption. Although most adoptive parents successfully overcome the challenges involved, this transitional stage can be a stressful time. From the initial phases of the adoption process onward, social supports are important in ameliorating stressors.

Other research has looked at adoptive parents' experiences and concerns. Adopting older children can be particularly stressful. Not only are these parents faced with the challenges of parenting an adolescent, they may be dealing with the child's history of negative experiences in his or her biological or foster family. The strength of parent–child bonding and attachment is a frequent concern, although rates of serious attachment disorders, such as the inability to form close emotional ties, appear to be low.

Most adoptions are successful; family members adjust well and stay together as a family unit. Post-adoption services may provide continued family supports after an adoption is finalized to help ensure this success. Such services may include support groups, access to case workers, and family therapy. Their availability and range varies widely by such factors as state, agency, provider accessibility, and cost. Additionally, adoptive parents may benefit from counseling throughout the adoption process. Counseling may help parents to deal with preadoption issues such as any emotions evoked by their fertility experience, adjustment to parenthood, dealing with moody teens, or other issues that might arise.

Some adoptions are not successful. Estimates suggest that a small percentage (perhaps 15% or less) of all adoption placements disrupt, meaning that the adoption is never finalized in court. Adoption dissolution, when a child is returned to state custody after a legal adoption, is even more rare. Adoptions of teens or of children who

exhibit psychological or behavioral problems are most likely to disrupt. Case workers and post-adoption services and supports can be especially crucial in helping avoid disruption and dissolution. When adoptive parents divorce, adopted children are legally treated as biological children would be treated; however, some advocates argue that they may experience especially negative emotional impacts in such an event, reasoning that the adoptive children have already "lost" one set of parents (their biological parents), and this may compound feelings of loss and trauma.

## PUBLIC POLICY AND ADOPTIVE PARENTING

Providing homes and post-adoption services for special-needs children have been emphasized in recent research and policy. *Special needs* children are often children in the foster care system who are considered hard to place because of their older age, disability or health issues, race or ethnicity, or wish to stay together with siblings. Research shows that most special-needs adoptions have satisfactory outcomes for both the child and the adoptive parents. However, some adoptive parents of special-needs children will encounter high levels of stress and children's behavioral or educational problems. They may especially benefit from specific support services. Child welfare systems continue to struggle with many policy issues directly related to special-needs adoption to include the provision of adoption subsidies and medical care, legal and process delays in placing children for adoption while they are younger and have spent less time and suffered less potential damage in the foster care system, and recruiting enough adoptive parents (particularly minorities) to meet the needs of children waiting to be adopted.

Although African American families have historically adopted at higher rates than Whites, the high number of African American children in the foster care system overwhelms the number of Black families willing to adopt. Research finds that children adopted interracially generally grow up well adjusted with no racial identity problems. Factors such as the age of the child when adopted and parenting quality have been shown to be more important to outcomes than the racial composition of the family. However, whether African American children should be adopted by White families has been the subject of more than three decades of sometimes contentious debate. In 1972 the National Association of Black Social Workers equated interracial adoption to cultural genocide. Child welfare advocates for the next two decades often supported intraracial placement. It was not until 1997 that federal legislation addressed this issue, prohibiting race from being the sole determining factor in adoption placement.

Recent decades have also seen debate over sharing adoptive familial relationships and information. Depending on the level of "openness" in an adoption, adoptive parents and children may have ongoing contact with the biological parent(s) (*open adoption*), they may share information with the birthparent(s) only through an intermediary such as a social worker (*mediated adoption*), or they may have little or no identifying information about birthparents (*closed adoption*). Closed adoption was widely practiced during the mid-20th century in an effort to protect adopted families from public scrutiny and stigmatization characteristic of the period. Social changes during the 1980s, fed by reduced stigma, growing research on negative effects of secrecy, and activism by birthparents and birth children trying to reunite led to increasingly open adoption practices. By 2000 various types of adoption registries had been established in over half of the states to facilitate the process of adopted children and their birthparents locating each other. Thus, adoptive parents and their children increasingly have access to information about, or a relationship with, the birthparents and can share pertinent information such as health and genetic history.

# AGENCY

Agency refers to the human capability to exert influence over one's functioning and the course of events by one's actions. The concept of agency is based on a view of human nature that has changed markedly over time. Early and medieval theological thought placed agentive power in a divine being. Following this, evolutionism relocated agentic power in environmental pressures acting on random gene mutations and reproductive assortment of new combinations of genes. This regulatory process is devoid of deliberate plans or purposes. The symbolic ability to comprehend, predict, and alter the course of events confers considerable functional advantages. The evolutionary emergence of language and cognitive capacities provided the means for supplanting aimless environmental selection with cognitive agency. Human forebears evolved into a conscious agentic species (Bandura, 2008). This advanced symbolizing capacity enabled humans to transcend the dictates of their immediate environment and made them unique in their power to shape their circumstances and life courses. Through cognitive self-guidance, humans can visualize futures that act on the present; construct, evaluate, and modify alternative courses of action to gain valued outcomes; and override environmental influences.

## CORE PROPERTIES OF HUMAN AGENCY

There are several core properties of human agency (Bandura, 2006). One such property is intentionality. People form intentions that include action plans and strategies for realizing them (Bratman, 1999). The second property involves the temporal extension of agency through forethought. This includes more than future-directed plans. People set goals for themselves and foresee likely outcomes of prospective actions to guide and motivate their efforts anticipatorily. When projected over a long-term course on matters of value, a forethoughtful perspective provides direction, coherence, and meaning to one's life.

Self-reactiveness is the third agentic property. Agents are not only planners and forethinkers, they are also self-regulators. Having adopted an intention and action plan, one cannot simply sit back and wait for the appropriate performances to appear. The translation of plans into successful courses of action requires the self-management of thought processes; motivation to stick with chosen courses in the face of difficulties, setbacks, and uncertainties; and emotional states that can undermine self-regulatory efforts.

The fourth agentic property is self-reflection. People are not only agents of action, they are self-examiners of their own functioning. Through functional self-awareness, they reflect on their personal efficacy, the soundness of their thoughts and actions, the meaning of their pursuits, and can make corrective behavioral adjustments, if necessary, to change existing life course patterns (Bandura, 1986). The capability to reflect upon oneself and the adequacy of one's thoughts and actions is the most distinctly human core property of agency.

## MODES OF AGENCY

People exercise their influence through different forms of agency—including personal, proxy, and collective agency (Bandura, 1997). In personal agency exercised individually, people bring their influence to bear on what they can control directly. However, in many spheres of functioning, people do not have direct control over conditions that affect their lives. In such cases, they exercise proxy agency. They do so by influencing others who have the resources, knowledge, and means to act on their behalf to secure the outcomes they desire. For example, children work through parents to get what they want, marital partners through spouses, employees through labor unions, and the general public through their elected officials. However, people often turn to others in areas of functioning where they can exercise direct control but choose not to because they have not developed the competencies to do so, they believe others can do it better, or they do not want to saddle

themselves with the work demands, stressors, and onerous responsibilities that personal control requires.

People do not live their lives in social isolation. Many of the things they seek are achievable only by working together. In the exercise of collective agency, they pool their knowledge, skills, and resources, and act in concert to shape their future. In the collective mode of agency, participants have to achieve a unity of effort for a common cause within diverse self-interests. To do so they have to distribute and coordinate subfunctions across a variety of individuals.

Cultures that are individually oriented tend to favor self-initiative and the exercise of personal agency. Those that are collectively oriented place greater emphasis on group interests and collective forms of agency. However, cultures are internally diverse social systems, not monoliths. Diversity in lifestyles and ways of life demands calls for different forms of agentic practices. The distinctive blend of individual, proxy, and collective agency varies cross-culturally. But everyday functioning requires all three forms of agency to make it through the day wherever one lives.

## SELF-EFFICACY FOUNDATION OF AGENCY

Among the mechanisms of human agency, none is more central or pervasive than beliefs of personal and collective efficacy (Bandura, 1997; Schwarzer, 1992). This core belief is the foundation of human agency. Unless people believe they can produce desired effects and forestall undesired ones by their actions, they have little incentive to act or to persevere in the face of difficulties. Whatever other factors serve as guides and motivators, they are rooted in the core belief that one has the power to affect changes by one's actions.

Belief in one's efficacy operates through its impact on cognitive, motivational, affective, and decisional processes. People of high efficacy set challenges for themselves and visualize success scenarios that provide positive guides for performance. Those who doubt their efficacy visualize failure scenarios and tend to dwell on things that can go wrong, which undermines performance. A major function of thought is to enable people to predict events and to exercise control over them. People of high efficacy show greater cognitive resourcefulness, strategic flexibility, and effectiveness in managing their environment.

Efficacy beliefs play a central role in the self-regulation of motivation as well. People of high perceived efficacy set motivating goals for themselves, expect their efforts to produce favorable results, and view obstacles as surmountable or as challenges that can be overcome. People's beliefs in their coping efficacy also affect the quality of their emotional life. Those who believe they can manage threats and adversities view them as less inimical, are less distressed by them, and act in ways that reduce their aversiveness, or neutralize them. People have to live with a psychic environment that is largely of their own making. Beliefs about coping efficacy facilitate control over perturbing and dejecting brooding over problems.

People are partly the products of their environments. By choosing their environments and the activities they engage in, people can have a hand in what they become. In self-development through choice processes, destinies are shaped by selection of environments known to cultivate valued potentialities and lifestyles.

## INTERPLAY OF HUMAN AGENCY AND SOCIAL STRUCTURE

Personal agency operates within a broad network of socio-structural influences. These social systems are devised to organize, guide, and regulate human affairs in diverse spheres of life by authorized rules, sanctions, and enabling resources. The development of social systems and the way in which they exercise their influence is not disembodied from the behavior of individuals. People are contributors to their lived environment not just products of it.

Social systems are created and changed by human activity (Elder, 1994; Giddens, 1984), largely through the exercise of collective agency. The authorized rules and practices of social systems, in turn, influence human development and functioning. However, as already noted, in agentic transactions people are contributors to their life conditions, not merely conduits through which socio-structural influences exert their effects. These social influences operate, in large part, through psychological mechanisms. Hence, with the societal rule structures, there is a lot of personal variation in the interpretation, adoption, enforcement, circumvention, and opposition to societal prescriptions and sanctions.

## EXERCISE OF AGENCY OVER THE LIFE COURSE

Different periods of the life course present new types of competency demands for successful functioning (Bandura, 1997). Changes in roles, aspirations, time perspective, and social systems over the course of life affect how people structure, regulate, and evaluate their lives. Infants' exploratory experiences, in which they see themselves produce effects by their actions, provide the initial basis for the development of a sense of agency (Kagan, 1981). Recognition of personal causation is socially enhanced by linking outcomes closely to an infant's actions, by using aids to channel the infant's attention when there is a temporal disconnect between their actions and the outcomes they

are producing, and by heightening the salience and functional value of the outcomes.

There is also a good deal of intentional guidance in fostering young children's agentic capabilities. Parents create highly noticeable proximal effects for their children's actions, segment activities into manageable subskills, and provide their children with objects within their manipulative capabilities that enable them to produce desired outcomes. Through these mastery experiences, young children enlarge their repertoire of basic physical, social, linguistic, and cognitive skills for comprehending and managing the many challenges they encounter daily.

The initial efficacy experiences are centered mainly in the family. But as the growing child's social world expands into the larger community, peers become increasingly important in the formation of a child's sense of efficacy. In the context of peer relations, social comparison comes strongly into play in judging personal efficacy. During the crucial formative period of a child's life, the school functions as the primary agency for the cultivation and social validation of cognitive competencies essential for participating effectively in the larger society. Students' beliefs in their capabilities to regulate their learning activities and to master academic activities affect their academic aspirations, interests, and accomplishments (Pajares & Schunk, 2001).

As adolescents approach the demands of adulthood, they must learn to assume increasing responsibility for themselves in almost every aspect of life. This requires mastering many new skills and the ways of adult society. Learning how to deal with pubertal changes, emotionally invested partnerships, and sexuality becomes a matter of considerable importance. The task of choosing what educational or career paths to pursue also looms large during this period. These are but a few of the areas in which new competencies and self-beliefs of efficacy have to be developed (Pajares & Urdan, 2006). With growing independence during adolescence, some experimentation with risky behavior is not all that uncommon. Adolescents expand and strengthen their sense of efficacy by learning how to deal successfully with potentially troublesome matters in which they are unpracticed as well as with advantageous life conditions.

Adolescence has often been characterized as a period of psychosocial turmoil. While no period of life is ever free of problems, contrary to the stereotype of *storm and stress*, most adolescents negotiate the important transitions of this period without turbulent discord. The ease with which the transition from childhood to the demands of adulthood is made depends on the strength of personal efficacy built up through prior mastery experiences.

In young adulthood people have to learn to cope with many new demands arising from lasting partnerships, marital relationships, parenthood, and occupational careers (Bandura, 1997). Beginning a productive occupational career poses a major transitional challenge in early adulthood. Perceived self-efficacy shapes career paths (Lent, Brown, & Hackett, 1994) and how other evolving demands of young adulthood are managed. By the middle years people settle into established routines that stabilize their sense of personal efficacy in the major areas of functioning. However, the stability is shaky because life conditions do not remain static. Rapid technological and social changes constantly require adaptations calling for reappraisals of agentic capabilities.

The efficacy issues with advanced age center on further self-assessment and misappraisals of personal capabilities. Biological conceptions of aging focus extensively on declining abilities, as many physical capacities do decrease as people grow older. However, psychological functioning follows different trajectories of change for different abilities. Some improve, others remain stable, and still others decline (Baltes & Baltes, 1986). Gains in knowledge, skills, and expertise can compensate for some loss in physical reserve capacity. By its effects on proactive engagement in activities, perceived efficacy contributes to social, physical, and intellectual functioning, as well as to emotional well-being over the adult lifespan.

The course of aging is affected by the societal structures within which it occurs. Older people in the early 21st century are healthier, more knowledgeable and intellectually agile, and more proactively oriented toward life than previous generations. These changes are creating a structural lag in which people are growing older more efficaciously, but in which societal institutions and practices are slow in accommodating their expanded potentials (Riley, Kahn, & Foner, 1994). Hence, some of the declines in functioning with age result from divestment of the social and structural supports for it, as is the case of mandatory retirement and loss of roles that give meaning and purpose to one's life.

## GROWING PRIVACY OF HUMAN AGENCY

The revolutionary advances in communications technology are transforming the nature, speed, reach, and loci of human transactions. These transformative changes are creating greater opportunities for people to more effectively shape the courses their lives take. In the past, for example, students' educational development was dependent on the quality of the schools to which they were assigned. Now they have the best libraries, museums, and multimedia instruction at their fingertips through the global Internet. They can educate themselves independently of time and place. The Internet technology similarly gives people a greater chance to participate in social and political activities in their own way at their

own time. As these examples illustrate, the exercise of agency takes on added importance in this electronic era.

## AIDS

Acquired immunodeficiency syndrome (AIDS) is a disease found worldwide that afflicts both adults and children, has a high degree of mortality, and affects the well-being of families, communities, and entire nations. AIDS is an infectious disease caused by a virus, human immunodeficiency virus (HIV). The virus destroys a person's immune system, thus allowing opportunistic infections to affect his or her body. HIV is found in semen, blood, and vaginal and cervical secretions, with the highest concentrations found in semen and blood. Unprotected vaginal or anal sex places people at a high risk of contracting HIV. AIDS is a fatal disease, and at present there is no cure or vaccine. Thus control of the global AIDS pandemic relies heavily on prevention education, often a formidable challenge.

The HIV and AIDS pandemic is centered in sub-Saharan Africa where it is devastating the population, killing adults in what should be the prime of their lives, and leaving millions of children—some of whom are infected themselves—without parents. Multiple generations in some families have HIV or AIDS in both developed and developing countries. The pandemic has existed since the early 1980s, and the disease itself, as well as the population changes brought about by AIDS deaths, has widespread implications for public health, human rights, development, and national security. HIV and AIDS have proven to be difficult to control through primary and secondary prevention efforts. Primary prevention aims to prevent uninfected individuals from becoming infected whereas secondary prevention seeks to prevent those already infected from infecting others.

Originally AIDS was not a disease that spanned the life course because of its high mortality. Individuals did not live with and experience the disease over their life course. In the early years of the epidemic, persons with HIV or AIDS would usually live 6 to 12 months at most, which led to a heavy demand for hospice care (Stine, 2004). In the early 21st century, advances in antiretroviral therapy for HIV and AIDS allow persons with access to this therapy to have an improved quality of life and increased life expectancy. In the United States, the average time from infection with HIV to an AIDS diagnosis without treatment is 11 years, and this period is longer with treatment (AVERT, 2008). Because of longer life expectancies and a lower death rate, there is less need for hospice care. Drug therapies allow HIV and AIDS to be managed over the life course in a manner similar to the management of chronic diseases. As a result, the HIV and AIDS population has aged over the course of the epidemic in the United States. As the HIV and AIDS population continues to age, there will be a greater need for long-term care. This pattern is specific to the United States and other developed countries in which there is better access to antiretroviral therapies than in sub-Saharan Africa.

AIDS has a long latency from the time of infection with HIV to the onset of symptoms. New AIDS diagnoses

do not necessarily represent new infections because people may have actually had HIV for years prior to the onset of AIDS symptoms. This long latency has presented challenges for control because infected, asymptomatic persons may unknowingly infect others. It is estimated that about one-fourth of those infected with HIV do not know it (Macfarlane, 2008). Both primary and secondary prevention are important in the global control of HIV and AIDS.

## TRANSMISSION OF HIV AND AIDS

Sexual transmission is the primary means by which people become infected with AIDS throughout the world. Symptoms (which were later retrospectively diagnosed as AIDS) first appeared in gay men in the United States in 1981 (Centers for Disease Control, 1981). From the beginning of the U.S. epidemic, gay men have comprised the largest group of cases. Although homosexual transmission remains the largest route of transmission in the United States, heterosexual transmission has grown over the years. Heterosexual transmission is the more common means of infection in other parts of the world.

Other transmission routes in the United States include infection from sharing drug-injection equipment, contaminated blood products (affecting hemophiliacs and transfusion recipients), contaminated organs (affecting transplant recipients), and needlestick injuries (affecting health care workers). Because blood and blood products have been screened for HIV since 1985, the incidence of cases among hemophiliacs and transfusion recipients is lower compared to the early years of the epidemic.

## SOCIAL PATTERNING OF HIV AND AIDS

From the beginning of the epidemic, the majority of U.S. AIDS cases have been male, although women comprise an increasingly larger percentage of cases from heterosexual transmission (Macfarlane, 2008). Women are more vulnerable to HIV infection than men because there are high concentrations of HIV in semen and women have more mucosal area that is exposed for longer periods of time. Heterosexual transmission is the only category in which female cases exceed male cases. This gender difference has existed since the beginning of the epidemic. There is a close tie between transmission by sharing drug-injection equipment and heterosexual transmission, as many people infected through heterosexual transmission are female sex partners of male drug users. There is also a close tie between heterosexual transmission and perinatal transmission, because most infants with HIV or AIDS are infected by their mothers through perinatal transmission. Many infants perinatally infected with HIV, particularly those with access to antiretroviral therapy, have been able to reach adolescence and adulthood.

| | Adults & children living with HIV | Adults & children newly infected with HIV | Adult prevalence [%] * | Adult & child deaths due to AIDS |
|---|---|---|---|---|
| Sub-Saharan Africa | 24.7 million [21.8 – 27.7 million] | 2.8 million [2.4 – 3.2 million] | 5.9% [5.2% – 6.7%] | 2.1 million [1.8 – 2.4 million] |
| Middle East & North Africa | 460 000 [270 000 – 760 000] | 68 000 [41 000 – 220 000] | 0.2% [0.1% – 0.3%] | 36 000 [20 000 – 60 000] |
| South and South-East Asia | 7.8 million [5.2 – 12.0 million] | 860 000 [550 000 – 2.3 million] | 0.6% [0.4% – 1.0%] | 590 000 [390 000 – 850 000] |
| East Asia | 750 000 [460 000 – 1.2 million] | 100 000 [56 000 – 300 000] | 0.1% [<0.2%] | 43 000 [26 000 – 64 000] |
| Latin America | 1.7 million [1.3 – 2.5 million] | 140 000 [100 000 – 410 000] | 0.5% [0.4% – 1.2%] | 65 000 [51 000 – 84 000] |
| Caribbean | 250 000 [190 000 – 320 000] | 27 000 [20 000 – 41 000] | 1.2% [0.9% – 1.7%] | 19 000 [14 000 – 25 000] |
| Eastern Europe & Central Asia | 1.7 million [1.2 – 2.6 million] | 270 000 [170 000 – 820 000] | 0.9% [0.6% – 1.4%] | 84 000 [58 000 – 120 000] |
| Western & Central Europe | 740 000 [580 000 – 970 000] | 22 000 [18 000 – 33 000] | 0.3% [0.2% – 0.4%] | 12 000 [<15 000] |
| North America | 1.4 million [880 000 – 2.2 million] | 43 000 [34 000 – 65 000] | 0.8% [0.6% – 1.1%] | 18 000 [11 000 – 26 000] |
| Oceania | 81 000 [50 000 – 170 000] | 7100 [3400 – 54 000] | 0.4% [0.2% – 0.9%] | 4000 [2300 – 6600] |
| TOTAL | 39.5 million [34.1 – 47.1 million] | 4.3 million [3.6 – 6.6 million] | 1.0% [0.9% – 1.2%] | 2.9 million [2.5 – 3.5 million] |

* The proportion of adults [15 to 49 years of age] living with HIV in 2006, using 2006 population numbers.
The ranges around the estimates in this table define the boundaries within which the actual numbers lie, based on the best available information.

***Table 1.*** *Regional HIV and AIDS statistics and features, 2006.* CENGAGE LEARNING, GALE.

Worldwide, women account for 50% of total HIV and AIDS cases and 60% of cases in sub-Saharan Africa (Macfarlane, 2008). Female inequality, gender power relations, poverty, and economic dependence on men account for the gender balance in infection. Higher rates of sexually transmitted infections in sub-Saharan Africa also contribute to women's vulnerability. Women in sub-Saharan Africa comprise 75% of total female cases worldwide (Macfarlane, 2008). Incidence of AIDS has increased sharply among women and girls 13 years old and under worldwide. Condoms are a major strategy for the prevention and control of the sexual transmission of HIV and AIDS. However, because of gender power relations, women in sub-Saharan Africa are typically not in a strong position to ask their male partners to use condoms. Similarly, traditional heterosexual socialization that promotes promiscuity as a sign of masculinity interferes with safer sex advice to be monogamous. Men often have multiple sex partners, so a single infected man can infect several female partners. There is also a shortage of eligible male sex partners for women. This gender imbalance places women at great risk for HIV.

## LIFE COURSE PATTERNS

Since AIDS was first identified in 1981, 65 million people have been infected with HIV and 25 million have died worldwide (Macfarlane, 2008). In the early 21st century 36.5 million people are living with HIV and 24.5 million of them (or 64%) are in sub-Saharan Africa, a region that comprises just 10% of the world's population (Macfarlane, 2008). In the United States more than one-half million people diagnosed with AIDS have died. A majority (around 69%) of these individuals did not live to the age of 45 (AVERT, 2008). In 2005 persons ages 25 to 44 accounted for 39% of the AIDS diagnoses and 41% of AIDS deaths in the United States (AVERT, 2008).

Because AIDS has always led to a high degree of premature mortality, it is associated with a high number of years of potential life lost. AIDS has drastically reduced life expectancy in many countries in sub-Saharan Africa, where the majority of HIV and AIDS cases are found. For example, more than one-third of adults in Botswana have HIV or AIDS. Life expectancy there has dropped from 74 before AIDS appeared to 39 in 2008 (Macfarlane, 2008). Projections for life expectancy in 2010 for nations highly affected by AIDS range from 27 in Botswana to 36 in South Africa, Malawi, and Rwanda (Stine, 2004). Botswana and South Africa will experience more deaths than births by 2010, meaning that populations will begin declining.

Worldwide, the majority of HIV and AIDS cases are adults, but children comprise a substantial number. An overwhelming majority of children with HIV or AIDS and children orphaned by AIDS live in sub-Saharan Africa. The number of orphans there who have HIV or AIDS is expected to reach 25 million by 2010 (Macfarlane, 2008). Globally, the number of children living with HIV increased from 1.5 million in 2001 to 2.5 million in 2007 (Joint United Nations Programme on HIV/AIDS [UNAIDS], 2007). Although antiretroviral therapy has been available and has proven to be effective in preventing perinatal transmission in the United States and Europe, women in developing countries have not not had the same access to these therapies.

In terms of both prevention and care, inequality underlies the HIV and AIDS pandemic. Worldwide, HIV and AIDS disproportionately affect uneducated, impoverished, and disenfranchised populations. For example, a disproportionate number of U.S. HIV and AIDS cases are found among African Americans and Latinos (Macfarlane, 2008). Poverty, inequality, discrimination, racism, sexism, heterosexism, and ageism are important factors in the spread of the pandemic. Impoverished populations are consumed with daily survival needs such as food and shelter and, as a result, concern about their own risk for HIV may not be a priority in their lives. Unequal access to HIV or AIDS care and unequal quality of care also contribute to the pandemic's powerful impact

## HIV AND AIDS RISK

About half of all new HIV infections worldwide are among young people aged between 15 and 24, a majority of whom are women (Card, Amarillas, Conner, Akers, Solomon, & DiClemente, 2007). In the United States, among gay men, younger age is strongly correlated with high-risk sexual behavior (i.e., unprotected anal sex). After a notable decline in U.S. HIV and AIDS cases beginning in 1993, cases began to rise again in 1999, particularly among young gay men. This increase was referred to as the *resurgent epidemic* or the *second wave*. Gay men in the current epidemic differ from those in the earlier wave because they did not have the experience of losing members of their peer group to HIV and AIDS, a common experience for gay men during the 1980s. The introduction of effective antiretroviral therapies in the mid-1990s caused some gay men to see the epidemic as less serious. As a consequence, they relapsed into unsafe behavior.

## GENDER AND THE LIFE COURSE

Sociocultural factors play a role in young women's risk. Young women may become dependent on men as a way to achieve independence from their parents. They may become involved in relationships with older men whom they perceive as attractive because of the latter's greater status and wealth. These men, however, also are more sexually experienced and may present a higher risk for

HIV. Girls and young women in developing countries have limited access to education and jobs and may willingly initiate relationships with *sugar daddies*, that is, men who are much older, relatively well-off, and usually married (Card et al., 2007). Some girls may provide sex in order to earn money for school expenses or to help their families. Worldwide, young women's financial vulnerability creates challenges to HIV and AIDS prevention efforts.

In addition to sociocultural factors, physiologic factors play a role in young women's vulnerability to HIV and AIDS. Adolescent women are at heightened risk of HIV infection compared to older women because they have a larger zone of cervical ectopy and their vaginal mucosal lining is thinner. (Cervical ectopy is a condition whereby a small ring of cells extend beyond the normal border of the inner wall of the uterus to the neck of the uterus.) Their immature genital tract can also cause their cervixes to rip or tear during sex, heightening their vulnerability to HIV infection. In addition, vaginal secretions in adolescent women are not fully developed or functional and this physiologic immaturity may play a role in increasing young women's risk for HIV.

Women at the other end of the age spectrum are also vulnerable to HIV infection because of physiologic factors. Women over the age of 45 (perimenopausal women) are at heightened risk because of increased fragility of genital mucosa. In general, all factors, including infectious, traumatic, and hormonal, that impair genital mucosa may increase the risk of HIV transmission. Menopause is associated with a thinning of the vaginal lining and increased vaginal dryness. This can result in small tears and abrasions in the vaginal walls, thereby providing an entryway for HIV.

## CAREGIVING ROLES AND ISSUES

HIV and AIDS raise complex caregiving issues. Although gay men have provided a great deal of informal AIDS care to one another, women also have served important caregiving roles. Mothers and sisters of gay men with HIV or AIDS, as well as infected women with children, have provided care for infected persons during the epidemic. Infected mothers often have to plan for the welfare of their children after their own death. Some of these children also are infected with HIV and thus have special needs. Infected mothers who rely on kinship care usually assign the care of their children to their mothers or sisters (or their children's aunts and grandmothers) (Campbell, 1999). In developed countries when informal or kinship care is not available, children will enter a more formal system of foster care. That system in the United States is already overburdened because of foster care needs of children whose parents are addicted to drugs, incarcerated, or dead.

In regions of sub-Saharan Africa, AIDS has taken such a toll that middle-aged adults are virtually absent in many communities. Older parents of adult children with HIV or AIDS often are caring for grandchildren, some of whom are also infected. In those cases when there are no grandparents to provide care, older siblings often provide care to young ones.

## AGING AND AIDS

Most of the growth in U.S. HIV and AIDS cases among persons over 50 is because of the aging of persons with HIV and AIDS, rather than new infections. The number of mature adults with HIV and AIDS has grown because of the increasing time between infection, diagnosis, and death. Effective antiretroviral therapy is the primary reason for the growing number of people over 50 with HIV or AIDS. However, some growth in HIV and AIDS cases among persons over age 50 is due to people getting infected for the first time.

In the early years of the U.S. epidemic, most new cases among persons over 50 were caused by HIV-contaminated blood transfusions (Stine, 2004). In the early 21st century most cases are the result of sexual transmission. The number of older adults with HIV or AIDS from sexual transmission is expected to increase as the sexually liberated baby boom generation ages. Compared to previous generations, older people are staying healthier longer and are thus able to enjoy extended sex lives. Older adults are also able to remain sexually active because of hormone therapy and erectile dysfunction drugs. The growth in the baby boom population coincides with the growth in use of these drugs, thus creating a new target group for HIV and AIDS prevention strategies. Exposure to public health messages is critical for this population.

Older adults who have been in long-term relationships and who reenter the dating world after divorce or the death of a spouse may not be aware of how their own behavior puts them at risk for HIV. Because they were in a long-term relationship, they may not have been educated about HIV. Older postmenopausal women, no longer fearing pregnancy, may not think to use condoms for protection against sexually transmitted infections (STIs). A survey of sexual practices among older adults found that just 33% of those who were sexually active in the previous three months used condoms (Gorman, 2006).

In addition to older adults' own perceptions, society often views older persons as asexual. Thus older adults have not been targeted with HIV and AIDS prevention as much as younger age groups. The media have not featured stories about older adults with HIV or AIDS in comparison to stories about younger adults. Physicians and other medical providers may not think to discuss risks of HIV, AIDS, or other STIs with older patients as

part of their routine health screening. Nationally, seniors in the United States make up less than 5% of those tested at government funded testing sites (Stine, 2004).

Older adults with HIV and AIDS may experience particular physical and psychological distress. Societal ageism may make the stigma of HIV and AIDS more intense for older adults. Once diagnosed with HIV or AIDS, older adults are less likely than younger age groups to seek out AIDS support groups or other forms of emotional support (Hooyman & Kiyak, 2008). Most of older adults' care comes from friends who also have HIV or AIDS (Shippy, 2007). Older adults with HIV and AIDS are more likely to live alone compared to their younger counterparts, which has important implications for their care (Poindexter & Emlet, 2006). There appears to be a high level of unmet emotional need among older adults with HIV or AIDS.

Although the introduction of antiretroviral therapy in the mid-1990s produced a new optimism, some persons with HIV or AIDS ironically experienced serious side effects more commonly found as age-related conditions in older persons—high blood pressure, heart disease, and diabetes (Stine, 2004). Symptoms of HIV and AIDS are also sometimes confused with the normal effects of aging, because symptoms of HIV and AIDS may mimic those of aging. Some adults may be managing chronic diseases associated with aging, causing them not to recognize symptoms as being associated with HIV or AIDS and to seek treatment. Such symptoms include general aches and pains, headaches, nerve pain, visual problems, chronic cough, lack of energy, loss of appetite and weight, and problems with short-term memory (Hooyman & Kiyak, 2008). Older adults' immune systems are less equipped to combat the effects of HIV, thus allowing the disease to take an accelerated clinical course. The decline in immune system function may explain why the time from infection with HIV to the onset of AIDS is shorter in older adults. In adults over 50, the average time is 5.7 years compared to 7.3 years in people under 50 (Emlet & Farkas, 2002). Older adults are twice as likely as young people to already have developed AIDS by the time that they test positive for HIV (Mugavero, Castellano, Edelman, & Hicks, 2007). Thus early diagnosis in older adults is critical.

## FUTURE RESEARCH DIRECTIONS

Age-associated conditions in an aging HIV population present new research questions, such as whether age-associated conditions appear earlier in older adults with HIV or AIDS. Another research area involves interaction between antiretroviral regimens for HIV and treatments for age-associated conditions, particularly unwanted interaction between the two. There are relatively few studies of how medications for high blood pressure, osteoporosis, and other age-related conditions interact with antiretroviral therapies (Karpiak, 2006). Moreover, clinical AIDS drug trials often exclude older adults precisely because of their age and other health problems. These are among the many challenging research issues in addressing the needs of an aging HIV and AIDS population.

## AIDS POLICY ISSUES

A high priority in HIV and AIDS care policy is to assure that persons with HIV or AIDS in developing countries have the same access to antiretroviral drugs as those in developed countries. HIV and AIDS advocacy and activism will need to be unrelenting in its effort to provide this access.

There also are important policy implications of an aging HIV and AIDS population in developed nations. AIDS service organizations (ASOs) will need to retool and restructure services in order to reduce barriers in service delivery to this population. ASOs will need to increase their knowledge of age-related illnesses and the potential complications due to HIV and AIDS and its treatments. As the HIV population continues to age, more support services and long-term care for older adults with HIV or AIDS will be needed. When informal support systems are exhausted, more formal systems of care will be required to meet the needs of older persons with HIV or AIDS. More coordination between HIV and AIDS services and other services for older adults will be necessary for optimal service utilization.

In addition to HIV and AIDS care, the needs of older adults should be recognized in HIV and AIDS prevention education policy. The visibility of older persons with HIV or AIDS must increase and become a major focus of advocacy and activism. More targeted HIV and AIDS prevention education needs to be provided to sexually active older adults. Safer sex messages should continue to target younger persons at high risk for HIV and AIDS but should expand to include older persons at the other end of the age spectrum.

# ANDROPAUSE/MALE MENOPAUSE

Andropause, or male menopause, is a set of physical and emotional symptoms that are presumed to result from age-related declines in testosterone levels. Changing views of andropause over time reflect shifting cultural understandings of masculinity, aging, and sexuality. In the post-Viagra climate, with heightened public awareness of the risk of sexual decline with age, the notion of andropause as a widespread disorder has experienced a surge of scientific, commercial, and public interest (Marshall, 2006, 2007).

## EARLY RESEARCH AND MEDICALIZATION

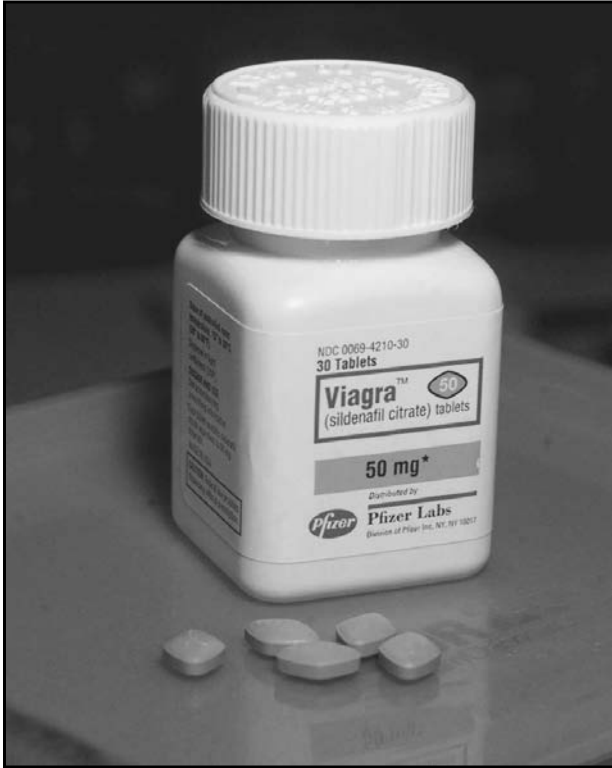
Research investigating the male climacteric and its treatment with testosterone first was reported in American medical journals in the 1930s and 1940s. The male climacteric was seen as clinically significant in only a small proportion of aging men and was attributed to a deficiency in the sex glands. Although sexual dysfunction was viewed as a key symptom of the disorder, it was not the main concern in treatment. Although potency treatment might inadvertently be stimulated by testosterone therapy, it was not to be given for this purpose, and at least one researcher suggested that "it is perhaps better for older men if this phase of the reaction does not result" (Werner 1945, p. 710).

The idea of a hormonally treatable male menopause gained little attention from mainstream medicine in subsequent years. Men's midlife problems were viewed as a period of emotional adjustment, or midlife crisis, not a medical problem (Featherstone & Hepworth, 1985, Hepworth & Featherstone, 1998). Only when sexuality reemerged as the key to men's midlife problems in the late 20th century was male menopause, or andropause, remedicalized, that is, conceptualized once again as a medical condition (Marshall, 2006). Since the late 1990s research journals, especially those which focus on urology and impotence, have featured articles on the diagnosis and treatment of andropause or androgen deficiency in aging males.

## DEBATES

However, there is a significant gap between andropause as a symptom complex and androgen deficiency—or hypogondadism—as a biochemical state. Research on andropause and its treatment with testosterone remains controversial, and there is more disagreement than agreement on the definition, diagnosis, and treatment of this condition. Researchers and clinicians generally agree that many older men report symptoms such as erectile dysfunction, a decline in libido, and a decrease in strength and energy. They also agree that testosterone declines moderately and gradually as men age but that many men remain within the normal range for younger men.

More contentious are issues such as whether declining testosterone levels have medical implications, whether they are caused by confounding factors such as obesity and inactivity, whether testosterone supplements provide clear benefits, and, if so, whether the benefits outweigh the potential risks. Controversies also remain over how to best measure testosterone levels and how to define what normal levels might be (Bhasin, Cunningham, Hayes, Matsumoto, Snyder, Swerdloff, et al., 2006). Data from the Massachusetts Male Aging Study showed that low libido is a poor predictor of low testosterone levels



***Viagra.*** *In the post-Viagra climate, with its heightened public awareness of the risk of sexual decline with aging, the notion of andropause as a widespread disorder has experienced a surge of scientific, commercial and public interest.* AP IMAGES.

(Travison, Morley, Araujo, O'Donnell, & McKinley, 2006). A meta-analysis suggested that the effects of testosterone supplementation on sexual function may be quite modest and may diminish over time (Isidori, Giannetta, Gianfrilli, Greco, Bonifacio, Aversa, et al., 2005). The National Institute of Health concluded that "the growth in testosterone's reputation and increased use... has outpaced the scientific evidence about its potential benefits and risks" (Liverman & Blazer 2004, p. 11).

## A DEBATABLE CONSENSUS

Despite these debates, pharmaceutical companies actively promote an appearance of consensus on the existence, definition, and treatment protocols for clinical entities such as andropause, androgen deficiency in the aging male (ADAM), and symptomatic late-onset hypogonadism. These strategies make use of Web sites, health promotion brochures, articles written or sponsored by pharmaceutical manufacturers that are published in clinical journals, and support to professional and patient groups organized around those disorders. Solvay, the manufacturer of Androgel, a testosterone product, sponsored two studies of primary care physicians' knowledge about andropause (Anderson, Faulkner, Cranor, Briley, Gevirtz, & Roberts, 2002; Pommerville & Zakus, 2006). The studies took as their premise assertions such as "Andropause is a testosterone deficiency that develops gradually over a number of years in all men aged 50 and over" (Anderson, Faulkner, Cranor, Briley, Gevirtz, & Roberts 2002, p. M796) and "The causes, symptoms and treatment options for andropause have been well documented" (Pommerville & Zakus 2006, p. 215) and proceeded to score primary care physicians' responses to questions about the nature of and treatment options for the disorder as correct or incorrect. In light of the lack of scientific consensus on these matters, an exercise of this type should be seen as being in the service of public relations rather than public health.

Mainstream media stories on andropause, usually prompted by press releases from pharmaceutical companies, follow a script suggesting that although the existence of male menopause was a subject of controversy in the past, there is now a scientific consensus that it is a real disorder that is treatable with hormone therapy. Stories of miraculous transformations (weight loss, muscle gain, better sex, better mood, renewed vigor) resulting from testosterone treatment overshadow any mention of possible risks and warnings from skeptical doctors and scientists. In many stories the libido-enhancing benefits of testosterone are added to the already accepted benefits of erectile drugs. Sexual decline and its pharmaceutical reversal are linked clearly with the general restoration of masculine vitality. Not unlike the "feminine forever" message promoted to women by those selling hormone replacement therapy in the 1960s, the newly remedicalized andropause reasserts a hormonal basis for masculinity. Thus, andropause reinvigorates the idea of biologically based lifelong sexual difference (Marshall & Katz, 2006).

Investigators from the Massachusetts Male Aging Study cautioned that viewing normal male aging as a medical problem raises both ethical and public health challenges, especially in the wake of what has been learned about the risks of hormone replacement therapy in women (O'Donnell, Araujo, & McKinley, 2004). It also raises theoretical challenges for those interested in the construction of gender across the life course. Gendered bodies are at the same time sexual bodies and aging bodies. The medicalization of andropause in the late 20th and early 21st centuries illustrates the manner in which such bodies are made and remade at the intersections of science and culture.

# ATTRACTIVENESS, PHYSICAL

Physically attractive individuals exhibit facial and bodily characteristics that most people perceive as beautiful or handsome. Physical attractiveness influences whether a person is liked or loved irrespective of age or stage in the life course. People recall falling in love not only because of similar interests but also because of their partners' looks. According to the social psychologist Susan Sprecher (2006), passionate love—an intense craving for another—is fueled by physical attraction and is especially strong early in a relationship. In a review of many research studies, Alan Feingold (1990) found that men place a slightly higher value on physical attractiveness than women. Yet gender and sexual orientation have only a limited impact on what is desired in a hypothetical sexual partner. Heterosexual men and women, as well as gay men, all reveal that what they desire most in a short-term sexual partner is physical attractiveness. However, the *matching hypothesis*—that people will actually date persons who are similarly attractive to themselves—is also supported, especially over the length of a relationship.

## PHYSICAL ATTRACTIVENESS, EVOLUTION, AND CULTURE

Scholars debate whether physical attractiveness is constant, composed of common elements, or variable over time and place. Based on the Darwinian idea of natural selection, evolutionary theorists believe that attributes thought to signify women's fertility, health, and innocence and men's power and social status are considered attractive across cultures. The psychologist Devendra Singh (2007) noted that what makes women physically attractive includes a low waist-to-hip ratio (e.g., hourglass shape), a combination of childlike (i.e., big eyes, small nose and chin, smooth skin) and sexually mature features (i.e., arched eyebrows, prominent cheekbones), and the overall symmetry of the features. Attractive men display a high waist-to-hip ratio, (i.e., straight torso), dominant features (i.e., prominent cheekbones, large chins) coupled with some "cute" features (i.e., large eyes and small nose), and facial symmetry. Studies in which volunteers rate the attractiveness of a set of faces find composite images (i.e., averaged features of many people) better looking than individual faces, especially when the faces of beauty contestants are averaged. Infants prefer pretty faces, indicated by data showing that they spend more time looking at them. This is important because infants have not yet internalized their cultures' preferences.

In contrast, cultural theorists, such as Lois Banner (1983), argue that physical attractiveness cannot be universal given that standards can and have changed over time. Banner showed that, in the United States, cultural preferences for women's shapes have been quite variable. For example, the ample and buxom "Gibson girl" of the late 1800s made heroic efforts to accentuate a tiny waist (i.e., with tightly laced corsets). Yet in the 1920s the ideal woman was thin, boyish (i.e., flat-chested and straight hips), and clothed in a loose-fitting, light dress. The standard for women in the United States in the early 21st century is a thin and well-muscled habitus that is still buxom. For men, the standards for body shape have varied less than those for women, although the value of muscularity has been variable. The early 21st century standard for men in the United States is trim and toned with discernable musculature.

## COSMETIC SURGERY

Cosmetic surgery is a medical and business enterprise whose purpose is to reshape healthy facial and body parts to approximate cultural ideals more closely. Although the techniques used in cosmetic surgery are similar to those used in reconstructive surgery, the former are considered elective rather than medically necessary. Cosmetic procedures grew dramatically in the latter half of the 20th century. Deborah Sullivan (2001) attributed the huge increase between 1992 and 2002 in the number of procedures performed in the United States to several factors, including advances in medical technology, exposure to mass media that upholds a cultural ideal of youthful beauty, and greater public acceptance of cosmetic surgery. By 2003 cosmetic surgery makeover programs were a popular genre of reality television.

Those who take a positive view of cosmetic surgery emphasize how it can be a form of self-healing and personal empowerment. However, critics argue that cosmetic surgery is a symptom of a shallow, media-driven culture that promotes ageism and sexism (i.e., women make up between 80% and 90% of cosmetic surgery patients). The most common procedure performed in the early 2000s was liposuction (i.e., fat is removed from the abdomen, hips, neck, and other bodily areas). Other common procedures for women include breast augmentation, face lift, and thigh lift and, for men, hair restoration, pectoral implants, and rhinoplasty (i.e., nose job).

### PHYSICAL ATTRACTIVENESS STEREOTYPING AND THE SELF-FULFILLING PROPHECY

Physical attractiveness confers social status because it triggers expectations that attractive individuals will have more advantageous outcomes. For example, attractive individuals are stereotyped as having greater leadership ability, more sociability, better mental health, greater marriageability, and even better intellectual ability than their less attractive counterparts. Sweeping, positive expectations for this range of capacities is known as the halo effect or the "what is beautiful is good" stereotype (see Dion, 1972, p. 285). However, Alice Eagly and colleagues (Eagly, Ashmore, Makhijani, & Longo, 1991) reviewed many research studies and found that attractive people are also perceived as having less integrity, less modesty, poorer parenting abilities, and less concern for others than less attractive individuals. Furthermore, attractive women are sometimes stereotyped as incompetent whereas attractive men are not. Sometimes attractive women are believed to have obtained jobs because of their looks rather than their abilities.

Evidence suggests that attractive people are often treated better than unattractive and, in particular, overweight people (Brownell, Puhl, Schwartz, & Rudd 2005). For example, attractive people tend to obtain better jobs, earn more money, be more popular, and have more dates and sexual experiences than unattractive people. Conversely, attractive people experience less loneliness and social anxiety than unattractive people. Juries are usually more lenient toward attractive defendants—who are more likely to be found innocent and less likely to be sent to jail or made to serve long sentences—than unattractive ones. Yet harsher sentences may be issued if jurors perceive that a woman's beauty was used to commit a crime.

Although plenty of studies discuss the stereotyping of attractive people, there is less evidence that attractive individuals actually meet these expectations, a phenomenon known as a self-fulfilling prophecy. Judith Langlois and colleagues (2000) found that attractive people have excellent social skills. Anne Haas and Stanford Gregory (2005) argued that, because social attention is lavished on attractive children, they probably develop good social skills and enhanced interpersonal power. Negative stereotypes about overweight people (e.g., that they lack will power) tend to lower their self-esteem and increase their social anxiety.

### PHYSICAL ATTRACTIVENESS OVER THE LIFE COURSE

Physical attractiveness has an impact on people's lives over the entire life course. Evidence that infants recognize beauty suggests that the social status conferred by attractiveness is activated early in life, especially when coupled with evidence that mothers pay more attention to attractive infants. Attractive infants are assumed to be more sociable and competent than less attractive infants, and the stereotyping continues into childhood. Dion (1972) found that bad behavior among attractive 7-year-old children was explained by their having a bad day, or what is known as a situational attribution. Conversely, bad behavior on the part of unattractive children was attributed to major dispositional character flaws.

Little girls are socialized to pay attention to their appearance, which becomes a part of their self-concept. These messages come from their parents, teachers, peers, mass media, and toys. In 2008, a popular toy marketed to 4- to 7-year-old girls were Bratz Babies who, much unlike

real infants, wear sexy lingerie and full makeup that accentuates their exaggerated "babyface" features. The dolls also have long highlighted and styled hair, as well as painted finger- and toenails. The only indication that this toy does, indeed, represent a baby is a bottle of milk attached to a thick gold chain around her neck. Feminists believe that a toy that blurs the boundaries between babies and sexually viable women could be harmful. The concern is that girls might internalize the message that their value as women depends on their sexual attractiveness. Toys meant for little boys, on the other hand, draw on popular stereotypes about masculinity. Critics are concerned that representations of "real men" as big, tough, competitive, and warlike could stifle boys' developing nurturing qualities. For example, the popular G.I. Joe action figures have acquired giant muscles in the past 40 years, at the same time that boys have learned that steroids can be used to increase muscle mass.

Appearance takes on still more importance for adolescents and young adults. These are stages in the life course during which young people are susceptible to poor body image and eating disorders, including anorexia nervosa and bulimia nervosa for girls and body dysmorphic disorder for boys. Although the gap is closing, most people with eating disorders (about 85%) are female. It is not uncommon for adolescents to diet, which they are more likely to do if they view idealized and, often digitally altered, images, especially in fashion magazines. As people age, gender plays a role because women are expected to look ageless throughout their lives, which causes depression when their looks, and therefore their feelings of social worth, decline. However, rising rates of cosmetic surgery for men as well as women attest that men also feel cultural pressures to be attractive.

## FUTURE DIRECTIONS FOR PHYSICAL ATTRACTIVENESS RESEARCH

Although a great deal is known about physical attractiveness and its effects on life chances, several important gaps remain. More cross-cultural and historical research is needed to understand how different groups of people have defined standards of physical attractiveness. In the United States and other developed societies, most research on physical attractiveness has been done with college-age convenience samples, which means that the results have less generalizability. Older and/or aging samples should be used to determine the relative importance and dimensions of attractiveness over time. In addition, more research is needed on the types and degrees of harm caused by the accentuated value of physical attractiveness in European and American cultures. Finally, there is a dearth of physical attractiveness research about men, racial/ethnic minorities, mature people, and gays and lesbians. For minorities, it remains unclear whether entry into the middle class is associated with assimilating to the physical attractiveness norms of the dominant culture (e.g., regarding body weight).

## BABY BOOM COHORT

The term *baby boom* generally refers to a large, usually sudden, increase in the number of births in a population, after which the number of births declines and eventually stabilizes at a lower level. The higher fertility period may last only a few months or persist for a number of years. The birth cohorts born during a baby boom are large relative to those preceding and following them, and the overall population is larger than it would have been had the baby boom not occurred.

Baby boom is also used to refer specifically to the sustained increase in fertility rates experienced in the United States in the decades following World War II (1939–1945). Because of the substantial magnitude and long duration of the postwar baby boom, the baby boom cohorts (composed of *baby boomers* or *boomers*) are especially large relative to other birth cohorts in the U.S. population. Consequently, they have had an impact not only on the size of the population, but also on American social, economic, cultural, and political life.

### DIMENSIONS OF THE U.S. BABY BOOM

The U.S. postwar baby boom began in 1946 and lasted until 1964. Following the technical definition of a baby boom, these start and end dates are based on quantitative assessments of postwar fertility trends and reflect the start of the significant fertility increase and the onset of significant decline (O'Connell, 2002). At times, commentators use other dates to demarcate the baby boom cohorts; however, such dates are usually based on criteria other than fertility trends, such as subjective judgments about the extent to which people born in various years share similar cultural or historic experiences.

The baby boom caught scholars and the public by surprise. In the 1930s American fertility rates were at a historic low, as the steady fertility decline that began in the 19th century was exacerbated by the economic difficulties of the Great Depression (1929–1939). In 1936 the total fertility rate (TFR), a measure used by researchers to gauge the level of fertility in a population, reached a prewar low of 2.15 children per woman (Heuser, 1976). The low levels of births led to both popular and scholarly concern about their potential consequences.

The increase in births between 1945 (TFR of 2.42) to 1946 (TFR of 2.86) surprised no one, as people made up births postponed during the war. However, the continuation of the upward trend and the persistence of the higher level for 19 years were indeed surprising. The TFR reached a maximum of 3.68 in 1957, 11 years after the war ended. Shortly thereafter, fertility began its steady decline and by 1964 had reached a TFR of 3.1. The years following are often called the *baby bust*, as fertility continued to decline, reaching a low in 1976 (TFR of 1.76) and then increasing slightly to hover around a TFR of 2.0 through the 1990s and 2000s (National Center for Health Statistics 2008). However, the term baby bust is something of a misnomer, as the decline represents a return to the long-term trend.

A key feature of the U.S. baby boom is that it was pervasive: Births increased among all racial, socioeconomic, and geographic groups. This pervasiveness within the United States was mirrored globally; many developed nations also experienced postwar baby booms (Morgan,

***Figure 1.*** *Total Fertility Rate, United States 1918–2005.* CENGAGE LEARNING, GALE.

2003). The baby booms were especially pronounced in the United States, Canada (peak TFR of 3.93), and Australia (peak TFR of 3.51).

## ORIGINS OF THE U.S. BABY BOOM

The proximate causes of any increase in the yearly number of births in a population are due to one of two things: either an increase in the number of women in the population who are "at risk" of childbearing or an increase in the likelihood that at-risk women will give birth. "At risk" means that one is a potential candidate to give birth; it typically refers to women between the ages of 15 and 45. Because of low fertility in the years prior to World War II, the absolute number of women of childbearing age actually declined during the baby boom. In other words, because birth rates were low in the late 1920s and 1930s, the number of women in their 20s and 30s during the mid-20th century was lower than at other points in recent history. This decline was offset somewhat by younger and more widespread marriage, so that a higher proportion of women were married and thus at risk of childbearing (childbearing outside of marriage was rare in the United States at this time).

Thus the principal cause of the postwar baby boom was an increase in the likelihood that an at-risk woman would give birth in a given year. Such an increase may be due either to shifts in the *timing* of childbearing, such that women have children earlier rather than later, or to increases in the *total number* of children a woman bears. In a well-known analysis, demographer Norman Ryder (1980) showed that half of the increase in births in the postwar period was because of differences in timing, in particular to women having children at younger ages. The remainder of the increase was due to increases in the average number of children women bore over the life course. However, much of this second component was due to increases in the number of first and second births, not to increases in higher order births. In other words, the baby boom was not caused by some women having huge families, but by nearly all women having at least one, and probably two, children during the baby boom years. Earlier in the century, especially during the Depression, a higher proportion of women remained childless.

As Ryder pointed out, identifying the proximate causes of the baby boom helped in the search for the fundamental causes, that is, the broad social and economic forces that encouraged couples who would have had children in any case to have them relatively young and couples who might have otherwise remained childless to have children. The most comprehensive answer to date was provided by sociologist Andrew Cherlin (1992), who argued that the postwar period was characterized by a temporary, and somewhat ahistorical, surge in familistic values. In combination with a robust economy, these values led most people to marry and have children at relatively young ages. For example, in the late 1950s and early 1960s, women typically married at age 19 and had their first child at age 20. Other scholars point to the introduction of the birth control pill in the early 1960s as a factor in the decline in births that heralded the end of the baby boom (Morgan, 2003).

## THE BABY BOOM AND SOCIAL CHANGE

The baby boom cohorts have had a significant impact on American society. At the most basic level, the U.S. population is larger than it would have been had the baby boom not occurred, due both to the boomers and to the boomers' children (larger cohorts produce more offspring). Beyond this, however, the large size of the boomer cohorts relative to cohorts born before and after means that the boomers have had a profound effect on American social, economic, cultural, and political life.

First, accommodating these huge cohorts has been a recurrent issue in the United States and the concerns of the age group occupied by the boomers at a given time have tended to dominate national agendas. Thus, as the boomers moved through childhood, to young adulthood, and into midlife, institutions such as schools, universities, and then labor and housing markets were forced to adapt to larger numbers. More recently, a great deal of attention has been directed to the potential impact of aging boomers on the economy, the health care system, and social programs for the aged.

Second, the large size of the boomer cohorts has meant that members of these cohorts faced increased competition for valued resources (e.g., admission to college, or entry-level jobs). This theme was highlighted by economist Richard Easterlin (1980), in the "cohort size hypothesis," which stated that all else equal, the average economic and social outcomes of a cohort will vary inversely with its size. Easterlin suggested that larger cohorts experience, on average, lower quality and levels of education, delayed or forgone marriage and fertility, depressed wages, blocked job mobility, more spells of unemployment, higher levels of daily stress, life dissatisfaction, and even higher suicide rates. Although these patterns are true for the boomer cohort as a whole, the hypothesis has been criticized for ignoring variation within cohorts. In addition, outcomes among members of the smaller baby bust cohorts have not been significantly better than those among the boomers, as the hypothesis predicts. Diane Macunovich (2002) has reformulated Easterlin's hypothesis to account for the different experiences of boomers born early (between 1946 and 1956) and late (between 1957 and 1964).

Third, the boomers played a pivotal role in the social changes that transformed the life course in postwar America (Hughes & O'Rand, 2004). As their lives unfolded, the boomers experienced the profound changes that marked the decades between World War II and the millennium, including a series of economic shifts and shocks, the civil rights movement, a change in U.S. immigration policy that opened the doors to millions of newcomers, a revolution in cultural values that changed the way Americans thought about the individual and society, new perspectives on gender roles, and the sexual revolution. In general, the boomers did not initiate these changes, although they are sometimes credited for doing so. However, because the boomers encountered these shifting social contexts in young adulthood, their lives were disproportionately affected. The choices that boomers made about education, work, and family then reinforced some existing trends and set other new trends in motion. The boomers responded to historical change by living in new ways, ways that set patterns for successive cohorts.

The lives of the boomers thus embody the postwar transformation of American society. Their experiences show some continuity with those of persons born earlier in the century. More noticeable, however, are the ways in which the boomers' lives differ from the lives of their counterparts in earlier cohorts. A key feature distinguishing the baby boom cohorts from cohorts born previously is their heterogeneity: that is, the boomers' experiences are not just different from those of their predecessors; their experiences are different from each other's (Hughes & O'Rand, 2004). For example, boomers are more ethnically diverse than cohorts born previously, and this diversity has increased as immigration swelled the ranks of native-born boomers. Boomers are highly unequal in economic achievements and educational attainments. On nearly every measure, family life among boomers is more heterogeneous; boomers have a wide array of family histories and at midlife live in a wide variety of family situations. Thus the net effect of social change has been to diversify the life course.

The lives of the boomers show clearly how the life course is shaped by the intersection of individual and historical time. As noted above, scholars, policy makers,

and the public are increasingly concerned about the impact of the aging of the large boomer cohorts. The heterogeneity of the boomer cohorts suggests that planning for these cohorts' old age will be challenging. At the same time, however, their prior history suggests that in later life the boomers will be able to adapt to social change.

# BIRACIAL/MIXED RACE ADULTS

In the contemporary United States, multiracial, or mixed race, adults usually are defined as those who self-identify as having two or more racial origins. Although this concept seems straightforward, there are contradictory historical and popular images of what constitutes a mixed race person, and both the criteria for inclusion and the terminology used to describe multiracial populations vary.

## DEFINING MULTIRACIAL IDENTITY

Sociologists have long recognized that racial identity is related to but conceptually distinct from racial ancestry. Racial ancestry is an objective measure of the geographic origins of a person's ancestors, whereas racial identities are largely subjective claims of membership within groups that are socially (rather than biologically) defined. Data collection on racial subpopulations usually favors the second concept. For example, the decennial census relies on individuals to identify their race by choosing from a set of listed categories. Individuals also may supply write-ins to provide additional detail (e.g., a specific tribe) or identify with an unlisted category. The 2000 Census was the first to allow multiple responses, and roughly 7 million persons, 4 million of whom were age 18 or older, reported two or more races. Only a small percentage (approximately 3%) of non-Hispanic Blacks and Whites claimed to be multiracial, but 14% of Asians, 40% of American Indians, and 54% of Pacific Islanders listed two or more races, as did 6.5% of Hispanics (people are asked about Hispanic ethnicity in a separate question). Regionally, one-fifth of Hawaiian residents self-identified as multiracial, and 5 to 12% of persons self-identified as multiracial in various counties in the Southwestern states (U.S. Census Bureau, 2001).

Although the official multiracial population includes everyone for whom two or more races are recorded on the census, mixed race persons commonly are viewed as the offspring of interracial unions. Both definitions are problematic. On the one hand, focusing only on persons who are recorded as multiracial excludes the offspring of interracial unions who self-identify or are classified as having only one race. For example, fewer than 55% of children from interracial households are recorded as biracial on the census (Jones & Smith, 2003), and many mixed race children come to identify with only one parent's race as they age (Harris & Sim, 2002); this leads to an even greater underreporting of multiracial ancestry among mixed race adults. On the other hand, limiting attention to the offspring of interracial parents excludes those whose parents are biracial or multiracial (and not necessarily intermarried) as well as those for whom parental data may be incomplete (e.g., single-parent households). Finally, neither definition expressly includes the tens of millions of persons who identify with contemporary racial and ethnic categories that are products of historically admixed (blended) populations (e.g., most Hispanics and Native Americans). As a result, standard reports of the multiracial population underestimate the number of Americans with a complex racial heritage.

## A HISTORICAL PERSPECTIVE ON MULTIRACIAL IDENTITY

Although multiraciality often is viewed as a recent phenomenon, historians have noted a rich history of population

blending that predates the founding of the United States. Admixed Spanish/indigenous peoples settled in what is now the American Southwest decades before the English landed at Jamestown in the early 17th century (Brading, 1993), and by the 19th century Americans of mixed African/European ancestry had a significant demographic presence in Charlestown, South Carolina; New Orleans; and other Southern cities (Davis, 1991), much like their modern-day equivalents in South Africa and Brazil (Fredrickson, 1981; Telles, 2006). As the 19th century progressed, there was a strong social backlash against intermarriage in the United States, culminating in the rise of antimiscegenation laws throughout the Jim Crow South. Efforts to enforce those bans led to radical changes in the classification of mixed race persons, whose identities were reassigned in accordance with "one drop" ideologies that classified persons with any African ancestry, visible or otherwise, as Black. Those efforts hid much of the nation's multiracial history both by shifting the balance of interracial unions to the illicit, often involuntary variety (Spencer, 2006) and by reallocating untold numbers and future generations of multiracial persons to either the Black or the White community (Piper, 1992).

With the rise of the "color line," multiraciality vanished from American racial consciousness. Before the changes on the 2000 Census there had been few efforts to count persons of mixed ancestry. The 1930 Census was the last to use the mulatto category, which was specifically for persons of mixed African/European heritage. The other major source of diversity—immigration—also fell from the historical highs set in the first two decades of the 20th century to a near trickle after the restrictive quotas set by the National Origins Act of 1924 (Massey, 2002). With the absorption of the children of the Southern and Eastern Europeans who immigrated at the turn of the century, the United States became a predominantly "White" nation with a small (approximately 10%) Black minority, at least according to the official record.

## THE OFFICIAL RETURN OF MULTIRACIAL IDENTITY

The situation changed dramatically in the decades after 1970, spurred by liberal immigration reform in the 1960s and the Supreme Court ban on antimiscegenation statutes in the landmark *Loving v. Virginia* ruling. The elimination of legal restrictions coincided with the growing acceptance of interracial unions, and rates of intermarriage for all racial and ethnic groups (Asians and Hispanics in particular) began to trend upward (Qian & Lichter, 2007). These trends have contributed to an increasingly diverse American population and a growing number of children and young adults who claim multiple racial origins.

The official statistical record was slow to record these changes, however. The census and most surveys continued to measure race with mutually exclusive categories despite growing evidence that racial boundaries had become blurred. Defying explicit instructions not to do so, more than 1 million Americans marked or wrote in multiple races on the 1990 Census (Office of Management and Budget, 1995), and during the ensuing decade a small but vocal coalition of multiracial and multiethnic advocacy groups sought and ultimately secured a place for mixed race persons within the federal statistical system (Williams, 2005), which was amended to allow individuals to "mark all races that apply," starting with the 2000 Census and later expanding to other national data sources (Office of Management and Budget, 1997).

With the option to report multiple races, there were reasons to expect that a large number of persons would choose to do so. First, Hispanics had become a sizable and fast-growing panethnic group, and their largely *mestizo* (mixed) heritage seemed difficult to reconcile with mutually exclusive racial categories (Moore, 1976). Second, the population of persons reporting indigenous ancestry on the 1990 Census had ballooned to just under 9 million—nearly five times the number who reported their race as American Indian (1.8 million)—sending a clear signal that the vast majority of persons with indigenous ancestry were of mixed descent (Nagel, 1996; Snipp, 1997). Third, in a striking divergence from the one drop ideology of the recent past, multiraciality had become an increasingly prominent fixture in popular culture. From Keanu Reeves to Tiger Woods and from Halle Berry to Barack Obama, some of the most widely recognized and celebrated Americans proudly acknowledge the complexity of their racial origins.

Although these factors imply that the number of Americans who could have claimed multiple races numbered in the tens of millions, there were indications that the actual count would fall short of those expectations, even substantially, long before the 2000 Census was conducted. Civil rights organizations opposed a stand-alone multiracial category, and Republican-sponsored bills to add an item of that type to the census were defeated. As Kimberly Williams (2005) showed, minority leaders feared that multiple racial identities would reduce the counts and even undermine the legitimacy of their constituencies. Because the government uses census counts to draw electoral districts, allocate Congressional seats, help monitor and enforce civil rights, and provide billions in federal funding to local governments and municipalities, any changes that threatened to reduce the (notoriously undercounted) headcount of minorities even further would not be welcome. Many viewed with suspicion the endorsements of an ostensibly progressive multiracial category by leading conservatives, some of whom expressly championed its existence as proof that race-attentive policy

had become unnecessary and unenforceable. The most telling preview of things to come was given by Charles Hirschman, Richard Alba, and Reynolds Farley (2000), who analyzed data from a census pretest that included different multiracial response options. The authors noted that only 1.5 to 2% of respondents reported multiple races, leading them to conclude that the new format probably would have little impact on the racial composition of the United States as a whole.

## FINDINGS FROM THE 2000 CENSUS AND 2006 AMERICAN COMMUNITY SURVEY

Their predictions were confirmed when the 2000 Census figures were released and especially when the original count of 7 million was revised downward after a large overcount of multiracial persons was discovered (U.S. Census Bureau, 2005). Later intercensal estimates showed little if any growth in the population of persons reporting two or more races between 2000 and 2006 despite an overall increase of nearly 20 million (mostly minority) persons during that period. As a result, the multiracial population of 6.1 million in the 2006 American Community Survey was nearly 1 million lower than had been enumerated in the census six years earlier (U.S. Census Bureau, 2007).

This trend, like the "disappearance" of mixed-race communities in the nineteenth and early twentieth centuries, cannot be explained by traditional demographic forces such as mortality, fertility, migration, and marriage rates. There is no evidence that interracial marriage declined appreciably in those years or any signs of excessive mortality or emigration among multiracial persons. In fact, every racial and ethnic group grew between 2000 and 2006, especially Asians and Hispanics, who are disproportionately multiracial. The idea that the mixed race population has experienced little if any growth suggests that reluctance to report multiple races has not abated.

Consistent with the perspective that racial identities are sociohistorical constructs, the underreporting of multiple racial origins at once reifies long-held, socially meaningful categories and discredits the notion that those categories represent discrete races with clear boundaries and separate lineages. However, although the lines between racial groups remain blurry, many racial disparities remain. It is certainly telling that even historically fluid and anthropologically suspect racial categories are correlated with so many contemporary life outcomes. Without further reductions in the social and economic inequities that reinforce the differences between racial groups, multiraciality is unlikely to displace discrete racial categorization even if that categorization persists at the expense of nuance and historical accuracy.

# BIRTH CONTROL

In its broadest scientific scope, birth control may be defined as any attempt to limit the number or control the spacing of births. In this sense, birth control includes a wide variety of modern contraceptive technologies and traditional non-technological contraceptive methods, male and female sterilization, as well as the postconception birth control methods of abortion and infanticide. Modern contraceptives generally refer to technological methods, from condoms to birth control pills; traditional contraceptives generally refer to nontechnological methods, particularly withdrawal (ejaculation outside the vagina) and the rhythm method (which tries to determine women's fertile periods and avoid intercourse during those times). Although the role of postconception methods of birth control remains significant in both developed and developing nations, this entry will focus solely on birth control methods designed to prevent conception (i.e., contraception).

It should be noted that in common American parlance, birth control often connotes "the pill," whereas contraception connotes condoms or contraceptive technologies. Although the distinction between modern and traditional methods remains important in the study of birth control, the most important distinction in the study of contraceptive technologies is between barrier and hormonal or intrauterine methods of contraception. Barrier methods include condoms, diaphragms, and spermicidal agents and attempt to create a physical barrier between the sperm and the egg to prevent conception. They are coitus dependent, meaning that they are only used during and near coitus (i.e., sexual intercourse), and they are characterized by moderately high efficacy levels in the prevention of pregnancy, although male and female condoms offer extremely effective prevention against sexually transmitted infections (STIs).

Hormonal and intrauterine methods of contraception include oral contraceptive pills (OCPs) and intrauterine devices (IUDs) and are methods that attempt to suppress the release of eggs or create an inhospitable uterine environment for an embryo's development. These methods are used independently of coitus, meaning that they are used essentially at all times, and they are characterized by extremely high efficacy levels in the prevention of pregnancy but offer no protection against STIs. As fertility rates around the world have plummeted, contraception has become a normal part of adolescents' and adults' lives in many countries; meanwhile, fears about the spread of HIV have made condom use a major public health concern.

## TRENDS IN BIRTH CONTROL USE ACROSS TIME

Attempts at birth control have been made since ancient times. Such attempts included lambskin condoms and tortoiseshell diaphragms. By far the most successful of these premodern methods was withdrawal, which was an approved Islamic practice for centuries (Santow, 1995). Demographers believe that the first stage of the demographic transition in Europe, the period when birth rates declined sharply, was accomplished primarily through the use of withdrawal. By the late 1800s early versions of condoms and diaphragms had been invented, but the historical accounts suggest that the early formulations of these methods were awkward and that their use was not widespread because of physical discomfort and strong social stigma; the more contemporary versions of these contraceptives were not used until the 1930s.

The modern contraceptive era really began in the early 1960s with the introduction of the OCP, followed several years later by the development of the copper IUD. OCPs, IUDs, condoms, and diaphragms remained the primary methods of contraception from the 1960s to the 1980s. However, since the early 1990s, there has been a proliferation of birth control methods, including new OCP and IUD formulations, as well as hormonal birth control delivery through a patch, a ring, shots, and implants. Emergency contraception (popularly known as "the morning after pill") also emerged in the late 1990s as a method that women could take up to 78 hours after unprotected sex to prevent pregnancy.

Male hormonal methods have been in development for years, but at this writing, none are currently available on the market. Since the 1980s the HIV and AIDS crisis around the world has increased the desirability of condoms as a method of protection and prompted the development of a variety of improved condoms. Among these new condoms are female condoms, which are condoms that are inserted into the vagina and intended to provide a female-controlled method of STI prevention. Unfortunately, their successful use requires male cooperation, which may reduce their usefulness for women. Male condoms remain the standard

method of STI prevention. Because male and female condoms possess the dual capacity to prevent pregnancy and STIs, encouraging the use of condoms has become a major public health priority. In order to promote a greater variety of methods of both disease and pregnancy prevention, researchers have been pursuing the development of female-controlled vaginal microbicidal agents, which seek to kill sperm to prevent conception and disease; unfortunately, initial trials have not been promising in effectiveness and women's willingness to use them.

Access to OCPs and IUDs varied greatly among nations for decades, with many predominantly Catholic countries, such as Spain and Italy, not legalizing them until the late 1970s. The last highly developed country to legalize OCPs was Japan, which did so in 1999. However, dates of legalization often do not correspond directly with dates of widespread access. The United States, for instance, legalized OCPs in 1961 but continued to restrict unmarried women's access to them until 1972 when a Supreme Court ruling assured access. Although widespread use of hormonal or intrauterine methods is often still very limited in many developing countries, most new birth control methods—including the first OCPs—were first tested in developing countries.

As of the early 21st century, the most popular method of birth control worldwide is female sterilization, followed by the IUD, although there is significant variation by country. In the United States, for example, the most popular form of birth control is female sterilization, followed closely by OCPs; the pattern is similar in Latin America. Asia, dominated by the contraceptive patterns of China, shows a strong preference for female sterilization and IUDs but not OCPs. Although contraceptive use is uncommon in much of Africa, preference patterns there resemble those in Europe; on both continents, female sterilization is rare, and the favored methods are OCPs and IUDs.

Hormonal or intrauterine methods of birth control are distinguished by their extremely high rates of effectiveness in preventing pregnancy, their independence from coitus, their feminine control, and their medical supervision. In developed countries, where these methods are widely used, the combination of these factors has resulted in women experiencing an increase in control over their reproductive health, while producing a simultaneous increase in medical surveillance over women's bodies. OCPs are generally considered essential in propelling the *sexual revolution* in developed countries during the 1960s and 1970s and disconnecting sexual desire from pregnancy and childbearing, which had traditionally been closely linked, particularly through the institution of marriage. Prior to the post–World War II (1939–1945) baby boom, family size had been steadily declining, and the decline continued after the introduction of hormonal and intrauterine methods. Scholars generally agree that these contraceptive methods played a significant role in this family size decline but disagree about how large that role really was.

Although the role of hormonal and intrauterine methods in creating smaller families is debatable, the widespread use of these methods undoubtedly helped to create the expectation that the timing and number of births could be easily controlled. This expectation, in turn, allowed women to enter the labor market seeking not merely jobs but careers—that is, jobs that required extensive education and training and that assume a trajectory through promotions. In the early 21st century, many European countries are facing average fertility levels that are well below replacement levels (that is, below 2.1 births per woman), a situation that would probably be impossible without the widespread use of hormonal and intrauterine birth control.

The effect of hormonal and intrauterine birth control methods has been slower to reach many developing countries, where demand for smaller families is often lower and where medical institutions are often poorly equipped to meet existing demands. Scholars continue to debate the extent to which economic development and urbanization drive the demand for smaller families and birth control versus the extent to which smaller families and birth control permit greater development and urbanization. China continues to be the most famous case study for examining this question. Through the imposition of a system of major governmental rewards and penalties, China successfully created a massive demand for contraception (particularly the IUD) and overhauled normative values about family size. The centerpiece of China's population policy is its one-child policy, which penalizes most couples for having more than one child. Although China's population control program would probably not have been possible without hormonal and intrauterine contraceptive technologies, most demographers agree that the existence of birth control cannot in and of itself create a demand for smaller family sizes. Rather, the individual, economic, social, or cultural pressures for family planning must first be in place before birth control is likely to be used. Yet birth control is not always used to create smaller families. Researchers in Africa have documented many cases in which modern birth control methods are desired as a means to accomplish careful birth spacing, which in turn is viewed as a means to attain *larger*, not smaller, family sizes.

## BIRTH CONTROL USAGE AND EFFECTIVENESS

Evaluating the efficacy of birth control methods in preventing pregnancy (and to a lesser extent, in curbing

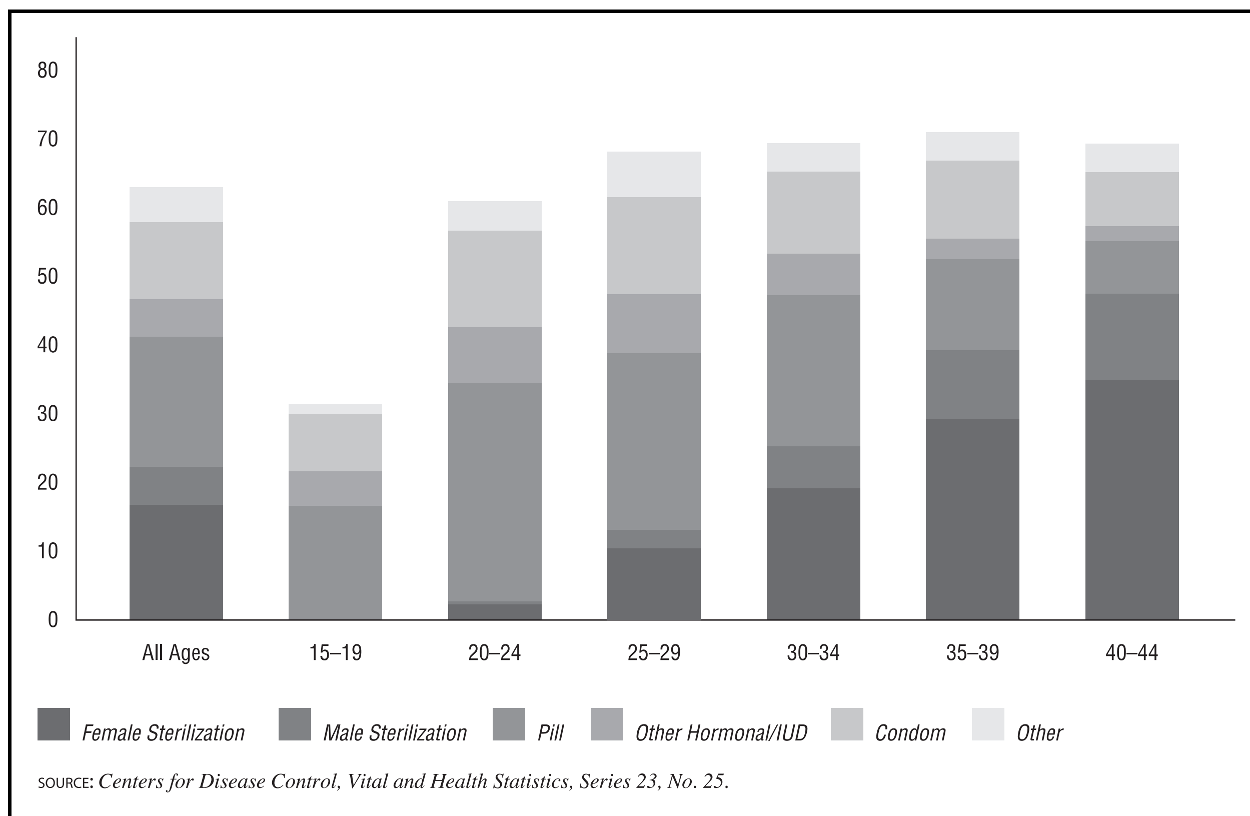

***Figure 1.*** *Perentage of current contraceptive use among all U.S. women, by age, 2002.* CENGAGE LEARNING, GALE.

disease transmission) is one of the major goals in the study of birth control. Clinical studies produce *perfect use* estimates by rigorously monitoring the use of a birth control method according to its instructions and calculating the probability of becoming pregnant while using the method in the first year. Perfect use statistics for most hormonal and intrauterine methods are typically around 99.9%, meaning that in the first year of use, 1 out of every 1,000 women will become pregnant if she uses the method according to directions. Given the millions of women using these methods, however, thousands may become pregnant every year despite these unlikely sounding odds. Perfect use statistics for barrier methods vary widely but are generally around 90%, meaning that in the first year of use, 10 out of every 100 women using them will become pregnant. For short-term methods such as OCPs and barrier methods, the probability of becoming pregnant declines in subsequent years of use (i.e., women are less likely to become pregnant in the second than the first year of use), but for long-acting methods such as IUDs and contraceptive implants, pregnancy is more likely to occur in later years of use.

Perfect use statistics are contrasted with *typical use* statistics, which are derived from surveys conducted with contracepting women about the actual likelihood of becoming pregnant while using a particular method. These statistics typically make use of questions asking women whether or not they were using a particular method in the month that they conceived and thus may include condom users who only used condoms once among many acts of intercourse during a month. Not surprisingly, typical use efficacy estimates are often much lower than perfect use estimates, with OCP effectiveness down to about 93% (7 in 100 women becoming pregnant) and condom effectiveness down to between 80 and 85% (20 to 15 in 100 women becoming pregnant) in the first year of use. Some researchers argue that the user error—for example, women forgetting to take their pills—should not be considered in evaluating contraceptive effectiveness, but others argue that considering the effectiveness of contraception without clinical assistance is essential to evaluating its real protective capacity.

In keeping with this line of reasoning, it should be noted that the difference between the perfect use and typical use rates of many long-acting methods of birth control, particularly the IUD and birth control implants, is almost nonexistent, meaning that they generally achieve their theoretical effectiveness level in normal

use. Birth control researchers are also attentive to socioeconomic differences in method choice (that is, what groups prefer which methods and why) and failure rates, with statistics often indicating that underprivileged women are less likely to use contraceptive methods consistently and more likely to experience contraceptive failures even when they do use them, although the mechanisms behind this trend are not well-understood.

One of the major goals of birth control researchers has been to identify women who say they do not want children in the near future but who are not using a method of birth control; in aggregate, this is referred to as *unmet need.* Numerous criticisms have been leveled against the traditional conceptualization of unmet need, particularly its focus on hormonal and intrauterine methods of contraception. Critics point out that many of these women have valid reasons for not using modern methods of birth control and that portraying these women as traditional or primitive for failing to use appropriate methods ignores the many legitimate objections that women have for avoiding these methods. These objections include the many uncomfortable side effects that arise from hormonal and intrauterine birth control, such as disrupted menstrual cycles and moodiness, diminished pleasure from condoms, and financial expense. Feminist critics have also argued that fertility researchers' almost exclusive emphasis on hormonal and intrauterine methods ignores the problematic implications of widespread medical surveillance of women's bodies and vastly underestimates the health consequences of extended hormonal and intrauterine method use. Researchers have responded to these criticisms in ways that have reshaped the study of birth control.

First, rather than focusing exclusively on women's unmet need, researchers have moved toward a greater focus on the contraceptive needs of women and men, often specifically looking at couples. Whereas earlier research was frequently accused of portraying men as obstacles to women's contraceptive access, recent research has begun to look more broadly at the way that women and men facilitate and deter each other's contraceptive use. Second, in response to the criticism that unmet need did not adequately address the relationship between fertility desires, contraceptive desires, and contraceptive use, researchers have begun to explore the relationship between pregnancy intentionality and birth control use in more depth. *Pregnancy intentionality* refers to women's, men's, and couple's desires and intentions for more children. Research has emphasized the often uncertain nature of pregnancy intentionality, conflicts between partners, and the effects of these patterns on contraceptive use. Both of these changes to contraceptive research have been strongly informed by the contributions from qualitative research (interviews, focus groups, and ethnographies), both in developed and developing countries. Although the study of contraception continues to be dominated by quantitative research based on surveys, mixed-method studies combining qualitative and quantitative data, as well as qualitative studies on their own, have proliferated in this field. Qualitative contributions have demonstrated the role of social networks in spreading contraceptive use, as well as illustrating some of the social and cultural obstacles people encounter in trying to negotiate contraceptive use with significant others.

Despite these developments, research on birth control use around the world continues to focus disproportionately on adolescents. Critics argue that this focus both reflects and contributes to the problematic aspects of adolescent sexuality, but proponents argue that contraceptive habits formed in adolescence will probably continue into young adulthood. In the U.S. context, at least, the emphasis on adolescent contraceptive use seems perhaps unwarranted because unintended pregnancies are actually most likely to occur to women between ages 18 and 24. Research focusing specifically on adults' contraceptive use has been so lacking that one of the key journals in the field, *Perspectives on Sexual and Reproductive Health*, plans a special issue on the subject. The paucity of research in this area raises many questions about birth control use across the life course, particularly in the face of major fertility-related events, such as abortion, childbirth, marriage, and divorce. Scholars do not know, for example, how women and men decide that they are finished with childbearing, even though they regularly refer to *completed fertility*. Researchers also know that rates of male and female sterilization differ considerably among nations yet know very little about why this is.

Another issue that has been neglected in the study of birth control is the way that considerations of pleasure influence contraceptive use, decision making, and negotiation. Researchers have posited many different reasons why condom use in every society is so much lower than public health officials would like, often emphasizing women's lack of control over male condom use. However, few researchers have addressed the fact that both men and women in many different cultures feel that condoms seriously diminish their sexual pleasure, which may be the most salient reason for not using them. The limited attention the issue has received has almost always been directed toward reductions in men's sexual pleasure, typically ignoring women's lost sexual pleasure from condoms as well as their reduced libido from many hormonal methods.

## POLICY ISSUES

Birth control continues to be the subject of religious, policy, and political controversy. The Catholic church still officially condemns all methods of birth control

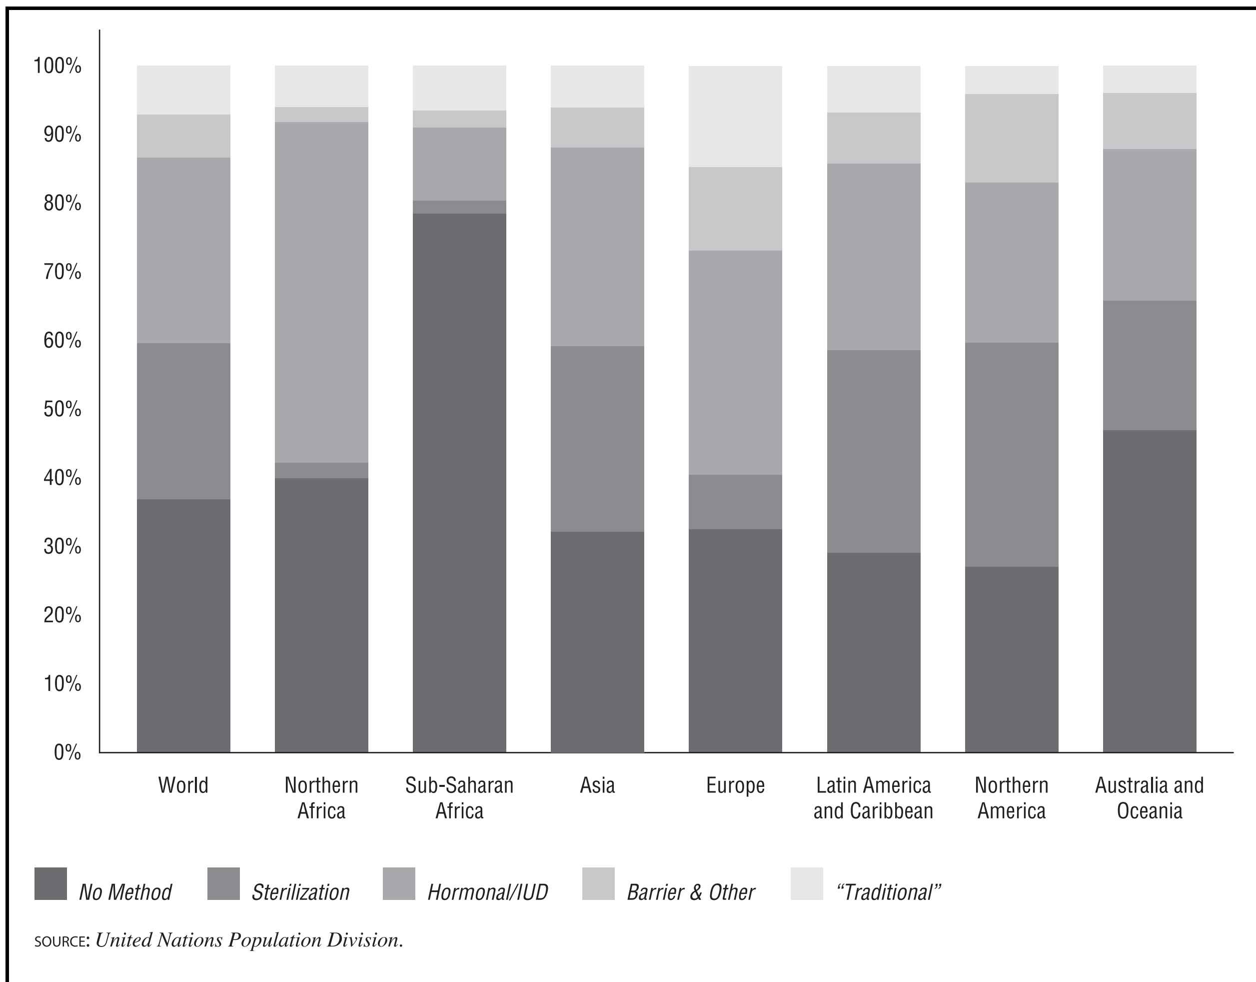

***Figure 2.*** *World contraceptive use trends among women, 2007.* CENGAGE LEARNING, GALE.

other than the natural family planning method it developed based on the rhythm method; yet there is little evidence that most Catholics obey this religious tenet. Other religious groups, such as the Mormons, strongly promote the value of large families while still approving of birth control. National policies likewise range from active government promotion of birth control in China and Iran to government discouragement of population limitation in some African countries.

In general, developing countries frequently struggle with issues of access to, availability of, and acceptability of contraception. One of the greatest obstacles for developing countries is establishing a medical infrastructure capable of managing women's reproductive health care needs, from the safe implantation of IUDs to the timely distribution of OCPs. Normative societal mandates also may prevent unmarried women from obtaining contraceptives, especially in cultures where husbands must approve of their wives' use of contraceptives. Furthermore, distrust of foreign doctors and medicine often make many people in developing countries wary of unfamiliar contraceptive methods. Contraceptive concerns vary widely by region, with some African countries, such as Botswana (where one in three people may be infected with HIV), facing an HIV epidemic that makes condom use seem essential but other methods of birth control superfluous. Meanwhile, many Asian countries, particularly India and China, have made population control a major social priority and have been successful at distributing contraceptives to large swaths of their populations.

Birth control controversy in developed countries also focuses around access but more specifically the issues of adolescents' access and medical intervention. Some countries allow adolescents unfettered access to contraception, whereas others require parental permission for them to obtain it. Even when it is ostensibly available to them, adolescents may have difficulty obtaining contraceptives because of financial, transportation, or confidentiality

issues. In many countries, hormonal contraceptives are available without a doctor's prescription (over-the-counter), whereas others, such as the United States, restrict access through medical providers. The United States recently made emergency contraception available to people over 18 over-the-counter, but the issue was clouded in controversy, especially because many view emergency contraception as an abortion-inducing intervention. Political controversy also continues about the extent to which young people should receive formal education about the use of contraception. Research, however, overwhelmingly demonstrates that education about contraceptive methods does not make adolescents more likely to have sex but does make them more likely to use protection when they do. For both adolescents and adults, birth control use is essential in assuring family limitation and the prevention of STIs, and the study of birth control provides insights into the most efficient and user-friendly means to accomplish these ends.

## BODY IMAGE, ADULTHOOD

Although scientists have always regarded body image as more than a mental photograph of oneself, its scientific meaning has evolved over time. In the early 1900s, body schema was a neurological concept—the brain's registration of the body's sensory and motor activities. It emerged in an attempt to understand the *phantom limb* phenomenon, in which patients felt pain or other sensations from amputated limbs.

Subsequently, a psychoanalytic approach to body image was developed. Through the works of Paul Schilder (1886–1940) and Seymour Fisher (1922–1996), body image came to be seen as the complex experience of one's physical being at varying levels of consciousness. Because the body is the boundary between the self and everything outside of the self, one's experience of the body was viewed as the result of early emotional learning. Thus, from a psychoanalytic perspective, body image has less to do with conscious feelings about the body per se than with unconscious feelings about the self. Projective methods (e.g., inkblot and drawing tests) are typically used to study body image from this perspective, albeit with dubious success.

A more recent perspective (e.g., Cash & Pruzinsky, 2002) regards body image as a perceptual representation of the body's size and shape. This view emerged from researchers' attempts to understand the distorted perceptions held by patients with eating disorders, such as anorexia nervosa and bulimia nervosa. However, the empirical meaning of perceptual size distortion is unclear and it represents a very limited conception of body image.

The most contemporary perspective defines body image as a multidimensional attitude toward one's own physical characteristics, especially one's appearance (Cash & Pruzinsky, 2002). Body-image attitudes are evident in people's mostly conscious, body-related cognitions, emotions, and behaviors. A distinction is made between two core dimensions: *Body-image evaluation* pertains to one's feelings about one's looks, such as satisfaction or dissatisfaction, whereas *body-image investment* refers to the psychological importance of one's appearance to one's sense of self and self-worth. Researchers typically use self-report questionnaires to measure body-image attitudes—including evaluations of physical attributes, beliefs about

the importance of one's appearance, body-image emotional reactions in everyday situations, and behaviors to manage one's appearance or one's own reactions to it. Popular validated questionnaires include the Body Shape Questionnaire, Multidimensional Body-Self Relations Questionnaire, Body Esteem Scale, and Appearance Schemas Inventory.

Since the late 1980s body-image research has flourished. Thousands of scientific studies and more than a dozen scholarly books have been published on the subject. In 2004, a new journal commenced, *Body Image: An International Journal of Research*. This continuing boom is likely the product of several forces—for example, the recognition of the pivotal importance of body image in the growing prevalence of eating disorders, feminist concerns about how cultures socialize girls and women to overinvest in and loathe their appearance, and an emergent realization that the field must expand to include children and men and to study the body-image issues inherent in many medical conditions or their treatment.

## BODY-IMAGE DEVELOPMENT

A person's sense of self is partly rooted in the experience of embodiment, that is, the experience of existing within a physical body. Socialization about the meaning and significance of physical appearance to the self is influenced by the norms and expectations of one's culture, family, and peers. Social learning entails the acquisition of emotion-laden attitudes about one's own body. Largely as the result of explicit and implicit social feedback, people acquire beliefs about the acceptability and attractiveness of their physical characteristics. They develop beliefs about what they look like, and they also internalize standards or ideals about what they should look like and how important these standards are.

An understanding of body image must recognize that the body and its appearance change over the life span. Adolescence is a period that involves increased personal and social emphasis on physical appearance. Appearance-altering conditions such as weight gain or facial acne can diminish a teenager's body satisfaction and sense of social acceptability. These experiences stamp body image in ways that can persist into adulthood. During adulthood, the normal physical changes that come with aging can lead some appearance-invested individuals to worry about losing their youthful looks. For example, common genetic-pattern hair loss can provoke body-image concerns among many men and women. Still, cross-sectional research reveals that older adults do not necessarily have a more negative body image than younger adults. One explanation is that aging tempers one's investment in physical appearance relative to other sources of self-worth, such as family and career roles.

Whereas some physical changes result from the biological aging process, others are precipitated by unforeseen illness or injury, such as traumatic burns, HIV or AIDS, and cancers and their treatment (e.g., chemotherapy or mastectomy). These conditions challenge body-image adaptation, as individuals must integrate their altered appearance into their self-view and manage unwanted social consequences of this altered appearance. Acutely acquired disfigurements are generally more disruptive of body image than are congenital deformities that are incorporated into one's early body-image development.

## BODY IMAGE, GENDER, AND CULTURE

National surveys from the 1970s through the 1990s, as well as some meta-analytic research, point to Americans' growing body dissatisfaction, especially among women. Regardless of respondents' age or when the survey was conducted, women consistently report less favorable body-image evaluations than men. For both sexes, body weight, shape, and muscle tone are typically the foci of greatest dissatisfaction. Most weight-dissatisfied women believe that they are too heavy, even if average in weight. By contrast, men who are unhappy with their weight are fairly equally divided into those who believe they are either overweight or underweight. Cross-sectional studies suggest that, despite heavier body weights, college-attending women may have become more accepting of their bodies than was true in the 1990s.

Relative to men, women are more psychologically invested in their appearance and engage in more appearance-management behaviors. These differences mirror European and North American society's greater emphasis on a woman's attractiveness. Considerable evidence points to powerful media influences on societal physical ideals, which if internalized can produce overinvestment in appearance and body dissatisfaction.

To understand the role of cultural differences, body-image researchers have studied various subgroups within European and North American societies. For example, African American women appear to have a more positive body image than European American women, and this is especially apparent at higher body weights. Like various African cultures, African Americans view a more full-figured female shape as feminine and attractive. Individual differences in body image may also depend on sexual orientation (Roberts et al., 2006). Relative to heterosexuals, gay men are more invested in and less satisfied with their appearance. This difference may reflect their inclination to please men who, to a greater extent than women, stress physical attractiveness as a criterion of sexual or romantic desirability. Although not scientifically clear, lesbians may be less appearance-invested

and more satisfied with their bodies than heterosexual women.

## BODY-IMAGE DISSATISFACTION, DISTURBANCES, AND DISORDERS

Not only is body dissatisfaction a common human experience, for some it can lead to psychosocial problems. Body-dissatisfied individuals are at risk for poor self-esteem, social anxiety, depression, sexual difficulties, and eating disturbances. In turn, these problems can also impair body image satisfaction. However, body-image dissatisfaction is not the same as body-image disturbance. The latter occurs when dissatisfaction entails preoccupation, self-conscious distress, avoidance of situations and experiences that portend such distress, and interference with everyday life.

Substantial research attests to the central role of body-image disturbance in eating disorders. Persons with eating disorders hold an extremely disparaging view of their body weight and shape and overestimate their true size. They are also heavily invested in their appearance as a criterion of self-worth. Prospective studies suggest that these body-image disturbances are precursors to disordered eating and serve to worsen and maintain the behavior once it has begun.

Another severe body-image disorder is body dysmorphic disorder. This disorder was included in the *Diagnostic and Statistical Manual of Mental Disorders* by the American Psychiatric Association in 1994, although it was recognized by Asian and European clinicians long before this time. Comparably affecting men and women, body dysmorphic disorder refers to an excessive preoccupation with a nonexistent or minor physical defect. Persons with this disorder believe that the so-called defect is quite socially noticeable. They spend an inordinate amount of time compulsively inspecting their appearance in mirrors or other reflective surfaces, and they self-protectively avoid ordinary social events because they expect to experience intense self-consciousness and anxiety. Although they may recognize that their perceptions are distorted, they are more likely to consult with a medical or surgical professional to fix the perceived physical flaw than to seek mental-health assistance. A subtype of this disorder is muscle dysmorphia, in which the subjective focus is on perceived insufficient muscularity. This condition is more prevalent among men, who actually may be very muscular and may exercise or use bodybuilding supplements to excess.

## BODY-IMAGE IMPROVEMENT

The most common approach to body-image improvement is to alter the body so that it will conform to the person's body-image ideals. Many people pursue weight loss, physical exercise, and cosmetic surgery, as well as aesthetic grooming changes in attempts to create a more personally satisfying appearance. Such body-modifying methods can improve body-image satisfaction. However, critics argue that many of these so-called remedies have inherent health risks and that all ultimately reinforce conformity to unrealistic expectations of physical attractiveness and fail to reduce excessive body-image investment.

Psychotherapeutic interventions have been designed to promote body acceptance without bodily change. Most thoroughly studied is cognitive behavioral therapy (CBT), which has proved effective for a range of psychosocial disorders. It is based on the premise that people can overcome problems by learning more adaptive patterns of thought and action and by eliminating self-defeating patterns. Considerable research supports the effectiveness of cognitive-behavioral body-image therapy with various populations, including body-dissatisfied college students, obese persons, and individuals with eating or body dysmorphic disorders. Such body-image improvement also promotes gains in self-esteem and other aspects of psychosocial well-being. For some people, CBT programs can be successfully implemented as structured, guided self-help via workbooks or Internet-based programs.

## CARE WORK

SEE Volume 3: *Caregiving.*

## CAREERS

In a life course approach careers are defined as observable pathways that consist of patterned trajectories and transitions over time. Although the term *career* most often refers to a series of occupational positions, life course scholars apply it to a range of pathways, such as family careers, mental health careers, and relationship careers.

Research documents the socially patterned timing of career transitions as well as socially patterned career trajectories (or sequences) and the way those patterns differ by gender, age, cohort, social class, race/ethnicity, health, education, occupation, and/or industry. Careers also are studied in terms of people's assessments of their past trajectories, current situation, and prospects for the future. In light of the centrality of paid work in contemporary adult development, this entry focuses on occupational paths and beliefs.

Individuals often assess their occupational careers as coming up short in terms of cultural expectations, making cognitive appraisals of being on or off time in their occupational careers. Their yardstick is what Phyllis Moen and Patricia Roehling (2005) call the career mystique: ingrained cultural beliefs (institutionalized in rules, regulations, and expectations) about continuous long-hour hard work throughout adulthood as the path to status, security, and satisfaction. In other words, most people have an ideal concept of a career as the path to the American dream of upward mobility, an orderly and hierarchical progression up occupational ladders.

### CAREERS AS BLUEPRINTS FOR THE ADULT LIFE COURSE

The idea of a career is a modern invention, having emerged as a social fact only after the development of corporations, bureaucracies, and white-collar employment. As C. Wright Mills (1956) pointed out, before the Industrial Revolution, which occurred in the United States in the second half of the 19th century, most people worked in agriculture or a family business. Though individual farmers, craftspeople, and family entrepreneurs might have had life plans, they did not have careers. It was only after industrialization and in tandem with the Great Depression, two world wars, and a booming postwar economy that a large white-collar and unionized blue-collar workforce experienced the bureaucratization of occupational paths or careers.

Governments, schools, and workplaces developed policies and practices in the 1930s through the 1960s that institutionalized careers as identifiable pathways of full-time employment. Those in white-collar and unionized blue-collar occupations could count on wages and job security increasing with seniority, from entry-level jobs for young people to retirement. Educational, labor market, and

retirement policies based on the career mystique produced a three-part life course: full-time education as preparation for employment, an adulthood of continuous full-time employment, and the one-way, irreversible exit to the leisure of retirement, thereby opening job opportunities to younger cohorts of employees. Thus, in the middle of the 20th century most middle-class white men followed a lockstep pattern: a one-way path from schooling through full-time continuous occupational careers to retirement.

A number of life course scholars have pointed to occupational careers as providing an organizational blueprint for the adult life course. Careers embody both structure (relationships between jobs, public- and private-sector policies and practices) and process (moving through identifiable career lines, taking on the occupational identity such as lawyer or doctor). As paid work in corporations and governments replaced farming, the role of the employee became central in contemporary society and the work career came to shape life chances, life quality, and life choices in virtually every arena.

## OUTSIDE THE CAREER MYSTIQUE

The lockstep career mystique is a myth and has never been a reality for most ethnic minorities, women, and poorly educated adults. Moreover, the career mystique has become increasingly obsolete even for middle-class men. In a competitive global economy seniority no longer provides protection against job insecurity. Still, this myth is built into the social organization of paid work and continues to shape and define adulthood, life chances, and life quality. Public policies (such as Social Security and unemployment insurance) and corporate policies (hiring, recruiting, firing, promoting, retiring) have reinforced the career mystique by promising rewards to people who work hard, continuously, and full time throughout their adult years in a single organization or "ladder hop" across organizations. Until recently employers have tried to recruit and retain people who are committed to such full-time continuous employment by offering them health insurance and pensions.

One result of this institutionalization of the lockstep career mystique is that individuals who experience uneven or downward career pathways have been seen and often see themselves as deviant. Employers view people moving in and out of the workforce and those employed less than full time as less committed to their jobs, reaping and deserving fewer economic and psychological rewards. Moreover, because a career is equated with occupational history, unpaid work, whether as a participant in a family business, a homemaker, a family care provider, or in formal or informal civic engagement, has been rendered marginal to the real work of society. Individuals who do not or cannot follow this lockstep pattern of continuous full-time work (e.g., those in insecure jobs, those with family responsibilities) are penalized.

## DIVIDING ADULTHOOD BY GENDER

Occupational careers have been fundamental to men's identities—the purported path to security, success, and status—and for their families as well. However, men in the middle of the 20th century were able to lead work-centered lives because their wives took care of their personal and domestic needs and responsibilities and often supported their career progression behind the scenes. By contrast, women's lives have been more contingent and accommodating than lockstep, developing in relation to marriage, motherhood, economic exigencies, and their spouses' occupational careers. However, minorities, the poor, and the poorly educated could follow neither career nor homemaking paths, often moving in and out of jobs that were unrelated (not leading to a particular career pattern) and poorly paid.

Nevertheless, most Americans in the 1950s and 1960s wanted a middle-class lifestyle and worked to achieve it. The breadwinner/homemaker template provided cultural guidelines and clear options related to occupational careers, family careers, and gender that effectively decoupled paid work from unpaid family care work, creating an imaginary divide between them. The ideal-typical "Ozzie and Harriet" family was seen by most Americans in the middle of the 20th century as the ideal arrangement even for those who could not afford or fit its parameters.

Betty Friedan's *The Feminine Mystique* (1963) depicted half of this cultural divide: the belief that women could achieve total fulfillment by devoting themselves to full-time domesticity as homemakers for their husbands and children. However, Friedan paid no (or scant) attention to the career mystique: the belief that most American men could achieve total fulfillment by devoting most of their adulthood and most of their waking hours to their jobs. Though some authors captured the reality of men's lives—C. Wright Mills wrote *White Collar* (1956), William H. Whyte described *The Organization Man* (1956), and Sloan Wilson provided a vivid fictional account in *The Man in the Gray Flannel Suit* (1955)—none of those works had the impact of Friedan's book.

The women's movement of the 1960s and 1970s effectively destroyed the feminine mystique. In rejecting its norms and values, many women in the second half of the 20th century sought equality by embracing the career mystique, wanting men's jobs, salaries, and power and status. Women now constitute nearly half the U.S. workforce, but careers remain designed for those who can

focus their time and efforts fully on their jobs. Outdated policies and practices combined with the growing numbers of households with all adults in the workforce have created a fundamental mismatch. Employees struggle with and try to find strategies to adapt to their obligations at work along with the unpaid care work of families, homes, and communities.

In the 21st century most American women have not simply traded one mystique for another, moving from strictures about the good mother or the good wife to the good worker, but instead are trying to fill all three roles. However, the outdated structures and cultures of jobs and career paths make it impossible to do so. Research shows that women who scale back at work, take time off, or shift to jobs that are less time-consuming pay an economic price.

The pervasive gender bias in the ways people think about and study careers also is reflected in the exclusive emphasis on individuals. Dual-earner households have become the norm, and so there are often two occupational paths in a single household. Research shows that couples strategize, prioritizing one person's (typically the husband's) career by having the other person (typically the wife) modify her occupational commitments in light of family considerations as well as considerations of the spouse's career, scaling back to part-time work or leaving the workforce when family care demands are high. Most employees and family members also adjust by modifying the family side of the work-family equation by delaying marriage and/or parenthood and/or having fewer children.

## OUT OF STEP

The 20th-century contract between employers and employees that undergirded career paths was based on the seniority system and the notion of a primary and a secondary workforce. Middle-class (mostly White) men with many years of employment were sheltered from economic dislocations. It was the last hired—typically women and minorities—who were the first fired. However, thus far in the 21st century the proportion of workers under union contracts have reached an unprecedented low, and implicit contracts (trading mobility and job security for a continuous commitment to work) have disappeared.

The career mystique vision of orderly careers as the successful path through adulthood has lagged behind 21st-century realities. Unprecedented numbers of Americans are college-educated, expecting to have interesting, challenging, secure jobs but not always finding them. Salaries no longer are sufficient to support families on one income. The amenities of the 1950s—air-conditioning, color televisions, fancy appliances—have come to be viewed by most Americans as necessities. Most workers are part of dual-earner households, married to other workers. Growing numbers of workers are heads of single-parent households, doing all their families' paid work and unpaid care work. In fact, in 2001 only one in four workers had a full-time homemaker for backup and support. Another challenge looms on the horizon: The workforce is aging as the large boomer cohort moves into and through their fifties and sixties.

Equally consequential, the U.S. economy has become a globalized economy, grappling with new technologies, international workforces, and fast-paced changes, including mergers, buyouts, and acquisitions. The ambiguities and uncertainties in boardrooms, offices, and factory floors affect the sensibilities of workers and their families as they face the realities of frequent employer restructuring, often accompanied by forced early retirements, layoffs, fewer benefits, and greater workloads.

What has not changed is the career mystique: Employers and workers see good employees as those who are willing to make heavy investments of time and energy in their jobs. Not for the U.S. workforce are Western European institutions such as long summer and winter vacations, paid parental leave, and part-time jobs with benefits. Studies show that Americans pride themselves on working hard, taking work home, staying late at the office, and not taking all their vacation time.

## SHAPING COGNITIVE BELIEFS, VALUES, AND EXPECTATIONS

The career mystique not only became an organizing principle shaping options and opportunities over the life course, it also shaped people's identities, self-appraisals, and expectations for the future. As Stephen Barley (1989) pointed out, early sociologists acknowledged the "Janus-like" aspects of the career concept as both institutional (a series of structural positions) and subjective (ways employees define and give meaning to their unfolding occupational experiences). Occupational careers as movement through positions also entail changes in peoples' subjective self-definitions, expectations, evaluations, and meaning.

Walter Heinz (1996) pointed out that status passages such as job shifts and retirement "link institutions and actors by defining time-tables and entry as well as exit markers for transitions" (pp. 58–59). However, institutional guidelines for career paths are outdated. Against a backdrop of 21st-century social transformations, even white men with college educations and professional experience are finding fewer career ladders that bring job and income security, much less success.

## FUTURE DIRECTIONS

Human development over the life course is shaped by socially patterned expectations related to roles in the form of norms about the right time for adults to begin a career job, get a promotion, or retire, as well as socially structured entry and exit points and durations that shape the opportunity for and reward some pathways

and not others. Studying occupational careers involves thinking about and attending to employment over time, referring to, for example, the processes of job development, mobility, and plateauing as well as entries and exits. Three key themes characterize a life course perspective on career development. The first places careers in context, considering the ecology of employees' social location, in terms of their historical cohort, ethnicity, gender, life stage, occupation, and workplace. All these factors shape opportunities and constraints at work and at home. The second is the notion of linked lives, as individuals and couples strategize to synchronize their goals, expectations, and obligations. The third theme is the dynamic notion of pathways, involving transitions, trajectories, and timing.

The term *career* usually refers to recognized patterns of organizational and occupational movement throughout adulthood and the widely accepted career mystique that depicts lockstep careers as the path to the American dream. Even though notions of orderly careers are out of date, government and business rules and regulations continue to reinforce the primacy of full-time continuous employment, rendering marginal all other types of labor force attachment: part-time jobs, temporary work, and intermittent employment. The solution, some scholars have concluded, is to enable customized rather than lockstep career paths, widening the options for employees at different ages and life stages. Research is needed on customized career innovators: both employers and employees who are reshaping possibilities.

The study of careers contributes to the understanding of the dynamic links between lives and organizations as well as the dislocations brought about by both the work-family mismatch and the job security mismatch. In 1977 Seymour Spilerman pointed to the discrepancy between career characterizations and accounts on the one hand and people's actual patterns of job sequences on the other. These discrepancies may have become even more acute. What is required are empirically derived new typologies that capture the experiences of contemporary employees in different employment and home environments, their assessments and strategic responses to those experiences, and the consequences for their health and well-being as well as for business, the family, and society.

A global risk economy, advances in communication and information technologies, an aging workforce, and a workforce with family care responsibilities mean that conventional beliefs about careers are outmoded, with diminishing numbers of workers fitting the traditional orderly career pattern. New public policies and practices and new corporate rules and regulations will be required to widen the career path options and safety nets. However, the concept of careers remains a useful lens with which to view both the dynamic relationship between choice and constraint and the dynamic interplay between organizations and lives that play out over time.

# CHILDBEARING

A life course framework is central to the study of childbearing. Physical maturation is required before women can bear children and before men can impregnate women. This reproductive potential, or fecundity, generally lasts about three decades for women and considerably longer for men. During these fecund years, women could conceivably have a birth each year, but such high levels of childbearing (30+ births per woman) are exceedingly rare. The survival

strategy of humans has focused instead on far lower levels of childbearing and intense efforts to increase infant and child survival. The strategies used to limit fertility and aid child survival vary dramatically across societies.

For instance, in many societies marriage norms limit coitus (i.e., sexual intercourse), and therefore childbearing, to particular ages and circumstances. Other norms have specified times when married women should not have coitus or the length of time that they should breastfeed, increasing the interval between births. Thus, at the heart of fertility research is not just the number of births a woman has in her lifetime but the ages at which she has them, their spacing vis-à-vis their siblings, and their sequencing vis-à-vis other life events such as marriage. Childbearing is a prototypical life course event—childbearing is possible for only a segment of the life course, and it is a repeatable event whose timing and sequencing have demonstrable effects on subsequent fertility, other life events, and overall life chances.

Despite the necessary role of males in reproduction, the fertility research literature focuses mainly on women. The reasons are many. First, only women become pregnant and give birth. Thus, the study of maternal and child health closely links women and fertility. Second, women are frequently the primary child caretakers, and, in general, women's lives are more influenced by childbearing and childcare than are men's. These mother–child bonds and interactions generally make mothers more knowledgeable and accurate respondents to surveys that assess matters of childbearing and rearing. As a result of these factors and others, researchers tend to choose women as research subjects. This woman-centered focus does cause some problems, but some of these have been addressed since the late 20th century.

## POPULATION-BASED MEASURES OF FERTILITY

Childbearing is generally measured as live births per woman. Miscarriages, abortions, and stillbirths are not counted (live births plus these events equals the number of recognizable pregnancies), but infants who die very early in life (even in the first day of life) are included. Births can be summed across a woman's lifetime to produce the number of children ever born (CEB), and the mean CEB is a useful childbearing measure for a cohort, or study group, of women. However, the most commonly used measures of childbearing are period rates—the ratio of events (births) per years of exposure for a given population in a given time period. The most common period rate is the total fertility rate (TFR), which is an answer to a hypothetical question: If a woman were to experience the age-specific fertility rates of year *x*, she would have *y* children. Put a bit more formally, the TFR is the sum of age-specific birth rates from (usually) age 15 to age 45. With the low levels of mortality that characterize contemporary industrialized countries, a TFR of 2.1 is replacement level fertility—the level that would lead to long-term stability in the size and structure of the population. Contemporary TFR levels vary from highs of 7.5 in poor countries such as Afghanistan and Niger to below 1.25 in places as varied as South Korea and Poland (United Nations, 2007).

Period fertility rates can be calculated for any population; crucial distinctions from a life course perspective are age, parity (i.e., the woman's number of previous births), and marital/union status (hereafter union status). Fertility rates vary dramatically by these characteristics due to their strong links to the proximate determinants of fertility, which are discussed more fully below. Age can index fecundity or normative ages for childbearing; parity greater than zero provides evidence of fecundity and may indicate that preferred family size has been reached and, thus, could be a signal to use contraception or resort to abortion. Union status can indicate one's likelihood of engaging in coitus or becoming pregnant and is often the preferred relationship status for childbearing. In any given year, the distribution of a population across age/parity/marital status will have an impact on its aggregate level of fertility.

The TFR (as the sum of age-specific rates) accounts for any differences in age structure between populations, which might otherwise distort a comparison of fertility rates if one population has more women of childbearing age than the other. The popularity of the TFR follows from this feature, its interpretability, and widely available data for its calculation. Age-specific rates (the components of TFR) can also be examined to determine if one population has an earlier or later pattern of childbearing. Subsequent sections focus on adolescent childbearing and delayed childbearing—the fertility rates of teenagers or those over the age of 30 (or 35), respectively. This focus is justified because of the implications of childbearing at these ages for the individuals and for their social groups (families, communities, and countries).

Fertility rates are frequently decomposed by parity. A common strategy (largely due to data availability) subdivides the numerator of age-specific rates by parity (while leaving the denominator, years at risk, fixed). Thus, one can sum these parity-specific and age-specific rates to create a set of parity-specific TFR rates ($TFR_{i;}i$ = 0, 1, 2, 3+); this set sums to the original TFR. This is useful because changes in fertility can be concentrated at given parities, or stages of family building. For instance, and as discussed below, the fertility transition (changes in birth rates from high to low) is generally caused by the decline in higher parity births. That is, $TFR_0$ and $TFR_1$ change little whereas $TFR_{2+}$ declines dramatically.

Like increasing age and parity, union transitions can have large effects on fertility, but these effects vary greatly by time and place. Preferred measures of childbearing by

union status disaggregate the populations into married and unmarried and then calculate fertility rates as discussed above. Fertility rates for married women are generally much higher than for the unmarried, but this differential varies greatly over historical periods and geographic locations.

## THE PROXIMATE DETERMINANTS OF FERTILITY

The fundamental challenge in fertility research is to understand the factors that produce variation in fertility across individuals and across populations. There are many reasons; some focus on the proximate determinants of fertility. In a classic typology, Kingsley Davis and Judith Blake (1956) identified variation due to the likelihood of coitus, of becoming pregnant, and of carrying a pregnancy to term. John Bongaarts and Robert Potter (1978) elaborated this typology and then traced most subgroup variation in fertility to four key proximate determinants: (a) marriage or the age at which one becomes sexually active; (b) the length of breastfeeding, which is the primary determinant of the anovulatory (suppressed ovulation) period following a birth; (c) the use of contraceptives; and (d) the use of abortion. A huge body of research accounts for group differences by attributing it to these causes.

However, an important critique of this work is that these proximate answers only beg additional questions: If fertility levels vary because of earlier marriage or greater contraceptive use, then what causes early marriage or greater use of contraceptives? The answers lie in the social environment that constrains and enables action—more fundamental determinants. In sum, there is an important distinction in the fertility literature between proximate and more fundamental determinants (or causes). There is far greater agreement about the former than the latter due to the greater challenges of demonstrating fundamental causes.

With respect to the key proximate determinants listed above, the first two can produce vast variation in fertility across groups (Bongaarts & Potter, 1978). For groups in which contraception and abortion are unknown or rare, fertility has been reliably measured as high as 10 births per woman (among the Hutterites, a religious sect that resides on communal farms in the northern United States and western Canada) and as low as 4 births (among the !kung, a nomadic hunter-gatherer society in the Kalahari Desert). The proximate determinants approach shows that the !kung spend considerably more of their fecund years outside a sexual union (due to widespread union disruption) and that women breastfeed for periods as long as three or four years. As a result, the !kung have long intervals between births. With three fecund decades for childbearing, long intervals imply fewer births. The Hutterites, in contrast, marry relatively young, remain married throughout the fecund years, and breastfeed for relatively short periods (Bongaarts & Potter, 1983; Howell 1979).

Research shows that other potential proximate determinants generally do not affect fertility levels across time or space. For instance, poor nutrition and disease do not usually cause differences in fertility among populations, although they clearly cause variation within populations (that is, among individuals). Likewise, the frequency of coitus within sexual unions seems not to vary greatly cross-culturally. Age at menarche (i.e., the onset of menstrual periods) does vary across populations and eras, but childbearing at these young ages is rare and thus negates its potential influence on the population level. Age at menopause varies little across populations (Bongaarts & Potter, 1983).

In populations in which birth control (i.e., contraception and abortion) is widely used, these become proximate determinants of overwhelming importance. The acceptability of various contraceptive strategies or techniques (hereafter techniques) varies sharply across populations, and the theoretical and use effectiveness of strategies vary. Theoretical effectiveness, the reduction in fecundity if the technique is properly used, is fixed for a given technique (i.e., for the pill or condom); but use effectiveness (the fecundity reduction achieved in practice) can vary in a population. Condoms have high theoretical effectiveness, but use effectiveness varies because the appropriate regimen (always using them) is sometimes not practiced.

Other important sets of proximate determinants have proven useful in place of those mentioned above or to supplement them. Perhaps the most important is the number of children a woman (or couple) intends to have. Fertility intentions, or the number of children one plans to have in the future, are relatively stable plans of action; they are the cognitive integration of the factors and forces motivating and constraining childbearing. For instance, less educated women might intend more children because their opportunity costs (in terms of lost wages) are lower than are those for more educated women. Fertility intentions, in turn, can be a primary determinant of proximate behaviors (such as use of contraception). Many fertility analyses focus on fertility intentions and the factors that aid or hinder women (or couples) in realizing intentions.

One aspect of the disjuncture between intentions and fertility behavior are unintended births—both mistimed and unwanted. Mistimed births are those that are unintended at the time of conception, but the respondent reports intentions to have a child or children in the future. Again stressing intentions at the time of conception, unwanted births are those that are not intended

now nor were intended in the future. Unintended births can result from contraceptive failure or from nonuse of contraception. The latter is related to the important concept of unmet need for contraception. The proportion of sexually active women who do not intend additional children and are not using contraception represent the percentage of women whose need for contraception is unmet. Reducing unintended births and lowering unmet contraception needs are frequent foci of public policy.

## WORLD FERTILITY TRENDS AND PATTERNS

Historically, fertility trends are generally couched within the demographic transition framework. Simply stated, the demographic transition is the process of change from high rates of fertility and mortality to low rates. In historical experience, mortality (i.e., the death rate) tends to decline sooner and faster than does fertility, producing a sharp divergence in vital rates—a period with high fertility and low mortality. Thus, the process of demographic transition includes a period of rapid population growth (when vital rates are not in equilibrium).

Much theoretical and empirical work has focused on the demographic transition. Some work has described fertility trends or the trends in proximate determinants that produce the fertility change. As noted earlier, empirical work shows that declines in higher parity births primarily produce the fertility transition. A prototypical case is Taiwan, where Griffith Feeney (1991) showed the fertility transition resulted entirely from declines in births to women with two or more children. Other work has described context-specific mixes of proximate determinants that produce relatively slow or more rapid declines in fertility. Slower declines, for instance, can be produced by increasing contraceptive use that is partly offset by declining duration of breastfeeding; more rapid declines can be produced by simultaneously increasing age at marriage and decreasing the proportion of high parity births.

The more fundamental causes of fertility change have received the greatest attention. Major arguments have stressed cultural/social change, economic change, policy interventions, and other demographic change. Cultural and social change arguments stress the acceptability of fertility control and changes in the importance of children or large families; economic arguments focus on the increasing costs of children due to a changed economic environment, such as a shift from agrarian, or extractive, to manufacturing or service economies. Policy interventions occasionally play a crucial role (e.g., China's one child policy) but more frequently have only a contributing role. Some argue that declining mortality, resulting from improved living standards or public health efforts (such as those that provide clean water or medical care), has decreased the demand for large families. Specifically, families' fertility desires reflect their wish for *living* children. In periods of high infant and child mortality, individuals need a greater number of births to ensure that the number of surviving children meshes with their initial preference.

Empirical work provides some evidence for all of these claims but demonstrates that when fertility declines take place, various economic and demographic regimes can exist. In Ansley Coale's 1973 classic formulation, fertility declines (a) when control of fertility is legitimate, (b) when individuals are motivated to have fewer children, and (c) when effective contraceptive strategies are available. These preconditions in a population can be attained in a variety of ways and can be encouraged or impeded by a number of factors. Thus, the demographic transition is part of multifaceted social change, including social, economic, demographic, and policy changes. No society develops economically without experiencing the demographic transition; however, the social history of transitions is highly variable in the timing of transition vis-à-vis economic change or in the import of policy interventions. The most attractive explanations focus on changes in (a) the way people live, including increases in education, nonagricultural jobs, and female employment; and (b) how individuals interpret the world around them—what they believe is reasonable, moral, or acceptable.

## FERTILITY RATE STATISTICS

Table 1 shows the number (and percentage) of countries by the level and trend in their total fertility rate. Column 1 shows that only 13 countries (7%) have high fertility rates and little evidence of substantial declines over the past 25 years. All but two of these countries are in Africa (Timor and Afghanistan are the exceptions), and all of them are characterized by low levels of socioeconomic development. A larger second set (see Column 2) also have high fertility (mean TFR of 5.1) but show clear evidence of decline—these countries exhibit an average decline of 1.7 births over the past quarter century. These countries are in the earlier stages of the demographic transition.

The third column contains the largest number of countries (77); these countries are in the midst of the demographic transition and show large declines over the past 25 years (average declines of 2.8 births). This tabulation is largely consistent with a global transition toward low levels of fertility—a few countries have yet to begin, some show clear evidence of decline, and a third set is rapidly approaching replacement level fertility. Some

interesting questions remain: Will some countries fail to move through the demographic transition? Will the decline of some countries' fertility rates stabilize well above replacement? Only the future can answer these questions, but most demographers would predict *no* to both questions—the transition will be global and the endpoint will be low fertility.

The last two columns of Table 1 show countries that have already completed the demographic transition—the decline of fertility to low levels and, for 31 counties, declines to very low levels. Very low fertility is now reported from a broad array of countries, including South Korea, Japan, Poland, Romania, Italy, Germany, and, according to some sources, China. These fertility levels have raised country-level concerns about both population aging and eventual population decline. Furthermore, as S. Philip Morgan (2003) pointed out, the spread of very low fertility raises the question of whether below-replacement fertility will become a global concern during the 21st century.

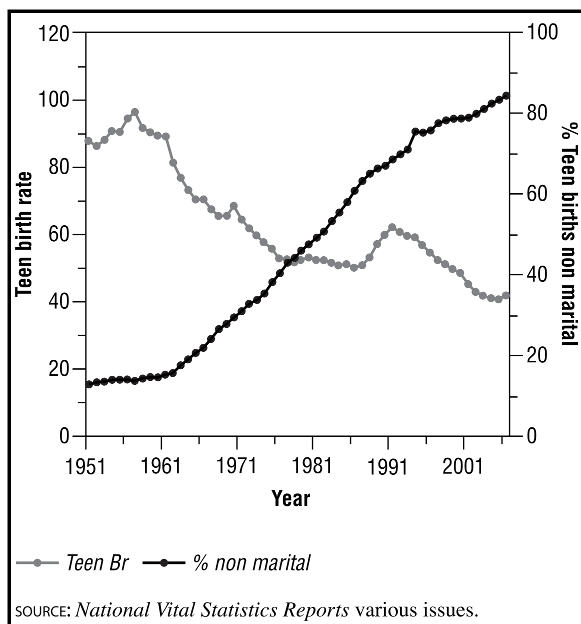
## ADOLESCENT CHILDBEARING

A focus on adolescent (or teen) childbearing returns the life course perspective to center stage. By definition, teen childbearing occurs relatively early in the life course. Thus, key questions focus on the timing of childbearing vis-à-vis a woman's physical maturity to bear, and her emotional maturity and general resources to rear, a child. Whether teenage childbearing is problematic for mother and child depends on the social setting, including the helpmates available to rear the child and the human capital the child needs to become successful. Frank Furstenberg, Jeanne Brooks-Gunn, and S. Philip Morgan (1987) argued that teenage childbearing in the United States became a major social concern in the 1970s.

Figure 1 shows that this was a period when teen childbearing was actually declining. Heightened concerns were the result of the changing context of teen childbearing, not its increase. First, the human capital demands of the labor force were growing, thus increasing the importance of schooling. Young women were encouraged to postpone childbearing and stay in school to acquire an education and skills that were important for their economic well-being. Increased education also produced more skilled mothers who were deemed important for rearing a future generation of productive citizens. The second major change, also shown in Figure 1, was the increased proportion of teen childbearing that was nonmarital—suggesting the absence of a male helpmate to care and provide for children.

For reasons noted above, adolescent childbearing is considered problematic in industrial and post-industrial society. The attention it receives is linked to its prevalence; generally, its frequency declined in the last two decades of the 20th century and early in the 21st century but varies greatly across societies. In the 1970s, 1980s, and early 1990s the United States stood out as having one of the highest rates of teen childbearing among industrialized countries (Alan Guttmacher Institute, 2002; Jones et al., 1985). This distinction remains, although U.S. teenage birth rates declined substantially in the 1995 to 2005 period. Figure 1 shows the U.S. teen childbearing rate from 1950 to 2005. Overall, the rate declined during this period (although there was an upturn from 1985 to 2001).

In terms of proximate determinants, the high U.S. teen childbearing rate compared to similar countries (e.g., Canada, Great Britain, France, and Sweden) is not due to an earlier age at first intercourse or to a higher frequency of sexual activity. Rather it results from lower levels of



SOURCE: *National Vital Statistics Reports* various issues.

***Figure 1.*** *Trends in teen birth rate and in the percentage of teen births that are nonmarital.* CENGAGE LEARNING, GALE.

contraceptive use and use of less effective contraceptives. In terms of more fundamental causes, these higher rates and the role of these proximate causes can be traced to negative societal attitudes toward teenage sexual relationships. These attitudes, in turn, inhibit access and increase the costs of reproductive health services, and they increase the ambivalence of parents and teens toward contraceptive use by teens. Also, dramatic inequality of opportunity can erode motivation to delay parenthood or to avoid unintended pregnancy. For young women with few promising prospects for education or careers, the potentially detrimental effect of early childbearing may not be considered all that serious (see Alan Guttmacher Institute, 2002; Jones et al., 1985). Recent declines in U.S. teen fertility (1995–2005) have occurred among Whites, Blacks, and Hispanics and have been accompanied by declines in abortions. Thus, there is evidence that increased abstinence and more effective use of contraceptives have both contributed to these sharp declines. The more fundamental causes of this decline remain an unanswered question and an active research area.

The consequences of teen childbearing have been the focus of much research and debate. The dominant view of the 1960s and 1970s is captured by Arthur Campbell's (1968) often quoted statement: "The girl who has an illegitimate child at the age of 16 has 90% of her life's script written. . . . Her life choices are few. And most of them are bad"(p. 238). Purported repercussions of teen childbearing include truncated schooling, poor job opportunities, more rapid subsequent childbearing, larger completed family size, and few good marriage opportunities. Evidence that teen mothers fared poorly on these dimensions was widespread. Further, "children bearing children" was widely posited as a key mechanism perpetuating poverty and disadvantage.

However, a critique of this view emerged that positioned teen childbearing in a broader context. Specifically, the critique pointed out that those who bore children as teenagers were disadvantaged prior to the birth; they had limitations or constraints that made their educational/economic/marital success less likely (than for others) even if they had postponed childbearing. Thus, their relatively poorer outcomes were due, at least in part and perhaps in their entirety, to these preexisting characteristics. Evidence for this view is impressive and rests on several clever research designs.

One design by Saul Hoffman, E. Michael Foster, and Frank Furstenberg, Jr. in 1993 compared sisters, one having an early birth and one not. This strategy controls for many family characteristics and aspects of the home environment that are shared by the sisters. The effects of teen childbearing estimated from this design are sharply attenuated, compared to the effects detected using more naive research designs. A second strategy by V. Joseph Hotz, Susan Williams McElroy, and Seth Sanders in 2005 used the occurrence of a spontaneous miscarriage as an event or "treatment" that postponed childbearing for a random sample of women. As in the sisters design, effects estimated using this strategy suggest modest impacts of teenage childbearing on many purported consequences. This research places a teen birth in the context of the life course—an important event but one closely connected with prior experience and contributing to subsequent events. In sum, teen childbearing is not nearly as determinative as was often assumed in the 1960s and 1970s.

## DELAYED CHILDBEARING

Contrasting delayed childbearing with early (adolescent or teen) childbearing is useful. Clearly delayed childbearing is normative if compared to teen childbearing. Postponing parenthood until one has the physical and emotional maturity to parent well, has established a reasonable level of economic security, and has entered a stable union are frequent normative preconditions for parenthood. That is, social norms encourage that childbearing be timed appropriately and placed in proper sequence in the unfolding life course. Appropriate timing and sequencing are justified by their advantages for the child, mother, and family.

The most common measure of delayed childbearing is change in the mean (or average) age of first births across time periods (or across groups of women defined by

successively more recent birth years, i.e., birth cohorts). The 1990s and early 2000s showed remarkably pervasive and consistent increases in the postponement of first births. In many places mean age at first birth has risen by one to two years per decade since the 1980s.

The most proximate determinants for this change are clear: Contraception and abortion are used to postpone childbearing. Women (or their partners) use these techniques to fit their children into a changing life course that includes longer periods of schooling, less secure employment, postponement of marriage, and increased longevity. The process is best characterized by a sequence of decisions to "not have a child now," to allow for greater economic security (a better or more secure job), to accumulate more wealth (e.g., to buy a home), or to build a more secure relationship with a partner. These postponements can be a process that changes goals and intentions. For instance, an interesting career may emerge, and its pursuit may lead to further postponement or a decision to forego childbearing. Postponement allows for the possibility of a union disruption prior to childbearing, and the absence of a partner may lead a woman to postpone or forego childbearing.

The more distal causes are fundamental social and economic changes that have altered the life course centrality of parenthood and the sequencing and duration of other aspects of the life course. Broadly, perceptions of appropriate and advantageous behavior have changed, as have the structural aspects of adolescence and adulthood. Central structural changes have included a declining proportion of manufacturing jobs and increasing proportions of service and white-collar jobs. This shift places a premium on education and training and produces job niches that include many women. The expansion of women's education, now surpassing men's in many places, and the increase in female employment have provided legitimate alternatives to early marriage and the economic independence to realize them. Ideologies that stress the importance of self-actualization and independence encourage a lengthened life course stage for training, experimentation, and emotional maturity. These changes led Ronald Rindfuss (1991) to characterize contemporary late adolescence and early adulthood as a "disorganized" life course period—normative and structural constraints on the transitions from schooling, to work, to marriage, to parenthood have lost their force. As a result, the timing, sequencing, and duration of these events or activities have become uncertain and highly variable.

Although fertility delay is advantageous and normative, repeated delay can have adverse consequences for individuals and populations. For individuals, repeated postponement can lead to unintended childlessness or to smaller than desired family size because of the diminished fecundity that accompanies aging. Repeated fertility postponement can mean that women may try to have a first child at 30, 35, or even 40 years of age. However, fecundity declines with age, with periods of subfecundity (i.e., reduced capacity to reproduce) generally preceding infecundity. Subfecundity does not preclude childbearing but on average increases substantially the time to pregnancy and/or live birth. Precise estimates are not available, but the percentage of women infecund is low at age 20 (perhaps 2 to 3%); this percentage doubles approximately every 5 years.

Thus, at age 40, many women (perhaps one third) are infecund and many more are subfecund (compared to a decade before); by age 50 nearly all women are infecund. Thus, simulations show that some family-building strategies are difficult—for example, a woman marrying at age 35 or 40 and having two children. A substantial proportion of women with such goals will not be successful because they will become infecund before having the second child (see Bongaarts & Potter, 1983, chapter 8). As Sylvia Hewlett (2002) pointed out, some who are unable to realize their strong desire for children may face huge disappointment , which leads them to seek expensive and invasive treatments for infertility. Childbearing at later ages can also carry new and unique risks; some infertility treatments increase dramatically the likelihood of multiple births and associated complications.

At the aggregate level, the increased demand for infertility treatments and the different set of risks experienced by older mothers and their children have consequences for medical provision. Also, later fertility for a birth cohort is strongly associated with lower fertility—"later" translates as "fewer" in the aggregate according to Hans-Peter Kohler, Francesco Billari, and José Antonio Ortega (2002). So to the extent that low fertility in a population is seen as problematic, fertility postponement is clearly part of the problem. Finally, even if women are able to postpone childbearing *and* have all the children they want, Bongaarts and Feeney (1998) pointed out that postponement lowers fertility levels in the current period. A useful way to think about this is that when births are postponed, they are pushed into a subsequent time period. The TFR combines this timing effect with any possible change in the number of births. The implication of this is that when ages at childbearing are increasing, the TFR (as an indicator of long-term or completed fertility) is biased downward. For many countries, Tomás Sobotka (2004) noted, this bias accounts for up to one third of the difference between observed and replacement level fertility (i.e., one third of the difference between 1.5 and 2.1 equals .2 of a birth).

## MARITAL AND NONMARITAL CHILDBEARING

The focus on the marital status of the mother (or the legitimate/illegitimate status of the child) has long cultural, legal, and intellectual roots. Details can vary, but cultures have often linked marriage with socially sanctioned sexual intercourse; that is, marriage legitimated sexual intercourse between a husband and wife. In some social contexts the discovery of illicit (premarital or extramarital) intercourse, or even credible rumors of it, could result in strong sanctions, especially for women. Clearly chastity until marriage and sexual exclusivity in marriage would guarantee men of the paternity of their wife's children; paternity in turn linked a man to an identifiable number of children to whom he had rights and obligations. These norms often coexisted with inheritance laws that specified that only children born within marriage were legal (or legitimate) heirs to family rights and property. This recurring attention to offspring legitimacy is reflected in various theoretical attempts to explain its historical and geographic reach by authors such as Bronislaw Malinowski (1964) and Randall Collins (1975).

Twenty-first century attention to marital/nonmarital childbearing has important differences and similarities to this legacy. Differences include the availability of genetic paternity tests that can take the place of marriage in linking men to their progeny. However, as in the past, these links are desired so that responsibility for the support and care of children can be assigned. Other differences include a reduced importance of father's status in determining children's status in contemporary contexts, because contemporary societies are less patriarchal, and status is more often achieved rather than ascribed. Most important, studies, such as those done by Sara McLanahan and Christine Percheski (in press), show residence in a family with both biological parents remains a strong predictor of children's well-being and later life success.

Measurement of marital/nonmarital childbearing is not as straightforward as it might seem. First, there is an issue of the timing and sequencing of the marriage vis-à-vis the conception and the birth. In many contexts, norms specify that marriage precede sexual intercourse and conception. However, in some times/places these norms are frequently violated. They may not produce nonmarital births because premarital conceptions may be "legitimated" by marriage after conception but prior to the birth (these marriages are often in the first three or four months of pregnancy); the prevalence of legitimation varies by social groups and across time (see Parnell, Swicegood, & Stevens, 1994, for U.S. trends and differences). In the United States a birth is considered marital if the mother was married at the birth of the child or at anytime during the pregnancy.

A second definitional issue is posed by marriage—when is someone married? Contemporary definitions of nonmarital births include births to long-term cohabiting couples even if they subsequently marry. Such long-term cohabiters provide the stable family environment thought to advantage children. To the extent that the distinction between cohabiting and marital unions fade, the distinction between marital and nonmarital births should become less important. Such definitional issues must be kept in mind when interpreting data on nonmarital births.

With the above cautions in mind, there are two common measures of nonmarital childbearing: The first is the nonmarital birth rate, and the second is the nonmarital birth ratio (or the percentage of all births that are nonmarital). The first measure treats unmarried women as a separate population and estimates their number of births (*b*) divided by an estimate of risk (the population of unmarried women [*w*]). This statistic measures the likelihood that an unmarried woman will have a birth. The second measure, the nonmarital ratio, indicates the proportion of children born in a particular year to unmarried mothers.

In the United States the nonmarital ratio has increased steadily over the past several decades: from 5.3, to 14.3, to 28.0, to 36.9 in 1960, 1975, 1990, and 2005, respectively, according to Stephanie Ventura and Christine Bachrach (2000) and Joyce Martin and colleagues (2007). In 1996 Herbert Smith, S. Philip Morgan, and Tanya Koropeckyj-Cox indicated that the reason for this increase is that the nonmarital ratio has four distinct components: the number of women in the (a) married and (b) unmarried populations and the birth rates for (c) married and (d) unmarried women. Again in the U.S. context, the most important of these factors is the increasing number of unmarried women (and a relative decline in the married). In effect, the postponement of marriage among Whites and the decline of marriage at all ages among Blacks has put more women in the unmarried category and thus at risk of a nonmarital birth. Of secondary importance, an increasing birth rate among unmarried White women (but not Blacks) has contributed to this trend. For both racial groups a decline in the rate of marital childbearing plays a tertiary but significant role.

## ADDITIONAL FERTILITY DIFFERENTIALS

Other fertility differences have and continue to attract research attention. The nature of these differences varies over time and place. Four important differences became the focus of U.S. research beginning in the late 20th century.

Fertility differences by education are frequently examined; a common finding is modestly higher fertility for the less educated. A life course perspective helps account for these differences. In the contemporary United States, for example, most young women intend to have small families. Those who do well in school and have high aspirations tend to remain in school and postpone childbearing. Following their investments in higher education, they pursue jobs that have career ladders, which can produce further postponement of childbearing. Thus, those attaining high levels of education are more likely to follow the pattern of delayed childbearing. This results in later and less childbearing. In contrast, those doing poorly in school are less likely to continue their education and are more likely to take jobs seen as less rewarding. These women are also more likely to bear their children early and to have more of them. As noted by some researchers (Rindfuss, Morgan, & Offutt, 1996), the most striking differences by education are in fertility timing with differences in number of children relatively modest.

Racial or ethnic differences receive considerable attention. A first level of explanation is to see if the different socioeconomic standing of the racial or ethnic group accounts for the differences. For instance, does one group have higher poverty or lower educational attainment than another (perhaps due to past or current discrimination)? Such differences are often part of the explanation for overall differences. However, if differences persist after these comparisons, then hypotheses of "minority status" may be employed. The role of minority status depends on the historical context of the race/ethnic group. In a classic formulation, Calvin Goldscheider and Peter Uhlenberg (1969) argued that Jews in the United States reduced their fertility to invest in the education of their children because upward mobility was possible. In contrast, Blacks in the United States faced harsher discrimination such that upward mobility was less promising, and, as a result, fertility limitation was less attractive. Further, in contexts in which racial/ethnic tensions are also political, higher fertility may be encouraged as a means to strengthen the minority group politically.

Differences in fertility by immigrant status are frequently observed; for instance, in the contemporary United States, immigrant Hispanics, especially Mexican immigrants, have higher fertility than do non-Hispanic Whites or Blacks. Assimilation models commonly are invoked to account for these differences. In short, assimilation models posit declining differences across generations as the immigrant group is incorporated into the economic and social fabric of the receiving country. As a result, convergence in behavior is expected in a broad range of behaviors, including speaking the host country language, attaining similar levels of education, and adopting similar marriage and fertility behavior. This assimilation model explains well the fertility and socioeconomic convergence of European immigrant groups and U.S. natives across the 20th century. Further, when data are appropriately examined, Emilio Parrado and S. Philip Morgan (in press) found evidence that Hispanic/non-Hispanic fertility convergence exists. Nevertheless, some authors, such as Douglas Massey (1995), have questioned whether this model is appropriate for the 21st century flow of Hispanic immigrants and suggested that a continuing influx of immigrants into segregated areas will retard socioeconomic integration and assimilation.

Religious differences may be overlaid on group differences in socioeconomic standing, racial/ethnic composition, and in some cases immigrant status. In their work in 2007, Charles Westoff and Tomas Frejka used the example of Muslim immigrants in Europe and found evidence of all of these factors. In such cases isolating socioeconomic, racial/ethnic, and religious differences can be difficult, impossible, or even inappropriate; these factors can combine in powerful, but historically unique, ways. For instance, different family behaviors (including fertility) may take on significance as markers of identity, for instance in South Asia (Morgan et al., 2002) or India (Dharmaligham & Morgan, 2004). Similarly, in some contexts substantial religious differences persist among groups that are not disadvantaged or identifiable as another race. These differences highlight the importance of religion for maintaining a set of ideas (or an interpretive frame) that privileges certain lifestyles.

In the United States in the 21st century, for instance, primary religious differences are not by denomination (i.e., Protestant versus Catholic) but by measures of intensity of religious belief (i.e., respondents' reports of the "importance of religion in their life"). Those reporting religion as "very important" (as opposed to "not important") have a TFR .5 higher (2.3 versus 1.8). In terms of proximate determinants, this difference can be traced to intentions for larger families among the more religious. Further, this intent to have more children is embedded in a set of ideas that privilege marriage, family, and traditional views of family life. Consistent with this evidence, Ron Lesthaeghe and Lisa Neidert (2006) showed strong state- and county-level associations among levels and timing of fertility, cohabitation and marriage, and political indicators such as the percentage voting for George W. Bush in the 2000 and 2004 presidential elections. They argued that the density of secular versus religious orientations across U.S. states and counties explain these aggregate associations.

## FUTURE RESEARCH DIRECTIONS AND ISSUES

In the future, researchers of childbearing will continue to wrestle with all these issues, but important new questions lie ahead as well. Three deserve mention here.

## PRONATALIST POLICIES

A growing number of industrialized countries have fertility rates substantially below replacement levels. This low fertility produces aging populations that increase government expenditures for old age financial support and health care. In the long run, very low fertility produces dramatic population decline. One policy response would aim to increase fertility. A major reason for low fertility is fertility postponement due to the competing demands in young adults' life courses. An appropriate intervention would provide high quality, affordable, and widely available daycare, which would allow women to work outside the home or pursue other activities while beginning a family.

Data from Norway (Rindfuss, Guilkey, Morgan, Kravdal, & Guzzo, 2007) showed that state-subsidized childcare reduces age at first birth. However, these effects depend on the systematic placement of daycare centers. Specifically, these centers open in locales where the tension between work and family is greatest (and where fertility is initially lowest). Once daycare placement is completed, the expected pronatalist effects are apparent.

First, is the proliferation of very low fertility inevitable? Will its global spread be pervasive? In 2000 to 2005, 31 (17%) had TFR rates below 1.5; another 37 (19%) had below replacement level rates (a TFR $< 2.1$; see Table 1). These low fertility countries are not confined to one or two geographical regions, nor do they share cultural/historical similarities. Below-replacement fertility exists in China, Japan, South Korea, virtually all of Europe (East and West), Australia, and North America—with the United States above or below replacement depending on the year examined (see Morgan & Taylor, 2006).

This low fertility seems not to be a rejection of children or parenthood but instead is closely linked to delayed childbearing. In industrialized countries men and women intend to have small families (usually a stated intention for two children), but education, careers, leisure pursuits, and economic insecurity conspire to produce a long sequence of postponements. Although many achieve the two children they intend, falling short of this goal is more common than exceeding it. Thus, couples are having fewer children than they intended and fewer than their societies require for long-term population stability. The sidebar discusses possible policy interventions. However, a number of countries are well into their third decade of very low fertility—a low fertility crisis has arrived for these societies. How widespread will low fertility become, and how responsive will it be to pronatalist policy?

A second important question focuses on the role of men in fertility and parenting behavior. Fertility research has focused primarily on women. Some attention is shifting toward men, but some of this new work focuses on the fertility of men and largely ignores women. Instead, what is needed is a focus on the fertility of both married and unmarried couples. Such a focus is challenging because it requires longitudinal life course analysis of both partners. Further, in many contexts, this analysis must include the multiple partnerships that are part of many women's and men's life courses. The previous unions and childbearing of women and men have implications for their subsequent unions and fertility decisions. Early 21st century research on "multipartnered fertility" and "blended families" has begun to address such issues.

Finally, what are the likely impacts of recent and emerging reproductive technology? In general, new technology will be adopted if its use is considered moral and acceptable and if people are motivated to use it. Over the long term, technological advances have increased control over fertility—some methods reduce the likelihood of pregnancy and childbearing whereas others increase the chances. Active debates focus on whether and which methods are considered moral or acceptable. These debates have an impact on the social and political environment in which new technology is developed and deployed. For instance, will the morning-after-pill become more widely available and acceptable? Will assisted reproductive technology (ART) become less expensive?

The fecundity reductions associated with delayed childbearing are increasing the demand for ART. In 2004 the Centers for Disease Control and Prevention reported that more than 45,000 births (more than 1% of

all births) resulted from ART. Screening these embryos for healthy genetic predispositions or for their gender (daughters or sons) is possible and will become increasingly affordable and thus will reduce obstacles to their use. Pregnancy and childbirth may be transformed as well; Fay Menacker (2005) noted that cesarean delivery is becoming more common in cases in which it is not a medical necessity. Such changes could fundamentally alter the costs, constraints, and patterns of future childbearing.

# CHILDLESSNESS

In general, the term *childless* is used to describe adults who have never had biological or adopted children, and the term *childlessness* is used to refer to this state. These general terms, however, encompass several distinct groups: people who want children but are biologically unable to have them, people who have made a voluntary choice never to have children, people who are postponing parenthood until later in their adulthood, and people who have outlived their children, who are sometimes called "functionally childless" (Dykstra and Wagner, 2007; Rowland, 2007). Researchers who study childbearing and parenthood usually conceptualize childlessness as a lifetime, permanent condition. From this perspective, only members of the first two groups are childless. Although members of the latter two groups are childless in a broad sense (they currently have no living children), they may become parents in the future or they were parents in the past.

The *involuntary childless* are a group of men and women who want and intend to become parents but whose ability (or partner's ability) to reproduce is constrained (biologically or socially) and who have not become parents through other means (e.g., surrogacy, egg or sperm donor, adoption). Note that the label "involuntary" is not necessarily clear-cut. For example, persons unable to conceive and/or maintain a pregnancy can at times become parents by opting for biomedical interventions and/or legal processes (adoption). The decision to parent *exists* for them, but they *choose* to forgo parenthood. From another perspective, however, the inability to reproduce is not a choice, especially if people consider "natural" biological childbearing the only acceptable route into parenthood. With respect to social constraints, some people may want to have children but are selected out of the pool of potential mates because of institutionalization (e.g., incarceration), compromised physical or mental health, or lack of self-sufficiency (e.g., unemployed, living with parents, homeless). Although these people may intend to form romantic relationships and have children (with no known biological constraints), their limited ability to marry and work results in social constraints against having children (e.g., remaining unmarried, not qualifying for adoption). The key issue is that people who are involuntarily childless may differ in their fertility intentions and behaviors.

In contrast, *voluntary childlessness* defines a group of women and men who have not become parents either because they made a conscious decision not to have children or made other decisions in life that postponed parenthood repeatedly and, eventually, permanently. The topic of voluntary childlessness thus highlights the question of whether and when people make decisions about childbearing. Many voluntarily childless adults report that they made their decision to be childless during adolescence or childhood (Veevers, 1980). In contrast to people who actively decided early or late in their lives to remain childless are people who become childless by repeatedly postponing childbearing and eventually end their reproductive lives without having had children. The latter type of childlessness unfolds as a series of more or less passive decisions often based on other aspects of the life course, for example timing (e.g., not now) or events (e.g., after I am married). Thus the voluntarily childless is composed of three groups: early deciders, late deciders, and perpetual postponers (Dariotis, 2005). Taking into account this heterogeneity is central to understanding voluntary childlessness because the decision process differs among these types. Note also that the perpetual postponers may be difficult to identify early in the life course because they have not yet made the "decision" to not bear children.

## IMPLICATIONS OF CHILDLESSNESS FOR SOCIETIES AND INDIVIDUALS

To continue its existence, a society needs its members to reproduce themselves. This is true not only because new births replace people who have died, maintaining the size of the population, but because societies rely on younger members for certain tasks, for example financially and physically supporting the aged. Because reproduction is essential to societies' survival, societies developed norms, customs and beliefs that, to varying degrees, encouraged and regulated parenthood (for example, by discouraging births outside of marriage or marriagelike unions) and discouraged and stigmatized childlessness (for example, endorsing the motherhood mandate by which every woman was expected to have children as a sign of her womanhood). Some argue that vestiges of pronatalist norms sanction the childless, especially the voluntarily childless, who are viewed as selfish and immature.

Permanent childlessness challenges these societal needs and the pronatalist norms surrounding them. The extent to which they do so, however, depends on the demographic situation of the society. Prior to the widespread use of fertility control, most childlessness was involuntary and the main obstacle to maintaining the size of the population was mortality. Only once mortality rates declined and the use of birth control became widespread could low fertility levels, resulting from both smaller family sizes and increases in voluntary childlessness, be viewed as a threat to a society's continuation. Demographers define "replacement level" fertility as the average number of children women will need to bear in their lifetimes to maintain the size of a population. This number is around 2.1 children per woman. Currently, a number of nations in the developed world are experiencing or approaching below-replacement fertility. For example, between 1995 and 2000 Italian fertility rates were 1.2 children per woman; for Spain and Greece the rates were 1.16 and 1.3, respectively (Morgan and Hagewen, 2005). Although the ultimate concern about low fertility is whether these societies can continue in their present form, the more urgent concern is that low fertility results in an aging population, which in turn raises a host of social, economic and political challenges.

Childlessness has implications for the individual life course as well. Historically (and in many contemporary developing nations), the transition to parenthood marked a rite of passage into adulthood. In modern societies the importance of childbearing as a marker of adulthood has diminished, and the fraction of the life course spent as a parent to minor children is lower (especially with smaller family sizes and longer average lifespan). Nevertheless, the majority of individuals become parents, and the childless need to rely on other transitions to mark their adult status (e.g., self-sufficiency, marriage).

People who are childless may experience different life courses than those in the parent majority. First, people who are childless do not experience the financial and opportunity costs of parenthood. To the extent that they have other resources—temporal, financial, and human—voluntarily childless people may devote these resources to other activities, such as careers, education, charitable causes, or personal development. In fact, the prevalence of permanent childlessness has increased in part because alternatives to parenthood have emerged in modern societies (e.g., careers, educational attainment, self-actualization) and because norms supporting individualized life choices support these alternatives. For other people, not having the financial and time resources (for whatever reason—e.g., poverty, low-paying career choice) to raise children according to societal standards is a motive not to have children.

Second, Heaton, Jacobson, and Holland (1999) found that the decision to have children corresponds with the decision to marry. In other words, voluntarily childless people feel less compelled to marry or to marry during their childbearing years. As a result, they may spend more (or all) of their adult years unmarried. Given that marriage confers health and social benefits to men, this may mean that never-married childless men will experience greater health disparities relative to their married parent counterparts. The extent to which observed disparities are attributable to childlessness per se, to the lack of marriage per se, or to individual characteristics (e.g., low education, unemployment), however, remains to be determined.

Most childless adults are well adjusted and do not report elevated negative mental health outcomes. As Dykstra and Hagestad (2007) report, childless older adults are not "a sad bunch," contrary to popular stereotypes. For example, they found that childless never-married women evidence greater advantages to their female and male parent counterparts in terms of socioeconomic status, educational attainment, and other factors.

## TRENDS IN VOLUNTARY AND INVOLUNTARY CHILDLESSNESS

Rates of childlessness in most developing nations are relatively low because of low levels of contraceptive use and large family size norms. Childlessness that does occur in developing nations mostly results from malnutrition, disease-induced sterility, early widowhood, and never marrying. Developed nations have a higher prevalence of childlessness because of widespread use of contraceptive and lower family size norms. In addition, alternatives to childbearing are more pervasive as well as the norms of individualism that make these alternatives viable choices.

In the United States at the turn of the 20th century, childlessness resulted equally from infecundity/sterility and voluntary intentions (Morgan, 1991). Over the second half of the 20th century, this proportion shifted such that two-thirds of childlessness was attributable to personal choice and one-third to infecundity (Houseknecht, 1987; Morgan, 1991; Poston and Trent, 1982; Rowland, 2007). Better nutrition, general medical advances, and new treatments for infertility meant that infecundity was no longer the primary determinant of childlessness. In the early 21st century only 3% of couples experience infecundity (Rowland, 2007). Whereas the incidence of involuntary childlessness declined over time, the incidence of voluntary childlessness increased and accounts for a greater proportion of total childlessness (Houseknecht, 1987). Intentionality, personal choice, life course preferences, and postponed marriage coupled with increased reliance on birth control and voluntary sterility

remain the primary mechanisms underlying childlessness. National estimates of childlessness range between 10% and 20% of the population, on average, with Australia, England, Scandinavian nations, and the United States having rapidly increasing rates approaching or exceeding 20% (Rowland, 2007). Cross-national comparisons, however, are plagued by differences in reporting biases and sampling issues (Rowland, 2007).

Depending on the definition of childlessness and the sample used, the proportion of childbearing-aged women in the United States who are voluntarily childless ranges from 6.4% (for married couples studied in the 1980s) to 20% (projections for women born in 1962) (Heaton, Jacobson, and Holland, 1999; Houseknecht, 1987; Rovi, 1994). In a nationally representative sample of adolescents aged 16 to 22 in 2001, 17% reported that they intended to be childless (Dariotis, 2005). The fact that Americans have experienced decreased fertility is well documented, and voluntary childlessness has and continues to play a part in that decline (Bianchi and Casper, 2000; Morgan, 1991; Morgan, 1996; Rindfuss and Brewster, 1996; Teachman, Tedrow, and Crowder, 2000). Although this trend is well evidenced, researchers lack a unified explanation for why the decline has occurred (Hirschman, 1994). Such a unified explanation most likely does not exist because of the heterogeneity of motivations across subgroups of people (discussed below).

## PATHWAYS INTO PERMANENT CHILDLESSNESS

People can become permanently childless *involuntarily* through a number of means. Some people (or their partners) are subfecund (i.e., their ability to reproduce is impaired), which may result from genetic factors, disease-induced sterility due to untreated infections and conditions, and malnutrition. Others may intend to have children, but have difficulty marrying and mating because others perceive them as low-quality mates (e.g., incarcerated, unemployed, or physically unhealthy people). Other people may marry, become widowed before having children, and never remarry.

Similarly, people become childless *voluntarily* by different paths. *Early deciders* (Houseknecht, 1987; Veevers, 1980) make an active decision to forgo parenthood during their mid- to late adolescence. Retrospective, qualitative studies (Veevers, 1980) suggest that early deciders' decisions stemmed from issues in their families-of-origin, most notably parentification, whereby they were expected to assume parenting responsibilities for younger siblings or siblings with a disability. These early deciders claim that they already completed their parenting duties by rearing their siblings, an experience they do not want to relive. Other commonly reported reasons include the fear of being "bad" parents, de-identification with same-sex parents, incompatibility of parenthood with career and leisure preferences, disinclination toward children, and traumatic early life events—such as experiencing parental divorce during youth and attributing it to parental demands and child presence (Houseknecht, 1987; Veevers, 1980).

Some early deciders remark how negative parenthood was for their parents and believe that parenthood destroyed

the quality of their parents' marriages and/or limited their parents' goal achievement. Still others de-identify with the parenting role to prevent "becoming their parents." Hearing negative messages about parenthood and observing parental and marital distress becomes internalized and develops into negative working models of parenthood (e.g., parenthood destroys spousal relations; parenthood precludes freedom and personal growth). These early experiences and rationalizations appear robust and resilient to change (Pol, 1983; Veevers, 1980). Using prospective data, Dariotis (2005) showed that voluntary childless intentions begin in adolescence and that strong predictors included family-of-origin experiences, attitudes toward children, and intentions to remain permanently single.

*Late deciders* make an active decision, during adulthood, not to have children. Late deciders typically attribute this decision to career and lifestyle factors. For instance, late deciders may perceive parenthood and career aspirations as inconsistent/irreconcilable or believe that parenthood does not offer the same satisfaction as independence. Others may fear that parenthood would compromise their relationship with their romantic partner. Additional reasons include partner choice (becoming involved with a partner who does not want to have children or a partner who they believe will not be a good parent), experience with others' children (observing the demands and related consequences of parenthood for their peers), and health (physical and mental health–related problems that lead the person to doubt his or her parenting capabilities). Still others report philosophical reasons not to have children. For example, people who espouse zero population growth and environmental conservationists want to minimize their contribution to the world's population and depletion of natural resources, respectively.

*Perpetual postponers* make a sequence of decisions that "the time is not right" to have children because of career, education, and/or marriage (postponement) outcomes. Eventually, they postpone childbearing until a point in their lives when childbearing is not likely (at ages over 40 women are increasingly less likely to conceive) or childbearing is not preferable. Postponement occurs for many reasons. For instance, late nest-leavers may continue to live with parents into their 30s and 40s because they are caring for aging parents, live at home while building human capital (advanced degrees and prolonged workforce participation), or have difficulty finding stable employment. Later onset of independent living and prolonged time pursuing educational and career goals has a ripple effect whereby marriage or stable cohabiting union establishment is postponed. Late union formation, in turn, postpones childbearing. Relationship disruption, via divorce or break-up, perpetuates the ripple effect; it takes time to find another suitable partner, establish a relationship, and consider having children. "Timing out" of the fecund years for women is a product of when they leave home, finish their education, spend enough time establishing a foothold in the workforce, find a mate, stabilize a relationship, and whether the relationship ends prior to having children.

**Encouraged Childlessness—a Special Case** Yet another group of voluntarily childless individuals are people who experience pressure from family, friends, partners, and health care providers not to have children because of debilitating and/or transmittable conditions (e.g., HIV/AIDS). Even with antiretroviral medications that reduce the chance of disease transference to offspring, HIV-positive women (and men) worry about their own longevity and ability to manage the physical and emotional strains of parenthood. People who suffer from genetic-related conditions (e.g., psychological and/or physical) consider the potential of passing these conditions onto the next generation as well as their likelihood of living long enough to observe their children grow up. Much more research is needed to assess the degree to which disease and genetic conditions contribute to voluntary childlessness intentions.

## GAPS IN RESEARCH

Given increasing trends in permanent childlessness, this historically neglected area of study warrants far more attention. Unanswered questions abound, and past findings based on retrospective accounts and limited samples need to be reexamined with improved methods (longitudinal, prospective studies using mixed methods and biological and self-report data). For example, future research needs to examine childlessness among all relationship statuses—not just married couples—and across development. Furthermore, understanding how sex hormones (e.g., testosterone), disease status (e.g., HIV-positive), genetic conditions, and physical and psychological limitations influence the decision to remain childless warrants investigation. Taking a process-oriented approach to the study of permanent childlessness will provide a more in-depth understanding of how and why women and men come to the end of their reproductive lives without bearing or adopting children and how a life without children affects their lives, positively and negatively.

If societies want to maintain or increase total fertility rates (TFRs), pronatal policies need to target alleviating the life-course competition individuals experience with respect to individual goals and parenthood demands (Pierre and Dariotis, 2005). Yet it is not clear such policies will have the desired effect. European nations adopting policies that subsidize childcare costs, provide generous parental leaves, and so on, have not resulted in

increased TFRs; instead, TFRs continue to drop in those nations (Pierre and Dariotis, 2005).

## COHABITATION

Cohabitation is defined by social scientists as two adults of the opposite sex living together in an intimate, nonmarital relationship. Cohabitation has rapidly become a prominent feature on the landscape of American family life. Using the 2002 National Survey of Family Growth (NSFG), Kennedy and Bumpass (2007) estimated that 58% of women aged between 25 and 29 had cohabited at some point in their lives. Moreover, about 40% of children in the United States will spend some part of their childhood in a cohabiting household (Kennedy & Bumpass, 2007). Young people in the United States approve of cohabitation at much higher rates than their older counterparts, so it is likely that cohabitation rates will continue to rise in the United States (Smock, 2000).

In attempting to understand the causes and consequences of the rise in cohabitation, scholars have tried to identify whether cohabitation is an alternative to marriage, a prelude to marriage, or a convenient dating arrangement. Clearly all three forms of cohabitation exist, but most agree that the most common form, at least among young adults, is as a prelude to marriage. However, consensus is growing that cohabitation is still an *incomplete* institution in the United States with wide variations in the meanings and norms associated with it.

### COHABITATION OVER THE LIFE COURSE

The 2000 U.S. Census counted 5.5 million households that are maintained by a cohabiting couple. Although this number reflects a substantial increase in the incidence of cohabitation over the previous 20 years, it still underestimates the true prevalence and impact of cohabitation. The Census figure is an underestimate because cohabitations are usually short-lived, either quickly dissolving or progressing to marriage. Thus, at any given time the number of cohabiting couples is very small relative to the number of people who have ever cohabited. By contrast, examining cohabitation trends across the life course can provide a more accurate account of cohabitation's dramatic increase in frequency and impact.

Young adults increasingly delay marriage and many cohabit in the meantime. Data for 2002 indicate that 62% of women's first marriages are preceded by cohabitation either with their spouses or with someone else. Cohabitation is even more common following a divorce and may partly account for observed declines in remarriage rates (Kennedy & Bumpass, 2007). Although cohabitation in later life has received substantially less attention than other life course stages, anecdotal evidence and small-scale studies suggest that cohabitation is on the rise among the elderly as well (Chevan, 1996; Brown, Bulanda, & Lee, 2005). Cohabitation, like marriage, tends to cluster with other important life course transitions, such as job changes, residential moves, and breaks in school enrollment (Guzzo, 2006).

These trends among adults have important implications for children's family experiences. According to 2002 data, about one in three births involve an unmarried mother and of these, about half the mothers are cohabiting with the baby's father. In addition, many mothers cohabit with a man who is not the father of their children, for example, following a divorce. The result is that approximately two in five children spend some time living with a cohabiting parent before they reach age 16 (Kennedy & Bumpass, 2007).

### DIFFERENCES BETWEEN COHABITATION AND MARRIAGE

The implications of a societal shift from marriage to cohabitation depend partly on how much these arrangements differ and partly on the ways they differ. Scholars have focused on five dimensions along which marriage and cohabitation differ: stability and commitment, relationship quality, economic security, fertility, and cooperation. Starting with stability and commitment, most cohabiters (about 75%) expect to marry their partner (Manning, Smock, & Majumdar, 2004). Of those who expect to marry, most have *definite plans* to do so. Thus, many cohabiting couples are in committed relationships, but a significant minority is not. Despite the high levels of commitment, cohabiting unions are unstable. Among first cohabiting unions in the period from 1997 to 2001, only about one third resulted in marriage and among those who had not married, fewer than two thirds were still together after two years (Kennedy and Bumpass, 2007). When compared with prior estimates (Bumpass & Lu, 2000), these findings suggest that long-term cohabiting relationships are becoming more common, but cohabiting unions continue to be less enduring than marriages.

Cohabiters also are less satisfied with their relationships than married couples. Importantly, the lower average levels of stability and relationship quality among cohabiters are driven largely by the very low stability and quality levels of the minority who do not plan to marry. Cohabiters with marriage plans, especially those who are in their first cohabiting relationship, enjoy similar levels of relationship quality and stability as those who are married (Brown & Booth, 1996; Teachman, 2003).

| | 1960 | 1970 | 1980 | 1985 | 1990 | 1992 | 1994 | 1996 | 1998 | 2000 |
|---|---|---|---|---|---|---|---|---|---|---|
| Total number of unmarried couple households (000s) | 439 | 523 | 1.589 | 1.983 | 2.856 | 3.308 | 3.661 | 3.958 | 4.236 | 4.736 |
| Number of unmarried couple households with children under 15 years | 197 | 196 | 431 | 603 | 891 | 1.121 | 1.270 | 1.442 | 1.520 | 1.675 |
| Percent total unmarried couples households with children under 15 years | 44.9% | 37.4% | 27.1% | 30.4% | 31.3% | 33.8% | 34.6% | 36.4% | 35.9% | 35.4% |

Other important dimensions along which marriage and cohabitation differ are economic potential and employment security. Generally, cohabitation is more common among couples with lower socioeconomic status. Among men, higher levels of education and earning potential are associated with a lower likelihood of forming a cohabiting union and a higher chance of marrying (Thornton, Axinn, & Teachman, 1995; Xie, Raymo, Goyette, & Thornton, 2003). Further, men's job instability is associated with a couple's decision to cohabit rather than marry (Oppenheimer, 2003). Both qualitative and quantitative accounts of cohabiting families describe economic insecurity as a key factor blocking marriage (e.g. Smock, Manning, & Porter, 2005).

In some European countries, Sweden for example, cohabitation is viewed as an alternative form of marriage (Heimdal & Houseknecht, 2003). One reason why Swedes tend to see cohabitation as similar to marriage is because most children in that country are born to cohabiting couples. In the United States, however, an increasing proportion of children are born outside of marriage. Given the steep rise in cohabitation among single adults, many of these births occur in cohabiting couples, leading some researchers to question whether fertility continues to distinguish marriage and cohabitation. On the one hand, the proportion of pregnant cohabiters who marry before the birth of their children is declining, suggesting that cohabitation is becoming an acceptable context for childbearing. On the other hand, there is no growth in the likelihood that cohabiting couples will become pregnant, indicating that cohabitation is not becoming a preferred arrangement for parenthood. Mexican-American women are an exception to this general pattern. Among cohabiting women, levels of fertility for Mexican Americans are much higher than for Anglo-Americans, suggesting that for this group cohabitation may be a preferred and accepted arrangement (Wildsmith & Raley, 2006). In other words, fertility continues to distinguish marriage from cohabitation, but marriage is becoming less distinct from cohabitation along this dimension, perhaps especially for Mexican Americans.

Two of the foundations of marriage are economic cooperation and specialization. That is, married couples tend to pool resources and, although there is some overlap, husbands typically do different tasks than wives, which may include differential involvement in paid work. The interdependence that specialization creates may serve as a barrier to divorce. This is one way that marriage is distinct from cohabitation. Whereas among spouses having similar incomes is positively associated with the risk of divorce, among cohabiters having similar incomes is associated with stability (Brines & Joyner, 1999). Research on housework provides further evidence that specialization and cooperation are less evident in cohabitation than marriage. The difference in time spent on housework performed by husbands and wives is greater than the difference between cohabiting partners (South & Spitze, 1994). This is not because cohabiting women do less housework than their married counterparts; cohabiting men do more housework than married men do (Davis, Greenstein, & Marks, 2007). In addition, cohabiting couples with a more traditional division of labor move more quickly to marriage (Sanchez, Manning, & Smock, 1998). Taken together, this research supports the idea that specialization and economic cooperation distinguish marriage from cohabitation. This distinction may arise because cohabitation, at least in the United States, is a relatively short lived and sometimes tentative arrangement, which reduces the benefits of specialization and increases the risks associated with pooling economic resources.

## THE IMPACT OF COHABITATION ON ADULTS AND CHILDREN

Scientists and policy makers alike are interested in the long-term ramifications of the rise in cohabitation rates. This impact is difficult to study for a number of reasons. First, as indicated already, the meaning of cohabitation is unclear and different groups are likely to understand and be affected differently by it. Second, cohabitation is a *moving target* with the norms and meanings associated with it rapidly shifting over time. Third, many of the purported effects of cohabitation may be due to social selection. In other words, the kinds of people who enter cohabiting relationships may also be disposed to other kinds of behavior so that, for example, what seems to be an effect of cohabitation on relationship quality is actually caused by the characteristics of people who choose to cohabit. Despite these limitations, scholars have compiled an impressive trove of information about the outcomes associated with cohabitation for both adults and children.

As already mentioned, cohabiting relationships in the United States tend to be unstable compared with marital relationships. One way in which the instability associated with cohabitation affects cohabiters is the quality and availability of resources from kinship networks. Some evidence suggests that young adult cohabiters reap fewer benefits from parents compared with married young adults (Eggebeen, 2005). Cohabiters also differ from married adults in the impact of relationship dissolution. Although formerly married men tend to be better off after a divorce, formerly cohabiting men experience little financial change after dissolution and formerly cohabiting women suffer about the same financial loss as formerly married women (Avellar & Smock, 2005). Cohabiting relationships also tend to be more violent than married relationships although this is likely the result of the least violent cohabiting couples choosing to marry and the most violent married couples choosing to divorce (Kenney & McLanahan, 2006). Entering a cohabiting relationship appears to have some risk-reducing benefits, especially for men. Men experience similar reductions in marijuana use and binge drinking whether they enter cohabitation or marriage (Duncan, Wilkerson, & England, 2006).

Cohabiters are less healthy than their married counterparts, likely because cohabiters have fewer coping resources and lower relationship quality (Marcussen, 2005). For example, among older adults, cohabiting men experience significantly poorer mental health compared with married men, but cohabiting and married women have similar levels of mental health. Scholars hypothesize that, among older adults, a population for whom caregiving roles are highly gendered, married men benefit from the security of having a caregiving wife, whereas cohabiting women may benefit from having fewer caregiving obligations (Brown et al., 2005). So overall, although some of the differences between cohabitation and marriage in adult outcomes appear to be due to selection, the relative instability of cohabitation may also contribute to some negative outcomes.

An increasing number of children spend part of their childhoods in households headed by a cohabiting couple. Social scientists have developed a modest literature investigating how children fare in cohabiting households. Cohabitation appears to be a significant source of instability in the lives of some children in the United States. This is especially true when a child's mother (or father) moves in and out of several cohabiting relationships while the child is living in the parental home (Raley & Wildsmith, 2004). Several studies indicate that children (and adolescents) in cohabiting households exhibit more behavioral, health, and educational problems than children living in married households.

What is less clear is whether the presence of two adults in a cohabiting household is better for children than a single-parent household is. Most evidence suggests that factors such as instability, lower socioeconomic status, and poorer mental health among mothers in cohabiting relationships offset any potential gains that children may accrue from having a second adult in the household. Indeed, as some research on stepfamilies has shown, the presence of an adult who is not a biological parent may be a stressor for children (Manning & Brown, 2006; Raley, Frisco, & Wildsmith, 2005; Artis, 2007; Ginther & Pollack, 2004; Brown, 2004; Manning, et al. 2004; Manning & Lamb, 2003). Selection is probably responsible for many of the differences between child outcomes in cohabiting households versus findings in married households. Instability, however, may also contribute to poorer childhood outcomes in cohabiting households.

## COHABITATION OUTSIDE THE UNITED STATES

Cohabitation is on the rise in many parts of the world. As in the United States, the role of cohabitation in the family systems of many of these nations is unclear. In a few countries, such as Sweden, cohabitation appears to be a stable and entrenched alternative to marriage (Heimdal & Houseknect, 2003). In others, such as New Zealand, cohabitations are short lived and unstable, similar to cohabitations in the United States. Cohabitation has spread rapidly throughout much of Europe, including the United Kingdom, but the practice has been slow to spread in Italy and Spain (Heuveline, Timberlake, & Furstenberg, 2003; Heuveline & Timberlake, 2004; Seltzer, 2004). In Latin America, cohabitation has a long history, because *informal unions* have long existed as an alternative to marriage. Some

evidence, however, suggests that in countries such as Mexico, cohabitation is becoming a normative precursor to marriage as well as an alternative (Heaton & Forste, 2007). Less research has been conducted on cohabitation in Asia, where rates have been generally lower. Some evidence in Japan indicates that increases in cohabitation may be forthcoming, as Japanese young people report accepting cohabitation as a legitimate precursor to marriage at much higher rates than older people do (Rindfuss, Choe, Bumpass, & Tsuya, 2004). Little is known about cohabitation in the Middle East, although it is presumably low in traditionally Muslim countries. Cohabitation rates have risen in sub-Saharan Africa in recent years, with some countries, such as Botswana, exhibiting dramatic growth (Mokomane, 2007).

## POLICY IMPLICATIONS AND OPPORTUNITIES FOR FUTURE RESEARCH

High rates of cohabitation have a number of policy implications. Lawmakers and business leaders will need to formulate policies that account for cohabitation. Some states and many large corporations already allow adults to nominate domestic partners as beneficiaries and, as cohabitation rates climb, access to health benefits for cohabiters is likely to increase. The welfare of children in cohabiting relationships is another important policy issue. Research showing that children fare worse in cohabiting relationships than marital relationships has been used by some lawmakers to help pass marriage promotion policies. Some scholars are skeptical about marriage promotion legislation, contending that the negative association between cohabitation and child well-being is largely due to the characteristics of people who decide to cohabit. They argue that simply getting cohabiters married will not solve children's' problems and the money would be better spent on addressing underlying problems such as poverty, poor health care, and substandard education (Smock & Manning, 2004). These and other issues will continue to be debated as cohabitation rates rise.

Future research will demonstrate whether cohabiting unions in the United States become stable like the unions observed in parts of Europe and, if so, whether more stable cohabiting unions produce better outcomes for adults and children. Researchers will also find fruitful ground for investigation in the cohabiting unions of older adults, especially if current youth maintain their positive attitudes toward cohabitation as they age. Although it is often assumed that cohabitation fits somewhere between marriage and noncoresidential romantic relationships (or *dating*), very little is known about the diversity and character of modern noncoresidential romantic relationships. As researchers fill this knowledge gap, scientists will be able to make valid and useful comparisons between cohabitation and dating. Finally, there is much more room for understanding how the forms of cohabitation vary by socio-economic status and race and ethnicity.

## CONCLUSIONS

Cohabitation rates are rising around the world, prompting some scholars to suggest that a major demographic transition is underway, one in which cohabitation will become a normative alternative to marriage (Van de Kaa, 1988). In the United States, the most recent evidence suggests that cohabitation is mostly a prelude to marriage and is still far from the stable alternative to marriage observed in some European nations. The relative instability of cohabiting relationships in the United States likely contributes to poorer outcomes for both adults and children in cohabiting households compared with married households. After nearly 30 years of rapidly rising cohabitation rates, cohabitation has become an important family form with potential impacts at every stage in the life course.

# COMMUNITARIANISM

*Communitarianism* is a sociopolitical philosophy that views individual character virtues and social bonds as central to the lives of social actors. Communitarians believe that social groups—particularly communities—must strive to balance individual freedoms and the welfare of the collective. Elements of communitarian thinking can be found in sociological, philosophical, and political writing and teaching. Contemporary proponents of this movement include Amitai Etzioni (b. 1929), Robert Bellah (b. 1927), Philip Selznick (b. 1919), and Daniel Bell (b. 1919), but aspects of communitarianism are traceable to earlier theorists such as Karl Marx (1818–

1883), Emile Durkheim (1858–1917), and Ferdinand Tönnies (1855–1936). Furthermore, particular facets of communitarian thought such as identity formation, value internalization, and generativity, are exceptionally useful for understanding different stages of the life course and human development.

## DEFINING COMMUNITARIANISM

Balance is a consistent theme within communitarianism. Etzioni (1993), in particular, states that the movement is concerned with society's ability to balance the needs of individuals with the collective good. These opposing goals represent the centripetal and centrifugal forces (Etzioni, 1996). According to physicists, centripetal forces sustain a body's circular path at a consistent speed. Similarly, in the communitarian sense, these forces are the resources that individuals provide to the community that enhance the collective good. By contrast, centrifugal forces are the rotational forces that are oriented *away* from the axis of rotation and therefore, according to communitarians represent individuals' quests for independence from the collective. Communitarianism argues that all social groups, especially communities, are pulled in opposing directions by these competing forces. Communitarians therefore envision a sociopolitical environment where individuals are given a particular level of freedom and rights to seek their autonomy at the same time as they work for the common good and to uphold their social responsibilities.

D. R. Karp (2000) argues that communitarianism reflects a struggle with the conditions of modern societies and, in particular, contemporary societies' overt focus on individual liberties. He notes that communitarians believe that modern societies separate individuals from communities, cause a subsequent decline in community life, and promulgate personal independence and individuality. Therefore, according to communitarians, fundamental aspects of modernity destroy communal bonds and shared values and stifle the social obligations and voluntary activities that contribute to the common good.

## CLASSIC AND NEW COMMUNITARIAN THOUGHT

The classic and new forms of communitarianism must be distinguished. Although the term *communitarianism* was not used until the last few decades, basic elements of communitarian thought can be found in the writings of classical sociological theorists such as Tönnies, Durkheim, and Marx. The primary distinction between classic communitarian thought and the new communitarianism is that the latter is more concerned with the balance between the *person* and the community, whereas the classic sense focuses almost entirely on the importance of social forces and social bonds.

For example, O. Newman and R. de Zoysa (1997) suggest that communitarianism bears a conceptual resemblance to Tönnies' models of *Gemeinschaft* and *Gesellschaft*. *Gemeinschaft* is a German word that in this sense refers to social life within small-scale communities that emphasize shared social values and an active voluntary approach to social responsibilities. By contrast, *Gesllschaft*, as used sociologically, characterizes communities with weaker civic bonds, strained social relations, and a heightened sense of self-interest. The distinction between *Gemeinschaft* and *Gesllschaft* mirrors Etzioni's contemporary concepts of *authentic* and *distorted* communities. Within the new communitarian approach, the ideal community—that is, the *authentic* community—is responsive to the *true needs* of all its members, respecting and maintaining the balance of centripetal and centrifugal forces. Such a community allows individuals to flourish creatively and separately, while providing moral and social boundaries that reflect the responsibility to the common good.

According to Etzioni (1996), the term *communitarian* was adopted for the social philosophy to emphasize the necessity of individuals to acknowledge and engage in their responsibilities to the community. He states that since the 1950s, developed society has not heeded the "moral voice" and has therefore experienced the faltering of the traditional family structure, the diminishing role of schools in transmitting moral and social values, and the erosion of confidence in institutional leaders (Etzioni, 1995).

## CRITIQUES OF COMMUNITARIANISM

D. E. Pearson (1995) argues that Etzioni's vision of an authentic community is impractical, unattainable, and does not fully take into account that humans are naturally motivated to strive for status and power through competition, and are not motivated through compassion and altruism for others within their community. S. Prideaux (2002) states that communitarian leaders such as Etzioni employ a restricted and short-sighted view of community in that he has confined his analysis to American social relations. Others contend that the whole communitarian movement is overly nostalgic, longing for a past that was not as pleasant as memory leads one to recollect.

## COMMUNITARIANISM AND THE LIFE COURSE

According to communitarians, it is the individual's duty to fulfill his or her social responsibilities actively at all stages of the life course. Individuals should have the rights to express their individuality, but be grounded by the moral and ethical requirements necessary to reproduce society. This line of thinking echoes Erik Erikson's (1950) lifespan theory of human development and the

concept of *generativity*, which consists of actions taken to benefit society through guiding younger people to become custodians of society.

Aspects of communitarianism are also present in literatures emphasizing agents of socialization (e.g., family and schools), as well as the timing and sequencing of individuals pathways through the life course (e.g., becoming a parent, spouse, or worker). Institutions within communities such as families, schools, and groups provide the frameworks upholding social values and order. Furthermore, individual identities are developed and formed within these frameworks of understandings and values (Sayers, 1999). It is the balance of social order and the individual's quest for independence that not only propels the community but also yields a more fruitful environment for individual identity formation. Thus the tension between the individual and society central to communitarian thought is also central to analyzing and understanding the life course.

# CONSUMPTION, ADULTHOOD AND LATER LIFE

Consumption is a diverse set of practices at the intersection of human life and the material world. In its everyday meaning, consumption is about individuals satisfying needs and doing so as a private matter. However, as soon as one inquires how individuals come to understand both their needs and the resources that would meet them, consumption becomes a public and social matter. The study of consumption is about acts of using and using things up, but also necessarily about the way such acts come about. In this regard, age and life course change are more than mere contexts for consumption; they in fact propel it.

Researchers who study consumption approach it from many different points of view. One perspective focuses on the stages of consumption, the number of which, in turn, depends on whether people or objects are the primary focus. A tendency to focus on the person—the consumer—sets out stages such as acquisition (by purchase, gift, or creation), transient use or extended possession, and eventual disposal. A focus on objects or commodities may raise questions about their origin (i.e., their production) and, preceding that, their extraction from the environment. The complete cycle thus runs from extraction to disposal. For example, this encyclopedia, in its print or electronic form, is an object that will have had a multistage career, but it is of only present interest to consumers (readers) who have little regard for its origin or fate.

Another way to think about consumption practices is with an emphasis on either the collective or the individual. At the former, *macro* level, what comes to the fore are the enterprises, industries, and social institutions that drive the consumption cycle. At the *micro* level, the consumer and his or her outlook and behavior are central; for example, what are the individual's motives for acquiring or keeping things? The reasons for consumption—retail purchase being a huge topic here—are many but they can be reduced to two: things are practical (they serve some useful function) or things are symbolic (they communicate something about oneself and others) (Belk, 1988). The reasons for having a single thing can be mixed and they can shift over time. Eyeglasses, for example, assist vision but they also adorn the face. A particular pair of glasses is an object worth having, at least until one's prescription changes or fashion renders them outdated or obsolete.

Human development and aging lend a dynamism to the ways that the material world furnishes daily life. Across the years of adulthood, bodily changes occasion alterations in the way that needs are defined and met. The progression of life circumstances and the role sequences of family and work careers likewise bring shifts in the provisioning of everyday activity. At the aggregate level, cohorts of (aging) consumers are also moving through the life course, replacing one another at various stages of life, thus layering the consuming public with different tastes and habits shaped by cohorts' unique historical experience.

Given the wide array of consumption practices, almost every branch of knowledge and scholarship can contribute perspectives on this subject. This article considers consumption as a social activity and addresses how consumption unfolds over the course of adulthood, how marketers supply both goods and models of consuming, and whether some age groups consume at the expense of others.

## CONSUMERS AT DIFFERENT AGES

Theorists of consumer culture maintain that, in the modern world, people's values and identities are defined in relation to what they consume (Giddens, 1991; Slater, 1997). Whereas traditionally people may have derived a fixed sense of themselves from religion, work, or family, the dominant resources for identity construction are now to be found in the materials and symbols of the marketplace. Moreover, the self-representations of consumer culture are a fluid, emergent, and ongoing, thus contributing to an unsettledness in modern life. The desirable and undesirable aspects of this condition have generated much social criticism.

The fluidity of identity only accentuates the adult experience of time's passing. To some extent, aging already schedules the obligation to reinvent oneself. Against a backdrop of culturally given age-related norms, expectations, and roles, people use the material world to manage age-appropriate presentations of themselves. As the body changes, consumption changes. Continuing with habits learned in youth and adolescence, adults employ grooming, clothing, and projects of self-care to stage and restage the apt appearance of their person. Fitness routines, lifestyle regimens, cosmetics, and drugs may be deployed to delay, resist, or mask the signs of aging (Katz & Marshall, 2003). Also pacing bodily change, the consumption of health care rises inexorably with advancing age.

Consumption abets not only the long arc of adulthood, but also the recurring events that mark time. For example, anniversaries of birth and marriage are unthinkable without greeting cards, gifts, and festive meals—commodities all. Not to shop on behalf of birthdays and anniversaries is to let these events pass unremarked.

The social roles comprising the life course and the transitions between them are enacted with goods and services. When young adults establish independent residence, perhaps with a partner, living areas and kitchens will need to be stocked. Acquiring a house will extend the task of homemaking to an entire property. Homes, however, are rarely bought outright. Rather, the funds are purchased at extra cost—a mortgage—over a long period of time. Work roles compel the acquisition of specialized clothing, tools, transportation, and self-care materials. Upon changing jobs, these materials may need to be refreshed. Daily and weekly release from work—leisure—is the occasion for lifestyle explorations via entertainment and recreational consumption.

Parenthood multiplies the obligation to consume, but with a new wrinkle. Parents undertake surrogate consumption for dependent children who are themselves on developmental timetables with their own requirements for types, sizes, and styles of commodities as well as their own projects of identity construction. For all the attention to children and youth as a consumer market, it is primarily parents who choose and buy on behalf of the young, from baby rattles to braces to college tuition.

Having homes and responsibility for others orient adults to maintain their employability and well-being. They purchase insurance of various kinds to minimize the risk of property or income loss. When possible, they also save for old age, which is deferred consumption, but also present consumption to the extent that they pay fees for financial services. With a nest egg (e.g., retirement savings or a 401[k] plan), workers are eventually permitted the leisure of a self-indulgent retirement. Retirement, in fact, can be regarded as an item of consumption, perhaps the largest of a lifetime, and the reformation of identity that it permits is what makes it alluring, delightful, and worth saving for over so many years (Ekerdt, 2004). Another open-ended role of later life—grandparenthood—has few norms for performance, but the bestowal of gifts and experiences on grandchildren is common. Finally, survival into later life will almost certainly involve the continued use of health services and perhaps long-term care, though the ability to consume these goods may need subsidizing by government or the family.

As adults acquire consumer resources in order to enact the sequential roles and stages of life, the goal is not merely to use or have things but also to *be* someone—a homeowner, a hunter, a hostess. Consumption assembles a story about oneself and it is often the means by which to evaluate how well life is going. Two life course transitions merit special mention as market-mediated events: marriage and death (i.e., the funeral and body disposition). Both transitions typically entail extraordinary expenditures for short-term celebrations that are undertaken to honor the social significance of the particular lives in passage.

Recalling the consumption cycle, possession is a life course constant along with acquisition. People proceed through adulthood accompanied by a convoy of material support. Some items are transient (children's toys) and some endure (major furniture, photographs). Goods flow in and out during daily life, but some stick and this residue accumulates over time. The resulting possessions are not mere inert lumps of matter. What is kept must be placed, stored, arranged, maintained, cleaned, insured, emotionally invested, and even animated in the sense that the possessor attributes to them an inner life. People

***Eaton Center Mall in Toronto.*** © RICHARD T. NOWITZ/CORBIS.

cultivate their holdings, taking mass-produced goods such as cars or cookware and make them over as their own (McCracken, 1988). Some things are special, but a lot of personal property is mundane. Out of intergenerational responsibility, individuals adopt family items—curios, heirlooms—as a way to preserve a collective family identity. There has been some research suggesting that younger adults value possessions more for their usefulness, whereas older adults prize symbolic value, but life course differences in the quality of attachment to possessions are not well understood (Kleine & Baker, 2004).

The conclusion of the consumption cycle—disposal—also has life course dimensions. Possessions become candidates for disposal for many reasons, including when their total volume grows too large over time. The imperative to downsize is a staple of popular media, giving rise to the anti-clutter industry that is, ironically, another form of consumption. Life course change is one circumstance that invites disposal, for example, when people exit social roles, become disabled, or need to manage age-related vulnerability, perhaps by moving to a smaller residence. Upon the death of older adults, it may fall to survivors to disassemble the household and discard things.

If keeping things is work, then so is disposal. Whether people give, sell, donate, or discard possessions, the process often involves social calculation and strategizing, efforts to make things presentable, contracting with others, and emotional management. The convenience of storage may well outweigh the inconvenience of disposal, especially if rising affluence across adulthood allows trading up to larger homes.

## AGE SEGMENTATION OF CONSUMER MARKETS

A market is a system or structure for exchange, such as commercial exchange between buyers and sellers. A market also denotes a category of the population grouped according to some characteristic, such as geography, to which things might be sold. Grouping by age yields such target segments as the *youth* market or the *mature* market.

It is a chicken-and-egg question whether merchants induce the demand for goods or consumers create it. In consumption studies, competing viewpoints about the priority of supply and demand generate competing portraits of the consumer (Gabriel & Lang, 1995). On the one hand, consumers are compliant dupes, their desires manipulated by seductive marketing. On the other hand, they are creative agents of self-expression, rationally choosing what and when to consume. Over various moments of adulthood, consumers are likely to evince both ideal types and every gradation in between.

Marketers offer goods, but they also cultivate the market for those goods, predisposing consumers of different ages to understand their welfare in relation to certain products. Each wave of young adults arrives from adolescence already socialized to the idea that every generation has its own music, fashion, and pastimes. The next-stage task is to lead maturing adults to shift their tastes from the things of youth to the goods of grown-ups (e.g., the cut of clothes, breakfast cereal, or real estate). The matter is tricky, however, because advertisers will also want to preserve brand loyalty. Life stages such as

motherhood or retirement can be portrayed as important aspirations. At the same time there are products that stand for rebellion against age, such as sports cars and motorcycles for middle-aged men. The marketplace deals in discrete commodities but also suggests entire careers of consumption. The American Dream is a standard life course script that implies a sequence of successively richer goods and experiences (the home is iconic), culminating in residential, familial, and occupational contentment at midlife. Adopting this ideal, people then conduct their lives to bring it about.

Marketers have long concentrated on consumers younger than 50 and especially coveted those aged 18 to 34 in order to "get them young." But companies are awakening to the potential of middle-aged and older buyers. Household income increases with age to peak in the 50s, and wealth rises to peak in the 70s. Compared to preceding generations, current cohorts over the age of 50 (now including the baby boom) are more affluent and more willing to endure debt. The rising wealth of older adults and, not incidentally, the post–World War II (1939–1945) habits of consumerism they have brought along with them, portend a shift in the image of later life (Gilleard & Higgs, 2000). Rather than being viewed as dependent and needy, elders will increasingly be courted for their market power. The models of maturity already advertised include the fun grandparent, the foresighted financial planner, the restlessly active retiree, and the rational, discriminating consumer of senior housing.

Age-based or cohort-based marketing has various guidelines (Moschis & Mathur, 2007). Most important of these guidelines is being cognizant that age groups are not homogeneous. A small industry has arisen to advise companies how, depending on product, to subdivide age categories by values and lifestyles, shopping behaviors, and service and price consciousness. For example, what product qualities, promotion strategies, and retail arrangements would beckon larger consumer outlays? Do buyers prefer a sales force that is younger, of the same age, or older? In advertising, direct appeals to, or reminders about, chronological age are unwelcome. Rather, the pitch works better when made indirectly, to life circumstances or cohort experiences. For example, a gray-haired model or spokesperson in an ad can convey the intended audience, but is acceptable only if somewhat younger than the target demographic. Finally, an age or cohort link may be inadvisable for some products and services, which are better marketed with an intergenerational appeal.

## FAIRNESS

Consumption is necessarily threaded with ethical issues because the definition of needs and ways to meet them have implications for the common good. Moral and political discourses have long addressed whether resources are justly allocated; whether the values of consumerism are constructive; the environmental costs of the consumption cycle; and whether markets are conducted with fairness (Wilk, 2001). What is ostensibly an activity of the private sphere—satisfying one's needs—raises very public questions about economic, political, and cultural institutions.

Fairness debates have been a life course issue since the 1980s in most of the advanced economies (Moody, 2006). In the United States, the question has been posed under the heading of *generational equity*. Observing that the aggregate economic well-being of children has fallen while that of elders has risen, some quarters of the policy community have asked whether federal old-age programs deprive families with young children of their fair share of social resources. It is a fair observation that old-age entitlement programs such as Social Security and Medicare transfer, via taxation, buying power from younger cohorts to older citizens. At the same time, it is far from assured that any retrenchment in these programs would benefit the neediest children. Intense discussion has surrounded proposals for age-based rationing of health care. Older cohorts consume a disproportionate amount of health care, which is subsidized by public funds, and costs are always rising. Might age be used as a criterion for allocating and limiting health care? Debates about generational fairness are likely to continue, being sometimes philosophical and often sharply ideological. Against the contention that one age group consumes at the expense of another, others have argued for the essential interdependence of generations in furnishing one another's needs across the life course.

# CONTINGENT WORK

SEE Volume 2: *Flexible Work Arrangements; Self-Employment.*

# CONTINUING EDUCATION

*Continuing education* is a term used by policy makers and educators in many countries. It refers to any form of educational provision for people who have completed their initial fulltime education and entered the adult stage of their life course, which usually involves entering employment. This is a broad definition of continuing education since it includes liberal adult education, professional updating, vocational training, and regular degree or other award-bearing courses that are undertaken by mature students. However, the term is also sometimes used in a narrower sense—to refer only to short courses provided for adults who have completed their substantive formal education.

Several other terms are related to the concept of continuing education. *Recurrent education* carries the implication that an individual alternates formal education with employment across the life course, rather than completing his or her formal education before entering into adult life. Thus, like the broad concept of continuing education, recurrent education seeks to move away from a "front-end" model of education, which takes education in adulthood to be an indulgent or a remedial "add on" to the main education obtainable in compulsory schooling. The term *adult education* also rejects the front-end model; it implies that there are forms of knowledge and ways of learning distinctive of adulthood.

In the late 20th and early 21st centuries, the term *lifelong learning* became increasingly prominent and influential in research and policy making. For example, the 1990s saw the publication of many national policy papers and influential reports from the Organisation for Economic Co-Operation and Development (OECD), the European Commission, the Group of Eight (G8) governments for the eight largest economies, and from United Nations Educational, Scientific, and Cultural Organization (UNESCO), thus bringing in many non-European countries. Lifelong learning is connected to the notion of cradle-to-grave educational provisions and to the idea that education must meet the needs of rapidly changing modern industrial democracies.

Lifelong learning includes vocational and professional updating, liberal education for personal development, and political education for good citizenship. A "learning society" is one that values a broad range of learning and is organized to provide maximum learning opportunities for its members across the life span. Like continuing education and adult education, the concept of lifelong learning recognizes formal, nonformal, and informal learning as worthwhile and valuable to both the individual and to society. (Formal education refers to courses provided by formal educational institutions, such as colleges or universities. Nonformal learning encompasses educational programs provided by organizations whose primary purpose is not education, such as voluntary organizations, churches, or synagogues. Informal learning is learning that takes place in daily life, ranging from watching TV documentaries to holding conversations with friends).

*Further education* refers to full-time and part-time education provided by educational institutions for persons over compulsory school age. It carries a vocational emphasis and is often referred to as "further education and training." Higher education refers to more academic (university) provision.

The key point is that there are several distinguishable but overlapping terms used to refer to various forms and stages of education beyond formal schooling in childhood and adolescence. In terms of the life course, it is extremely important to recognize the validity and value of education throughout life, up to and including old age.

## VALUES IN AND THE VALUE OF CONTINUING EDUCATION

The concept of continuing education values education beyond school and assumes that there is worthwhile learning appropriate to all stages of the life course. For example, people begin to gain skills for the world of work in early adulthood, but the idea of continuing education suggests that adults should continue to gain in competence, broadening and deepening their understanding

and skills across their working lives. Parents and children gain from the provision of parental education and also from family learning where children and parents can learn together. In adulthood and later life, too, people may become part of communities where continuing education may be both politically and personally important. The educational awareness gained by women through the women's movement in the 1960s and 1970s is a good example of this sort of continuing education. Retirement also may bring the opportunity to engage in learning of interest to the individual, an engagement that is known to have both health and social benefits.

The value of continuing education is immense. Levels of education and engagement in learning have been linked to enhanced physical and mental health, as well as economic prosperity. Learning has both intrinsic value, in that it provides satisfaction to the learner, and extrinsic rewards, in that it leads to better employment opportunities, health benefits, and correlates to levels of income.

Educators involved in continuing education, aware of its value and power, are often highly committed to widening access to post-school educational opportunities. "Widening" in this sense means not only increasing the number of people who participate, but also increasing proportional participation by members of disadvantaged social groups.

## EQUITY AND CONTINUING EDUCATION

The issue of equity and continuing education is multi-dimensional, dynamic, and complex. However, many research studies have shown that social groups that face prejudice and systematic individual and institutional discrimination have fewer educational opportunities and obtain fewer educational qualifications than more advantaged members of the population. Thus, for example, many minority ethnic groups and physically disabled persons suffer educational disadvantage across the life course. Moreover, specific forms of knowledge possessed by such groups, such as cultural art forms, tend to be undervalued.

The OECD's work on equity and education includes comparisons across countries, by gender, social class, ethnicity, and disability levels of participation in continuing education (OECD, 1993). Such research supports the general consensus that major gaps persist between social groups in educational access and participation. Further rigorous research to refine our broad understandings about equity and education would be welcome.

Because knowledge, the process of learning, and educational qualifications are all highly valuable to individuals and to communities, there are implications for policy makers and funding organizations that seek to establish more equitable opportunities. The movement to lifelong learning has encouraged efforts to reach underrepresented groups but there remains cause for concern. A tendency to concentrate on employment-related education, for example, excludes retired people and the long-term unemployed. Narrow forms of assessment might penalize the disabled, and barriers remain. For example, problems related to information flow are particularly acute for minority ethnic groups (Field and Leicester, 2000).

## THEMES AND THEORIES

The study of continuing education is multidisciplinary—drawing on established disciplines including psychology, social psychology, sociology, and philosophy. From psychology and social psychology much has been discovered about how adults learn and social studies have shown why, where, and when such learning occurs. Because education is value-laden and the provision of opportunities for continuing education involves political decisions, and because education involves the development of knowledge, philosophical and epistemological analyses have also contributed to understanding continuing education.

Learning is a central component of human life, and thus occurs across the lifespan as individuals change and develop. Knowles's theory of androgogy, or adult learning, has been particularly influential for adult educators and rests on four major assumptions:

- a change in self concept, because adults need to be more self-directive;
- experience, because mature individuals accumulate and expand a reservoir of experience that becomes an exceedingly rich resource in learning;
- readiness to learn, because adults want to learn in the problem areas they confront and that they regard as relevant;
- orientation toward learning, because adults have a problem-centered orientation and are less likely to be subject-centered (Knowles, 1984).

Compared to Knowles's, Freire's ideas, arising out of his experience of the oppression of the masses in Brazil, focus to a lesser degree on the study of how individuals learn and to a greater degree on a more radical form of education to promote active political participation in the wider world. Education in adulthood should raise the level of the consciousness of oppressed groups so that the operation of the economic, political, social, and psychological forces of oppression can be understood and opposed. These political ideas have been influential in encouraging community education, prompting community educators to develop and deliver forms of education that benefit communities and disadvantaged communities in particular.

Research on continuing education conceptualizes post-compulsory education as a social commodity, requiring policy decisions and implementation, funding and administration—practical aspects that also require monitoring and analysis. This research is also itself imbued with implicit value judgments and philosophical and political assumptions.

### POLICY ISSUES IN THE NEW MILLENNIUM

Given the prominence of lifelong learning in the first decade of the new millennium, it seems likely that learning across the life course will continue to be an important educational goal with important policy implications. In the rapidly changing modern world, updating skills and acquiring new ones makes economic sense for individuals and for their societies. And if good teaching is to be offered to students of all ages, the professional development of educators themselves needs to become a matter of career-long learning (Day, 1999). In schools, the curriculum needs to include equipping children with the skills and commitments to become lifelong learners.

Cross-generational learning—in which individuals at different phases of the life course learn with and from each other—has been relatively neglected. Within the movement toward lifelong learning there has been some development of family learning. A key issue for the future will be to monitor and identify good practice in this kind of cross-generational educational provision. Parental education and health education also are crucial areas in connection with individual flourishing and well-being. These forms of education might (and should) be given increasing support. Citizenship education to equip people to be active good citizens is currently receiving attention. This meets the political aspect of lifelong learning and also might (and should) become increasingly supported. A future issue that requires both scholarly and public attention is how to find ways to interrelate these three strands of lifelong learning (vocational/professional, individual/liberal, political/citizenship) in order to provide education across the life course that meets all three of these crucial learning needs.

### CONTINUING EDUCATION AND THE LIFE COURSE

The voluntary nature of post-school learning is important. Adults must be free to choose what kinds, and how much, educational provision in which to participate. However, a corresponding ethical requirement is, surely, that all citizens have an equal opportunity to genuinely choose to partake. OECD studies indicate that more than 10% of 30- to 39-year-olds in Australia, Finland, New Zealand, Sweden, and the United Kingdom are enrolled in continuing education (full- or part-time) compared to the OECD country mean of 4.8%. Similar patterns, although with lower overall rates, are found for persons ages 40 to 49 (Schuller, 2006). Such cross-national differences challenge the notion of free choice and have policy and funding implications.

In schools, lifelong learning implies a need for further curriculum development to increase the agency of pupils by giving more extensive career education and by equipping children with the skills and commitments that will help them to become lifelong learners. Perhaps the most important point is that, given the importance of worthwhile learning to human flourishing across the life course, it is imperative that societies do indeed seek to provide appropriate continuing education. This entails encouraging and supporting learners from all social groups to partake in good quality educational provision at all stages of their lives.

## CRIME, CRIMINAL ACTIVITY IN ADULTHOOD

Criminologists have long recognized a strong life course pattern in criminal activity. Involvement in crime increases dramatically during the teen years, peaks at

around age 20, and then declines steadily over the rest of the life course, with very low levels observed after age 65. This general pattern is observed regardless of time period, place, and type of crime. However, rates of violent crime appear to peak a bit later (around age 25) than do those for property crimes (around age 20).

This pattern holds whether one considers official statistics (crimes reported to police), self-report data (respondents' reports of their own criminal activity), or victim reports of offender characteristics. Each type of data has limitations—official statistics are subject to vagaries as a result of selective enforcement and underreporting, and self-report and victim data may be biased because of sampling errors and both over- and underreporting—yet all sources confirm the general age–crime relationship. Indeed, the association is so robust that some scholars have referred to the relationship as invariant.

## CRIME ACROSS THE LIFE COURSE

Differences in criminal involvement by gender and race are well documented, with males and minority group members exhibiting higher rates of crime, particularly violent offenses, than females and Whites. For example, the 2006 male arrest rate of 10.8 per 1,000 for the eight most serious crimes reported to the police (homicide, rape, robbery, assault, burglary, larceny, arson, and motor vehicle theft) was almost three times higher than the corresponding rate for females. Similarly, African Americans tend to exhibit higher levels of criminal involvement, with arrest rates about three times those of Whites. These figures should be interpreted with caution because of the possibility that police enforcement practices and biases may distort actual levels. However, self-report data obtained from offenders tend to corroborate these general patterns.

Despite these stark gender and race differences in levels of criminal involvement, the age–crime relationship is apparent within gender and racial groups. For example, female age-specific rates for the eight most serious crimes rise dramatically during the early teen years, peaking at about age 16 and declining steadily afterward. For males the pattern is similar, although rates tend to peak a bit later, at age 18, and rise to dramatically higher levels. Both first arrest and recidivism (or subsequent arrest) rates are considerably higher for males than for females. Aggregate arrest rates are much higher for Blacks than for Whites, yet there is little difference between the two racial groups in recidivism rates. Racial differentials result more from differences in patterns of criminal participation than from differences in the frequency or duration of individual offending.

The age–crime relationship could indicate that criminal activity declines with age among all individuals. However, it also could reflect other scenarios. For example, the same pattern would be observed if the majority of individuals stopped criminal activity once they reached adulthood even though a minority continued to participate actively in crime through adulthood. Alternatively, the age pattern may reflect declines over time in the frequency with which active offenders commit crime or declines over time in the number of active offenders as a result of incarceration, death, or declining health (because of substance abuse or the natural aging process). These scenarios are all consistent with the observation that criminal activity declines with increasing age in a population.

There has been debate about these issues in the field of criminology. One argument suggests that the relationship between age and criminal involvement does not exist for all types of criminals. Terrie Moffitt (1993), for example, classified offenders into two distinct categories: "adolescence limited" and "life course persistent." An adolescence-limited offender engages in delinquent and criminal behavior during adolescence and stops after reaching adulthood. Criminal activity is confined to a relatively short period, and a clear decline in crime with increasing age is observed among this group. The vast majority of delinquent adolescents can be characterized this way. Criminal activities among life course persistent offenders, or so-called career criminals, are marked by considerable frequency, seriousness, and a long duration. Moffitt suggested that offense and arrest rates in this group remain fairly constant over the life course. Other scholars have included additional types of criminals in this categorization, noting the presence of a low-level chronic group whose members continue to offend but with less frequency through adulthood (Nagin & Land, 1993).

One frequently cited statistic that supports the contention that criminal behavior is concentrated heavily among a few individuals with criminal careers comes from a 1972 study titled *Delinquency in a Birth Cohort* (Wolfgang, Figlio, & Sellin, 1972). Researchers found that although a significant proportion of the young men in that birth cohort had had at least one run-in with police, only 6% of them were responsible for the majority of crime in that cohort. A 1979 study by Alfred Blumstein and Jacqueline Cohen focused on serious offenders in Washington, D.C., and showed that the relationship between age and crime disappeared when cohorts were followed over time, with rates of criminal involvement for these serious offenders remaining fairly constant with age.

Other scholars disagree with that characterization. Travis Hirschi and Michael Gottfredson (1983) argued that the relationship between age and crime is explained by biological (e.g., hormones or physical characteristics) rather than social factors and supported their thesis by showing that the relationship between age and crime does not vary across persons, time periods, place, and type of crime. Other researchers have noted that studies

supporting the notion of a career criminal tend to be limited by several design flaws. First, these studies typically follow offenders for a relatively short period and certainly not through midlife and later life. Second, types of criminals tend to be identified retrospectively rather than prospectively, and thus this approach by definition observes only high-level criminals who have not desisted (Laub & Sampson, 2003).

Certainly, some research shows that even among career criminals, involvement in crime seems to diminish with age. For example, retrospective self-reports by incarcerated offenders indicate that involvement in crime declines as offenders age. Independent evidence supports this notion. John Laub and Robert Sampson (2003) found in their sample of highly delinquent boys who were followed up to age 70 that offenses eventually declined among all groups of offenders. The peak age of offending varied, as did the rate of decline with age, but the results clearly showed that the age–crime relationship holds even among the most serious, persistent, and frequent offenders.

## LIFE COURSE THEORIES OF CRIMINAL BEHAVIOR

Most theories of crime focus on explaining differences in criminal behavior among individuals. Strain theory emphasizes economic disparities among individuals as a key reason for differential criminal involvement, whereas social disorganization theory focuses on environmental factors. Such explanations are static in nature rather than dynamic and do not attempt to explain the extent to which the criminal behavior of an individual may change over time.

Developmental or life course explanations for criminal behavior focus on this question, asking how criminal behavior develops and changes over the life course. Although there are a number of variants of developmental criminological theories, they all recognize that life events and circumstances can alter criminal behavior. Specifically, these theories focus on three primary issues: identifying factors that explain the initiation and development of antisocial and criminal behavior, documenting risk factors for crime at various ages, and determining the degree to which life events alter the trajectories of those engaged in crime.

## FACTORS EXPLAINING THE INITIATION AND DEVELOPMENT OF CRIMINAL BEHAVIOR

Numerous studies indicate that problematic childhood behavior such as temper tantrums, poor school performance, and bullying are linked to antisocial behavior in adulthood. Furthermore, those who initiate delinquent behavior at an early age tend to commit crimes more frequently and for a longer duration than do those with a later onset. Indeed, early antisocial behavior often is viewed as the single best predictor of antisocial behavior in adulthood. A review of studies exploring this topic reported a substantial positive correlation (0.68) between early aggressive behavior and later criminality (Olweus, 1979). This stability in antisocial behavior has been demonstrated by using data from different countries and varied methods of assessment, including official records as well as teacher, parent, and peer reports of aggressive behavior (Caspi & Moffitt, 1993).

What causes the early propensity among some to engage in aggressive behavior? Gottfredson and Hirschi (1990) and others have argued that personal characteristics such as lack of self-control and a tendency toward impulsivity explain an early onset of antisocial behavior. Other research points to the importance of family factors in predicting problematic behavior in childhood and adolescence, in particular, low levels of parental supervision and involvement, a disciplinary approach that is both erratic and harsh, and weak attachment to parents (Loeber & Stouthamer-Loeber, 1986). Other possible explanations relate to school involvement and attachment, neighborhood factors (e.g., poverty), parental criminal involvement, and heredity.

Antisocial behavior in childhood may influence later behavior though multiple mechanisms. To the extent that personal traits such as low self-control do not change over time, they continue to affect behavior in later life (Gottfredson & Hirschi, 1990). Other researchers note that prior behavior may increase the probability of future problematic behavior either by weakening inhibitions or by increasing motivations (Nagin & Paternoster, 1991). For example, the process of being apprehended and officially sanctioned or labeled for antisocial behavior at a young age may propagate problematic behavior in the future by removing opportunities. Devah Pager (2003) documented the "mark of a criminal record," demonstrating that arrest and incarceration negatively affect future employment prospects.

All this research pointing to stability in antisocial behavior over time seems inconsistent with the notion that individuals desist from crime as they age. Yet stability and desistance are not mutually exclusive patterns. A substantial body of literature reveals that most antisocial children do not manifest similar problematic behavior in adulthood (Robins, 1978). These seemingly contradictory statistics can be reconciled by returning to the research design problem mentioned above: Most studies have been retrospective in design, beginning with adult criminals and tracing their behavior and experiences back in time. That approach excludes delinquent adolescents who eventually desist from

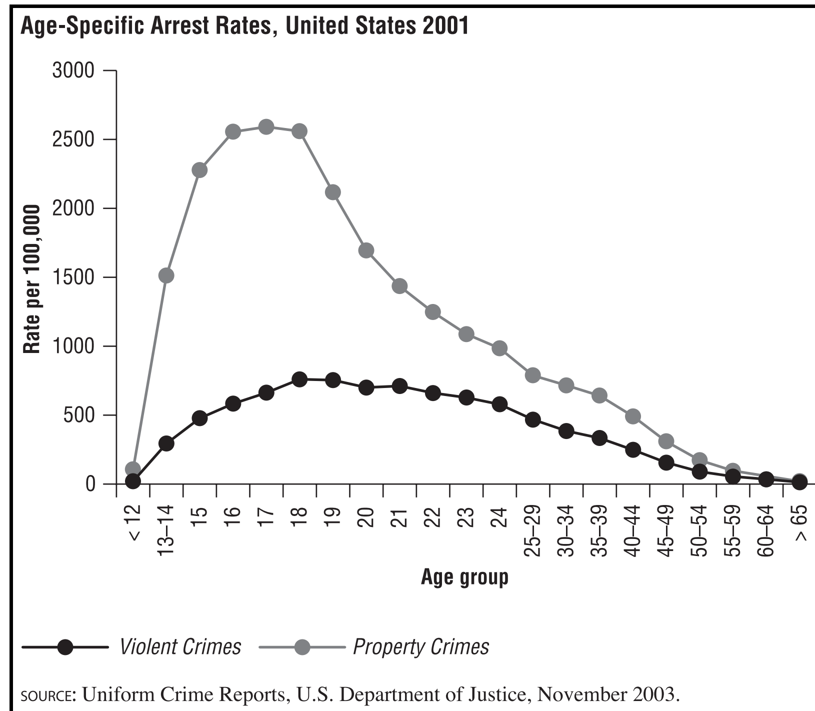

*Figure 1.* CENGAGE LEARNING, GALE.

crime. Although virtually all adult criminals experienced severe problems as children, most antisocial children grow up to become law-abiding adults.

## FACTORS THAT EXPLAIN DESISTANCE FROM CRIME WITH AGE

What factors determine whether antisocial children desist from or persist in criminal behavior in adulthood? Some argue that the causal mechanisms underlying criminal behavior differ in important ways for those whose problematic behavior is confined to late adolescence and early adulthood as opposed to those who persist into later adulthood. Moffit (1993), for example, argued that those on a career criminal path offend because of what she terms "early neuropsychological deficits" such as hyperactivity, impulsiveness, and low self-control. These qualities, which may be inherited or acquired, are exacerbated by poor family relationships and other environmental features but are largely immutable. In contrast, the motivation for offending among adolescent-limited offenders is rooted in peer influences or "social mimicry," forces that lose their sway once individuals reach adulthood.

However, evidence is accumulating that shows that criminal trajectories are not predestined in this way. Instead, certain key life events or turning points explain how and why many antisocial children and delinquent adolescents are able to change their life trajectories and desist from criminal behavior. Perhaps most influential in this regard is the work of Sampson and Laub (1993, 2005), which demonstrates how informal social controls that are exerted through institutions such as marriage, employment, education, and military involvement can promote changes in problematic behavior. Such turning points separate past history from the present, offer both supervision and monitoring, and provide structure, social support, and economic opportunities. These transformative events are linked closely to age and hence offer an explanation for the declining rate of criminal involvement with age.

Sampson and Laub's study resurrects life histories originally gathered by two Harvard researchers, Sheldon Glueck and Eleanor Glueck, between 1940 and 1965. The Glueck team gathered data on 500 highly delinquent youth and 500 control participants in the Boston area, matching them on several characteristics, including age, IQ, socioeconomic status, and ethnicity (Glueck & Glueck, 1950). The participants originally were followed from age 14 to age 32. Sampson and Laub tracked down some of those men and updated their life histories to age 70.

The analyses conducted by Sampson and Laub provide support for the stability of antisocial behavior. Men who experienced difficulties in childhood and adolescence were most likely to report problematic behavior in adulthood.

For example, 55% of those with an official record of delinquency before age 14 reported at least one arrest in midadulthood (between ages 32 and 45) compared with 16% of those without a record of official delinquency. However, the analyses also revealed that high-quality social bonds to important institutions, such as a close attachment to a spouse and expressed commitment to a stable job, are effective in promoting change. About a third of men who reported stable jobs and strong marital attachments at ages 17 to 25 were arrested between ages 25 and 32 compared with about three-quarters of men with low job stability and weak marital attachments.

Other research has led to similar conclusions. One study (Horney, Osgood, & Marshall, 1995), using retrospective survey data on more than 600 serious offenders, found that school attendance and living with a wife reduced the chances of reoffending in the short term in a sample of male felons. Another study, using prospective panel survey data gathered in the United Kingdom, indicated that delinquent youths who largely were reformed by adulthood had work records and marital relationships that were substantially better than those of chronic offenders. However, those individuals continued to report noncriminal deviant behavior such as heavy drinking and physical disputes (Hagan, 1993; Nagin, Farrington, & Moffitt, 1995).

Of course, an important question is whether such life events actually cause people to desist or whether the individuals most likely to desist anyway are those who obtain good employment and/or choose a stable, supportive partner. In other words, can it really be concluded that such life events actually cause desistance? Sampson and Laub (2003) provided evidence that suggests that the answer is yes, showing that the same person is less likely to offend when married than when unmarried even after controlling for age.

Christopher Uggen (2000) approached this issue by examining data gathered from a national work experiment for individuals with a criminal record. Offenders were assigned randomly to either a treatment group or a control group; those in the treatment group were offered minimum-wage jobs, and random assignment ensured that the nature of employment was not associated with personal traits such as work ethic and commitment level. The results revealed that participants age 27 or older in the treatment group were less likely to report crime and arrest than were those in the control group. However, for younger offenders marginal job opportunities elicited little change in criminal behavior. This study provides convincing evidence that, for older offenders at least, employment is in fact an effective turning point.

## FUTURE RESEARCH DIRECTIONS

Past research on adult criminal activity, which is quantitative in nature and typically relies on official statistics (arrest data) or self-report data, has provided much information about how childhood circumstances and key life events such as employment and marriage affect criminal trajectories. What is less well understood is the role of human agency—the degree to which individuals actively make their own decisions about the course of their lives—and how those individual decisions interact with environmental factors to affect criminal trajectories (Sampson & Laub, 2005). Qualitative research would complement quantitative data in this regard. Moreover, future research that attempts to incorporate both self-reports and official measures of offending and considered other types of deviant behavior, such as domestic violence, would further understanding of adult criminal activity (Piquero & Mazerolle, 2001). Also, the degree to which other life events such as the discovery of religion affect criminal involvement is not well understood, nor are the main life events that contribute to persistence in rather than desistance from crime.

## INTERVENTION STRATEGIES

The mechanisms through which crime begins and persists suggest two alternative paths for intervention and prevention. To the extent that problematic behavior in childhood contributes to difficulties in adulthood, one set of strategies focuses on targeting youths and their families as early as possible. Programs such as the Seattle Social Development Project, which promotes strong bonds between children, families, and schools, and the Montreal Longitudinal-Experimental Study, which focuses on parent training (e.g., literacy, effective discipline strategies), have had success. Youths participating in those programs exhibited significantly lower levels of delinquency and substance abuse at older ages than did similar youths not involved in the programs (Hawkins, Kosterman, Catalano, Hill, & Abbott, 2005; Tremblay et al., 1992). Nurse home visitation during pregnancy and continuing through infancy also proved effective: Fifteen-year follow-up results show that adolescents from single-parent, economically disadvantaged homes who received nurse home visits report lower levels of official delinquency, substance abuse, and truancy than do those in control groups (Olds et al., 1998).

The other strategy for reducing criminal activity focuses on adults to ensure that protective social bonds are not severed. Community-based corrections, such as residential community institutions, home confinement programs, and day reporting centers, may be most successful in this regard. Laub and Allen (2000) argued that such community incarceration programs emphasize surveillance but also recognize the importance of treatment, such as job training and employment, education, and family counseling. Evidence shows that education and vocational training improve the prospects of employment and reduce reoffending rates. The participants in one such program, the Court Employment Project, could have their criminal charges dropped if they

completed 90 days of a job training and placement program. Offenders who successfully completed the program did appear somewhat less likely to reoffend (Bushway & Reuter, 1997). These community-based strategies are in direct contradiction to the current emphasis in the U.S. criminal justice system on incarceration, which may increase the likelihood of crime by severing social ties to family and work, which are important for changing criminal trajectories over the life course.

# CRIME AND VICTIMIZATION, ADULTHOOD

Although victimization has a clear reality in the public mind, efforts to provide a coherent and comprehensive definition have proved notoriously difficult. Most social scientists view victimization in the context of physical

attacks on individuals (e.g., assaults, sexual assaults, and murders), the destruction or unwanted removal of property (e.g., vandalism, theft, break and enters), or some combination of the two (e.g., robbery, kidnapping). Still, such definitions are almost always incomplete or contested as seen in descriptions of emotional abuse, pet abuse, or stalking, to name only a few.

Nevertheless, for the most part, victimization (as it is generally measured) is a rare event. Only a select segment of any population is victimized in any given year and fewer, still, experience more frequent or severe incidents such as violence. Thus viewing victimization as a random and perhaps fleeting occurrence is natural. However, the age grading of victimization risk is very strong and the extent and type of this risk is closely connected to adult social roles. Moreover, the experience of victimization may in turn affect how an individual's life course unfolds, with negative consequences for his or her life chances.

## LIFE COURSE ANTECEDENTS OF VICTIMIZATION

Research consistently shows that the likelihood of criminal behavior increases steadily through the teenage years, peaks in late adolescence or early adulthood, and then declines steadily with advancing age. Whether this age pattern is the same across times and places has been hotly debated (Blumstein, Farrington, & Cohen, 1988); however, the age grading of crime seems indisputable.

The relationship between age and victimization is much more complex, however. Both social science and public discourse focus considerable attention on specific types of victims defined largely in terms of age. The victimization of children and the elderly is the subject of a great deal of this attention. Likewise, laws often target age-specific victimizations; Megan's Law, for example, requires the identity of persons convicted of sex offenses against children to be made public. Similarly, the Texas Penal Code, like other states, specifically criminalizes someone who "intentionally, knowingly, recklessly, or with criminal negligence, by act or intentionally, knowingly, or recklessly by omission, causes to a child, elderly individual, or disabled individual ... serious bodily injury, serious mental deficiency, impairment, or injury, or bodily injury." In light of such interest, it is not surprising that organizations, such as the National Center for Missing and Exploited Children or the National Center on Elder Abuse, exist to increase public awareness and advocate on behalf of young and old victims of crime.

The difference between age patterns of crime and age patterns of criminal victimization reflect the fundamental belief that *vulnerability* is key to understanding victimization. The assumption is that people are victimized because they lack the personal and social resources to prevent their victimization. Yet, this perception ignores the importance of factors that put potential offenders and potential victims together in time and space. Sociologists Larry Cohen, James Kluegel, and Kenneth Land (1981) describe an opportunity model of crime victimization that emphasizes the importance of *proximity*, *exposure*, *guardianship*, and *attractiveness* as key determinants of victimization. Proximity refers to an individual's distance to pools of potential offenders, whereas exposure refers to activities that put potential offenders and potential victims in the same place. Guardianship, a potentially countervailing influence, is the capacity of individuals or their circumstances to prevent victimization by increasing resistance, difficulty, or the likelihood of detection. Finally, attractiveness is the relative symbolic or material value of a given target for a potential offender. An attractive target may simply be someone who looks like they have more money or a nicer house or car. Some even speculate that the overall volume of attractive targets has increased in recent decades with the literal explosion of portable electronic devices such as cell phones, BlackBerries, iPods, and so forth. Importantly, age and life course stage shape these determinants in complex ways, which makes predicting the age pattern of victimization difficult. Still, a number of key themes are important in understanding victimization.

If the risk of victimization increases when potential victims share time and space with potential offenders, then people who are close in age or share a similar lifestyle with potential offenders should be at greatest risk. Given the age pattern of crime, a natural expectation is that people in the age group at which crime rates are highest are most at risk of victimization and indeed considerable research bears this out. In 2007, the Bureau of Justice Statistics reported that rates of violent victimization increased from 47.3 per 1,000 for those aged 12 to 15 to 52.3 for those aged 16 to 19 but then declined steadily with advancing age (Rand & Shannan, 2007). People ages 50 to 64 had a rate of violent victimization approximately one-quarter (13.1 per 1,000), while persons age 65 or older had a rate almost one-fifteenth of those in their teenage years (Rand & Shannan, 2007). When considering property victimization, the story is the same. Heads of households between the ages of 12 and 19 have victimization rates of 370 per 1,000 compared with only 70.3 for heads of households 65 or older. In general, data from a wide variety of sources, time periods, and countries show that victimization is strongly concentrated in the adolescent years.

However, the story does not begin and end with adolescent victimization risk. Also important is how unfolding social roles shape victimization risk over time. Such a view is anticipated in one of the earliest statements of victimization risk, where Michael Hindelang, Michael Gottfredson, and James Garofalo (1978) argued that the idea of *lifestyle* is the key determinant of

victimization. In their view, lifestyle refers to the broad pattern of relationships and activities that constitute the core features of an individual's everyday life. Lifestyle is strongly connected to the social roles that people occupy, especially to those that signal the transition to adulthood and give shape to the unfolding life span. How and when people exit from schooling, enter the workforce, get married or begin cohabiting, have children, and leave the parental home all have an impact upon their likely exposure to crime by virtue of the lifestyles they promote. These factors also influence proximity and exposure to potential offenders, as well as guardianship and attractiveness.

Educational roles are a good example. The number of years spent in formal education has increased in the United States. For many, this involves movement into and through higher education and the completion of two- and four-year degrees in the early to mid-20s. For others, schooling is less linear and involves movement into and out of educational institutions, often switching programs and colleges, throughout one's 20s and even into one's 30s. Although the extension of formal schooling has many life course implications, a particularly important one is that the period in which individuals are proximate and exposed to potential offenders also is extended. Although institutions of higher learning are quite safe in comparison to other social spaces, despite recent high-visibility campus shootings, there is also evidence that college students have higher than expected risks. College worlds seem particularly conducive to alcohol related assaults, date rape, and various forms of personal theft.

Another key feature of adulthood is the movement into full-time work. Work is related to victimization in a variety of ways, the two most significant being work-related victimization and socioeconomic inequality in victimization risk. In the former case, considerable violence actually occurs in and around workplaces. Data from the National Crime Victimization Survey (NCVS) indicates that 8% of rapes, 7% of robberies, and 16% of assaults occurred while victims were working or on duty (Bachman, 1994). Moreover, a person's type of work also matters, in that victimization rates appear particularly high in restaurant, bar, and nightclub settings. More generally, criminologist James Lynch (1987) concluded that jobs that involve high amounts of face-to-face contact, the handling of money, and mobility between locations were particularly conducive to victimization. Not surprisingly, research on homicide shows that the risk of being murdered is significantly elevated among cab drivers, bartenders and waitresses, and clerks in convenience stores.

In addition to shaping the kinds of activities in which individuals are involved, jobs are a foundation of socioeconomic status. As such, jobs affect the likelihood of victimization by shaping the types of neighborhoods people live in, the types of housing they have, the private or public transportation available to them, and their capability to buy protections helping prevent their victimization. However, the relationship between socioeconomic status and victimization risk is complicated. In terms of proximity, money should be able to buy distance and those with more resources should be better able to insulate themselves from potential offenders. Similarly, greater resources should also increase guardianship, as those with more resources are better equipped to purchase protections such as private parking or home security. At the same time, people with more resources usually have more valuable possessions, which increases their attractiveness to potential offenders. More resources also increase people's ability to purchase leisure, increasing exposure as well. These countervailing forces play out differently for various types of victimization risk, so that the relationship between risk of victimization and socioeconomic status varies by type of victimization. For example, the risk of rape victimization is particularly high among those who earn less than $15,000 per year (U.S. Department of Justice, 2003). The pattern is even more pronounced for robbery and assault; those with incomes of less than $7,500 per year have double the risk of victimization of the next highest income group. In contrast, there is no clear relationship between socioeconomic status and risk of personal theft; victimization rates are similar across income categories.

Marital status has a complicated relationship to victimization risk. On one level, being married is generally associated with lower risk of predatory crimes, such as stranger assaults, robberies, and personal theft. According to data from the NCVS, married persons have one-quarter the risk of violent victimization compared with persons who never married (Catalano, 2006). Similar, if not more extreme, differentials appear for rape, robbery, aggravated assault, and personal theft. The complexity of the relationship is revealed by examining the risk of separated and divorced persons, whose risk of victimization for rape, robbery, or aggravated assault is similar to the risk of persons who never married, even though the former are typically much older than the latter and presumably have less exposure to potential offenders.

The question of why formerly married people have such high rates of victimization highlights the unique opportunities and circumstances of marriage that might foster violence between partners, violence that is typically not well-measured in national crime surveys such as the NCVS. As a result, researchers often turn to studies that focus on violence among intimate partners: Studies such as the National Violence against Women Survey (NVAWS), for instance, reveal that there is considerable violence between intimate partners, that women have considerably

higher rates of victimization than those shown in traditional crime victimization surveys, and that women who are leaving or have left a relationship are particularly likely to experience violence (Tjaden & Thoennes, 2000). Thus, whereas marriage decreases some forms of victimization by altering individuals' lifestyles and routine activities, it also increases other forms of victimization by situating individuals in a unique social relationship with norms, expectations, and practices that may elicit, and perhaps even allow and encourage, the use of violence.

## LIFE COURSE CONSEQUENCES OF VICTIMIZATION

Although life course events affect the risk of victimization, experiences of victimization are nevertheless concentrated in adolescence and early adulthood. The experience of violence, both social and psychological, has the potential to shape life course outcomes by altering the ways in which individuals approach the world and its challenges and opportunities and even the extent and type of relationships that one has (Macmillan, 2001). One particularly prominent vein of research focuses on exposure to violence in early life, be it violence from strangers, peers, or kin, and the likelihood of it resulting in mental distress and poor psychological well-being. Indeed, a core explanation of mental distress focuses on the presence of life stressors of which exposure to violence is a salient theme, regardless of whether the focus is on broad life course linkages such as that between early childhood and later adulthood (Kessler & Magee, 1994) or on life stages such as adolescence (Hagan & Foster, 2001) or old age (Harrell et al., 2002).

An equally provocative literature focuses on the relationship between victimization and offending. Although it is well-established that involvement in crime and deviance dramatically increases risks of victimization, there is also compelling work that views victimization as a precursor to crime. Some suggest that victimization produces the impetus for revenge, whereas others speculate that victimization may induce nihilistic or anomic feelings that neutralize anticrime values (Singer, 1986). Still, there is much more work to be done given the problem of embeddedness where those whose lifestyles involve crime may be more likely to offend and be victimized by virtue of how they spend their time and who they spend it with. Yet what seems clear is a strong association between victimization and offending over the life span (Macmillan & Hagan, 2004).

With effects on mental health and involvement in crime and deviance, it is not surprising to imagine further effects victimization has on other life course trajectories. Recent years have seen the emergence of two streams of work. One area of study is the impact of victimization on social relationships. Constance Fischer (1984), for example, argues that victimization upsets and undermines people's world views and helps foster mindsets where individuals are seen as predators rather than allies and sources of threat rather than safety. Although the social network implications of this are largely speculative, some work by Andrew Cherlin and colleagues (2004) suggests that physical and sexual abuse in relationships has important effects on the character and likelihood of subsequent relationships. Although further study is clearly necessary, evidence is emerging that victimization shapes social relationships in profound ways.

A final area of study examines the relationship between victimization and trajectories of educational and occupation success. Building off the work of Fischer and others, Ross Macmillan (2000; 2001) proposed a theoretical model that viewed the immediate consequences of victimization as threats to agency and long-term orientations and investments. From these consequences stemmed lower aspirations and less investment in educational endeavors such as homework. This further leads to poorer educational performance and lower grades and lower educational attainment in general. As educational attainment is the lynchpin of socioeconomic attainment, victimization ultimately undermines labor force participation, occupational prestige, income, homeownership, and risk of poverty. Indeed, analysis of high-quality data showed widespread socioeconomic consequences of adolescent victimization in the transition to adulthood (Macmillan & Hagan, 2004).

Although studies of the consequences of victimization are comparatively new relative to studies of victimization risk, there is an impressive and increasing body of evidence that shows victimization in adolescence to be part of a chain of adversity where early experiences shape the character and content of later experiences, with exposure to violence being a recurring feature of an individual's life course and thus dramatically diminishing quality of life. In some respects, early adversity puts people at risk for victimization, which contributes to cycles of disadvantage. In other respects, victimization may constitute a turning point in the life course and derail trajectories of success. In both respects, it appears an important element in the structuring of the life course.

# CULTURAL IMAGES, ADULTHOOD

Cultural images of adulthood, or the prevailing ideas about what it means to be an adult in a particular society, have not been researched systematically by social scientists. Knowledge of these images might provide a framework in which to monitor social change in a variety of areas, including intergenerational relations, age consciousness, lifestyles, gender and ethnic inequalities, and the life course.

The few historical analyses of these images are impressionistic rather than being based on rigorous statistical techniques. Cultural images could be studied by using content analyses of the depiction of adults on television, in movies, and in novels, but no studies of this type have been reported in the literature. Nonetheless, the impressionistic reports are a useful point of reference. Perhaps the best place to start in understanding the evolution of cultural images of adulthood is with an examination of the etymology of the word *adult*.

## ETYMOLOGICAL ANALYSIS

An etymological analysis suggests that adulthood as it is known in Western countries is a cultural artifact. This is demonstrated by the fact that in most languages the idea is not important enough in cultural life to require a word to express it. Even among the European languages only English has a specific word designating a distinct stage of the life course as adulthood. In fact, it appears that the differentiation of the life course that occurred in the modern period created the need for a lexicon to describe it, with the term *adult* following a similar etymological path to that of other terms that represent the life course. For example, the word *adult* first appeared in the language in 1656, but it is instructive to note that it is derived from the Latin *adultus* (grown), which is the past participle of *adolescere* (to grow up, mature). The term *adolescent* came into English usage in the 1400s, a half century earlier than the word *adult,* whereas *adulthood* did not appear until 1870 (Côté, 2000; Merser, 1987).

This etymological analysis suggests that historically, people did not make the age distinctions that Anglophones and others do now. These age distinctions appear to be the result of the rise of modernity: the massive social, economic, and technological transformations of the last

several hundred years. Those transformations altered social institutions, and as those institutions changed, so did people's lives: People lived longer and were healthier, and adults were less likely to raise large numbers of children. Those changes led to the formation of age groups whose members were similar to one another but distinct from the members of other age groups. Thus, people of different ages became different in terms of social roles and responsibilities as well as social expectations about cognitive and emotional attributes.

According to Cheryl Merser (1987), the relatively recent appearance of a word to describe adulthood suggests that people needed a way to depict the new social conditions they faced, especially increasing uncertainty and the need to make life-altering choices. Traditionally, most people had little choice about how their lives played out. Regardless of their age, people were bound by duties and obligations to fulfill ascribed family and community roles. Young and old alike were expected to work for a common welfare regardless of their personal preferences. However, Merser argued, the rise of uncertainty and the consequent need to know more about the world to be able to make choices gave new meaning to the notion of maturity and widened the gap between those with little experience (children) and those with more experience (adults). The process was hastened by the decline of absolute religious authority and the rise of secular authority; people increasingly were seen as responsible for their own destinies and choices.

## CHANGING IMAGES OF MATURITY

In a 1978 essay about the study of adulthood, "Searching for Adulthood in America," Winthrop Jordan explored the changing meaning of adulthood in the United States. In his search of the archives that chronicled early English settlers in the United States, Jordan found little evidence that people held images of different stages of the life course. Instead, he found references to the roles and duties assigned to husbands, wives, children, and servants. Within those roles there was no reference to growth, maturing, or psychological needs and preferences. Among Puritans, for example, people were compelled to know their existing conditions, not to change those conditions. Jordan argued that the decline of patriarchy made way for binary ideas about personality characteristics such as maturity-immaturity and mastery-dependence. Increasingly, family members other than the dominant male gained status and rights, and so people were defined less in terms of their roles and duties and more as individuals with needs and potentials.

In addition, Jordan argued, in the past concern about gender roles overrode age roles in the sense that the dominant images were of manhood and womanhood as distinct but complementary states. Accordingly, it was more important to distinguish males from females than to distinguish children from adults. Over time that changed, with age roles and distinctions gaining importance in relation to gender distinctions. In other words, in early American history it appears that women and men had more in common with those of the same sex regardless of age; over time adult men and women came to have more in common with one another than with children of the same sex.

Complementing those trends was a fall in both fertility and mortality rates. When there were fewer children to raise, each child could receive more attention. At the same time more parents lived to see their children leave their homes. Therefore, a period of the life course without dependent children became common and people could turn their attention to themselves and reflect on their psychological states and needs. Jordan argued that with the rise of the social sciences in the 20th century a technical language emerged that labeled the life stages of childhood, adolescence, and adulthood as real rather than as historically produced and changeable cultural experiences.

From Jordan's historical analyses of the changing ideas of adulthood it is possible to trace the emergence of the fault lines associated with contemporary age consciousness, especially in terms of being a nonadult ("becoming" and "incomplete") versus an adult ("arrived" and "complete") (Wyn & White, 1997). Cultural images of the differences between these age statuses now apparently vary by dimensions such as immature-mature, selfishness-selflessness, and ignorant-knowledgeable.

## IMAGES IN THE MASS MEDIA

With the rise of the mass media in the 20th century social scientists were drawn to study various forms of (mis)representations of men and women (Lindsey, 2005) and various ethnic groups (Basow, 1992). For example, men are overrepresented in the proportion of characters, especially those who play a significant role in the outcome of plots, and both males and females are depicted in gender-stereotyped manners: Adult females tend to be linked to home and family roles, whereas adult males are linked to more power-oriented roles and goals, including self-indulgence, wealth, and revenge.

However, little attention has been paid to the representations of adults per se as characters in the mass media, perhaps because adulthood is taken for granted as a self-evident phase in the life course. Still, one can find evidence of the new age consciousness being fed by media that target different age groups. For example, programming directed at young people, especially in forms such as MTV, can depict adults as boring, stupid, and pretentious. Mark Crispin Miller (2001) argued that in rock video imagery

***The Cosby Show.*** *Bill Cosby, as Dr. Cliff Huxtable of "The Cosby Show," listens to a point made by his grandson Gary Gray, as his granddaughter played by Jessica Vaughn looks on.* AP IMAGES.

"parents are creeps, teachers are nerds and idiots, [and] authority figures are laughable."

Taking this line of thinking further, Marcel Danesi (2003) contended that some of the mass media have encouraged a "dumbing down" of cultural images as a way to appeal to the rising youth market and that this approach influences self-conceptions among narcissistic adults who do not want to grow up. In the youth-oriented television programming of the 1980s and 1990s parents were caricatured in ways that corresponded to rebellious adolescent views: shallow in their self-absorption and inept in their ability to make decisions for the family. These images stand in sharp contrast to programming of the 1950s, in which parents were depicted as firm, caring, and ultimately knowing best. These more recent forms of mockery became possible, according to Danesi, because of the overall obsession of contemporary culture with youthfulness and attempts by adults to avoid the commitments and duties attached to their adult roles, including controlling the media images that influence their children. Juliet Schor (2004) attributed some of these changes to marketers who have created "a sophisticated and powerful 'antiadultism' within the commercial world" (Schor, 2004, p. 51) by depicting adults as forcing "a repressive and joyless world" on children who just want to be left in peace to play with their newly acquired consumer items.

However, television programming in the early 21st century has been replete with heterogeneous images of adults depicted for other adults. It has become commonplace for adults to remain happily unmarried (*Friends*), gay relationships are depicted openly (*Will & Grace*, *Desperate Housewives*), and single women take on the predatory role in dating that men once were shown to hold (*Sex and the City*, *Desperate Housewives*). In addition, there have been more depictions of married couples in egalitarian relationships (*Medium*) and a trend toward showing wives who are more educated and successful than their spouses (*Commander in Chief*).

## FUTURE RESEARCH

These historical and impressionistic analyses suggest that the study of adulthood and its cultural images is a potentially rich area of research awaiting more rigorous techniques such as content analysis of contemporary mass

media and archival material from past eras in the form of diaries, literature, plays, and fine art. Adulthood as it is socially constructed is the longest and least studied portion of the life course. The 21st century probably will see increased research efforts devoted to helping people understand the images they hold of adults, especially as those images contrast with images of other age groups.

### I. GENERAL ISSUES

Much of what social scientists know about the life course has been learned from social surveys. Family formation, employment, political preferences and behavior, health and psychosocial adjustment, housing preferences, and health and well-being have all been studied by asking people questions in the context of sample surveys. A sample survey is defined as a formal questionnaire (the survey) that is administered to a group of individuals selected in a statistically valid way (the sample). The goal of a sample survey is to not only obtain answers to questions from the respondents (as the individuals who answer survey questions are called) but also to have these answers represent the answers of the larger group of people from which the sample is drawn (the population). This is possible because when certain methods of selecting respondents are used, researchers can utilize the respondents' answers to estimate (or infer) the answers for all members of the population. This procedure is called *statistical inference*.

Several types of survey designs are useful in life-course research, particularly repeated cross-sectional surveys and longitudinal (sometimes called panel) surveys. The dense sets of personal events that characterize adulthood are often difficult to capture using a questionnaire, but modern advances in survey technology, such as using personal computers or the World Wide Web, have improved researchers' capabilities. In all steps in the survey process, there are also many sources of error that can affect both the accuracy of the information gathered and the validity of inferences made from respondents to a population.

#### SAMPLE DESIGN, SAMPLING FRAMES, AND METHODS OF COLLECTING DATA

Most sample surveys rely on the science of statistics to ensure that the respondents chosen for the survey represent the population of interest. Probability samples are

defined as those survey samples in which the probability of selection into the survey is known for every respondent. There are many types of probability samples, including simple random, stratified, and clustered samples. Stratified samples are used for a variety of purposes, the most important of which is to ensure that a sufficient number of individuals with characteristics relatively rare in the population are included. Most of the large surveys conducted by the federal government of the United States use stratified sampling techniques to ensure adequate representation of ethnic and racial minority populations. Research comparing people with different characteristics requires adequately sized samples of all groups. Thus, stratified sampling is an important tool for making research successful.

To ensure that survey respondents are selected with a known probability, survey professionals must have some method for knowing the potential universe of respondents available to be surveyed. This universe is called a *sampling frame*. A sampling frame should be as complete a listing of the entire study population as possible. Individuals are then selected from this list with some known probability depending on the sampling strategy. *List frames* are simple lists of individuals generated from some source. State driver's licenses, birth and death certificates, mailing lists, and lists of postal addresses are all used by the survey staff to generate a sampling frame. An *area frame* is based on geography rather than a listing of names. Within census groupings such as county, census tract, and census block group, households are listed and then selected using a sampling technique. *Nonlist frames* are used in the case of random digit dial phone surveys. In this case, all households with telephones are considered eligible for interview and are selected with known frequency using random digit dialing technology.

Not all surveys are designed to be representative of the population or to allow for valid inference to a more general population. In nonprobability sample surveys, respondents are chosen by methods other than scientific sampling. These methods include, among others, *convenience* and *snowball sampling*. Convenience sampling means selecting respondents who are close at hand, whereas snowball sampling uses social networks of friends and neighbors to identify respondents. There are many good reasons to use nonprobability samples, including the relatively low cost and studying a population that is difficult to list. Inference about more general population trends from answers to these types of surveys, however, should be limited.

Finding and selecting respondents are the first two steps in survey design. These two steps affect how representative respondents are of the population. The third step is to choose the method of data collection used to gather the information, which includes the means used to ask questions and the technology used to record answers. Interviewer-administered questionnaires can be delivered in person or over the phone. Computers can be used to record the answers and help improve data collection and data quality. Self-administered questionnaires can be on paper, in e-mail, or on Web-based forms. The different methods of collecting data have different strengths and weaknesses.

Three main criteria are used to select a method for administering a questionnaire; the first is cost consideration. Interviewer-administered questionnaires are expensive yet likely to yield higher response rates and more accurate data. The second criterion is the complexity of the questionnaire. For data on the life course, such as that involving complex employment or marital histories, interviewer-administered instruments tend to be more successful because respondents are guided through questions in a systematic way. The third criterion for selecting a data-collection method is the sensitivity of the topic matter. Respondents are often more at ease when allowed to answers questions about sensitive topics such as drug and alcohol use, sexual history, or illegal activity without the intervention of an interviewer (Groves et al., 2004).

In all stages of the survey process, error is introduced, which affects both the quality of the data and the statistical inference for which it is used. Much of survey design and administration are focused on reducing error in all aspects of data collection. Three types of error, in particular, affect most inference and analysis of survey data. *Sampling error* is the error introduced into inference by collecting data on only a subset of the population of interest. The smaller the subset of the population drawn, the larger the sampling error. The importance of sampling error is that it diminishes the precision with which conclusions from survey data can be drawn. In studies of the prevalence of particular characteristics, diseases, or opinions, the concern is how precise the estimates of these characteristics are; thus, the size of the underlying sample is highly relevant. *Nonresponse error* arises when the chosen respondents do not return a survey or ignore repeated attempts to be interviewed. Nonresponse error is critically important when those who do not respond to the survey request are different than those who do. For instance, a survey of mothers of young children about attitudes toward the transition to motherhood that yields a much higher response rate among women who stay at home with their first child might well give a biased understanding of the feelings of new mothers because of the preponderance of women who are home in the sample (Groves, 2006). *Measurement error* is another important source of error in survey data. This type of error arises when the questions asked do not capture the concept of interest.

### STUDYING ADULTHOOD THROUGH DIFFERENT FORMS OF SURVEY DESIGN

Surveys are often specifically designed to address the issues associated with adult life transitions. Two survey designs, in particular, are often used to understand how individuals move through the life course. *Cross-sectional surveys* are designed to take a "snapshot" of a large group of individuals in a single time period. To understand different life stages, individuals from different age groups at the time of the survey are used to represent those life stages. For instance, to understand how marital quality changes with age, responses in a cross-sectional survey from people of different ages are used to represent how feelings about marriage change with aging. *Repeated cross-sectional surveys*, in which different individuals are asked the same questions in more than one time period, allow expanding the understanding of life transitions by introducing the effect of historical period. In the above example, perhaps the same marital quality questions were asked in 1985 and 2005; then the way aging effects marital quality in the two time periods could be compared to see if changes in social norms influence how marriage quality varies with age. The difficulty with using either cross-sectional or repeated cross-sectional data to understand adult transitions is clear. Individuals in different age groups with very different life experiences are used to represent the biography of a typical person. Cross-sectional data confuses the process of individual aging with the experience of a cohort in history.

Another method of collecting data to understand the life course of adults is a longitudinal (panel) study. In this case, respondents are interviewed more than once. In some of the large longitudinal studies conducted by the U.S. government, respondents have been followed for more than 30 years. The ability to follow individuals through the life course has greatly enhanced the understanding of adulthood. However, the methodological difficulties of longitudinal data collection do cause some inferential problems for life course analysis. Differential panel attrition—that is, the loss of people who cannot be found after one or more panels—can bias inference because individuals who stay in a survey tend to be different from the ones who leave. Studying marriage with longitudinal data, for instance, is made difficult because those who divorce are much less likely to be found in the next wave of data collection. Those persons who remain are then less likely to represent the original population. Nevertheless, longitudinal data provide important insights into the dense processes of employment, marriage, and family formation in the adult life course (Singleton & Straits, 2005).

## II. AMERICANS' CHANGING LIVES (ACL)

The Americans' Changing Lives (ACL) study has been an important source of data for understanding the structural and psychosocial context of life course processes. This four-wave panel survey of a nationally representative sample of U.S. adults was conducted under the direction of sociologist James S. House at the University of Michigan and was funded by the National Institute on Aging. Beginning in 1986, face-to-face interviews were conducted with 3,617 men and women between the ages of 24 and 96. Blacks, adults ages 60 and older, and married women whose husband was over age 64 were oversampled. Follow-up interviews were conducted in 1989 ($n$ = 2,867), 1994 ($n$ = 2,562), and 2001, 2002, or 2003 ($n$ = 1,787).

Among the broad range of topics addressed, several are particularly relevant to life-course development and change. These include mental and physical health (self-assessed health, mortality, health behavior, health-care utilization, depressive symptoms), social relationships (quantity and quality), and stress exposure. Also included are sociodemographic characteristics such as household composition, marital status, sex, race/ethnicity, employment, income, and religious practices.

The ACL data have made substantial contributions to the literature on social processes and health over the life course. An influential body of work by House and colleagues uses the ACL to examine the age patterning of socioeconomic disparities in health (House et al, 1990; House, Lantz, & Herd, 2005; House et al, 1994; Lantz, House, Mero, & Williams, 2005; Robert & Li, 2001). The data have also been used to identify life-course variation in a range of outcomes, including depressive symptoms, personal control, volunteering and other productive activities, and the nature and quality of marriage and other personal relationships.

## III. CURRENT POPULATION STUDY (CPS)

The Current Population Survey (CPS) is a nationally representative study of households in the United States that has been conducted monthly since 1940. In addition to providing the government's official statistics on unemployment, the survey examines many key features of the life course, including schooling, marriage, fertility, and civic involvement. As a long-standing panel study, the CPS is particularly useful for describing time and cohort trends.

The CPS has a panel structure with an embedded longitudinal component. Each month, a new panel of 60,000 households is selected and surveyed for two periods of 4 months each with an 8-month interval between surveys (U.S. Census Bureau, 2006). The survey is most commonly used for time-series analysis of monthly panels across years, but individual-level longitudinal analysis can also be conducted by matching respondents across months.

Basic questions about household structure and employment are asked of all members of the household over the age of 15 years. In certain months, supplemental data are collected on such wide-ranging topics as fertility, voting, and tobacco use. The most used supplement is the Annual Social and Economic Supplement on employment, income, and health insurance conducted in March.

Many key demographic shifts have been documented and explained using CPS data, including increased returns to schooling and wage inequality (e.g., Juhn, Murphy, & Pierce, 1993), female labor force participation and the gender gap in wages (e.g., O'Neill & Polachek, 1993), and the growth of single parenthood (e.g., Eggebeen & Lichter, 1991). Other studies have used the CPS to identify the determinants of adolescent smoking (e.g., Farkas, Distefan, Choi, Gilpin, & Pierce, 1999), children's health insurance coverage (e.g., Dubay & Kenney, 1996), and preschool enrollment (e.g., Bainbridge, Meyers, Tanaka, & Waldfogel, 2005).

The Census Bureau provides CPS data and extraction software at no cost (http://www.census.gov/cps/). Unicon Research Corporation sells *CPS Utilities*, a version of the data formatted for time-series analysis (http://www.unicon.com).

## IV: GENERAL SOCIAL SURVEY (GSS)

The National Data Program for the Social Sciences (NDPSS) has been conducted since 1972 by the National Opinion Research Center (NORC)/University of Chicago, with the support of the National Science Foundation. Its two main goals are to conduct basic scientific research on the structure and development of American society and to distribute up-to-date, important, high-quality data to social scientists, students, policy makers, and others.

These goals are carried out by a data-collection program that monitors societal change within the United States using the General Social Survey and compares the United States with other nations as part of the International Social Survey Programme. The NDPSS is directed by James A. Davis (NORC/University of Chicago), Tom W. Smith (NORC/University of Chicago), and Peter V. Marsden (Harvard University).

Data on societal change in the United States is collected as part of the General Social Survey (GSS). The GSS has been conducted 26 times from 1972 to 2006. It is the only full-probability, personal-interview survey designed to monitor changes in both social characteristics and attitudes in the United States. More than one thousand trends have been tracked since 1972. Age groups can be compared across time; changes within birth cohorts across the life cycle can be analyzed. Among the many topics covered are civil liberties, crime and violence, intergroup tolerance, morality, national spending priorities, psychological well-being, social mobility, and stress and traumatic events.

Cross-national data are collected as part of the International Social Survey Programme (ISSP). ISSP was established in 1984 by NORC and other social science institutes in the United States, Australia, Great Britain, and what was then West Germany. The ISSP collaboration has grown to include 43 nations. ISSP is the largest program of cross-national research in the social sciences. More information on ISSP is available at its Web site.

The GSS has carried out an extensive range of methodological research designed both to advance survey methods in general and to ensure that the GSS data are of the highest possible quality. More than 110 papers have been published in the GSS Methodological Report series. GSS data and documentation are available at the GSS Web site.

## V. LONGITUDINAL STUDY OF GENERATIONS (LSOG)

The Longitudinal Study of Generations (LSOG) provides life course scholars the unique opportunity to explore intergenerational relationships as experienced by four distinctive cohorts of men and women. The LSOG began in 1971 as a cross-sectional study of 358 three-generation families, comprising more than 2,000 individuals in southern California. This initial sample was obtained through a multistage stratified sample of grandfathers enrolled in a large, southern California health maintenance organization (HMO), as well as the men's descendants. Each three-generation family included grandfathers (then in their 60s), their middle-aged children (then in their early 40s), and their young adult children (then ages 16 to 26). These three generations are referred to by the study investigators as G1, G2, and G3, respectively. Spouses of family members in each generation also were surveyed. The study was unique at the time of its inception, because respondents were linked to each other on the basis of their shared family membership, and thus data analysts could examine parent-child, grandparent-grandchild, sibling, and spousal relationships. As a result, the LSOG's measures are considered the gold standard for studying family solidarity and intergenerational relationships.

Since 1985, interviews have been conducted at 3-year intervals with persons from G1, G2, and G3. In 1991, a fourth generation (G4) of Generation X young adults (i.e., those born between 1960 and 1979) was added to the study and followed up on at 3-year intervals. An extensive collection of LSOG materials is available at the University of Southern California Web site or at the Inter-university Consortium for Political and Social Research (ICPSR) at the University of Michigan Web site.

## VI. MIDLIFE IN THE UNITED STATES (MIDUS)

In 1995–1996, the MacArthur Midlife Research Network carried out a national survey of more than 7,000 non-institutionalized Americans in the contiguous United States, aged between 25 to 74 years old, called the National Survey of Midlife Development in the United States (MIDUS). The purpose of the study was to investigate the role of behavioral, psychological, and social factors in understanding

age-related differences in physical and mental health. The study was innovative for its broad scientific scope, its diverse samples (which included twins and the siblings of main sample respondents), and its creative use of in-depth assessments in key areas (e.g., daily stress, cognitive functioning).

With support from the National Institute on Aging, a longitudinal follow-up of the original MIDUS samples: core sample (*N* = 3,487), metropolitan over-samples (*N* = 757), twins (*N* = 998 pairs), and siblings (*N* = 950), MIDUS 2 was conducted between 2004 and 2006. The foci and content of the MIDUS and its affiliated studies are shaped by the guiding hypothesis that behavioral and psychosocial factors are consequential for physical and mental health. MIDUS 2 respondents were aged between 35 and 86 years old. Data collection largely repeated baseline assessments (e.g., phone interview, extensive self-administered questionnaire), with additional questions in selected areas (e.g., cognitive functioning, optimism and coping, stressful life events, caregiving).

To enhance the diversity of the MIDUS 2 sample, an additional African-American sample (*N* = 592) was recruited from Milwaukee, Wisconsin. Participants completed a personal interview and a self-administered questionnaire that paralleled the MIDUS 1 and 2 content. In an effort to capture those people who might have been missed in earlier waves of the study, MIDUS 2 also administered a modified form of the mail questionnaire, using the telephone, to respondents who did not complete a self-administered questionnaire. Overall, complete data were collected from nearly 5,900 people in the follow-up. To date, more than 200 studies based on the MIDUS data have been published in medical, psychological, sociological, gerontological, and epidemiological scholarly journals. See Brim, Ryff, and Singer (2004) for an overview of the study. An extensive and growing collection of MIDUS materials is available at the Inter-university Consortium for Political and Social Research at the University of Michigan (www.icpsr.umich.edu).

## VII. NATIONAL LONGITUDINAL SURVEYS (NLS) OF MATURE MEN AND WOMEN

The National Longitudinal Surveys (NLS) of Older Men and Mature Women represent two cohorts of the larger NLS project: a group of longitudinal studies sponsored by the U.S. Bureau of Labor Statistics.

Interviews of 5,020 American men ages 45 to 59 began in 1966, with data collection focused on work experiences, retirement planning, health conditions, insurance coverage, and leisure-time activities. Interviews with the men continued at regular intervals until 1981. A follow-up interview took place in 1990 with information collected from the men or their widows. The 1990 data include information of cause of death collected from vital records. During the regular 1966–1981 data collection period, a cohort of younger men (ages 14 to 24) was interviewed as well.

Interviews started in 1967 for the NLS mature women, a group of 5,083 American women ages 30 to 44. Much of the information gathered over the years included issues for women reentering the labor market at middle age after child rearing, along with retirement decisions and health issues. Extensive information about pension plans also was gathered, including characteristics of each pension provider and each plan. The mature women were interviewed a total of 20 times; data collection ended in 2003. During roughly the same period a group of younger women (ages 14 to 24 in 1968) also was interviewed. Many of the individuals in that group were the daughters of the mature women, and a series of questions about intergenerational transfers was asked of both groups so that for a subsample the NLS has reports about such transfers that were provided by both the mothers and their daughters.

Data collection continued for two younger mixed-gender NLS groups: one initiated in 1979 (known as the NLSY79) and one begun in 1997 (known as the NLSY97). In addition, age-eligible children of the female respondents in the NLSY79 group have been interviewed since 1986. The NLS database containing data from all cohorts can be accessed free of charge at the web site of the U.S. Bureau of Labor, Bureau of Labor Statistics. The *NLS Annotated Bibliography*, a comprehensive record of research based on NLS-related data, also is available online from the Bureau of Labor Statistics.

## VIII. PANEL STUDY OF INCOME DYNAMICS (PSID)

The Panel Study of Income Dynamics (PSID) is a longitudinal study of a representative sample of U.S. individuals and the families in which they reside. The PSID emphasizes the dynamic aspects of family economics, demography, and health. Data have been collected since 1968 and continues to be collected as of 2008, making the PSID the longest running panel on family and individual dynamics. It has consistently achieved response rates of 95 to 98%, and as of 2005, 8,041 families were currently participating in the survey. Over the years the PSID has collected information on nearly 70,000 individuals spanning as much as four decades of their lives.

Through multiple waves collected over long time periods, these data are the only data ever collected on life course and multigenerational health, well-being, and economic conditions in a long-term panel representative of the full U.S. population. The PSID has collected data on employment, income, housing, food expenditures, transfer income, and marital and fertility behavior annually between 1968 and 1997, and biennially between 1999 and 2005. Additionally the PSID collects data on health status, health behaviors, health care utilization, health insurance, and philanthropy. Beginning in 1985 comprehensive retrospective fertility and marriage histories of individuals in the households have been assembled.

The PSID sample, originating in 1968, consists of two independent samples of the U.S. population: a cross-sectional national sample and a national sample of low-income families. The Survey Research Center (SRC) at the University of Michigan drew the cross-sectional sample, which was an equal probability sample of households from the 48 contiguous states designated to yield about 3,000 completed interviews. The second sample came from the Survey of Economic Opportunity (SEO) conducted by the Bureau of the Census for the Office of Economic Opportunity. In the mid-1960s the PSID selected about 2,000 low-income families with heads under the age of 60 from SEO respondents. The PSID core sample combines the SRC and SEO samples.

From 1968 to 1997 the PSID interviewed individuals from families in the core sample every year, whether or not they were living in the same dwelling or with the same people. Adults have been followed as they have grown older, and children have been interviewed as they advance through childhood and into adulthood, forming families of their own. In 1997 the PSID changed from every-year interviewing to every-other-year interviewing. Moreover, a sample of 441 immigrant families was added to enhance the representativeness of the sample.

In 1997 and again in 2002, the PSID supplemented its main data collection with information on PSID parents and their children in order to study the dynamic process of early life experiences. The supplement, called the Child Development Supplement (CDS), included a broad array of development measures such as (a) age graded assessments of cognitive, behavioral, and health status of children obtained from the caregivers and the child; (b) a comprehensive accounting of parental, or caregiver, time inputs to children as well as other aspects of the ways in which children and adolescents spend their time; (c) teacher-reported time use in elementary school; and (d) other-than-time use measures of additional resources such as the learning environment in the home, teacher reports of school resources, and decennial-census-based measurement of neighborhood resources. In 1997 CDS-I collected data on 3,563 children aged 0 to 12 in 2,394 families. Five years later, CDS-II reinterviewed 2,021 of the CDS-I families, providing data on 2,907 CDS children and youth.

Since its inception, more than 2,000 journal articles, books, book chapters, and dissertations have been based on the PSID, and in 2008 a paper is published in a peer-reviewed outlet roughly every 4 days. The study was named one of the National Science Foundation's (NSF) *nifty fifty*, which refers to the most notable NSF-funded inventions and discoveries in NSF history between the years 1950 and 2000.

It is difficult to briefly summarize the scientific impact of the PSID. Areas of significant contribution include intergenerational transmission of economic status, children's time use, the dynamics of poverty and economic status, resource sharing among extended family members, the interconnection between well-being and marriage and fertility, and neighborhood effects on individual social and economic outcomes.

## IX. U.S. (DECENNIAL) CENSUS

Every 10 years since 1790, the Census of the United States has tried to count everyone in the country and note several of his or her characteristics. The enumeration is done by contacting someone in every household—by mail since 1960, in person previously—and asking respondents to describe themselves and also the people living with them. Characteristics of the population accumulated in this way are selected to be most widely useful in the society. They include questions such as age, sex, relationship in family, and marital status; questions about education and work; and questions about race, ethnicity, and geographic origin of the person and his or her ancestors. Some questions appear only in some decades as policy interests wax and wane. Some of the questions are asked only in a sample of these households, often 15 or 20%, so the samples are quite large. Although not perfect, census data have an extremely high response rate by survey standards. More is known about the magnitude and pattern of errors in the Census than in any other social science data set.

Census data are especially useful for describing the social and demographic context, often as part of a research presentation, as the introduction to a paper, or to describe a problem generally. They are useful as a benchmark against which to check the representativeness of data collected from another source, for example an independent and more detailed sample survey. Because data for everyone in the households are collected, census data can yield a lot of information about the living arrangements and the family context of the population. Because of the large sampling fraction and very detailed geographic coding, the Census can provide information about relatively small geographic areas—down to city blocks for some characteristics. The large sampling fractions also mean that the Census is particularly good for obtaining data about numerically small subgroups of people living in the United States. Census data can be used to investigate historical trends over a longer time span than any other kind of data.

Census data are unlikely to provide the researcher with exactly the variable needed to test a detailed hypothesis. Inventive scholars, however, have managed to investigate a remarkable number of issues using data from the Census. For example, a good deal of what is known about ethnicity in the United States is derived from census questions on the immigration status of people and their parents. In the early days of the cohabitation trend, census data on persons of the opposite sex sharing living quarters gave an early indication of the prevalence and trend of this cultural change.

The age variable in census data, however, can present difficulties. For many older people, age is reported by someone else in the household, and that person may not answer accurately. In some decades the Census Bureau has chosen to top-code age (that is, classify the oldest persons into an aggregated subgroup, such as "85 or older") because of concerns about its reliability at the oldest ages.

One can access census data in many ways, from generating a statistic interactively on the Census website to acquiring sample data from many decades to use in a detailed statistical analysis. The official website (http://www.census.gov) provides access to many pages that provide considerable detail on specific topics.

The Public Use Sample Files are samples of census households designed to preserve the confidentiality of the respondents. The result is usually a 1% sample of the total population. The Public Use Sample Files can be acquired in original census form from the Inter-University Consortium for Political and Social Research (http://www.icpsr.umich.edu). Historic census data and data reflecting questions matched across decades (useful for trend analyses) can be obtained from http://www.ipums.org.

# DATING AND ROMANTIC RELATIONSHIPS, ADULTHOOD

Broadly defined, dating refers to social activities between individuals romantically interested in each other. However, there is wide variation among scholars and in popular culture as to what dating entails. Finding a long-term partner, entertainment, and increasing social status are among the many reasons that adults give for dating and engaging in romantic relationships. It is not surprising, then, that dating has many outcomes; it can be a satisfying endeavor, increasing the quality of life for individuals, or it can lead to violent or coercive interactions. Although dating may seem trivial or unimportant, the scientific study of dating attitudes and behaviors is vital to promote healthy relationships and prevent or intervene in harmful ones.

## HISTORICAL CONTEXT

In the United States, modern dating did not emerge until the 1950s and 1960s. Before then, couples engaged in courtship practices. Courting was a public activity exclusively focused on finding a marriage partner. Although arranged marriages per se were not standard practice, familial input into courtship limited young people's partner choices. In the 19th century it was customary for parents (especially a woman's parents) to give their consent before their children began courting.

Because of heavy parental involvement and the public nature of courting, couples would attend social events in the community, where family members could monitor the young people's activities. Should a more serious interest develop, young men could "call on" young women in their homes, but only if a woman or her mother issued an invitation. Thus, women and their families controlled and initiated courtship situations.

Perhaps in reaction to the rigid rules of courting, later in the 19th century, couples themselves began to have more control over their correspondence and social activities. Enjoyment, rather than marriage, became a central motivation for romantic relationships. Peers, instead of parents, defined conventions concerning these relationships; couples had more freedom and privacy. Control and initiative in the romantic relationship also changed. Rather than waiting for an invitation to call, men asked women out socially, and planned and paid for activities. Women served as the gatekeepers to affection and sexual activity; however, without parental monitoring, barriers to sexual behaviors were weaker.

Several cultural transformations in the early 20th century shaped modern dating patterns. Affluence and mass consumption turned attention from working to consuming (Whyte, 1992). Increasing numbers of telephones in homes allowed people to formulate plans, connect, and have private conversations more easily. The advent of the automobile gave people the means to leave home and seek recreational activities, as well as providing a private space for romantic and sexual activities.

By the 1920s and 1930s, going out romantically more closely resembled modern dating. Going on dates was no longer directly tied to marriage; rather, there were several steps in between to denote levels of commitment, such as going steady (i.e., dating exclusively), receiving a high school ring or pin, and becoming engaged. Individuals dated for a variety of reasons; enjoyment and romance was a main motivation, but people also dated to gain experience, to experiment, and to enhance their social status.

## DATING SCRIPTS IN THE LATE 20TH AND EARLY 21ST CENTURIES

Late in the 20th century, scholars began to theorize about the behaviors and meanings in romantic relationships. Within a society, people develop cognitive schemas, or mental representations, of various scenarios. In the 1980s and 1990s researchers began to study *dating scripts*, defined as the expected behaviors and events for a typical date (Alksnis, Desmarais, & Wood, 1996). Dating scripts are shaped through peer and parental interactions, media outlets, and popular culture. Although individuals have varied dating experiences, people have surprisingly similar ideas of what dating should encompass.

People in the early 21st century are more likely to report egalitarian values than in the past, with a balance of power between members of a couple, but research suggests that women and men have distinct dating scripts that mirror traditional gender roles. One way researchers measure dating scripts is by asking people about hypothetical first dates. Christine Alksnis, Serge Desmarais, and Eileen Wood (1996) asked a primarily White sample of college students to report events that occurred on good, bad, and typical dates. Overall, males and females agreed about what makes a good or a typical first date; however, some gender differences existed regarding appropriate sexual behavior. These findings suggest that

gendered dating scripts are particularly salient for sexual events; men may have a greater expectation of sexual activity, whereas women may deter those behaviors.

Other researchers have found support for expectations in which men are the initiators of dating activities, and women are responsible for the emotional aspects of the date (Bartoli & Clark, 2006). These scripts also exist within homosexual dating couples. In response to hypothetical and actual dating scenarios, gay men, like heterosexual men, tended to emphasize sexual aspects of dating and taking initiative for sexual behaviors and date activities. Like heterosexual women, lesbian women tended to focus more on the emotional aspects of the dating experience, such as evaluating feelings about the date. Whereas dating behaviors and partner selection may look different for heterosexual and homosexual dating couples, dating scripts appear similar within gender regardless of sexual orientation.

## DATING SCRIPTS FOR DIFFERENT CULTURAL GROUPS

Great variability exists within different cultural and ethnic minority groups regarding attitudes about dating. However, some scholars theorize that there is conflict between dominant culture (White) dating scripts and minority cultural values. Some research has suggested that Latino Americans and Asian Americans adhere more closely to traditional gendered dating scripts (Anderson & Johnson, 2003), compared to Whites. Among African-American dating couples, there is evidence of both traditional gender roles, such as women seeking successful male partners, and more egalitarian relationships, in which women may be the successful partner, for example (Ganong, Coleman, Thompson, & Goodwin-Watkins, 1996). However, the African-American community faces unique dating challenges. High rates of incarceration and mortality for Black men limit the number of potential dating partners available for Black women. Additionally, Black women are more likely to attain a college education and achieve economic success than Black men (Kurdek, 2008). Because of this discrepancy, some Black women may find it difficult to find a compatible partner within the African-American community. Increasingly, both men and women may choose to date interracially (Wilson, McIntosh, & Insana, 2007).

## THEORETICAL APPROACHES TO DATING RELATIONSHIPS

**Equity Theory and Investment Models** Equity theory is one lens through which dating outcomes can be viewed. This approach focuses on the balance between relationship contributions and outcomes, in addition to an individual's characteristics. Relationships in which both individuals experience equal benefits and rewards, such as trust, intimacy, and companionship, have the highest relationship quality and satisfaction (Hatfield et al., 1979). Individuals who contribute more than their partner and receive fewer rewards are likely to experience the most relationship dissatisfaction. People who receive more benefits than they should, based on their contributions, are not as dissatisfied as their partners, but they are not as happy as couples with equal contributions. In general, individuals in unequal relationships report that their relationships are less satisfying, less stable, and individuals are less committed (Sprecher, 2001).

Investment models illuminate the power dynamic in relationships. Power and control in a relationship are determined by the individuals' comparative reliance on each other. Author Willard Waller (1938) first explained "the principle of least interest," in which the person who is the least invested in the relationship will have the most power or control. The more invested person, in trying to maintain the relationship, will concede to their partner's demands. Investment by either partner may be affected by a number of factors. The level to which individuals find their partner rewarding and attractive is primary, as well as the assessment of alternative partners. Individual characteristics, such as physical attractiveness, intelligence, personality, wealth, or popularity, can affect both one's desirability and investment, and thus the power dynamics of a relationship.

**Biosocial Models** Biosocial perspectives, which draw from many disciplines, including evolutionary psychology, biology, and anthropology, help to explain the motivations underlying dating behavior. Evidence suggests that biological mechanisms may facilitate relationship continuation; levels of testosterone, estrogen, dopamine, nonrepinephrine, serotonin, oxytocin, and vasopressin have been linked to various relationship stages (Bancroft, 2005). For example, in the beginning stages of a relationship, both men and women experience higher levels of oxytocin, known as the *love hormone*, because it produces euphoric effects (Buss, 2004).

**Attachment Models** Attachment theory has evolved out of John Bowlby's (1982) idea of an attachment system, where attachment to another person, an attachment figure, provides one with a sense of physical closeness and comfort, a safe place or safe haven when one is upset, a secure base from which to draw strength and security, and feelings of sadness, loneliness, and longing when the attachment figure is not present. Bowlby theorized that this system is necessary for survival in infancy, but it also appears to be necessary during adulthood; and, most often, attachment bonds between adults take the form of romantic relationships. Attachment bonds do not

form instantaneously, however. They take time. Dating provides the time and interpersonal experience to form attachment bonds. Across age cohorts (from ages 18 to 82), Cindy Hazan and Debra Zeifman (1999) found that it took an average of 2 years for romantic relationships to become bonded, or attachment, relationships.

**Ecological Models** The nature of dating and relationships is shaped by its context. Societal norms, cultural values, political and historical contexts, technology, and media are only a few of the overarching frameworks that impact the way in which individuals date, as well as the meaning and expectations of the relationship (Bronfenbrenner, 1979). For example, increased casual sex portrayal in popular television shows and movies coincides with the acceptance and higher levels of casual sex among generations X and Y.

## FUTURE DIRECTIONS

Advances in modern technology have created new opportunities and challenges for dating. Increasingly, young and older adults alike are using the Internet as a way to meet people, as evidenced by the popularity of social networking sites and online dating services. Researchers have started investigating online relationships (sometimes referred to as computer mediated relationships). Some have argued that online relationships are problematic because interpersonal connection is lost, whereas others suggest that the Internet may be helpful to shy or anxious people that find it hard to meet potential partners. Erich Merkle and Rhonda Richardson (2000) synthesized studies of computer mediated relationships and found that compared to traditional dating relationships, people disclosed and came to know their partner intimately more quickly over the Internet. They also suggested that it may be harder to be committed to an online dating partner or maintain a relationship without face-to-face interaction. How the Internet is used in face-to-face relationships has yet to be examined. Additionally, future research should examine how online communication shapes notions of intimacy, commitment, and fidelity.

Globalization is another force changing dating. In a globalized community, the behaviors, meanings, and scripts associated with dating are likely to be transformed. Cell phones and the Internet allow individuals to connect to virtually anyone at anytime, and advances in transportation give people the opportunity to travel great distances with comparative ease. Long-distance dating is becoming more common, particularly for dual professional couples. However, researchers have yet to examine this trend.

The aging of the U.S. population also means that dating may be transformed in future years. The dating needs of older adults are different from those of younger or middle-aged adults. Kris Bulcroft and Margaret O'Connor (1986) interviewed a group of adults aged 60 or older for their study. Older adults' narratives highlighted companionship aspects of dating; loneliness was a common concern. Additionally, older men accentuate their need to have a confidante. Interestingly, older women associated prestige with dating. This may be due to the unequal male to female ratio among older adults, as women tend to live longer than men. Older adults, compared to their younger cohorts, face obstacles such as diminished social support and more health difficulties. Because of such obstacles, companionship can be that much more vital to an older person's quality of life. Future research could and should give more attention to the impact of elderly dating relationships.

The changing cultural landscape has an influence on dating relationships. Future researchers investigating these trends may also develop innovative methodology, especially with the constant technological advances being made. As children grow up with modern technology in a globalized community, the behaviors, meanings, and scripts associated with dating are likely to be transformed.

## DEBT

*Debt* is money owed to a lender, and *credit* is an authorization to incur debt given by a lender (the creditor) to an individual, couple, or business. The amount of a debt is a function of the original amount borrowed (the principal), the interest charged, and any fees assessed by the creditor. Creditors typically set interest rates based on their estimated likelihood of being repaid. In modern economies, credit bureaus generate scores for individuals based on their personal characteristics, including past debt history, to estimate the probability the borrower will repay a loan.

Every society experiences tension between classes of debtors and classes of creditors. Legal institutions usually reinforce creditors' rights, and debtors in many societies are cruelly treated: Slavery, prison, transportation to colonies, debt peonage, and even execution have been employed to punish debtors in different times and places. In the United States, historic institutions such as share-cropping and company stores used debt to limit employee turnover and to control workers. In share-cropping the landowner lent money to the workers who farmed his land. In the case of the company store, employers allowed workers to buy goods on credit, but only at stores owned by the company. In both cases, workers routinely became heavily indebted to the land and store owners and were therefore often unable to leave for other employment.

In the contemporary United States, the extension of credit is a highly profitable business and central to the economy. The marketing of many goods and services is

### BANKRUPTCY

Bankruptcy is a legal proceeding for restructuring or eliminating debt and adjudicating multiple creditors' interests. U.S. law recognizes six types of bankruptcy, identified by chapter number corresponding to the chapter in the U.S. bankruptcy code in which each type of bankruptcy is described in detail. Approximately 99% of the bankruptcies filed annually are consumer or personal bankruptcies filed either in Chapter 7 or in Chapter 13. Chapter 9 is for municipalities, Chapter 11 is for large corporations, Chapter 12 is reserved for family farmers, and Chapter 15 involves international cases.

Consumers who file Chapter 13 bankruptcy keep their assets but devote their disposable income to repay a portion of their debts over a period of not more than five years. Only about one-third of all Chapter 13 filers are able to successfully complete their repayment plan. Chapter 7, the most commonly filed, requires consumers to liquidate their nonexempt assets; proceeds are distributed to creditors. In Chapter 7 most unsecured debts, such as credit card and medical bills, are discharged; student loans, taxes, and child support must be repaid. Layoffs and unemployment, divorce, and medical problems are the most common triggers for consumer bankruptcy.

In 2005 Congress amended the Bankruptcy Code to require that debtors seeking Chapter 7 pass a means test and receive consumer credit counseling. Debtors who earn more than the median income of their state are directed to Chapter 13.

successful because customers can finance the purchases over time. Some level of debt is widespread in all social classes, so that social class tensions are muted. Between 1989 and 2007 the revolving consumer credit outstanding among residents of the United States soared from 18.9 billion dollars to 97.2 billion dollars. Certain points in the life cycle are associated with greater consumption, such as beginning a household or having children, and for this reason debt patterns can be expected to have a relationship to the life cycle (Kish, 2006).

Credit card debt is one of the largest components of personal debt in the United States in the early 21st century (the others include home mortgages, automobile loans, and loans for purchases of major consumer durables). Credit cards are convenient because nearly every vendor accepts them and consumers can make purchases without cash in person, by phone, or online. Credit purchases constitute borrowing when the consumer *revolves* the card's balance, making a partial payment each month and incurring interest and fees. The minimum payment required each month to keep the account current is not sufficient to liquidate the debt unless continued for months. The very convenience and ubiquity of the credit card may encourage customers to charge more than they can readily repay. Because credit cards are a profitable business for financial institutions, they are aggressively marketed. Credit cards first saturated the United States, but are now marketed worldwide, with substantial penetration of the markets in Europe and Canada. In Japan, by contrast, credit cards are used much less often (Mann, 2006).

Research about debt has been difficult because the most accurate information about debt and credit scores is proprietary and so unavailable for research purposes. The federal government makes available to researchers some debt information collected through surveys such as the Survey on Consumer Finance. Bankruptcy filings are public data with detailed debt listings. Other research findings come from interviews with consumers, credit counselors, bankruptcy trustees, and attorneys. A small body of experimental evidence examines credit card use in various situations.

## DEBT ACROSS THE LIFE COURSE

Although the exact method used to score credit is proprietary, age is believed to affect the score because of its association with other characteristics that are positively valued in the credit formula, such as years of schooling, employment seniority, and residential stability. In addition, a characteristic age profile of expenditures has been observed. For example, young people often borrow money for a college education or a first car. Because their credit scores may not yet be high, and borrowers with lower credit scores are typically charged higher interest rates, young people may end up paying more in credit costs than middle-aged customers (Draut, 2007).

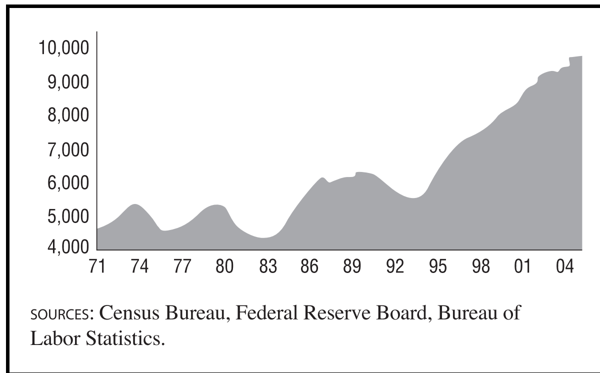
Although the legal age of contract is 18, credit cards are marketed to younger teenagers, usually with a parent as a cosigner. Credit cards are heavily marketed to college students, and several small studies of college graduates have indicated that college graduates' credit card debt may average several thousand dollars (Manning, 2000). One incentive for targeting young people is that consumers keep their original credit card for an average of fifteen years.

Many college students take out loans to pay for their tuition and other educational expenses. Some college loans are federally subsidized to keep the interest rates modest. Unsubsidized college loans are easy to obtain because lenders believe the future earnings of college graduates will be much higher than the earnings of high school graduates.

By the time of marriage, both spouses may have substantial debts, including credit card debt, college loans, and perhaps financing for cars or furniture. Early in a marriage, couples commonly pursue joint expenditures, often for a home or consumer durables. Unless the couple has substantial savings, financing major purchases through credit is commonplace.

Middle-aged consumers typically have higher incomes and potentially have better credit scores because of their greater job seniority, but they also have substantial expenditures for their children and perhaps for their elderly parents. Middle-aged consumers are likely to pay regular monthly debt service for home mortgages and perhaps for cars and consumer durables. Some also have remaining college debts to repay and may be cosigning college loans for their own children. Some borrowing is usually considered prudent, assuming that monthly income is stable or rising. But middle-aged consumers may experience sudden drops in income through unemployment, injury, or illness, leading to missed payments, which in turn lead to increased interest rates, especially on credit cards (Sullivan, Warren, and Westbrook, 2000).

People aged 65 and older are the fastest growing segment of the population in bankruptcy, countering a stereotype that the elderly are the most reluctant to incur debt (Sullivan, Thorne, and Warren, 2001). One factor is the cost of medical and long-term care among sick people. Even with Medicare, senior citizens may face unexpected expenditures for medicine, long-term care, medical equipment, and insurance company copays. Conversely, many senior citizens own their homes without a mortgage, have adequate retirement income, and enjoy relatively low rates of interest if they do seek to borrow money.



***Real Consumer Credit Growth.*** *Real consumer credit outstanding per American age 18 and older, 2004.* CENGAGE LEARNING, GALE.

Patterns of debt also vary by gender and by race/ethnicity. United States law provides for equal credit opportunities for women, especially married women, and for racial and ethnic minorities. In part because of their lower earnings and in part because unmarried women may have expenditures for children and other dependents, women appear to have higher debt levels relative to their earnings. Racial and ethnic minorities may also be subjected to higher interest rates because of their choice of lenders and because of practices such as redlining, a practice that charges borrowers high interest rates if they live in neighborhoods with characteristics considered to increase risk of default.

## PROBLEMATIC DEBT LEVELS

Both debtors and lenders assume that the debtors' income will continue uninterrupted. This assumption is potentially problematic. Unemployment or layoffs are a factor in 60% of consumer bankruptcies. Small business owners may receive too little profit as a result of a downturn in the business cycle or industry restructuring. A divorced person may lose income, take on additional expenses (e.g., child support, alimony), or both. People who become sick or injured may be unable to work, losing their income even if their medical expenditures are insured.

Moreover, debtors' other expenditures may exceed the anticipated level. Some expenses may simply be due to money mismanagement, but expenditures can rise for reasons beyond the borrower's control, resulting in further debt. Consumers may find themselves with involuntary debts, as when they are judged at fault in an accident. People without medical insurance may find that even the most minor illness or injury leads to serious debt. Failure to pay rent, utilities, or child support results in debt that accumulates interest. Finally debt itself is stressful and may lead to depression, marital strain, divorce, and other consequences that are in themselves costly (Sullivan, Warren, and Westbrook, 1995; Warren and Tyagi, 2004).

Debtors who are unable to repay have several options. Creditors may be willing to consider debt forbearance, such as a postponement of a payment schedule or even a reduction in the interest rate. Consumer credit counseling may be helpful in rebudgeting the debtor's income and teaching money management skills. At the extreme, the debtor may declare bankruptcy

Some debts are secured by collateral, so that failure to repay the debt results in the creditor taking ownership of the collateral. 68.2% of U.S. families have a home mortgage, which is a type of secured debt Reclaiming the home because of mortgage default is called foreclosure, and between January 2007 and January 2008 the number of foreclosures rose by 57%. Repossession is claiming a car or major appliance for failure to repay. In some states, creditors may also claim (*garnish*) a portion of the paycheck of a defaulting debtor.

## SUBPRIME LENDING

*Subprime lending* targets people whose credit history or income levels indicate that repayment is high risk (and therefore subprime), an assumption used to justify higher interest rates. *Usury* is defined as charging an illegally high rate of interest. Since U.S. usury laws were repealed in the 1970s, the amount of interest a lender may charge has been unregulated, so that market competition sets interest rates. Subprime borrowers, however, are considered such high-risk candidates that few will lend to them at regular interest rates. Beginning in the late 1980s, some lenders began aggressively marketing to the subprime market, which includes large numbers of people who are members of racial minority groups, have low incomes, or have histories of job instability. Subprime lenders may also use redlining, in the presence of characteristics such as high residential mobility, high unemployment rates, low levels of education, low incomes, and low levels of homeownership.

During the 1990s subprime mortgage lending, or making home loans to individuals and couples who did not qualify for conventional mortgages, grew increasingly common. Subprime mortgages often feature adjustable interest rates, with initially low (*teaser*) interest rates, even rates of 0%, which later increase to double-digit rates. Subprime mortgages may have prepayment penalties to discourage efforts to refinance the loans on terms more favorable to the borrower. Subprime lending has been implicated in the high rate of foreclosures in the early 21st century. It has also led to serious dislocations in the financial market, because bundles of subprime mortgages

were sold to third-party investors, and these investments have lost value as the subprime mortgages have failed.

### FRINGE BANKING

As many as 20% of residents in the United States have no regular banking arrangement and are instead served by lending institutions that charge high interest and market their services principally to the poor, to immigrants, and to racial minorities. These arrangements include pawn shops, title shops, rent-to-own, and payday loans. Pawn shops and title shops are somewhat similar to secured loans in that borrowers allow the lender to hold goods they own (anything of value for a pawn shop; a car title for the title shop) until the debt is repaid. Rent-to-own is superficially similar to ordinary consumer financing of household goods, except that the interest rates are much higher. Payday loans are a cash advance against a paycheck, and thus more similar to unsecured loans, again with a higher interest rate.

### REASONS FOR THE INCREASE IN DEBT IN THE UNITED STATES

An argument has been advanced that the current rise in debt results from a decline of the stigma attached to indebtedness, but the evidence for this hypothesis has not been compelling. An alternative hypothesis is that increased debt has risen as a result of consumer industries and the credit industry seeking to expand their markets. The profitable debt business has expanded to include even people who cannot readily repay, either through subprime lending or through the alternative fringe banking institutions. This alternative hypothesis sees the increase in debt as a corollary of advanced capitalism. The advanced capitalism hypothesis typically sees stagnant or declining real wages as an additional corollary to capitalism.

## DISABILITY, ADULTHOOD

Disability can occur at any age and anyone, at any time, can enter the ranks of "the disabled." Conditions such as blindness, deafness, mobility impairments, and mental retardation are commonly accepted (by the general public) as disabilities. However, in the United States, government definitions of disability include chronic illnesses such as diabetes and multiple sclerosis. Those with psychiatric disabilities, such as depression and mental illnesses, are also eligible for government disability services and benefits. Disabilities that are present at birth are termed congenital disabilities and the individual never develops an identity as a person without a disability. For individuals with congenital disabilities, disability is "normal." In contrast, disabilities either acquired or diagnosed in adulthood presents challenges because adults are faced with the developmental tasks of marriage, establishing a home, developing a career, and financial independence. With an adult-onset disability, often the spouse or partner (of the person with a disability) is involved in responding to the disability. Functional losses may be considerable when an individual acquires a disability in adulthood simply because these years are the period in which most individuals are at the peak of their professional lives.

The disability experience is unique to each person, even among individuals with the same type and severity of disability. The type of onset, the developmental stage

when the disability is acquired, the visibility of the disability, the environmental resources available, and personal characteristics and values specific to each individual make every disability experience different. Nonetheless, for purposes of organization and conceptualization, some sort of categorization is necessary. Categorization of disabilities is also necessary in order to provide government benefits and services to those who need them.

## CATEGORIZATION OF DISABILITIES

Two disability scholars (Smart, 2001, 2004, 2005 a, b; Vash, 1981) have categorized disabilities into three general types: physical disabilities, cognitive disabilities, and psychiatric disabilities. *Physical disabilities* include mobility impairments, such as quadriplegia (paralysis in both upper and lower extremities) and paraplegia (paralysis in trunk and lower extremities) (Crewe & Krause, 2002); neurologic impairments such as cerebral palsy and seizure disorders (epilepsy); sensory loss (blindness, deafness, and deafness/blindness); musculoskeletal conditions such as muscular dystrophy and chronic illnesses or conditions such as heart disease, autoimmune diseases such as lupus, and the various types of diabetes. Many injuries, after medical stabilization, result in long term disabilities. Often, the general public considers physical disabilities to be the only type of disability. *Cognitive disabilities* include mental retardation, Down syndrome, developmental disabilities such as autism, and learning disabilities, such as dyslexia. *Psychiatric disabilities* include affective disorders such as depression, and mental illnesses such as schizophrenia, alcoholism, and chemical and substance abuse.

An individual may experience a single disability or a combination of two or three disabilities. For the purposes of service provision, one of the disabilities is designated as the primary disability. The three classifications are organized by *symptoms* of disabilities, not by the *cause* (etiology). Often, the causes of disabilities are not known or understood, or there may be multiple causes. More important, the chief purpose of these categorizations is to devise treatment and service plans; therefore, the symptoms are of the greatest interest. Interestingly, there are known physical and organic causes for each type of disability and, therefore, if disabilities were categorized according to cause, all disabilities would be physical disabilities.

Categorization of disabilities also exerts a powerful influence on the degree of prejudice and discrimination directed toward people with disabilities and their families. Typically, those with physical disabilities experience the least degree of stigma and prejudice, probably because these types of disabilities are the easiest for the general public to understand. Persons with cognitive disabilities are subjected to more prejudice and stigma than those with physical disabilities, and individuals with psychiatric disabilities have historically been the targets of the greatest degree of prejudice and discrimination. The history of the provision of government services and financial benefits in the United States closely parallels this categorization of disabilities. Those civilians with physical disabilities received services in 1920 (Vocational Rehabilitation Act of 1920); those with cognitive disabilities received services in 1943 (Vocational Rehabilitation Act Amendments of 1943); and those with psychiatric disabilities in 1965 (Vocational Rehabilitation Act Amendments of 1965). The history of government service provision illustrates that laws and policy are legalized and systematic expressions of public opinion.

## RISING DISABILITY RATES ARE ADVANCES FOR SOCIETY

Disability is both common and natural and, furthermore, a larger proportion of the population has disabilities than ever before. Experts expect that this proportion will continue to increase. These rising rates of disability reflect an improvement in social conditions from both individual and societal perspectives because, in most cases, the alternative to the acquisition of the disability would be the individual's death. Innovations in neonatal medicine have allowed more babies to survive; but many are born with a disability. Likewise, advances in emergency medicine have saved the lives of many accident victims; but these survivors often have a disability, such as a spinal cord injury or a traumatic brain injury. Advances in medicine have led to longer life spans and rate of disability is positively correlated with age. For example, at present, there are more people who are blind in the United States than ever before due to the aging of the population. This is due to the higher rates of diabetes, sometimes a condition considered to be associated with old age. Medical progress also has increased the life spans of people with disabilities who, in the past, often did not survive to adulthood because of infections secondary to their disability.

The increase in the number of people with a disability may also reflect a statistical artifact. In recent decades, social and medical scientists have developed more accurate and complete counting of people with disabilities. Further, the definition of disability has been broadened. For example, over the last 25 to 30 years, alcoholism, learning disabilities, and mental illness were not considered to be disabilities. Before these conditions were considered to be disabilities, no services or treatment were provided and, further, these conditions were

considered personal and moral failures, thus evoking a great deal of prejudice and discrimination.

### THE INDIVIDUAL'S RESPONSE TO DISABILITY

Most people with disabilities do not want to be viewed as tragic victims or heroes. Rather, they would like to be considered ordinary people. After their initial physical symptoms stabilize, people with disabilities do not view their disability as their primary identity; but they also understand that society often considers a disability to be the individual's most important characteristic. (This view is captured in widely used phrases such as "the person is not the disability" or disability is not the "master status.") People with disabilities and their families do not deny the presence of the disability, nor do they fail to manage and make accommodations for the disability; they simply consider the many other identities, roles, and functions of an individual with a disability. Often, both people with disabilities and their families are proud of their mastery of the disability and experience satisfaction in negotiating life's demands. Indeed, many people with disabilities consider societal lack of awareness and prejudice to be more limiting and demanding than the disability.

Someone's response to a disability is influenced by factors in the disability including the type and time of onset. Types of onset may be congenital (present at birth) or acquired. Other types of onset include sudden, traumatic onsets, such as a stroke or an accident. In contrast, other onsets are slow and insidious, such as many types of mental illness or autoimmune diseases. The individual's developmental stage at the time of onset may influence his or her responses. The individual with a congenital disability, such as cerebral palsy, has no identity or memory of being a person without a disability. With a congenital disability, it is the parents, siblings, and grandparents who must negotiate the stages of acceptance. Conversely, someone in middle age, who has an established identity of success and achievement, will experience the onset of a disability very differently, considering the losses to be substantial. Research has shown that older persons tend to accept disability better than do younger persons. Researchers have posited three reasons for this acceptance: The functional demands facing older adults, such as working or raising children, are decreased;

## AMERICANS WITH DISABILITIES ACT

The Americans with Disabilities Act (ADA), which was signed into law in 1990, is the civil rights law for people with disabilities. Much of its wording was taken from the Civil Rights Act of 1964.

The ADA has five main sections or titles, each addressing a particular issue and each with different enforcing bodies. Title I is Employment; Title II is Transportation; Title III is Public Accommodations and Services (restaurants, theaters, art galleries, libraries, and so on); Title IV is Telecommunications; and Title V is Miscellaneous and includes guidelines for historical and wilderness sites.

The passage of the ADA in 1990 has facilitated the access of people with disabilities into many aspects of American life and has contributed to the collective identity of people with disabilities. The act also has spurred many advances in telecommunications, assistive technology, and job restructuring.

Despite these accomplishments, some political experts believe that the reforms have not produced much change in the overall social position of Americans with disabilities and that the gap between Americans without disabilities and Americans with disabilities has continued to grow.

many of the individual's age peers experience disability and, therefore disability seems *normal,* and people who are older typically have had a great deal of experience and expertise in responding to life's demands and the acquisition of a disability is simply thought to be another challenge. Interestingly, most, if not all, of the major developmental theories are silent on the issue of disability.

The course of a disability is the way in which the disability advances or progresses. There are three basic courses: stable, progressive, and episodic; each requires a different response from the individual. A stable course, such as would be expected with many types of blindness or spinal cord injury, presents fewer adjustment demands simply because the individual understands with what he or she is dealing. Progressive course disabilities (sometimes referred to as chronic degenerative disorders) require adjustment and response at each level of loss. Often, this includes a change in self-identity. Disabilities with an episodic course are probably the most difficult to deal with and the most stressful. Obviously, the individual feels a loss of control because he or she cannot predict when an episode will occur.

Some disabilities are visible and others are invisible. Diabetes and some types of mental illness are considered invisible while paralysis and blindness are visible disabilities. Often, it is not the disability itself which is visible, but rather assistive technology such as hearing aids or a wheelchair. For example, although diabetes is considered an invisible disability, those who wear insulin pumps on their belts are considered to have a visible disability. The individual with an invisible disability will be required to consider issues of disclosure. In addition, research has shown that there is a great deal more prejudice and stigma directed toward those with invisible disabilities than those with visible disabilities. Although no correlation exists between degree of visibility and degree of impairment, if the individual wishes to receive accommodations under the Americans with Disabilities Act (ADA), he or she must disclose the disability. Disclosure of disability in social situations, including the timing of the disclosure, is fraught with difficulty. If the individual discloses early in the relationship, the friend, associate, or romantic partner may terminate the relationship. Disclosure late in a relationship may be perceived as a lack of trust and a betrayal.

Not all disabilities involve disfigurement, but those that do, such as amputations, burns, and facial bodily disfigurements, elicit a great deal of stigma. These types of disfigurements do not hinder their activities; but service providers regard disfigurements as limiting simply because of the prejudice and discrimination in the general society. Therefore, we can see that it is society's prejudice, and nothing in the individual or the disability itself, which hinders the individual from full social integration. Obviously, disfigurements acquired in adolescence can undermine self-confidence in peer relationships and romantic and sexual partnerships.

People with disabilities must negotiate all of the developmental stages and, at the same time, respond to and manage both the disability and society's prejudice and discrimination. Adults with disabilities tend to marry at the same rate as those without disabilities; however, the average age at which a person with a disability enters a first marriage is higher.

### CURRENT TRENDS IN VIEWING DISABILITY

Until very recently, the *biomedical model of disability* dominated definitions of disability, provision of services and treatment, the public's conceptualization of disability, and the self-identity of people with disabilities. This model defines disability in the language of medicine, lending

scientific credibility to the idea that the cause and the management of the disability lie wholly within the individual, often called the *personal tragedy of disability.* Holding the individual responsible is also referred to as the *individualization* and *privatization* of disability. Underlying this model are the assumptions that deficit and loss are present and that disabilities are objective conditions that exist in and of themselves. This *objectification* process opens the door to the possibility of dehumanization because attention is focused on the supposed pathology.

The biomedical model is relatively silent on issues of social justice and one's interaction with the social and physical environment. This lack of awareness of society's collective responsibility to provide accommodations is termed the *medicalization* of disability. Certainly in the biomedical model, the emphasis is on the rehabilitation of the individual, rather than society's responsibility to provide accommodations to such people.

The biomedical model has a long history and, because of this, training in disability issues has been limited to medicine and other medically related fields. This is another example of the *medicalization* of disability. Furthermore, the history, values, and experiences of people with disabilities and their families have not been considered to be part of the general educational curriculum. Indeed, physicians have been the cultural translators of the disability experience. Rather than people with disabilities speaking and writing about the lived experience of disability, it is medical personnel who have described and explained disability to the general public.

The *sociopolitical model of disability* calls for a radical shift in perspective as to the location of the definition of disability from being almost exclusively that of the individual to a collective responsibility as is, for example, communicated in Canadian law. The Canadian Bill of Human Rights of 1960 defines the legal rights of all Canadians and states that it is the responsibility of all Canadians to provide equal opportunities to Canadians with disabilities. The sociopolitical model is an interactional model because it takes into consideration both the person with the disability and that person's unique situation. In this model, policy makers, professional service providers, and the general public become part of the issue of disability or stated differently, if disability is a collective concern, then the response is a collective responsibility. This model defines disability as a social and civil construction because there is nothing inherent in a disability that warrants prejudices or stereotypes and that reduces opportunity. The sociopolitical model has been called the *minority group model* and has fostered the involvement of many people with disabilities in advocacy movements such as the independent living movement and the disability rights movement. Given that the sociopolitical model considers disability a collective concern, advocates view disability studies and disability history as integral components of sociology, psychology, political science, and history curriculums.

# DIVORCE AND SEPARATION

Individuals rarely enter into serious relationships, especially marriage, with thoughts about how the relationship might end. However, the prevalence of divorce and separation ensures that virtually everyone will have some experience with relationships ending in this manner either personally or by observing others. Most social scientists agree that divorce and separation represent points in a process of marital breakdown rather than isolated events. Therefore, for the purpose of this entry, *divorce* is defined as the legal termination of marriage and is discussed within the context of a series of events, of which separation may be a part. *Separation* refers to the point in a relationship when spouses choose to live apart due to problems in the marriage. The term *marital dissolution* is used to describe the overall process of marital breakdown. The legal status awarded to marital unions sets these relationships apart from dating, cohabiting, and same-sex couples, and, consequently, the processes and implications of relationship dissolution are also somewhat different. Although much of what is said here may apply to these other relationship forms, the primary focus of this entry is married, heterosexual couples.

## THE PREVALENCE OF DIVORCE: PATTERNS AND TRENDS

The fact that divorce and separation are frequent experiences in contemporary U.S. society is widely accepted. The most commonly cited statistic is that about 50% of marriages will end in divorce, with other estimates as low as 44% or as high as 64%. One could easily wonder which number is the most accurate and why there is such variability in reports. A few considerations are important in determining the most accurate statistic. First, does the number refer to all marriages or only to marriages that were begun in a certain year? Second, are first marriages the focus or does the number include remarriages? Third, is the intent to describe the entire adult population or a specific subpopulation (e.g., race or age group) only?

One way demographers calculate the divorce rate is by documenting the number of divorces per 1,000 married women age 15 and above for a given year, using data from the census or from marriage and divorce records (Cherlin, 1992). As of 2008, this figure hovers around 20%, or 200 divorces per 1,000 married women in a year. Another way to determine the divorce rate is to estimate the percentage of first marriages begun in a particular year that will end in divorce at some point during the couples' lifetimes—this is the source of the 50% figure so often cited. Individuals who are in their second or later marriages are more likely to divorce than are those in first marriages; about 60% of remarriages end in divorce. Rates also differ by race and ethnicity such that Hispanics have the lowest rates of divorce, followed by Whites, whereas Blacks have the highest rates.

The rising divorce rate occasionally provides fodder for political, media, and even social science debates about the changes occurring in family structures. Some reports discuss the ways in which divorce is causing the decline of the family and the detrimental effects this has on society (Popenoe, 1993). Examination of the longer-term trends in marital dissolution makes apparent that the level of divorce and separation seen in the early 21st century is not new or unusual. The reference period for those who make arguments about the decline of the family is often the late 1950s and 1960s, a time in which divorce rates dropped sharply following a spike after World War II (1939–1945). In fact, observing the trend in divorce from the late 1800s forward shows the 1960s to be a blip in what has otherwise been a fairly steady increase in divorce over time. Additionally, as Andrew Cherlin (1992) notes, the overall rate of marital dissolution has remained generally stable since 1860, but the way in which marriages end has changed. That is, life expectancy has increased over time, reducing the proportion of marriages in a given year that ended due to the death of a spouse so that, since 1970, marriages are more likely to end in divorce than in death. Moreover, separation is not a new phenomenon, although it is perhaps better documented in the recent past than was the case previously. For example, in the past, it was not uncommon for men who had difficulty providing for their families to simply desert them, yet these marriages were never officially recorded as having been ended.

Marital dissolution is one of life's transitions that is important to social scientists both in and of itself and because of its consequences for other family behaviors, including cohabitation, childbearing, and childrearing. Similarly, separation and divorce generally occur at a point in the life course during which the consequences are significant not only for the members of the couple themselves but also for those around them—namely their children, parents, and friends. For example, children must adjust to different living arrangements, either with a single parent (or alternating between both parents), a parent in a cohabiting union or remarriage, or perhaps in a multigenerational home in which grandparents help with childcare. Rising rates of divorce also influence the nature of family formation because individuals change the ways they think about getting married and beginning childbearing (Smock, 2004). That is, the fact that cohabitation and divorce represent options to getting into and remaining in a marriage that may not be ideal appears to be leading individuals to wait longer to marry, waiting until they are sure that the high expectations they have for marriage can be met with a particular partner.

## THE CAUSES OF SEPARATION AND DIVORCE

A vast literature describes various causes and factors related to divorce. This work typically stems from several broad theories that help explain changes in patterns of family formation and dissolution over time. The major theories relate changes in the family to (a) secular and demographic trends, (b) stages in the life course, and (c) (inter)personal factors.

Secular and demographic trend theories focus on "big picture" factors that relate to changes in the ways in which families function. For example, a societal shift from an agricultural to industrial economy, and the resulting urbanization, is cited as one of the leading contributors to increasing marital dissolution in European and North American nations (Goode, 1993). Decreased reliance on the family is fostered when schools, jobs, and other nonfamily institutions usurp functions formerly relegated to the family, creating a sense of independence, rather than interdependence, on the part of family members (Nimkoff, 1965). According to the theory, this decreased dependency on other family members reduces familial bonds, and divorce or separation become more likely. Similarly, rising labor force participation and increasing levels of education, particularly among women, are believed to increase marital instability and dissolution by giving women higher status or "bargaining power" in relationships (White & Rogers, 2000).

It should be noted, however, that the relationship between education and divorce is not always straightforward. Women with college educations have experienced a declining divorce rate, whereas the rate continues to rise for those without a college education (Cherlin, 2005). Additionally, individuals are better able to visualize alternatives to their current marriage when more time is spent outside of the family. Alternatives might include a potential partner who appears more desirable than one's current spouse, a new option for childcare, or an alternative income source to offset the possible loss of a spouse's income contributions. Other societal factors such as the percentage of the population that is urban versus rural, changes from fault-based to no-fault divorce laws, and cultural shifts in attitudes toward reduced stigma and increased acceptance of divorce have also been used to contextualize changes in rates of divorce.

Life course theories emphasize characteristics of the marriage that have been consistently related to marital dissolution. First, lower average ages at first marriage, and individuals who marry younger than their peers, predict greater marital dissolution. Age at marriage has even been suggested to be the strongest predictor of divorce in the early years of marriage, possibly because individuals who marry young are less educated and less financially stable or are more likely to be marrying to legitimatize a premarital pregnancy than their older counterparts. Second, duration of marriage is important,

as about half of all divorces occur within the first 7 years of marriage (Cherlin, 1992). Third, as noted above, individuals in remarriages show higher rates of divorce than those in first marriages. Fourth, the presence of children reduces the likelihood of divorce, at least initially, and childlessness is related to higher rates of divorce. It appears that the presence of children in a family slows the process of marital dissolution so that couples who are prone to divorce will take longer to complete the divorce process (Gottman & Levenson, 2000).

Finally, life course theory suggests that divorce rates have increased as mortality rates declined because individuals grow apart in their interests and goals as they age. Individuals' interests and abilities continue to expand and move in new directions as they mature, and many couples find that, whereas the spouses may have shared much in common in the early years of their marriages, they begin moving in different directions later. In some cases, spouses amicably choose to move in their own directions, whereas in other cases, partners almost seem to weigh the option of ending the relationship against the amount of time they may have to spend living with a partner who is no longer meeting their intellectual and emotional needs. In the past, one partner may have been deceased before the couple really began to feel pulled in separate directions.

Explanations of separation and divorce also consider personal and couple characteristics. For example, evidence consistently shows that religious affiliation and participation is a buffer against divorce. Two common explanations are that (a) some denominations, particularly Catholics and evangelical Christians, are opposed to divorce and their adherents' attitudes and behaviors follow the religious proscriptions and (b) being a member of a religious community offers social integration and social support that promote marriage and family. Couples in which spouses are similar in terms of education level, age, race, and religion, for example, are less divorce-prone than those in which there are large differences between spouses on these characteristics. Likewise, communication style and marital satisfaction have been shown to predict divorce. (However, there are a relatively small percentage of marriages that continue for long durations even though the spouses report low levels of marital satisfaction and low-conflict marriages that dissolve.)

Factors that serve to reduce the risk of divorce are a feeling of commitment to the relationship as expressed by an identity as a member of the couple; a sense that one should stay in the relationship for the sake of the children, because friends or family might disapprove of separation, or for some other reason; or a perceived lack of alternatives (Johnson, 1991). Couples who have many shared assets may find it more difficult to separate; and overall, good economic circumstances reduce the risk of divorce. Finally, attributes or the behavior of one's spouse (such as alcoholism, domestic violence, infidelity, psychological problems, division of household labor, and so forth) are often cited by the other partner as having led to separation or divorce.

Scientists use census data as well as data from national and smaller-scale surveys to test and refine these theories. Many of the studies are cross-sectional, meaning that data are collected at one point in time, so that trends are deduced by comparing younger and older respondents and those who have experienced a particular event, such as divorce, to those who have not. Cause-and-effect relationships must be inferred. Longitudinal studies, however, collect data from individuals or couples at multiple points in time and allow a clearer picture of the mechanisms relating causes and outcomes. The most sophisticated studies of divorce and separation are prospective studies in which married individuals are sampled and followed over time so that comparisons can be made between those who separate or divorce and those who remain married.

## CONSEQUENCES OF DIVORCE AND SEPARATION

Just as theories describing the causes of separation and divorce are varied, so too are assessments of the consequences of these events. Because of differences in perspectives, data collection method, and study samples used, scholars are not in complete agreement about the consequences of divorce, but some strong patterns have emerged.

Undeniably, individuals experience significant changes in their economic status following a divorce. Divorced women's precarious economic well-being is a key factor underlying concerns about high levels of divorce in the contemporary United States. Numerous studies have documented the severe economic consequences of divorce for women (Smock, 1994). For example, in 1996 the median family income of divorced mothers was about $20,000, compared to more than $50,000 for married mothers. By contrast, most studies find that men do not experience the same drops in economic status and in some cases even gained economically following separation or divorce. Patricia McManus and Thomas DiPrete (2001) suggest that this trend may be changing, however, as they found that most of the men in their nationally representative sample did lose economic status because of the loss of their partner's income and an increase in support payments. Other stressors following divorce or separation, such as the need to downsize residences or relocate to be near family and a drop in standard of living to which one has become

accustomed, can be directly or indirectly related to this drop in income. The combined effects of various stressors can have large negative effects on the adjustment of both adults and children experiencing divorce.

In addition to changes in economic status, divorce precipitates strains in many types of relationships. When animosity exists between the separating spouses, this may extend to other family members and friends. Depending on the level of conflict between spouses, for example, in-laws may have difficulty maintaining quality relationships that have developed over the course of the marriage. This is especially important for grandparents who may lose contact with their grandchildren if their child is not the custodial parent; conversely, the custodial parent loses this set of grandparents as a source of help with childcare and support. Separating spouses must also adjust to the potential loss of friendships as they find themselves left out of couple activities or because their friends feel it is appropriate only to correspond with the member of the couple to whom they are closer. As there is often animosity between separating spouses, staying friendly with both members of the couple could be perceived as an act of betrayal. Relationships are strained when custody battles are intense or when the noncustodial parent becomes withdrawn from the child's life. Evidence suggests that both the parent and the child suffer when the parent withdraws. Changes in interpersonal relationships such as these increase the negative effects of divorce significantly by adding stress while removing potential sources of social support.

Certainly, the picture of postdivorce adjustment for children is not nearly as grim as it once was—neutral and even beneficial effects of separation have been cited. In general, it appears that many factors beyond the divorce event itself influence the way its effects will be played out for children. For example, if the parents' marriage is one in which little conflict is evident, the effects of the divorce on children appear to be negative, whereas if much conflict has been displayed, the effects are generally positive (Booth & Amato, 2001). A child's age and developmental stage at the time of divorce, gender, and quality of the predivorce parent–child relationships also have an impact on the way the consequences are felt. Scientists find negative consequences to be quite varied, ranging from behavioral problems in children (although some are likely to have been present prior to the divorce), to issues in psychological development and adjustment, to changes in levels of social support received from family and peers, and, later, to difficulties in the offsprings' own marriage(s).

Emerging research is beginning to examine when and how divorce or separation is beneficial to individuals, such as by giving members of unhappy couples a second chance at happiness or removing individuals from environments fraught with conflict, dysfunction, or abuse. Life cycle approaches and theories of adjustment to stress are also being employed to determine the ways in which people adjust to the negative effects of separation or divorce and whether those effects are short lived or long term, or both.

## THE STUDY OF DIVORCE AND SEPARATION: BEYOND CAUSES AND CONSEQUENCES

Research on divorce and separation has expanded greatly in the past few decades to include topics not previously examined in any depth. For example, social scientists are beginning to focus on smaller subgroups of the population, such as members of different racial or socioeconomic groups or individuals who divorce at later points in their marriage(s), with an additional focus on how the dissolution of nonmarital unions is similar or different from that of marital unions. Others are making strides in documenting relationships between biological factors and relationship behaviors, including divorce. These studies include the observation of levels of hormones such as testosterone and cortisol among those who divorce (and at various points in the dissolution process) and those who do not, as well as examining whether genetics might play a role in relationship stability. Remarriages and stepfamilies have been explored in the past, but much is left to learn about these complicated family forms.

Along with the expansion of topics of study, new data collection strategies and methods are emerging. Survey data remains the primary source of data in this area, but researchers are employing other methods as well. Focus groups and in-depth interviews provide rich detail about individual couples' experiences, and videotaped interactions allow researchers to examine the ways in which communication patterns and interaction styles predict marital success years later. Biological markers (e.g., measures of hormones, DNA) are being included with survey data for later exploration, and social network analyses and sophisticated statistical techniques allow investigators to fully appreciate the complexity of personal and family relationships.

The field is moving in many new directions, and each step forward uncovers a host of opportunities for further study. Much of the focus to date has been on the effects of divorce and separation on the immediate family, the couple, and their children. Research is just beginning to address how other relationships (e.g., grandparents or grandchildren) are affected in the long term. Another gap that remains in the study of divorce and separation is an evaluation of the various intervention strategies (such as therapy, mandatory mediation, and education-based

programs) available for couples and their children at various stages in the divorce process.

### POLICY IMPLICATIONS

The continuing concern over contemporary rates of separation and divorce is evident in family policy enacted in the late 20th and early 21st centuries. Marriage-promotion programs have been put into place by state and local governments in order to help families avoid divorce. The ongoing focus on marital unions as the preferred family form means that individuals experiencing dissolutions of other types of relationships—cohabiting unions or same-sex relationships, for example—are not entitled to the same limited resources (e.g., mandated support payments) as divorcing couples, even though the effects of the dissolution may be quite similar. The large body of research summarized here suggests that public policy is not meeting all of the needs of families experiencing the declines in economic circumstances and social support that accompany separation or divorce.

## DOMESTIC LABOR

**SEE** *Housework.*

## DOMESTIC VIOLENCE

Domestic violence research has expanded substantially since the 1970s, as scholars, activists, and policy makers have explored the many facets of this social problem. Research tends to focus primarily on the prevalence, causes, and consequences of intimate partner violence and on the effectiveness of prevention and intervention services for victims and perpetrators. On the one hand, the increase in this line of study has fundamentally changed social perceptions and knowledge about domestic violence and has led to increased resources for victims. On the other hand, the plethora of research makes it apparent that creating a universal definition of domestic violence, particularly of intimate partner violence, is challenging and becoming progressively more difficult. This complexity is essentially the result of typology scholarship that has empirically shown that intimate partner violence is not a unitary phenomenon and that more than one type exists. These new advances have challenged previous conceptualizations of the issue and compelled researchers, activists, and policy makers to reevaluate to whom research findings can be generalized and the appropriateness of ''one-size-fits-all'' models of understanding, preventing, and ending partner violence. By better understanding why individuals choose to use violence against family members, and by becoming more aware of its differing effects on victims' short- and long-term health and well-being, more can be done to effectively prevent violence, intervene on behalf victims and hold violent partners accountable for their behaviors.

## DEFINING DOMESTIC VIOLENCE

Domestic violence or intimate partner violence is typically thought of as a person's use of physical, emotional, or sexual abuse against an intimate partner. Though widely used, this simplistic definition masks the intricacies of this social problem and essentially fails to recognize the complexity of the issue. Mounting evidence suggests that intimate partner violence research explores a wide range of qualitatively distinct types of violence that, without making proper distinctions, can be misinterpreted and contradictory. Depending on the sampling strategy used (i.e., who is being studied and how they were recruited to participate), researchers may uncover very different types of intimate partner violence and subsequent findings about its prevalence, characteristics, and outcomes for victims.

Murray Straus, Richard Gelles, and Suzanne Steinmetz (1980; see also Straus, 1979, 1990, 1999) have contributed significantly to the field by employing large surveys that examine partner violence among the general population of heterosexual couples. This research has tended to focus primarily on the incidence and frequency of partner violence within the U.S. population. Their findings show that partner violence is relatively common in the United States, with about 12% of married couples reporting that at least one partner used an act of physical violence in the past year and about 30% reporting such violence over the course of the relationship. Their findings also suggest that women are as likely as men to use a violent act against an intimate partner, referred to as *gender symmetry*. Steinmetz's controversial 1977–1978 article, "The Battered Husband Syndrome," ignited an ongoing, rancorous debate concerning the issue of intimate partner violence gender symmetry. Steinmetz argued that "An examination of empirical data on wives' use of physical violence on their husbands suggests that husband-beating constitutes a sizable proportion of marital violence" (p. 501).

Straus and colleagues' findings largely contradict those of other researchers who have relied on samples of victims seeking services through the police, divorce courts, hospitals, and battered women's shelters. Data from these agency-based samples consistently show that in heterosexual relationships, it is unequivocally men using violence against women—violence that tends to be severe, frequent, escalating, and largely embedded in a pattern of power and control. Based on such research, the National Coalition Against Domestic Violence (2005) defines intimate partner violence or battering as

> a pattern of behavior used to establish power and control over another person with whom an intimate relationship is or has been shared through fear and intimidation, often including the threat or use of violence. . . . Intimate partner violence [is] intrinsically connected to the societal oppression of women.

Victim advocates and activists, therefore, conceptualize intimate partner violence as one of many types of violence against women (other types include rape, stalking, and sexual harassment) and consider it a social problem rooted in gender-based hierarchies and institutions that "support and reinforce women's subordination" (Goodman & Epstein, 2008, p. 2). This framework draws heavily from the Duluth Domestic Abuse Intervention Project, also known as the Duluth Model, which is considered the most well-known coordinated agency effort to confront the problem of men's violence toward their partners (Pence & Paymar, 1993).

Michael P. Johnson (1995, 2005, 2008) is one of several researchers (see also Holtzworth-Munroe, Meehan, Herron, & Stuart, 1999; Jacobson & Gottman, 1998) who have attempted to resolve the ongoing gender symmetry debate by arguing that more than one type of partner violence exists depending on the sampling strategy used. Johnson (2008) defined *intimate terrorism* as violence in which one partner (almost always the man in heterosexual relationships) uses physical violence to create and maintain general control over his partner. As such, physical and often sexual violence are part of a larger context of coercive control, which likely includes isolation, economic abuse, threats, using male privilege (e.g., treating the woman like a servant whereas the man acts like the master of the house), and using children. The motivation to use violence is essentially to demonstrate and reinforce control over a partner. This is the type of violence that comes to mind for most people when they think about or hear the term *domestic violence*, and victims of intimate terrorism generally show up in agency-based samples such as battered women's shelters and hospitals because of the severe physical and psychological harm that it causes. Sometimes women subjected to intimate terrorism will physically fight back in an attempt to defend themselves or their children. This type of violence is referred to as *violent resistance* (Johnson, 2008).

Intimate terrorism differs dramatically from situational couple violence, which is physical violence that erupts between partners and results more from a specific argument that has "gotten out of hand" with one partner striking out physically against the other (Johnson, 2008). This type of violence is not rooted in a general motivation to control one's partner; rather, it is a situationally specific response to some type of conflict. This is likely the type of violence exposed by Straus and colleagues, who rely on general population-based survey data, and it

is arguably the most common type of intimate partner violence (Johnson, 2008).

To date, most research does not clearly distinguish between types of violence, and the field has come to include data representing intimate terrorism, situational couple violence, and violent resistance with dramatically different findings concerning the nature and meaning of each form of violence. Unfortunately, all three of these types are often referred to generically as *domestic violence, domestic abuse, intimate partner violence*, or even *battering*, and often researchers will mix and match statistics from different types without specifically informing the reader which type of violence their study is about or to whom findings can be generalized. Different sampling frames yield different violence prevalence rates and differences concerning factors associated with violence. Moreover, each type of sampling method tends to be biased in its own way. For example, it is unlikely that situational couple victims would be in agency samples such as violence shelters or court samples because they are unlikely to experience a level of danger requiring such intervention. At the same time, intimate terrorism victims might not respond to general population surveys for fear that the abusive partner would find out and retaliate physically (Johnson, 1995).

## IMPLICATIONS FOR LIFE COURSE DEVELOPMENT

Depending on the type of violence used, violent partners can cause major psychological and physical harm to victims. The most common physical consequences of partner violence include injuries such as bruises, lacerations, broken bones, concussions, burns, miscarriages, and bullet wounds and also other noninjury-related health problems such gastrointestinal problems, chronic headaches and back pain, and general poor health. Intimate terrorism victims suffer significantly more severe physical consequences compared to situational couple violence victims, which is not surprising given the greater severity and frequency associated with intimate terrorism (Johnson & Leone, 2005).

Research shows that male partner violence is the primary cause of traumatic injury to women and is one of the leading causes of death for pregnant women (Griffin & Koss, 2002). Violence before pregnancy is a strong predictor of violence during pregnancy, whereas for other women violence increases or starts during pregnancy. Women's perceptions of violence during pregnancy indicate that power and control are central to this form of violence and cite their partner's jealousy of the unborn child, anger about the pregnancy, belief that the child is not his own, and/or anger about her lack of sexual interest as causes of the abuse. In some cases, a violent partner's anger and jealousy will drive him to attempt to cause a miscarriage by direction blows to the pregnant woman's abdomen (Campbell, Oliver, & Bullock, 1993). Approximately 1,300 women are killed each year by an intimate partner, comprising 34% of the murders of women (Rennison, 2003). Male partners are most likely to kill a female partner when she attempts to escape the relationship.

Jacqueline Golding's (1999) meta-analysis of the prevalence of health consequences of violence among female victims of partner violence supports this assertion. She found that about 60% of women studied through agency samples report symptoms of depression compared to 44% in general population samples; between 20% and 55% of women in agency samples report suicide attempts compared to 7% of women in general population samples; and about 33% of agency samples report alcohol abuse or dependence compared to 19% of general population samples. Finally, about 64% of agency samples of women meet the clinical criteria for posttraumatic stress disorder.

Some researchers have examined the association between growing up in a violent home and subsequently becoming involved in a violent marital relationship, the so-called *intergenerational cycle of abuse*. The vast majority of men who experience childhood family violence, however, do not grow up to be violent in their own families (Straus et al., 1980). A meta-analysis by Sandra Stith et al. (2000) found a weak to moderate relationship between the two, with the greatest effect among young males growing up in homes in which the father used highly controlling, often severe physical violence against the mother. These findings potentially support a learning model of male intimate terrorism perpetration and not necessarily one for victimization.

## INTERVENTIONS FOR VICTIMS/ PERPETRATORS

Intervention programs for violent partners (typically referred to as *batterer intervention programs*) have been shown to be minimally successful and tend to have low completion rates (i.e., few participants remain in the program for its full duration). For example, a review of effectiveness among both quasi-experimental and experimental studies estimated that 40% of treatment participants are successfully nonviolent compared to 35% of nontreatment participants (Babcock, Green, Webb, & Yerington, 2004). It is also important to note that program "success" is often equated to a cessation in the use of physical violence, which is problematic because many violent partners, particularly intimate terrorists, will likely continue to use coercive control tactics such as emotional abuse, stalking, and threats to use physical or

sexual violence even after a victim has escaped (Dobash & Dobash, 2000).

Contrary to common belief, partner violence victims seek help to end the violence against them, and within 2 years nearly half of victims experiencing controlling, severe physical violence escape and two-thirds no longer experience violence (Campbell, Rose, Kub, & Nedd, 1998). Intimate terrorism victims are more likely than situational couple violence victims to seek help from formal help sources (e.g., police, medical agencies, counselors) but are equally likely to seek help from informal help sources (e.g., family, friends; Leone, Johnson, & Cohan, 2007). Although research has not tested the effectiveness of different intervention programs among victims experiencing different types of violence, programs demonstrate relatively short- and long-term success for victims of controlling, physical violence—particularly when it is a part of a community-based advocacy program or a coordinated response. Chris Sullivan and Deborah Bybee (1999) used an experimental design to test the effectiveness of a 10-week post-shelter intervention with trained advocates and found that women who worked with advocates reported less violence and a higher quality of life and social support, and they were more likely to secure community resources over a 2-year period. These findings underscore how important social programs are in not only protecting victims from continued violence and abuse but also helping them secure the social and economic resources needed to recover from the trauma that they have endured.

## DUAL CAREER COUPLES

The term *dual career couples* captures the life-course concept of linked lives: Contemporary households increasingly must coordinate and strategize around two employment pathways (his and hers) along with their family pathway.

Some people define dual career couples as those in which both partners hold professional jobs. However, defining the term more broadly (as dual *earner* couples) is useful for understanding continuity and change in the family and occupational circumstances of all employed women and men who are married (or in marriage-like relationships), not just professionals. Dual earner households are now the norm. Only 6% of wives in the United States were employed outside the household in 1900, growing to only one in five by 1950. By contrast, in the early 21st century more than three in five wives are in the workforce. Investigations of dual earner couples are thus key to understanding the changing nature of families, work, and gender relationships.

Research shows that, given the mismatch between jobs designed for single (male breadwinner) earners without family responsibilities and the actual circumstances of their lives, dual earner couples engage in a range of adaptive strategies to coordinate their two occupational pathways and to manage the family side of their work-family equation. They also must adapt to inevitable crises (unemployment, an automobile accident, an unplanned birth, a geographical career move for one spouse) and contradictory gender norms and expectations. For example, many American women have been socialized to believe (a) they can (and should) pursue and move up career ladders and (b) they can (and should) simultaneously have a successful marriage and family life. Similarly, many new age American men have come to believe (a) they can (and should) continue to be the family breadwinners, following the traditional linear, male career path and (b) they can (and should) actively participate in childrearing and domestic work on the home front.

However, both men and women find these goals difficult to reconcile. Occupational career paths remain designed around the career mystique (a lockstep path of full-time, continuous employment as the only blueprint for good jobs, typical of middle-class men with homemaking wives in the 1950s). A global information economy means many jobs now demand far more than the traditional 40-hour workweek, making it difficult for wives and husbands to meet two sets of job demands and goals, along with their family demands and goals.

Life-course scholars examine the ways gender, relationships, and roles intersect and change, studying the interdependence between husbands' and wives' work and family obligations, couple divisions of both paid and unpaid labor, and immediate as well as long-term rewards and costs of various adaptive strategies. Research documents that, even though they may endorse and strive for gender equality in their relationship, couples tend to make strategic occupational and family decisions under the constraints of gender expectations that perpetuate gender stereotypes and inequalities (prioritizing the husbands' jobs, for example, or having the wife "opt out" of the workforce for a time). The fact that women are less likely to earn as much or to advance as far as their husbands colors couples' decisions about how to manage two jobs per household in a world that is organized to accommodate one job per household. The result of women scaling back as a strategy to achieve, retain, or aim for a better life course "fit" in the multiple dimensions of their lives perpetuates gender divisions in the amount of time each partner spends in paid work, homemaking, and the care of children and infirm parents or other relatives.

Demographic trends provide evidence that most couples also follow strategies that bend their personal lives to their occupational careers, rather than vice versa. Consider, for example, family strategies that have been adopted culture-wide: postponing marriage or childbearing, reducing family size, or remaining childless. All serve to reduce the family demand side of the dual career-family equation.

Research shows that couples pursue a variety of gender-based strategies around each spouse's paid work. First, a considerable minority of couples have both spouses highly invested in their jobs (the dual committed). Both spouses in this arrangement can be expected to put in long hours on the job, hold high-status (professional or managerial) jobs, and accord high priority to each of their jobs. Evidence shows that these couples are less likely to have children than those pursuing other work arrangements.

A second strategy is to put both partners' occupational careers on the back burner, giving primacy to the private aspects of their lives (those with alternative commitments). This can be either a deliberate choice or a situation in which members of the couple lack the education, skills, or opportunity to do otherwise. This category includes couples in nonprofessional occupations as well as those in a variety of jobs who deliberately choose to work (at most) a regular full-time workweek. Couples with alternative commitments may see both spouses' jobs as having equal (low) priority in their lives. However, studies show this option is likely to be rare, given the ways jobs, careers, pay scales, and consumption patterns are structured.

Often only one partner scales back on career investment and objectives. This compensatory strategy occurs when one spouse invests more in paid work while the other spouse invests more in the domestic aspects of their lives. A modified form of the traditional breadwinner-homemaker model (the neo-traditionalists) occurs when husbands are heavily invested in their jobs and their wives are not. This model perpetuates classic gender inequalities and differences. By contrast, when wives are the ones exclusively on a demanding occupational career track, couples are very much at odds with contemporary gender norms (those with crossover commitments).

The evidence suggests that many dual earner couples (e.g., 38% of the couples in the Ecology of Careers Study; Moen, 2003) follow the neo-traditional strategy. For example, husbands with highly time-consuming or psychologically draining jobs are apt to have wives who carry more of the emotional burden at home, which conforms to evidence on the gendered division of household labor and theories about the social construction of gender. Some research shows that when both spouses work regular full-time hours (39 to 45 hours per week), rather than long hours (more than 45 hours per week), both husbands and wives report higher life quality. This suggests the potential value of a more equal but, at the same time, reasonable division of paid work.

It is increasingly evident that work-life strategies are typically made by couples as couples, not as individual workers, and that they are fluid and dynamic processes. A focus on couple-level adaptations and how they shift over the life course provides a useful way of thinking about and studying gender, jobs, and families, along with the occupational paths of women and men. To do so requires recognition of (a) the value of using couples (rather than individuals) as the theoretical unit of inquiry; (b) possible life-stage variations in dual earner couples' adaptive strategies as couples set up a joint household; children are born, go to school, and grow up; aging parents (or spouses' or personal) health issues emerge; and couples plan for and negotiate two retirements; and (c) the continuing salience of existing gender norms and prepackaged career clocks, calendars, and expectations that privilege and reward the lock-step career mystique. These choices often serve to reconstruct and exacerbate gender inequality in a cumulative process of advantage and disadvantage over the life course.

Examining couples' occupational career development as a joint process illustrates a key policy challenge of modern times—the need for, and the opportunity to develop, new institutional arrangements that expand occupational career options, including opportunities for entries, exits, reentries, and scaling back that are not simply prescriptions for future disadvantage. Moving to greater, "no cost" career customization would enable dual-earner couples to better manage at home and work, improving the life quality of employees, couples, and families.

# DURKHEIM, ÉMILE
## *1858–1917*

Émile Durkheim is widely recognized as the father of sociology, and is credited with transforming sociology into a rigorous social science. His seminal writings on suicide, social integration, criminality, and religion have had a profound influence on life course sociology. Durkheim's works focused on the broad question of what makes a society stable and cohesive. He concluded that social integration, or the extent to which norms and shared beliefs hold members of a society together, has powerful influences on the health, stability, and efficiency of a society.

Durkheim was born in the Lorraine province in France on April 15. Following in the footsteps of his forefathers, he spent his childhood years preparing himself for the rabbinate. As an adolescent he discovered that teaching was his calling and moved to Paris to prepare for the École Normale, which he entered in 1879. Durkheim was inspired by his teacher, the classicist Numa-Denis Fustel de Coulanges (1830–1889). From Fustel he learned that the sacred could be studied rationally and objectively. He also read the pioneering work of early empiricists Auguste Comte (1798–1857) and Herbert Spencer (1820–1903), whose ideas shaped the philosophical and methodological foundations of Durkheim's work.

From 1882 to 1885 Durkheim taught philosophy in France. He took a leave of absence in 1885 and 1886, at which time he studied under the psychologist Wilhelm Wundt (1832–1920) in Germany. In 1887 he was named a lecturer at the University of Bordeaux, a position raised to a professorship in 1896, the first professorship of sociology in France.

The 1890s were a period of tremendous creativity and productivity for Durkheim. In 1893 he published *The Division of Labor in Society,* and in 1895 he published *Rules of the Sociological Method*, a manifesto stating what sociology was, and how sociological research and theorizing should be done. In 1898 he founded the scholarly journal *L'Année Sociologique*; his goal was to provide a venue for growing numbers of students and research collaborators to publish and publicize their cutting-edge work. He also had a broader mission: to bring the social sciences together and to demonstrate that sociology was a collective, not a personal, enterprise.

In 1902 Durkheim was named to a professorship at the Sorbonne. Because French universities historically served as training grounds for secondary school teachers, his position afforded him great influence; his lectures were the only ones that were required of all students. In 1912 he was assigned a permanent position of chair. Three years later, he published his last major work, *Elementary Forms of the Religious Life* (1915).

His personal and professional successes reached a tragic turning point during World War I (1914–1918). His son, as well as several of his former students, whom he had trained to become social scientists, were called to fight in the war and ultimately died. Rampant nationalism among the French right made Durkheim's leftism a target of criticism and attack. Emotionally devastated, he died from exhaustion on November 15, 1917, at age 59.

### DURKHEIM'S CONTRIBUTIONS TO LIFE COURSE RESEARCH

Durkheim's development of rigorous research methods and his attention to social integration are two of his key contributions to the study of life course. Durkheim proposed that a social system could only be understood through the analysis of social facts, and that contributing to the fund of reliable social facts was the key task of the sociologist. *Social facts* are social patterns that are external to individuals. For example, customs and social values exist outside of individuals, whereas psychological drives and motivation originates within people. Although social facts exist outside individuals, they nonetheless pose constraints on individual behavior. As Durkheim observed, "The individual is dominated by a moral reality greater than himself: namely, collective reality" (Durkheim 1997 [1897], p. 38).

The concept of social fact is exemplified in Durkheim's seminal work *Suicide* (1897); here he revealed that suicide is not necessarily a product of psychological demons, or a biological predisposition to sadness. Rather, Durkheim found that suicide rates were socially patterned: "A victim's act which at first seems to express only his personal temperament is really [caused by] a social condition." He conducted a rigorous analysis of official statistics, and compared and contrasted the suicide rates of diverse social groups across several nations. His analyses revealed that suicide rates were typically higher for men, Protestants, wealthy persons, and unmarried persons, whereas rates were lower for women, Catholics, Jews, and poorer persons. *Suicide* encapsulates a key concept upon which life course sociology is built: the sociological imagination, or the ability to seek the link

*Émile Durkheim.* ©BETTMANN/CORBIS.

between individualized thoughts and behaviors, and macrosocial patterns or influences.

Perhaps the most important conclusion of *Suicide*, however, was that social integration is critical for individual well-being over the life course. In interpreting his study findings, Durkheim highlighted that married persons and women tend to be embedded in more tightly-knit social networks than single persons and men. Similarly, both the social practices and belief structures of Catholicism and Judaism emphasize social integration, whereas the Protestant tradition upholds the traditions of individuality and personal choice.

Levels of social integration affect more than suicide rates, however; other important life course outcomes such as deviance are also shaped by the level of integration in a society. Durkheim argued that through the processes of modernization and urbanization, individuals would lose long-standing attachments and social ties that were a trademark of traditional rural villages. He noted that rapidly changing societies would suffer from anomie, or a condition of normlessness. People would not know what the norms (or behavioral expectations) were, and even if they understood the prevailing social rules, they may not obey them if they were not bound by a sense of moral obligation to others. Durkheim argued that in modern urban societies, individuals are without social ties and thus "no force restrains them."

Durkheim's development of the social fact concept has influenced empirical life course sociologists, who meticulously document the ways that social group memberships, such as race, class, gender, religion, and birth cohort, shape personal trajectories. His theorizing on social integration has shaped scholars' thinking about the ways that family, peers, religion, neighborhoods, and other social ties affect individuals at every stage of the life course. As Durkheim observed, such social classifications have an existence of their own and are themselves forces as real as physical forces (Durkheim 1997 [1897], p. 309).

## ECONOMIC RESTRUCTURING

Economic restructuring refers to a global change in the nature of labor markets that began in the late 1970s. The restructuring of economies across the globe generally took two forms: (a) declines in manufacturing or goods-producing industries and growth in service and information industries; and (b) increases in the transfer of business activities to external service providers (outsourcing), in contracting others for specialized jobs (subcontracting), and in temporary and part-time work contracts. These industry shifts altered the fundamental nature of work as firms, seeking to attain or maintain their competitive advantage in increasingly global markets, reduced their reliance on skilled workers by fragmenting work-related tasks and increasing their use of technology in the workplace. The result, as noted by Harry Braverman (1974), is what sociologists call *deskilling*, or the downgrading of jobs and occupations. At the same time, firms exercised cost-reduction practices such as mass layoffs, outsourcing, and substituting full-time with part-time workers to make themselves competitive. These demand-side changes in the labor market resulted in higher unemployment, lower wages, larger income disparities, and a dwindling supply of jobs with promotion ladders. Economic restructuring thus changed the context in which people's work lives unfolded over the life course.

### CAUSES OF ECONOMIC RESTRUCTURING

The restructuring of labor demands occurred throughout the 1980s and 1990s in countries across the world. Altough the causes of this restructuring have been debated, one causal factor that scholars agree on is globalization, or the flow of capital, goods, and people across national boundaries. Globalization facilitated the spread of technologies that were instrumental in the production of new ideas and innovations. Embodied in new products, new production processes, and new ways of organizing work, as Manuel Castells (1989) points out, the spread of technologies contributed to the growth of new economic activities. China, India, South Korea, and Japan, in particular, accelerated the pace of technology and scientific advances to improve their capacity to innovate.

A second important factor that fueled the restructuring of labor markets in industrialized nations is the state. National governments, in partnership with financial institutions, designed and implemented industrial policies to improve competitiveness in global markets. As Michael J. Piore and Charles F. Sabel (1984) explain, a number of countries adopted neoliberal economic policies, or strategies based on principals such as free trade in goods and services, free circulation of capital, and freedom of investment. In other words, countries sought to promote economic development by minimizing government regulation in the market in order to increase international trade relationships and manipulate industries and labor markets. For example, the Mexican government implemented a series of policies, endorsed and supported by international financial institutions and the U.S. government, that allowed the country to move away from its model of nationalized industrialization toward a market-driven model of competition and exports. By implementing new economic growth strategies, according

to Alejandro Portes and Kelly Hoffman (2003), Mexico was able to manipulate its industry base by trading its low labor costs for capital investments with countries like the United States.

The combination of globalization and state actions profoundly and fundamentally altered the economies of a number of countries. Globalization opened up new markets, industries used technological advancements to improve product designs and the quality of services, and national governments rearranged and reorganized the labor market through trade policies. Economic restructuring can thus be seen as a form of structural change because it systematically and widely changed employment and production processes, with long-term consequences for nations, firms, and the lives of individuals.

## UNEVEN CONSEQUENCES OF ECONOMIC RESTRUCTURING

Throughout the 1980s and 1990s, as Saskia Sassen (1991) notes, new economies were taking shape, showing rapid growth in financial and business services and sharp declines in manufacturing industries. These industry shifts generated global cities connected to each other by technology, trade, and production. New York, Tokyo, and London, for example, evolved into centers of finance and top management in part because most financial transactions between Japan, the United States, and the United Kingdom were concentrated in these cities.

At the same time, economic restructuring had devastating effects on some nations. Barry Bluestone and Bennett Harrison (1982) indicate that countries such as Sweden, the United Kingdom, and the United States witnessed growing class inequality. Much of this inequality was directly linked to the disappearance of blue-collar manufacturing jobs that required full-time workers, provided on-the-job training, and offered job mobility. Massive layoffs contributed to high unemployment rates among skilled blue-collar workers who faced shrinking job opportunities. Other blue-collar workers experienced underemployment because low-skill jobs in the growing service sector offered much lower wages, little opportunity for career advancement, and modest training. As manufacturing jobs continued to fade in a labor market with shifting priorities, traditional blue-collar workers and workers without a college degree were vulnerable. Overall, as Emilio A. Parrado and René M. Zenteno (2001) point out, the decline of manufacturing industries left workers facing stagnant career opportunities, weak attachments to the labor market, and downward mobility.

At the other end of the employment spectrum, economic restructuring stimulated unprecedented job growth in professional and managerial occupations. Frank Levy (1998) points out that employees with high levels of education saw their wages increase and unemployment levels drop. Individuals in these occupations benefited greatly from the reorganization of the economy. Changes in technology and information systems made it possible for highly educated workers to bargain with employers for flexibility, often through telecommuting, home-share work, and job-sharing, according to Leslie McCall (2001).

The consequences of restructuring went beyond falling wages at the bottom of the labor market, rising wages at the top of the labor market, and consequent increases in income inequality. Economic restructuring produced changes in the organization of work that had contradictory effects on women's work lives. On the one hand, the new organization of work undoubtedly shaped women's career choices. For example, the growth of part-time work allowed many women to enter the labor force (McCall, 2001). On the other hand, as Barbara Reskin and Patricia A. Roos (1990) note, occupations that were once predominantly male, such as nursing and clerical jobs, resegregated as they became predominantly female.

As Maria Charles (2005) observes, occupations in a number of industrialized nations were often influenced by cultural beliefs about what men and women are good at. For example, Mary Brinton (2001), in her comparison of Taiwan and Japan, found that large firms in Japan have mobility ladders for men but not women; in contrast, small, family-owned firms in Taiwan create opportunities for female family members to participate in the management of the firm. For women, the downside of economic restructuring was twofold. First, industry changes that encouraged women's labor force participation and new occupations contributed to "mommy tracks" in corporate environments. Second, growing income inequality adversely affected low-wage women as their wages fell and because they did not benefit from the flexibility that high-wage earning women did (McCall, 2000).

Another consequence of economic restructuring is the growth of "under the table" or "off the books" work, or economic activity that occurs outside the formal economy, which is regulated by economic and legal institutions. In the 1980s labor unions were hit hard by the rise in international trade, policies that favored employers, and economic restructuring. The power and protection that labor unions once provided workers withered away as new economic activities emerged. Facing rising unemployment rates and falling wages, workers in many countries turned to informal work for additional sources of income. For example, garment workers in industrialized and nonindustrialized nations saw their wages fall and jobs transformed into informal and home-based work that is neither recognized nor protected by law. With no formal employer, these workers get their own

materials, make the garments, and find markets to sell their goods.

### UNRESOLVED ISSUES

Although social scientists have documented the extent to which economic restructuring has fragmented and stratified groups by gender, income, and race, there are issues that remain unresolved. First, sociologists do not yet fully understand why economic restructuring has resulted in greater disparity among women. McCall (2001) argues that if the goal is to move toward equitable economic growth and higher wages for women across the board, gender scholars must continue to investigate the causes of rising income inequality among women. These investigations should explore the consequences of labor market policies that shape the career trajectories of men and women. For instance, research on company decisions and policies regarding gender equity would be helpful for understanding whether organizational change subordinates equity issues or enhances women's careers (McCall, 2001).

A second unresolved issue connected to economic restructuring relates to marriage and family life. Since the late 1990s research has shown that declines in marriage among low-educated women have been shaped by the eroding labor market opportunities for low-educated men, who thus appear to be poor prospects for marriage. In contrast, as Daniel T. Lichter and Diane K. McLaughlin (2002) observe, for highly educated women the retreat from marriage is less about the earning power of men and more about rising female earnings, which permit greater independence. To understand the relationship between the labor market and marriage, sociologists continue to debate why growing income inequality, a change produced by economic restructuring, has led to the retreat from marriage across the board.

Finally, because researchers have focused much of their attention on the patterns of wage and income inequality, less is known about how economic restructuring has affected the work histories of individuals. For example, questions remain about the rate of job change that individuals experience and how the sequence of job changes unfold over the life course.

## EDUCATIONAL ATTAINMENT

Educational attainment has been of long-standing interest to life course scholars. That interest results from several factors, including the role of education in nation-state development (Meyer, Tyack, Nagel, & Gordon, 1979), children's socialization (Sewell & Hauser, 1980), and adults' earnings (Card, 1999). As educational attainment has risen since the middle of the 20th century, the modal trajectory of the life course has changed, and researchers have tried to document the amount of schooling in populations and key subpopulations and to identify the determinants of educational attainment.

### MEASUREMENT AND TRENDS IN EDUCATIONAL ATTAINMENT

Analysts measure educational attainment in two ways. One approach involves counting the years of school a person completes. To document the educational attainment of a population, analysts report the mean (i.e., average) or median years of school completed. A second approach entails recording whether a person has attained certain key markers, such as a high school diploma, a bachelor's degree, or entry to advanced degree study. One then may calculate the proportion of persons in a

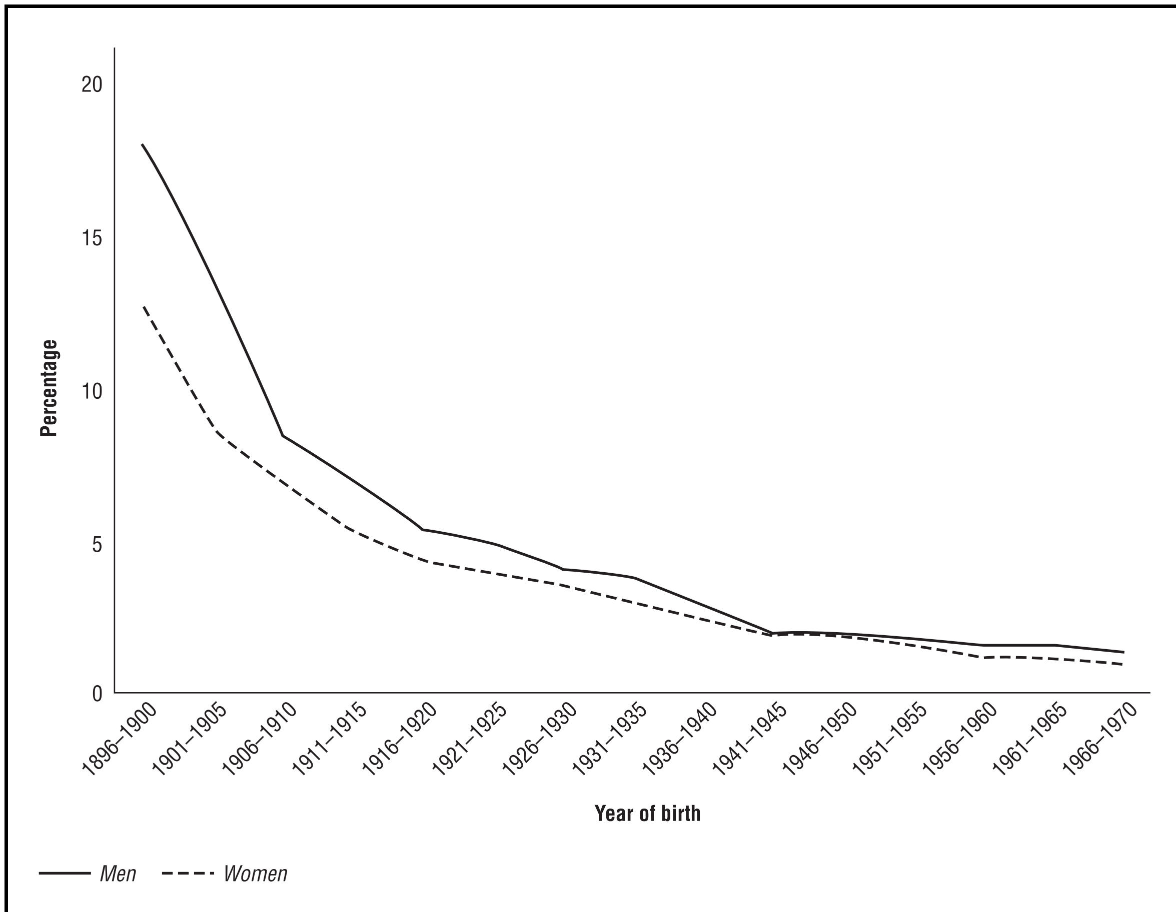

***Figure 1.*** *Percentage of persons completing four years of school or less, by sex and year of birth.* CENGAGE LEARNING, GALE.

population or subpopulation who have reached those thresholds.

By any measure, the level of educational attainment rose between 1901 and 2000. Throughout the 20th century in the United States the mean years of schooling increased for each succeeding cohort (Snyder & Hoffman, 2001). Further, the century witnessed a sharp decline in the proportion of persons with very low levels of education (Mare, 1995); corresponding increases in the proportions graduating from high school, entering college, and completing a bachelor's degree also were observed (Mare, 1995). The United States was not alone, as levels of educational attainment rose throughout the world during the 20th century (Shavit & Blossfeld, 1993).

Historically in the United States women have equaled or surpassed men's likelihood of completing high school, whereas men have exceeded the college attendance rates of women. With the birth cohorts of the mid-1950s, however, women surpassed men in the likelihood of college entry, and by the birth cohorts of the early 1960s women equaled men in the likelihood of obtaining a bachelor's degree (Mare, 1995). Thus, there are complex relationships among gender, cohort, and educational attainment.

Race/ethnicity is another sociodemographic factor that is associated with educational attainment. As of 2007, 93.4% of White persons 25 to 29 years old had completed high school, whereas for African Americans and Hispanics only 86.3% and 63.2%, respectively, had completed high school (Snyder, Dillow, & Hoffman, 2007). However, many Hispanics age 25 to 29 may not have obtained their schooling in the United States; consequently, the extent to which the completion rate reflects the operation of education systems in the United States is not clear.

An additional complexity concerns African Americans. When researchers control for (or hold constant) socioeconomic factors, the Black–White high school completion gap disappears (Bauman, 1998; Lucas, 1996). Researchers routinely find that those of higher socioeconomic status (SES) go further in school. The robustness of

this finding has motivated ongoing efforts to explain why SES matters.

## UNDERSTANDING THE CAUSAL EFFECT OF INDIVIDUALS' SES

Most educational attainment research is based on the presumption that well-developed educational systems exist. However, an individual cannot enter school, stay in school longer, or pursue postsecondary education unless educational institutions are constructed, expanded, and maintained. The historical process through which schools were constructed and expanded is contested. Key explanations that have been offered characterize the development of educational institutions as a nation-building activity (Meyer & Rubinson, 1975), a result of diffusion processes linked to the world system (Meyer, Ramirez, Rubinson, & Boli-Bennett, 1977), and a tool used by capitalists to create disparate forms of consciousness to slot persons into different—and unequal—positions in the economy (Bowles & Gintis, 1976). A full consideration of the institutional underpinnings of educational attainment must consider theories such as these, which view education from the macrosocial perspective. However, most research centers on explaining individual differences in educational attainment within a single institutional context.

The Wisconsin Social-Psychological Model of Status Attainment (the Wisconsin model) offers a social-psychological explanation for differences in educational attainment (Hauser, Tsai, & Sewell, 1983; Sewell & Hauser, 1980). The original work used Wisconsin Longitudinal Study data on Wisconsin high school graduates of 1957, but replications have extended the model nationwide (Alexander, Eckland, & Griffin, 1975) and beyond (Hansen & Haller, 1973; Nachmias, 1977).

The key factor in the Wisconsin model is the influence of significant others—encouragement by parents, teachers, and peers—as perceived and reported by the child. The higher their SES or academic performance, the greater the encouragement children perceive. The influence of significant others directly affects a child's educational aspiration and occupational aspiration, and educational aspiration affects educational attainment.

The Wisconsin model offers a powerful explanation of observed variation in attainment. The model explains 45% of the variation in significant others' influence, 74% of the variation in educational aspirations, and 68% of the variation in educational attainment. Further, it explains 73% of the variation in early career occupational status and 69% of the variance in occupational status at midlife (Hauser et al., 1983). By any estimation, this theoretical model provides a robust explanation of the process of educational attainment.

However, there are other explanations of the relationship of SES and educational attainment, although none provides the level of explanatory power of the Wisconsin model. The Wisconsin model contrasts sharply with the biogenetic explanation of variation in educational attainment. Biogenetic theorists see ability as the driver in educational attainment; ability is viewed as largely determined by one's genes, and genes are determined by one's parents. To complete the circle, assortative mating on educational attainment and other markers of social class reinforce distinctions of ability (Herrnstein & Murray, 1994).

Genetic explanations of educational attainment differentials have been refuted on scientific grounds. In *Inequality by Design: Cracking the Bell Curve Myth,* Claude Fischer and colleagues (1996) provided a thorough refutation of the biogenetic explanation of social inequality, including inequality in educational attainment. Additional authors, motivated perhaps by the apparent staying power of the biogenetic thesis in the popular imagination, have provided additional refutations (Devlin, Fienberg, Resnick, & Roeder, 1997; Jencks & Phillips, 1998).

Education researchers have found more support for human capital theory, which has affinities with the Wisconsin model. According to human capital theory, adults' productivity is a function of two factors: ability and investment. Individuals invest in their productivity in various ways, such as by acquiring skills through education. With all else equal, the more are able to invest more. However, ability is not completely free to develop, as many individuals face credit constraints and thus cannot make investments they otherwise would make (Becker, 1962). Hence, the socioeconomic gradient in education is due partly to credit constraints that prevent the poor from obtaining levels of education consonant with their ability (Becker & Tomes, 1986; Tomes, 1981). Thus, human capital theory suggests and explains a high association between parent and child educational attainment.

In *Reproduction in Education, Society, and Culture,* Pierre Bourdieu and Jean-Claude Passeron (1977) provided another theoretical explanation for the association between parental status and educational attainment. They contended that schools reward behavior that complies with the norms and standards of the dominant group in a society, yet those authors also noted that one's core (or habitus) develops in the family, is difficult or impossible to change, and directly affects one's likelihood of educational success. Bourdieu (1986) allowed one to interpret the association between parental status and educational attainment as resulting from gatekeeper exclusion, arbitrarily selected criteria of evaluation that advantage the previously advantaged, and parent–child interaction.

These broader theories highlight the ways individuals navigate systems of education by using their personal

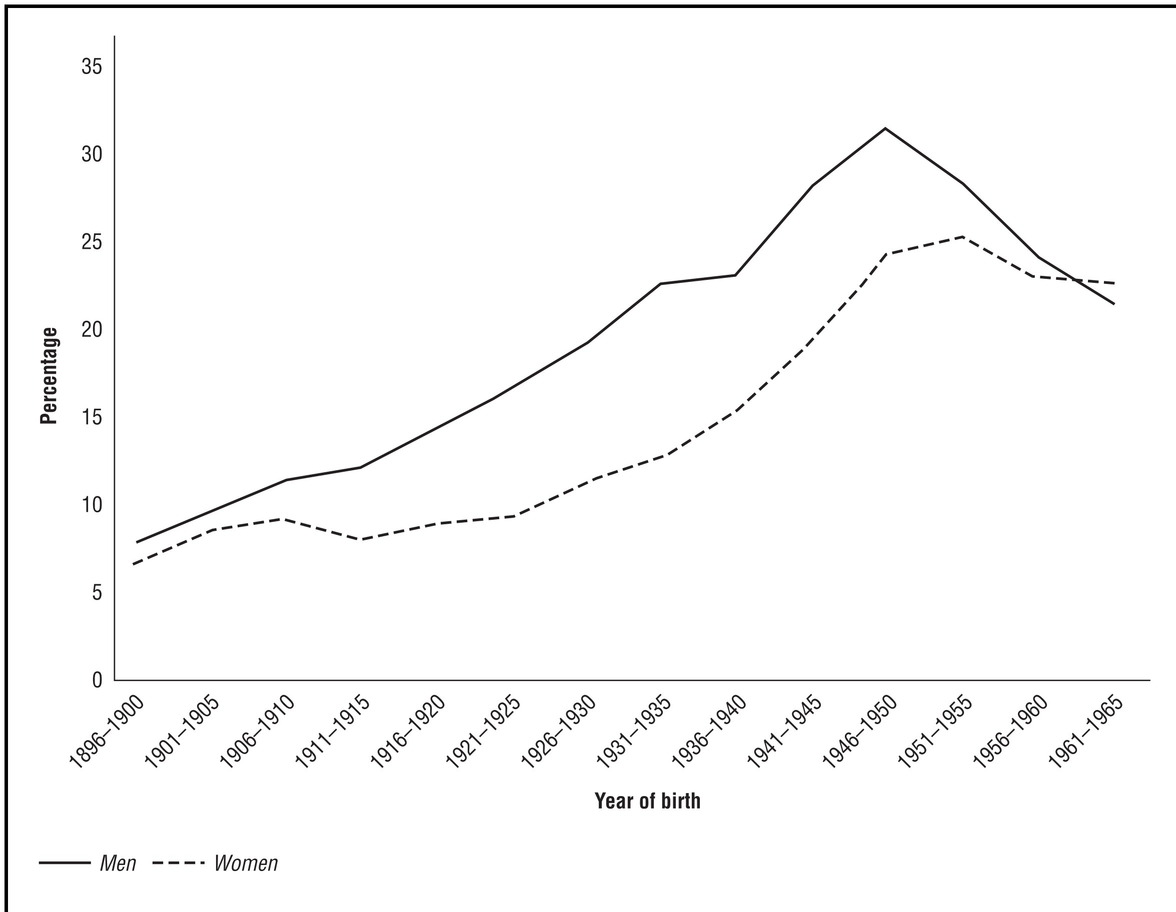

***Figure 2.*** *Percentage of persons completing at least a bachelor's degree, by sex and year of birth.* CENGAGE LEARNING, GALE.

resources as well as those provided by their families. More recent research highlighting cross-national comparisons has moved toward integrating macro-level considerations into the understanding of the production of educational attainment.

### INDIVIDUAL-LEVEL FACTORS IN THE CONTEXT OF MACRO-LEVEL DEVELOPMENTS: THE DIFFERING SOCIOECONOMIC GRADIENTS OF EDUCATIONAL ATTAINMENT

Cross-national comparative research has deepened analysts' understanding of educational attainment. The move to cross-national comparative research led researchers to recognize a problem with studying years of schooling. In response, Robert D. Mare (1980, 1981), following the work of Stephen E. Fienberg and William M. Mason (1978), observed that a person's years of schooling reflects a series of separate decisions to stop or continue schooling. Mare proposed that scholars could resolve the challenge raised by studying years of schooling by investigating the sequence of transitions instead. This education transitions approach (the Mare model) has become the standard for studies of educational attainment. The Mare model allows social scientists to observe (a) the changing association between socioeconomic background and educational attainment across transitions, (b) the different association between socioeconomic background and any particular transition across nations, and (c) the different association between socioeconomic background and any given transition across birth cohorts.

In his original research, Mare (1980) discovered a pattern of waning associations across transitions. Subsequent research replicated that finding with data from Israel (Shavit, 1993), France (Garnier & Raffalovich, 1984), Japan (Treiman & Yamaguchi, 1993), Sweden (Jonsson, 1993), Taiwan (Tsai & Chiu, 1993), and many other countries (Shavit & Blossfeld, 1993). Researchers also have detected stable associations across cohorts in the same country. Analysts have offered several theories to explain one or both of these patterns.

Mare (1980) originally proposed that selective attrition explained the waning association pattern. Fundamentally a statement of the statistical relations underlying the observed pattern, this explanation was revealed to be insufficient when the implications for the pattern of socioeconomic effects across cohorts were not observed (Shavit & Blossfeld, 1993) and when the statistical relations were shown to hold in a cohort even when the pattern of waning associations did not (Lucas, 1996).

Walter Müller and Wolfgang Karle (1993) proposed a life course perspective (LCP) to explain the pattern of waning associations between social background and educational attainment across successive transitions. They noted that students, older at each transition, depend less on their parents both socially and economically with each passing year. Hence, changes in the parent–child relation make parental characteristics decline in importance as a child matures.

Adrian Raftery and Michael Hout (1993; see also Hout, Raftery, & Bell, 1993) provided a further explanation for waning associations across transitions and changing associations across cohorts. They postulated four tenets of maximally maintained inequality (MMI). First, expansion of secondary and higher education reflects increased demand generated by population increase and the rising level of parents' education caused by earlier education expansion and other factors. Second, if enrollment rises faster than demand, the socioeconomically disadvantaged obtain more schooling. Even so, the socioeconomic association is unchanged. Third, if completion of a level of education becomes universal for higher SES persons, the effect of social background on that transition declines but only if educational expansion cannot be maintained otherwise. Fourth, falling SES can reverse and become rising effects; for example, if government support for educational attainment is reduced, socioeconomic effects will increase.

The fourth claim is a key difference between MMI and LCP. LCP emphasizes that as children age, they become increasingly independent of their parents and thus socioeconomic effects inexorably decline across transitions. MMI implies that adolescents' independence itself depends on the sociopolitical context and the resulting social support for particular levels of education.

Richard Breen and John H. Goldthorpe (1997) offered a rational choice model of relative risk aversion (RRA) to explain stable class differentials across cohorts, declining class effects across transitions, and rapidly changing gender effects. RRA draws on the Wisconsin model by highlighting perceptions of likelihood of educational success that are driven in part by ability and draws on human capital theory by highlighting cost constraints. However, Breen and Goldthorpe added the proviso that persons are risk-averse and seek to attain a social class at least equal to that of their parents.

RRA interprets MMI as a special case in which costs decline across the board for all classes. RRA claims that if costs decline differentially for different classes, the patterns highlighted by MMI will not occur. RRA points to rapid decline in the gender effect owing to changes in perceptions of appropriate roles, and thus likely levels of educational success. In Sweden, a rare case occurred in which class effects did decline with expansion owing to effective support for the education of disadvantaged children.

Although RRA is generally applicable to any choice set, both LCP and MMI explicitly concern attainment only. This is important because the traditional Mare model ignores potentially important qualitative differences in schooling. Richard Breen and Jan O. Jonsson (2000) found that the power of socioeconomic background varied with the path students took to their completed educational attainment. They concluded that suppressing qualitative distinctions weakens the understanding of the role of social background in educational transitions.

Consistent with that insight, Samuel R. Lucas (2001) proposed the theory of effectively maintained inequality (EMI), which considers both qualitative and quantitative dimensions of inequality. Lucas contended that socioeconomically advantaged actors secure for themselves and their children advantage wherever advantages are commonly possible. If quantitative differences are common, the socioeconomically advantaged obtain quantitative advantage. If qualitative differences are common, the socioeconomically advantaged obtain qualitative advantage.

Articulated as a general theory of inequality, EMI explained socioeconomic effects on educational attainment in one of at least two ways. When a particular level of schooling is not universal (e.g., high school completion throughout the first half of the 20th century in the United States), the socioeconomically advantaged use their advantages to secure that level of schooling. However, once that level of schooling becomes nearly universal, the socioeconomically advantaged seek out whatever qualitative differences there are at that level, using their advantages to secure quantitatively similar but qualitatively better education (e.g., qualitatively better, more challenging curricular tracks). EMI notes that actors' foci may shift as qualitative differences supplant quantitative differences in importance; alternately, actors may care about qualitative differences even when quantitative differences are common. Either way, EMI claims that the socioeconomically advantaged will use their advantages to secure both quantitatively and qualitatively better outcomes.

Each theory considers individual-level differences in larger dynamics—family dynamics, population dynamics, or power dynamics—all of which potentially differ across time and place according in part to social and political factors. In this way these theories provide resources for integrating macro-level narratives of the development of education systems with the micro-level narrative of persons' navigation of those systems.

## FUTURE RESEARCH

LCP implies an inexorable pattern of declining social background effects regardless of the situation. As researchers have found that this pattern reverses at times (Lucas, 1996), the claim of inexorable forces pushing weaker social background effects at older ages cannot be sufficient. However, it remains unclear whether MMI, RRA, or EMI best explains the pattern of socioeconomic background effects on educational transitions. Evidence consistent with each of the remaining three theories has been found. However, rarely have multiple theories been considered simultaneously. Hence, most studies are demonstrations of empirical patterns consistent with a focal theory, not efforts to test multiple theories on the same phenomenon to eliminate some from consideration. Future progress requires analysts to test the existing theories against one another under different conditions.

The effort to evaluate the theories is not aided by MMI and EMI sometimes being confused with each other (Tolsma, Coenders, & Lubbers, 2007). Some analysts fuel the confusion by merging EMI and MMI into one theory (Hout, 2006). Merging EMI and MMI, however, makes little sense because the two theories fundamentally disagree. Notably, MMI claims that socioeconomic inequality will be reduced through educational expansion, whereas EMI states unequivocally that education expansion need not reduce socioeconomic inequality. Thus, MMI points the way to a simple public policy response to socioeconomic inequality in education: expand schools. EMI maintains that expanding schools is insufficient because a plethora of qualitative differences in education can sustain inequality.

The reasoning behind this disagreement is that MMI states that for a transition made by every student or nearly every student the socioeconomic association will be zero and thus social conflict will be zero too. EMI directly contests this claim, explicitly stating that conflict may occur at universal transitions, may be intense, and will concern qualitative dimensions that matter for ultimate attainment. EMI points directly to the contestation around high school tracking as one example of intense class-based contestation at a nearly universal transition (Lucas, 2001; Wells & Serna, 1996). Consequently, MMI and EMI disagree on the crucial sociological point of what occurs when a transition is universal, suggesting that any merger of the theories can only produce an ad hoc melange.

Indeed, Hout's (2006) proposed merger appears ad hoc, as indicated by the statement that "MMI and EMI predict slow and contingent change over time in how strongly family background affects educational opportunity" (p. 239). Although MMI makes this prediction owing to its emphasis on slow-moving population dynamics such as changes in levels of parents' education, EMI suggests that the pace and pattern of change, if any, depend on the mix of qualitative and quantitative goods and thus need not be slow. As another example, Hout stated, "As post-secondary education expands, we can expect the association between family background and educational attainment to weaken.... I will propose an appropriate statistical model, fit it in each... country, and assess MMI/EMI in light of the results" (p. 240). Although MMI explicitly argues that large-scale educational expansion will lower the effect of background on educational attainment, the definitive claim of EMI is that educational expansion may fail to alter the effect of social background because the existence of qualitative positions may undermine the egalitarian impact of educational expansion. Thus, Hout's amalgam of EMI and MMI actually reflects only MMI.

In the few studies that have considered multiple theories, the empirical evidence contradicts MMI but is consistent with EMI, suggesting that any synthesis faithful to one will shortchange the other and any synthesis faithful to both will be incoherent. In the original paper on EMI, Lucas (2001) found support for MMI over LCP but support for EMI over both for 1980 U.S. sophomores. Hannah Ayalon and Yossi Shavit (2004) considered MMI and EMI in analyzing reforms of the Israeli educational system. They found that EMI offers a better explanation than MMI. Further work in Israel that focused on higher education institutions and field of study also preferred EMI (Ayalon & Yogev, 2005). If two theories disagree and analyses support one over the other, merging them is likely only to obfuscate matters.

The unhappy marriage of EMI and MMI may stem from the generality of EMI. Although EMI researchers have focused on education, EMI offers a general theory of inequality that is applicable beyond education. In contrast, MMI tenets pertain narrowly to education. Hence, pushing EMI and MMI together undermines both the reach of EMI beyond education and the utility of EMI for studies of education, a utility that has been proven in straight-up comparisons of EMI and MMI in existing research. For these reasons, combining the theories is unwise.

More research is needed to determine which of the existing theories, MMI, RRA, or EMI, best explains

patterns of socioeconomic effects on education transitions and under which conditions one theory is preferable. The selection of a theory has ramifications for the understanding of how educational attainment works and for the prospects of and methods for altering the patterns of social background effects. Thus, it is important to keep the theories distinct so that researchers can understand the dynamics of socioeconomic inequality and educational attainment.

# EMPLOYMENT, ADULTHOOD

Employment as a distinct sphere of life that entails significant training and expertise is unique to the modern world. When humans were hunters and gathers, work was not separated from leisure. People gathered or hunted food, made tools, cooked, relaxed, made shelters, and tended children in a fluid mix throughout the day. With the development of agriculture, work became more separate from leisure because tilling the fields required long and hard labor. Under classical empires such as the Mayan, Aztec, and Egyptian, many agriculturalists were enslaved and became subject peoples who worked as slaves or bonded laborers. Leisure was reduced to a minimum or disappeared. In contemporary societies, work, organized as paid employment, and leisure are highly distinct, with people working specific hours of the day and having leisure at home or in other settings different from the places where they work.

Work in modern society primarily takes the form of paid employment. Employment provides earnings that people use to buy the goods and services they once produced themselves, such as food and clothing. Modern society, however, provides a much richer set of goods and services than was available in earlier periods. An equally diverse set of industries and occupations produces those goods and services.

## DEFINING EMPLOYMENT

Employment generally is defined as work that generates earnings: either pay or, in the case of someone who is self-employed, profit. This definition highlights the modern orientation toward work as a means to acquire money. The definition of employment as paid work also necessitates the concept of unpaid work. Many household activities, such as cooking, cleaning, and mowing the lawn, require significant effort. These tasks typically are performed as unpaid labor. However, they also can be hired out to a maid, a repair person, or a lawn service company. Most people work for earnings, do quite a bit of unpaid labor, and sometimes hire out activities that they cannot do because of limited time or lack of skills. By contrast, leisure is composed of activities that people do purely for pleasure. There is a gray area, however, between unpaid work and leisure. For a parent, child care often seems like work, but it is also one of life's pleasures. Preparing a meal can be both work and a leisure activity. Shopping is a necessity and therefore is unpaid labor, but some people shop for fun. There is thus a continuum—complete with gray areas between these concepts—from leisure (activities purely for fun) to unpaid work (the chores of life) to paid employment (work for earnings). This entry focuses solely on paid employment. It is useful, however, to bear these related categories of activity in mind to understand the place of employment in people's lives.

Not everyone who would like to have a job is employed. People who lack employment but are looking actively for a job are considered unemployed. The labor force is the sum of these two groups: the employed and the unemployed. The labor force is the pool of people currently at work or available for work. The commonly reported unemployment rate is the number of unemployed (active job seekers) divided by the total labor force.

## EMPLOYMENT DEFINES PEOPLE

People's jobs define them in contemporary society. Gainful employment is a key marker of adult status. It allows financial independence and the establishment of one's

own household. Someone who is financially dependent often is treated by others as less than a full member of society with equal status and rights. Employment is thus the key to adult status.

Employment also defines people's friendship networks. Early in life people's networks are defined by their families; later they are defined by their schoolmates. After people enter the world of employment, their networks quickly shift to their work associates. This process is often accelerated by a geographic move, as in the case of a college graduate who relocates to start his or her career. However, even if new labor force entrants stay near home, they may spend so much time at work that their colleagues on the job become their new families. Old friends may slip away as one finds new friends, often with similar interests, in one's field of work.

Employment also defines a person's place in society through the level of earnings generated. In general, those in well-paid jobs live in larger homes in more exclusive neighborhoods, take more frequent and exotic vacations, and are able to send their children to expensive schools and colleges. Those who have jobs with lower earnings rent apartments or live in homes in more modest neighborhoods, take fewer and more local vacations (e.g., to visit relatives), and may struggle to help their children through college. Even politics follows employment. Many well-paid persons find sound reasoning behind Republican calls for low taxes and support of business. Those who are less well paid find greater resonance in Democratic calls for educational support, improved social services, and full employment.

Perhaps even more than friends and politics, employment defines people's identity and gives meaning to their lives. The best hours of the day, five or more days a week, and the best years of people's lives are spent working. When people introduce themselves, they most frequently say something about their work, such as, "I work at company X." Work is a foundation for identity because people get meaning and purpose from their productive activity and because many jobs in the contemporary economy are engaging or even fascinating. Practicing the skills of a doctor, lawyer, engineer, teacher, or carpenter can be rewarding. Who is a person as an adult? Most fundamentally a person is his or her job. The only status with comparable power is one's family, but with fewer children and more frequent divorce, the battle for identity increasingly is won by career rather than by family.

Along with its greater importance in people's lives, employment can bring great pressures. To the extent that others define people by their employment, people are more vulnerable to problems at work. If a person loses a job, that person may lose his or her friends, social class position, and economic security. In this context work-related problems can become major stressors in life. Fears of layoffs plague many people's lives. Bosses who bully their employees can make work unbearable; coworkers who gossip and slander can make it a nightmare.

## THEORIES OF EMPLOYMENT

Sociology has long been concerned with employment and its discontents. Karl Marx wrote eloquently on the plight of the working classes in early industrial society and provided important theoretical tools for the study of exploitation, inequality, and alienation. Émile Durkheim examined the same issues, also with great empathy, but came to different conclusions. He interpreted contemporary problems as transitory, arising from an increasing division of labor and rapid change. Those changes did divide society into warring classes, but the tension would be overcome by the emergence of new norms and values that would provide safeguards against abuse and exploitation. The new norms and values would be hammered out in employer, trade, professional, and employee associations arising from the new and more complex division of labor.

Max Weber focused less on inequality and more on the fact that in modern society people increasingly work in large bureaucratic organizations. Before the 20th century most companies were relatively small, employing at most a few dozen workers. The advent of modern industrial society has meant not only the emergence of new class conflicts but also the emergence of the modern bureaucratic form of organizing work on the basis of written rules and formal criteria for hiring and promotion. Weber recognized the immense efficiencies emerging from such regularized procedures, especially relative to earlier forms of organization that were based on nepotism and cronyism. However, he also gave voice to those who experienced bureaucracy as stifling. Prior systems were inefficient and corrupt, but bureaucracy was rigid and ungainly. Weber feared that the efficiencies of bureaucracy would lead to its inevitable spread and the eventual universal dominance of bureaucratic procedures, with the attendant stifling of creativity and initiative. Workplace innovations that allow greater initiative among self-monitoring teams are the latest response to the rule-driven nature of modern work. Their limited success in reducing bureaucracy speaks to the potency of bureaucracy and people's continuing struggles to tame it.

Modern theories of work often are grounded explicitly or implicitly in the writings of Marx, Durkheim, and Weber. However, contemporary theories have added to those broad models of societal conflict and change in at least two major areas, both of which involve a more detailed examination of the employment experience.

Sociotechnical theories focus on social interactions at work, both those between bosses and workers and those among coworkers, and on the technical and physical conditions of work. These theories grew out of the observation that employees respond much better to encouragement and humane direction than to bullying. Because of their focus on workplace social relations, these theories sometimes are called human relations approaches.

A related set of theories grew out of the observation that the formal world of bureaucratic rules and shouting bosses is often only a small part of what constitutes the lived experience of work. Employees constantly maneuver, interpret, and respond to the formal employment situation and in so doing develop their own interpretations of work. This focus on the negotiated order of the workplace highlights the constantly negotiated and renegotiated nature of work life. Even more than the human relations approach, it recognizes the employee as an active coparticipant in the employment relationship.

## METHODS OF STUDY

The methods by which contemporary sociologists learn about employment are as diverse as the topic and theories of employment. These methods can be grouped into three categories: surveys, ethnographies, and the use of archival data. All three methods rely heavily on empirical data and are thus part of the general movement in social sciences toward empiricism and away from broad social theories and philosophies.

Social surveys focus on individuals as respondents, most typically employees but also potentially managers or even chief executives. Given the chance, people love to talk about their work. Common survey themes include job satisfaction, autonomy at work, relations with management, coworker relations, job insecurity, stress, and burnout. Surveys are the major source of information about contemporary employment. In an effort to protect their interests or their self-respect, however, survey respondents are not always forthcoming about their experiences. At a minimum their responses to questions about work are filtered to be consistent with their broader sense of identity before being shared with an interviewer.

Accordingly, researchers sometimes seek more personal contact with employment situations rather than taking reports about work at face value. Such a type of contact can be obtained by shadowing a group of workers over time (nonparticipant observation) or by gaining employment in a workplace and experiencing its joys and burdens directly (participant observation). Such studies are called ethnographic accounts. Workplace ethnography is a significant genre of workplace studies and makes for interesting reading because of the details it provides about the dignity, tragedy, and humor that pervade work life. A classic example is Alvin Gouldner's (1954) *Patterns of Industrial Bureaucracy*.

The third major approach to empirical studies of the workplace uses prerecorded or archival data. Employment records; government reports on occupations, enterprises, and industries; discrimination cases; and any other event or activity that leaves a recorded trace can supply data for these studies. Archival data are particularly useful for extending observations across a range of employment situations and a greater time span, avoiding the significant limits of survey and ethnographic methods. The information from such studies has been foundational for the study of employment trends, occupational growth and decline, globalization, the spread of technology, and other pressing employment issues of the 21st century.

## EMPLOYMENT TRENDS

Two major forces drive both overall employment levels and the nature of employment in the 21st century: technology and globalization. Technological advances in recent decades built around the microprocessor and the attendant ability to collect and access information not only have created new high-technology industries but have revolutionized production across almost all industries, resulting in dramatic changes in employment. Sophisticated mechanical devices from previous waves of automation are driven by computer technologies that allow much more flexible applications. These technologies have displaced manufacturing workers, with manufacturing in the United States employing under 15% of the labor force in the first decade of the 21st century—reduced by almost half from its historical peak of 28% in 1960. Information technologies also have been applied to other industries, increasing efficiency by providing more precise information. For example, the driving routes of package delivery companies are arranged and plotted by computer at the beginning of the day. Packages are delivered quickly and precisely, but the efficiencies reduce the number of drivers needed and add to economy-wide downward pressures on employment.

Globalization contributes to these pressures through the outsourcing of lower-paid work to poorer nations. A car or computer in the early 21st century is made of components manufactured across many continents, assembled in one of them, and potentially sold in another. Companies search relentlessly for the cheapest labor, sometimes inadvertently finding that their quest undercuts the market for the goods they are producing because their own employees cannot afford those products.

As a result of the combined pressures of technology and globalization, employment in industrially advanced nations is relatively stagnant, particularly in middle-class and working-class jobs that face automation and outsourcing. Growth areas include professional occupations

***Take Our Children to Work Day.*** *Dawn Sciabaras and her daughter Torie, 7, work on Dawn's computer during Sears' 'Take Our Children to Work Day' event at its world headquarters.* AP IMAGES.

such as law, medicine, and engineering and low-wage service work such as fast-food preparation, which cannot be outsourced. However, even fast food can be automated in vending machines. Downward pressures on middle- and working-class jobs in the industrialized nations have created an increasingly divided class structure of well-paid professional and managerial workers and poorly paid service workers chronically at risk of displacement by automation and globalization.

## GLOBAL EMPLOYMENT

Americans dominate their hemisphere and have world military supremacy. The 20th century often is referred to as the American century. Futurists, however, are calling the 21st century the Asian century. Globalization thus poses a clear challenge to the era of American and perhaps even Western dominance.

European and North American industrialized nations are struggling with the problems of downward employment pressures for the working and middle classes and increasing inequality in society. However, they are managing to stay even. Incomes are stagnant, at least in the aggregate, although they are increasingly unequal. The reason for this stagnation is that increasing productivity in these nations resulting from new technologies balances the downward pressures on incomes from automation and globalization. The result is stagnation that is seen as starting as far back as the 1970s.

The rest of the world is extremely diverse. Terms such as *less developed* belie this diversity. The least developed parts of the world, such as parts sub-Saharan Africa, basically play little or no role in the world economy. They cannot compete technologically with the European and North American nations or with developing nations such as China and India. The employment situation in such nations is dire, with unemployment rates of 50% or more in some cases. In contrast, the unemployment rate in the United States hovered around 6% in the first decade of the 21st century, whereas the Great Depression of the 1930s saw U.S. employment rates of 20% or more. Such situations are ripe for civil wars and conflicts, which are prevalent in many of the least developed nations.

In developing nations such as China and India the situation is different. Stable political situations with varying levels of democracy have provided a setting for economic growth and development. The jobs lost to outsourcing in the Western nations are reborn there, at wages that are lower than those in Europe and North America but are attractive to workers forced out of agricultural pursuits by increasing mechanization. The prospects for these nations are reasonably favorable. Earnings, at least in the aggregate, are rising, although poverty is still pervasive in many rural areas. It is easy for those in Europe and North America to think of workers in India and China as competitors who now have "their" jobs and to forget that they are paid substantially less for doing them than Westerners once were paid. It is unlikely, however, that these jobs will ever return to the West, and in the current global economy the fate and earnings of these workers are linked closely to those of people in the West. Their success in winning a bigger share of the economic pie may be a precondition for the stabilization of employment in the Western nations.

## GENDER, RACE, AGE, AND EMPLOYMENT

In addition to the class inequalities arising from employment, jobs are differentiated by the groups that typically occupy them. Thus, women, members of racial and ethnic minorities, the young, and the elderly often face additional employment challenges that are changing rapidly, only sometimes for the better.

In recent decades women have experienced significant gains in employment, especially in the Western nations, and now have at least some representation across all occupations. These gains rest on federal legislation such as the Civil Rights Act of 1964, which made discrimination against women and minorities illegal. Somewhat ironically in light of the primary focus of the legislation on minorities, women have been the primary beneficiaries of this law. Women are distributed equally across the class structure, and many are able to attain college educations and take advantage of new employment opportunities. Women of poorer and working-class origins have been less advantaged by these opportunities because their class origins create barriers to securing the higher education credentials necessary for better-paid employment.

At least two fundamental challenges remain for women. First, women still have a very limited presence in engineering and related fields. Available cultural scripts for women do not support the occupational choice of engineering, and as a result few women enter these relatively well-paid professions. Second and more fundamental, cultural norms and business practices create serious hurdles to combining work and family. Job expectations, especially in the professions and management, often involve open-ended commitments of 60 to 70 hours or more per week. Jobs of this sort allow little time for raising children. The most popular current solution is to delay childbearing. Society is in an important transition period between the breadwinner-and-housewife employment model and the two-earner model.

Ethnic minorities also have benefited from the increased opportunities afforded by antidiscrimination legislation. However, their gains have been more limited, leaving many behind. Many minority group members have not been in a position to take advantage of the new employment opportunities. Decades or even centuries of discrimination have produced stark inequalities of wealth and income. In combination with residential segregation, these inequalities mean that many members of minority groups attend poorly funded public schools and thus lack the background or finances necessary for success in college. Affirmative action programs intended to lower those barriers have provided educational and employment opportunities for many minority group members. The accumulated depth of poverty in many minority neighborhoods, however, remains a formidable barrier.

There also are age barriers to employment. In the United States the wide availability of bottom-rung jobs in retail and fast food means that young people often gain some employment experience, although the skills obtained may be minimal. In other Western nations more restrictive job markets often mean lengthy training and waiting periods for employment, resulting in high youth unemployment and careers that may not start until one's middle or late twenties.

Older people also face serious employment problems. Senior employees who are laid off, often because their earnings are high relative to those of younger coworkers, may have difficulty finding comparable employment and may end up underemployed in fast-food or retail service jobs. In other parts of the world these problem are even more serious. In China, for example, the generation of 50-year-olds often is called the unlucky generation. In their youth this generation experienced a violent civil war followed by the disruptions of the Cultural Revolution. By midlife they settled into what was destined to be a very brief period of stability, only to be turned out of their employment in state-owned enterprises as those companies downsized to become more market-oriented. Older workers in many nations are targeted during downturns and in reorganizations.

## EMPLOYMENT POLICY

The most important current employment challenges are the promotion of full employment and the provision of

living wages for all workers. Most employment policies involve tax subsidies to businesses or public provision of supporting infrastructure such as utilities and roads for business parks to encourage growth. Industry-specific policies also are used to incubate new industries and product lines that can be competitive in the global market. Japan and some other developing Asian nations have used such programs to break into world markets for automobiles, electronics, and steel.

Policies for living wages are always subjects of contention because businesses do not want to pay a living wage if they can hire workers for less and argue that they will be able to hire fewer workers if they have to pay them more. The empirical support for this position is mixed. Living wages for low-wage workers mean that they can spend more, thus producing more employment as a ripple effect.

Another challenge is to develop employment practices that are family-friendly. This can mean onsite day care or flexible hours. Fundamentally, it means fewer hours of paid work. Many contemporary jobs require too many hours of work to allow for family life, leaving children to be raised in after-school programs. The insight that shorter workdays could mean more employment is not lost on policy makers, as can be seen if one considers the consequences of breaking one 70 hour per week job into two 35 hour per week jobs. Many Western European nations have promoted reduced workweeks with this rationale. In the United States, where employment policy is left almost totally in the hands of employers, such policies have not been received warmly.

## FUTURE DIRECTIONS FOR EMPLOYMENT RESEARCH

Future directions for employment research closely parallel the policy challenges noted above. Important topics include the success of competing strategies for dealing with job creation, employment discrimination, and work–family tensions. Multimethod approaches involving combinations of survey, observational, and archival data have emerged as important research strategies. When information from a variety of methods is triangulated, the limitations of any single method can be offset. Comparative research is growing in importance. In essence, the world is engaged in a massive experiment to develop effective responses to the employment challenges of the 21st century. Social science researchers thus have both a laboratory for their studies and an important role to play in identifying employment problems and developing effective policy options. The life course of adults has become more variable and uncertain as a result of the employment of the late 20th and early 21st century. New and developing methods of study have the potential to provide important guidance for developing meaningful policies to assist people in finding new pathways to stable and productive lives during these times of dramatic and continuing change.

# ETHNIC AND RACIAL IDENTITY

What does the term *racial and ethnic identity* mean? Briefly, when something is an identity, it is a part of self-concept. When something is part of self-concept, it influences how people make sense of themselves, what their goals are and how they try to achieve them, as well as the interpretations they give to others' responses to them. Racial and ethnic identity includes three basic components: (a) membership—knowledge that one is a member of particular racial and ethnic groups; (b) beliefs—beliefs about how the groups one is a member of fit into broader society and how members of these groups act, what they believe in, what their goals and values are, and the strategies they use to attain these goals; (c) action readiness—readiness to act in ways that are congruent with beliefs about group membership.

Race and ethnicity can be distinguished in theory: Racial categorization is often associated with beliefs about common physical characteristics that are thought to distinguish groups; these beliefs are often associated with power structures within a society. In contrast, ethnic categorization is often associated with assumed immigration histories and beliefs about shared nationality, history, language, and traditions. However, for a number of reasons, it may not be useful in practice to distinguish them. First, race and ethnicity are both social constructs, that is, their meaning is based on socially agreed-on categorizations, rather than on biologically meaningful categorizations. Second, both involve "imagined communities," groups with which one feels a sense of common fate or allegiance and a sense of common ancestry or kinship, whether or not one personally knows many group members. Third, in modern societies race and ethnicity intermingle. Therefore, this entry discusses racial-ethnic identities rather than attempting to separate the two concepts artificially.

Race and ethnicity are not always part of self-concept, but they often are because race and ethnicity carry social meaning and therefore are useful in making sense of oneself and one's experiences with others. As noted in the three-part operationalization of racial-ethnic identity, racial-ethnic identity includes more than simple knowledge of group membership, it includes both beliefs about one's group and readiness to take action congruent with these beliefs (see three-part operationalization, above). In this way, people's life courses will in part reflect their racial-ethnic identities.

## SELF-CONCEPT AND IDENTITY

The self is a basic cognitive structure; distinguishing self from non-self is an early developmental milestone. Self-concept is a theory about oneself, what one thinks about when one thinks about oneself; the self is experienced as content (who one was, is, and may become, how one fits in); and process (what one's goals are, what one is trying to do). The three basic self-processes are self-protection, self-improvement, and self-maintenance. Self-protection is involved when one's goal is to feel as good about oneself as possible given circumstances. Self-improvement is involved when one's goal is to critically focus on one's limitations in order to make changes for the better. Self-maintenance is involved when one's goal is to provide a stable anchor of self-knowledge from which to make predictions about self and others. A person's self-concept is involved in both intrapersonal processes (e.g., memory, motivation, and self-regulation) and interpersonal processes (e.g., interpretation of social contextual cues, reactions to feedback, relational style).

The idea of self-concept originates in the early theorizing of psychologist William James (1890). Within sociology, the term *identity* is more commonly used. However, modern usage of both terms overlaps in that individuals are assumed to define themselves with a multiplicity of self-descriptions. Thus, self-concept and identity are now seen as multidimensional, multifaceted, and dynamic structures, rooted in and sensitive to social contexts. For clarity, in this entry we operationalize the self-concept as containing diverse, potentially conflicting personal and social identities and self-schemas (cognitive generalizations about the self derived from past experience). Identities can encompass personal traits, feelings, images, and knowledge about the self as well as social memberships, social roles, and social statuses. Some of these identities are more central or "salient" to one's self-concept, while others are less central.

## RESEARCH ON RACIAL-ETHNIC IDENTITY

Theoretical development and empirical assessment of racial-ethnic identity draws on social identity theory. According to this perspective, social identities are the parts of self-concept derived from group memberships and adherence to group values (Tajfel, 1981). Social identities include at least three parts: information about group membership (that one is a member of one group and not of another), information about the nature of group boundaries (how permeable is membership, can one quit the group, how do others view one's group), and information about what it means to be a group member (including the norms, values, goals, and attitudes of one's group). From this perspective, racial-ethnic identities may influence behavior by providing information about group norms and expectations and by shaping a person's interpretation of social and contextual feedback (Oyserman, 2007). Perceived group norms can be positive. For example, Oyserman, Gant, and Ager (1995) found that when reminded of their racial-ethnic identity, African American students persisted more at math tasks if they believed that doing well in school was an in-group expectation. Perceived group norms are not always positive though. For example, Oyserman, Fryberg, and Yoder (2007) found that middle school, college-aged, and adult participants were less likely to believe that engaging in a healthy lifestyle is beneficial to one's health if they were reminded of their racial-ethnic identity and believed that people in their in-group did not engage in these behaviors.

Follow-up research suggests that among adult currently smoking African American women, smoking is more likely to be perceived as racial-ethnic identity congruent than it is among non-smokers. That is, smokers are more likely to believe that smoking was in-group normative, something that African Americans commonly do.

Social interactions are central in shaping both personal and social identities, including racial and ethnic identities (e.g., Turner, Oakes, Haslam, & McGarty, 1994). Most generally, who one is in the moment is defined in part by how one's interaction partner makes sense of oneself. In some sense, people have as many versions of themselves as they have interaction partners because different partners facilitate, encourage, and provide role models for different ways of being a self. Although active exploration of one's identity is considered

a primary developmental task during adolescence and young adulthood, self-concept and identity are not simply formed at this time and stable thereafter. Rather racial, ethnic, gender, and social class identities begin to develop in early childhood, and changes in social contexts influence identities throughout the lifespan (Demo, 1992). Whether race and ethnicity are part of identity and what this entails is likely to shift as well.

Early research on racial-ethnic identity focused on its content and possible implications for self-esteem (Clark & Clark, 1947; Proshansky & Newton, 1968). In the United States and elsewhere, this line of research focused on historically stigmatized groups (in the United States, African Americans and Jewish Americans). Researchers assumed that the experience of racism, hatred, or disdain from others toward one's racial-ethnic group would be internalized and result in self-hatred and self-disdain (Grambs, 1965; Nobles, 1973). However, the data did not support this idea, so conceptual and empirical models were refined to distinguish a sense of in-group (that is, persons sharing one's social group) worth and knowledge about out-group (that is, persons belonging to other social groups) responses (Cross, 1991). These newer models emphasized the importance of feedback from close, supportive in-group others (e.g., family, kin networks) for feelings of worth, as separate from racial-awareness, which focused on the negative attitudes and beliefs of out-group members (Gray-Little & Hafdahl, 2000; Phinney, 1996). As would be predicted by social identity theories, researchers demonstrated that a positive sense of self-worth was associated with feelings of in-group connection or pride. After the resolution of this conceptual debate, researchers developed new lines of inquiry, focused on identifying consequences of the content and structure of racial-ethnic identity for action, mood, and cognitive processes more generally.

Some evidence suggests that content of racial-ethnic identity matters in that how one describes one's racial-ethnic identity predicts behavior over time. In particular, how the connection between in-group membership and membership in broader society is described seems to influence how much individuals engage in the institutions of broader society. In terms of academic outcomes, teens who describe themselves only in terms of in-group memberships (e.g., American Indian, Black, Latino) were less likely to persist in academic tasks than teens who both described themselves in terms of in-group memberships and saw in-group members as integral members of broader American society, not as separate from broader American society (Oyserman, Kemmelmeier, Fryberg, Brosh, & Hart-Johnson, 2003). Similarly, in terms of health outcomes, women who described themselves as African American were more likely to obtain a mammography than women who described themselves as Black (Bowen, Christensen, Powers, Graves, & Anderson, 1998). In each case, it seems to be that identity terms convey beliefs about how much the in-group fits into broader society.

Research examining the content of racial-ethnic identities has shown that not all persons incorporate race-ethnicity into their identity (Oyserman et al., 2003). For some individuals, membership in a racial-ethnic group is simply a social fact about oneself, something that may be true but is not self-defining. However, in societies in which race-ethnicity is used by others to make predictions about what one is like and one's skills and abilities, not including race-ethnicity in identity is likely to leave one open to the negative psychological consequences of negative stereotypes. Race-ethnicity is likely to be incorporated into one's self-concept when it feels meaningful—when race-ethnicity has an impact on how in- and out-group others respond to oneself. Like other social identities, racial-ethnic identities are multi-dimensional; that is, one knows many things about oneself as a group member, not all of which are salient at any moment in time. Moreover, like other aspects of self-concept, racial-ethnic identities can contain competing or conflicting information. Which aspects of racial-ethnic identity are salient and influential at any moment in time will depend on social contextual cues. For example, in academic contexts, content and identity-relevant questions focused on academics (do "we" do well in school?) are likely to come to mind.

Research on racial-ethnic identities explores the ways that such identities affect well-being, motivation, goal pursuit, and behavior. Of particular interest are dimensions of identity including sense of connection to in-group, beliefs about the relationship between in-group and broader society, and beliefs about the goals, activities, and strategies effectively used by in-group members (Oyserman, 2007, in press). Sense of connectedness to the group focuses on the extent to which individuals perceive in-group membership to be central to their self-concept. Identities that are not central are less likely to be activated so are less likely to have an impact on behavior. Beliefs about the relationship between in-group and broader society are sometimes described in terms of the perceived boundaries between in-group and other groups and awareness of the attitudes of others toward one's racial or ethnic group. Knowing how others view one's in-group can provide important information about likely responses of others to oneself. More broadly, this dimension involves perceptions about the connections (or lack thereof) between in-group and broader society. The third dimension of racial-ethnic identity focuses on beliefs about in-group goals, attitudes, norms, values, and strategies. These beliefs are not necessarily accurate, but because they provide standards that are assumed to be accurate and self-relevant, they are likely to

influence one's own goals, attitudes, norms, values, and strategies. These beliefs can have powerful effects. For example, if one believes that people from one's own racial-ethnic group gain weight in middle age, one's own heavy future will feel inevitable, and, because effort to lose weight is assumed to be futile, individuals are less likely to expend effort to do so.

Once the in-group is a salient part of identity, then the other two dimensions of identity—being able to gauge how others may respond to the in-group and what in-group members are like—are more likely to shape individual behavior, perception, and motivation. Researchers differ in which of these dimensions they focus on, and individuals are likely to differ in the extent that each of these dimensions is a focus of identity (Cross, 1991; Jenkins, 1982; Sellers, Smith, Shelton, Rowley, & Chavous, 1998). When in-group membership is made situationally salient (e.g., being the only African American at a work conference), both similarity to the in-group (e.g., other African Americans) and the related meanings associated with that group identity will become prominent (Haslam, O'Brien, & Jetten, 2005; Sidanius, Van Laar, & Levin, 2004). Effects are also likely to be linked to salience of one's group in a location, profession, or social institution.

Because most research on racial-ethnic identity has focused on stigmatized groups, an important question is the extent that racial-ethnic identity predicts success across important life domains. Thus, researchers have asked about the relationship between content and structure of racial-ethnic identity and academic success in the adolescent and college years. Oyserman (in press) finds that effect of racial-ethnic identity depends on content. Simply feeling connected to in-group or being aware of racism are not sufficient to improve academic effort and outcomes; rather it is necessary to also believe that in-group members value and engage in effort to do well in school. With regard to engagement healthy lifestyle behaviors in the college years and beyond, Oyserman and colleagues (2007) find that when comparison between in-group and broader society is made salient, minority group members are less likely to believe in the efficacy of preventive health measures such as exercising as an adult if they believe that members of their group do not engage in them (or think that members of their in-group engage in risky health behaviors such as smoking cigarettes). Although research often focuses on a particular group, making sense of commonalities in impact of racial-ethnic identities across groups is beginning to be the focus of more research attention.

## FUTURE DIRECTIONS AND GAPS IN THE CURRENT LITERATURE

Literature on racial-ethnic identity has focused primarily on childhood, adolescence, and the early years of adulthood. Thus a major limitation of the research literature is the lack of attention to when and how racial-ethnic identity should matter beyond the college years. Although the previously described research gives some sense that racial-ethnic identity is likely to matter for engagement in health and health care, more needs to be done to conceptualize how racial-ethnic identity should matter to health and other aspects of adult life and to document effects over time and in real-world situations.

## IMPLICATIONS FOR POLICY

Research on racial-ethnic identity provides several implications for program development and public policy. First, this research suggests that programs and policies should highlight belongingness and connections between broader society and members of diverse racial-ethnic groups. That is, important social goals and values—including healthy lifestyle and civic engagement, education and career advancement, and effective strategies for obtaining these goals—should feel relevant to all racial-ethnic groups within a society. Second, to the extent that identities continue to be shaped over the lifespan, resources for engagement should be tailored across developmental phases. Globalization and international migration mean that societies across the world, including the United States, are becoming more diverse. Americans now reaching retirement face both the challenges of aging and the challenge of remaining engaged in an increasingly racially and ethnically diverse world.

## FAMILY PLANNING

**SEE** Volume 2: *Birth Control.*

## FAMILY AND HOUSEHOLD STRUCTURE, ADULTHOOD

Everyone has or at least had a family, and people live most of their lives in households, but the terms are complexly interrelated, in some ways very similar and in others very different. *Families* are people related by blood, marriage, or adoption; *households* are people who live together in a separate housing unit, defined by various criteria of use and privacy (and hence excluding group quarters such as hotels, college dormitories, and military barracks). Because so many close family relationships are contained within a single household, however, the two concepts are sometimes confused. Most households are still family households, that is, they include people who are related to each other, which reinforces their connection. Many other households, however, are nonfamily households, consisting of either one person or unrelated persons, such as roommates. Further, many family relationships transcend households, particularly those between generations (e.g., between parents and their adult children after they leave home). Hence these terms are related, although distinct, constructs.

### HOW CHANGING LIVING ARRANGEMENTS SHAPE FAMILIES AND HOUSEHOLDS

Both families and households changed rapidly, both in size and in composition, in the post–World War II (after 1945) period. In some ways, their changes are closely parallel. When parents have many children, households are large; when they have few children, households are small. This seems obvious, but it depends on a related concept, that of *living arrangements*. Changes in family and household size move together in response to changes in the numbers of children because in nearly every society, the vast majority of minor children live with their parents. A decline in birth rates immediately leads to smaller average household size. But for family relationships other than those of parents and young children, living arrangements can differ substantially, and hence, family changes can have very different effects on households. Further, as is discussed later, declines in fertility in the longer run have even stronger effects on reducing household size than does the immediate reduction in the number of children in households.

Consider a relatively recent change in living arrangements—the increase in independent living among unmarried persons. As recently as the period between 1940 and 1960, in the United States the increase in marriage rates among young adults meant that rates of household formation increased. By the 1970s, however, the increases in the divorce rates also meant that household formation increased. The conundrum is resolved by realizing that in the earlier period, the majority of unmarried adults (including the previously married) lived either with their parents, other relatives, or nonrelatives; by 1970 a

majority lived in independent households, often alone (Kobrin, 1976b, p. 237). Marriage was the usual route to residential independence in a separate household until 1970; since that time it has become normal for the unmarried to live independently.

Living arrangements, or who lives with whom, given the choice, are hence an important factor affecting the relationship between the numbers and structure of families and households. The rise of independent living among the unmarried has reduced household *extension* (another term that indicates whether a family household contains relatives other than a couple and their children) and increased the number of households. The people who used to live together in a single household are now spread across a greater number of households.

## WHY LIVING ARRANGEMENTS MATTER

Most research on the family pays relatively little attention to living arrangements. Studies of the likelihood of marriage are often vague about where the unmarried live before they marry or if they do not marry. Some researchers studying marriage patterns among women interpret their results as if the contrast were between getting married and remaining with parents (Michael & Tuma, 1985). By contrast, others interpret their findings to suggest that unmarried women are enjoying new opportunities of independent adulthood (Becker, 1991). Those studying men normally do not comment on alternative living arrangements to marriage at all (Hogan, 1981).

Similarly, studies of the consequences of widowhood rarely consider whether the widow(er) has remained independent or gone to live with relatives, normally children. The major change in living arrangements that has gained the attention of family scholars is more closely tied to central family processes: the rise in cohabitation. The question of whether or not it is a "family process" has received considerable attention. For example, is cohabitation an alternative to marriage with many marriage-like qualities, such as joint children? Or is it perhaps a prelude to marriage, a testing of compatibility? Or is it not a family process at all but only an economic arrangement to share living expenses, like roommates, but, as they say, "with benefits"? Or does it mean different things in different countries or at different stages of the life course (e.g., before and after divorce)? The jury is still out on this recent and dramatic change in the living arrangements of the unmarried.

Even beyond cohabitation, however, living arrangements matter a great deal. Clearly they are not the only factor shaping relationships, which can remain warm and supportive, sometimes even warmer, between those not living together. Also, as cohabiting couples normally discover, their lives change when they marry, even if they remain in the same home, because the institutionalization of marriage and the expectations of others, as well as their own expectations, reshape how they relate to each other. Nevertheless, living in the same household with another person has a major impact on any relationship, affecting as it does the sharing of space and tasks, gaining companionship, and losing privacy.

**Household Tasks** A historical perspective is important here, as not so long ago agriculture dominated most of the world's economies and the household was the center of economic production. Even in North America and the industrialized countries of western Europe, a majority of households were agricultural as recently as the beginning of the 20th century, and this state lasted even longer in the more recently industrialized countries of southern and eastern Europe, Asia, and Latin America. Married couples depended on each other's productive activities and no less on those of their children.

Although much work has left the household with the growth of the industrial and service economy, the need for other important activities persists. Even in the early 21st century, when fully independent adults decide to live together, whether for practical or romantic reasons, there are many productive activities that take place in households. Except for the very few households that can pay servants or fully outsource, there is food to be bought, prepared, and the results cleaned up; clothes to be washed and mended; and rooms to be straightened and cleaned or even sanitized, depending on the room. The benefits of shared finances still entail organizing bill-paying and account-monitoring, whereas the benefits of a shared social life still entail planning, gift-buying, and maintaining contact.

Further, the amount of work increases dramatically when the household includes dependents, such as small children or disabled adults. As noted earlier, no one questions that infants should live with parents or parent-like adults. Research on child development suggests that there are limits on the number of hours infant care that can be outsourced to institutions without there being at least some negative impact on the child (Belsky, 2001), with perhaps coresident or non-coresident nannies excepted. In addition, the demands of providing care for the elderly or disabled at home are also enormous.

Deciding who cooks, shops, does the dishes, and cleans is often a major problem for adults sharing a home, and the needs of dependent children and adults require deciding who does even more tasks. Living together does, indeed, matter. Some scholars, such as Thomas Burch and Beverly Mathews (1987), have suggested that all people would be happiest if they lived alone, coming together to share social events and occasional one-on-one time. What

motivates this approach to living arrangements is that even if all tasks (including meeting all dependents' needs) could be outsourced, there is still the matter of privacy, which for some, trumps companionship.

**Privacy and Companionship** Living with others undoubtedly reduces privacy. For those in a dependent position—adolescents vis-à-vis their parents, for example—living at home means that parents can monitor closely who their friends are, how they spend their time, and how they are feeling. This is much less of a problem for those in the less dependent position, in this case the parents, because the adolescent's knowledge of their behavior provides much less leverage (except perhaps for telling the neighbors about extreme or embarrassing behaviors or authorities about abuse); adolescents rarely have much power over their parents.

So the power differential matters. For such hierarchal relationships—whether for (near) adult children vis-à-vis their parents, the retired and perhaps disabled elderly vis-à-vis their employed midlife children, or even housewives vis-à-vis their provider husbands—having additional resources often allows the more dependent member to establish an independent residence, gaining privacy and autonomy. For the more powerful members, gains in resources simply allow them to continue to enjoy companionship and services with no loss of privacy and even more relative power. For trusting, equal relationships, however, the reduction in privacy linked with coresidence is much less of a problem. This is why many choose companionship, despite their having enough resources to live alone.

## HOW CHANGING DEMOGRAPHIC AVAILABILITY SHAPES FAMILIES AND HOUSEHOLDS

It is not always possible, however, to coreside with preferred others. An important consideration that limits who lives with whom is whether or not the person knows anyone who would be a compatible living partner. Some situations impair the formation of families, such as when there are too few young adults of a given gender relative to the numbers of their potential romantic partners. This normally occurs in situations of extensive sex-selective migration, such as when the movement of men to North America in the 19th century left many unmarried women behind, although the development of sex-selective abortion is also creating marriage market imbalances in societies with strong son preference, such as China. Large imbalances are rare, however, although even small imbalances are likely to have an effect. The marriage markets (or the pool of eligible potential spouses) for educated women, and particularly educated Black women, have narrowed (Tucker & Mitchell-Kernan, 1995).

Another change in availability, one that is the result of the demographic transition from high to low mortality and fertility, has had a more massive effect, this time on intergenerational living arrangements, sharply reducing household size. A major factor behind the increase in independent living arrangements among the unmarried—typically widowed—elderly is the result of a shift in the relative sizes of the generations: the number of children who are available for them to live with and the number of younger families who have elderly relatives available to live with them. This shift has confused analysts for a long time, particularly those studying family extension, and attaining a better understanding of it has come with difficulty (Kobrin, 1976a).

Declines in fertility and mortality, which on average have lengthened lives and reduced the number of children families have, have also reshaped generational relationships because of their effects on the relative sizes of the generations. When fertility was high, even though mortality was also high, populations were dominated by young people, both children and their relatively young parents, with few elderly. This meant that nearly all elderly persons could live with one of their children, but relatively few families would be extended by including a grandparent—there were simply too few elderly relatives to go around, and they did not live very long. In any cross-sectional count of families, very few would be extended.

Once fertility declined to approximately two children per couple, however, an increasing proportion of elderly began to have no children or grandchildren at all. Even among those who do have children, for all widows and widowers to live with a child would mean that as many as half of all families with children would experience family extension, and given the increase in longevity, this extension could last for many years. Scholars who studied trends in the proportion of families with elderly relatives living with them saw fairly stable, low levels of family extension (Laslett, 1972). Because they did not study those who did not live in families, they did not notice, as did those who studied living arrangements, that the proportion of widowed elderly living alone was skyrocketing and hence the proportion living with their adult children was falling rapidly. In the United States this revolution in the living arrangements of the elderly took place in the early 1940s. The elderly during this period had borne their children in an era of relatively high fertility in the last years of the 19th century and the early years of the 20th century. Later in the 20th century, however, the majority of elderly were the parents of relatively few children as a result of the fertility declines that followed (and even the baby boom of the 1950s did not produce large families, mostly just very young families). The ratio of middle-age to widowed elderly women (the daughter-mother ratio) had decreased sharply, from 2.7 in 1930 to 1.2 in 1973, with much slower declines

before and since (Kobrin, 1976a). Similar rapid declines occurred in Europe (Wolf, 1995).

## ETHNICITY, FAMILIES, AND HOUSEHOLDS

A particularly interesting phenomenon in the decline in household and family size in the United States is that racial and ethnic minorities, and particularly African Americans, have contributed much less to the decline than Whites. There has been an ethnic crossover in household size and structure. Prior to the rapid overall decline in household size that began in the 1940s, Black families had been less likely to include extended family members, and young Black adults had left home younger (and married earlier) than otherwise comparable Whites. By about 1970, these differences had reversed (Goldscheider & Bures, 2003). The growth in living alone was much less marked among African Americans.

Finding answers as to why the growth was less marked is a major challenge for understanding ethnic differences in family and household change in the United States. The much later move out of agriculture (in the South) and the move into the high-rent inner cities, which matched economic opportunities only for a short while in the years immediately after World War II, has meant that young African American adults have experienced extraordinarily high rates of unemployment, so that living with other family members appears to provide a financial safety net for those who need it. However, given that poverty was at least as great in rural areas, a full understanding of these ethnic differences in living arrangement trends remains elusive. Some scholars argue that higher levels of coresidence among African Americans are due to stronger kin obligations and relationships among African Americans than among Whites, but this cultural explanation has not been fully tested and in any case does not explain why extended families were less common among African Americans prior to the racial crossover.

## CONSEQUENCES OF FAMILY AND HOUSEHOLD CHANGE

An additional focus of current concern about family change is the consequences for children of experiencing alternative parental structures, whether cohabiting parents, stepparents,

or single parents. This is an important concern; however, there are several other issues regarding living arrangements that are underresearched—these include the consequences for families of the strengthened privacy preferences that have emerged with the growth in nonfamily living as well as the consequences for the environment of the more rapid growth in the numbers of households, despite slowing population growth.

Scholars studying the growth in separate living arrangements tend to celebrate it, reflecting the idea that privacy is, in economists' terms, a *normal good* or one that is consumed more as income rises. Journalists write with horror of the growth in living with or returning to live with parents among young adults (Gross, 1991). The values of companionship, and of helping out family members in need, are much less celebrated. The assumption is that these will take care of themselves.

There is evidence, however, that this is not the case. People who had the experience of having a grandparent living with their childhood family were considerably more positive about the phenomenon, so that as this experience becomes rarer, the need for outsourcing care in old age may grow. Further, women (but not men) who lived independently of family in young adulthood were less supportive of providing housing room for young adults who were struggling economically (Goldscheider & Lawton, 1998), reducing young adults' opportunity to leave an inappropriate job or relationship by returning to their parents' home.

In another study, women who had lived independently in young adulthood were considerably less approving of traditional marriage (Goldscheider & Waite, 1991). This finding should put pressure on marriage-minded young men to become more egalitarian as well. However, the alternative of nonfamily living means that the pressures for change that emerge within a loving relationship are not brought to bear on gender relationships.

Hence, the growth in the need for privacy and the reduction in willingness to use the family as an economic safety net for semidependent adults (early and late in adulthood) means that the new phenomenon of nonfamily living may have become a very expensive innovation. It is proving expensive on another dimension, as well—its impact on the environment. Coresidence leads to economies of scale; more households means that more furniture and appliances must be produced and electrified and more public rooms (the shared kitchens, bathrooms, living rooms, and dining rooms) must be heated. These costs of separate living are not trivial. The fall in household size has important implications for both families and the global environment.

# FATHERHOOD

The term *fatherhood* can mean both fertility status (i.e., whether a man has biological or adopted children) and the "behavior and identity enacted by men who have children" (Pleck, 2007, p. 196). Joe Pleck suggested that the term *fathering* may be more accurate for describing the behavior and identity aspects of fatherhood.

## FERTILITY STATUS VERSUS BEHAVIOR AND IDENTITY

Fatherhood as indicated by fertility status is achieved through one's recognition of having fathered a child, that is, by establishing the paternity of a particular child with a specific female partner. Because paternity establishment sets in motion a number of significant obligations to the child and mother, such as paying child support when fathers do not reside with their children, social scientists have paid considerable attention to this aspect of fatherhood. In contrast, fatherhood defined as an identity and a set of behaviors can apply to men in various types of relationships with a child. Stepfathers, adoptive fathers, grandfathers, and uncles may assume fathering responsibilities for a child. These men sometimes are referred to as social fathers. The links between fatherhood as indicated by fertility status and fathering behavior are also of interest. For example, several studies in nations with low fertility rates have found an association between fathering behavior and fertility: Couples are more likely to have a second child when fathers are more involved in domestic tasks (Olàh, 2003; Ronsen, 2004).

## CHANGES IN DEFINITIONS OF FATHERHOOD

A long tradition of research has examined what it means to be a father (i.e., beyond procreation) in different times and places. Margaret Mead (1969) argued that fatherhood has always been a social construction, that is, what it means to be a father varies historically and culturally.

Historians have documented how definitions of fatherhood have changed over time in the United States (LaRossa, Jaret, Gadgil, & Wynn, 2000). During the colonial era in the United States, fathers were responsible for instructing children in basic literacy, craft skills, and religion (Mintz, 1998). Fathers also were responsible for children's moral upbringing and had almost complete authority to make decisions about children's marriages, occupations, discipline, and behavior. The emergence of the Industrial Revolution in the 19th century resulted in greater separation of work and family life. Fathering during that period increasingly was viewed as a breadwinning role. At the turn of the 20th century there was a cultural and normative shift toward viewing fathers as companions to their children (Griswold, 1993). The shift occurred partially because of increasing concern that sons raised primarily by their mothers were at risk of becoming overly feminized (Mintz, 1998). The latter part of the 20th century and the early 21st century witnessed a shift toward defining fathers as nurturers (Morman & Floyd, 2006). Fathers no longer were expected to be only providers and friends to their children; they also were expected to participate in all facets of childcare and child rearing.

In some cultures the role of the father has been assumed by several males. In traditional Dakota families, the role of the father was assumed by both the biological father and *tiyospaye* fathers (paternal uncles), whose role was to teach their *tiyospaye* sons (nephews) about a man's responsibilities to his family, tribe, and nation (White, Godfrey, & Moccasin, 2006). The biological father provided nurturance but never disciplined his children. Having more than one father is not uncommon in the modern era; children may relate on a regular basis to both a stepfather and a biological father. Although the role responsibilities of stepfathers and nonresident biological fathers are not clearly defined, these men often communicate with each other about their respective responsibilities to the child (Marsiglio, 2006).

Michael Lamb (2000) suggested that although the definition of fathering has changed over time, there is much more consensus in any historical period on what it means to be a mother than on what it means to be a father. In most societies the mother has assumed the primary caregiving role, and the definition of her role has remained fairly constant. Feminists argue that because most societies are patriarchal, men determine who assumes privileged roles such as provider and who assumes low-status roles such as caregiver. Others argue that social and economic forces have had a strong influence on expectations for fathers (Doherty, Kouneski, & Erickson, 1998). For example, in

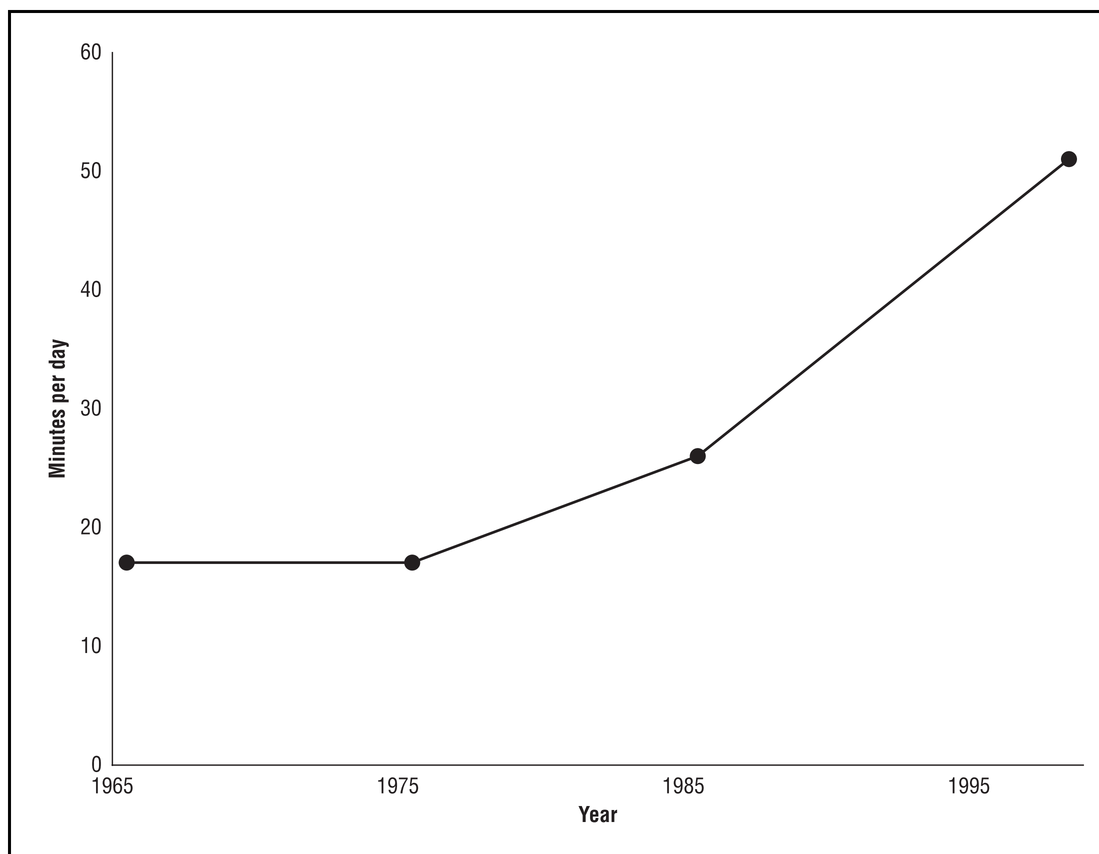

***Figure 1.*** *Married fathers' time spent on child care activities in U.S.* CENGAGE LEARNING, GALE.

the United States during most of the 20th century, fathers' economic responsibilities and military obligations often kept them on the outskirts of family life and minimally involved in the care of their children even though experts in child rearing encouraged fathers to become more involved in their children's daily lives (Neumann, 1926).

## TRENDS IN FATHERING

There has been considerable debate among researchers about how best to measure trends in fathering over time. One study (Lamb, Pleck, Charnov, & Levine, 1987) suggested that fathering behavior has three dimensions: (a) engagement, or fathers' shared interactions with their children; (b) accessibility, or a father's availability to a child whether or not he is directly engaged with that child; and (c) responsibility, or a father's organizing and planning activities in relation to a child and provision of resources to that child. These dimensions have been used in many cross-cultural studies. Although each of these dimensions of fathering is important throughout a child's development, fathers' engagement, accessibility, and responsibility vary within each developmental stage. For example, researchers have found that fathers' engagement with children increases between infancy and preschool. Trend studies most frequently examine levels of fathers' engagement with and accessibility to their children; few have focused on responsibility.

The research literature has documented a clear increase during the last three decades of the 20th century and the first decade of the 21st in the degree to which fathers who coreside with their children in the United States are actively involved with their children (see Figure 1). However, there has been considerable debate among researchers about the extent to which this change is meaningful. Findings from time diary studies reveal that between 1965 and 1998 married fathers engaged more frequently in childcare activities and spent more time in those activities each day (Sayer, Bianchi, & Robinson, 2004). About 40% of fathers reported providing childcare (including daily care, teaching, and play) on any specific day in 1965, whereas more than one half of fathers reported childcare activity in 1998. In addition, the amount of time married fathers spent in childcare activities increased from 17 minutes per day in 1965 to 51 minutes in 1998.

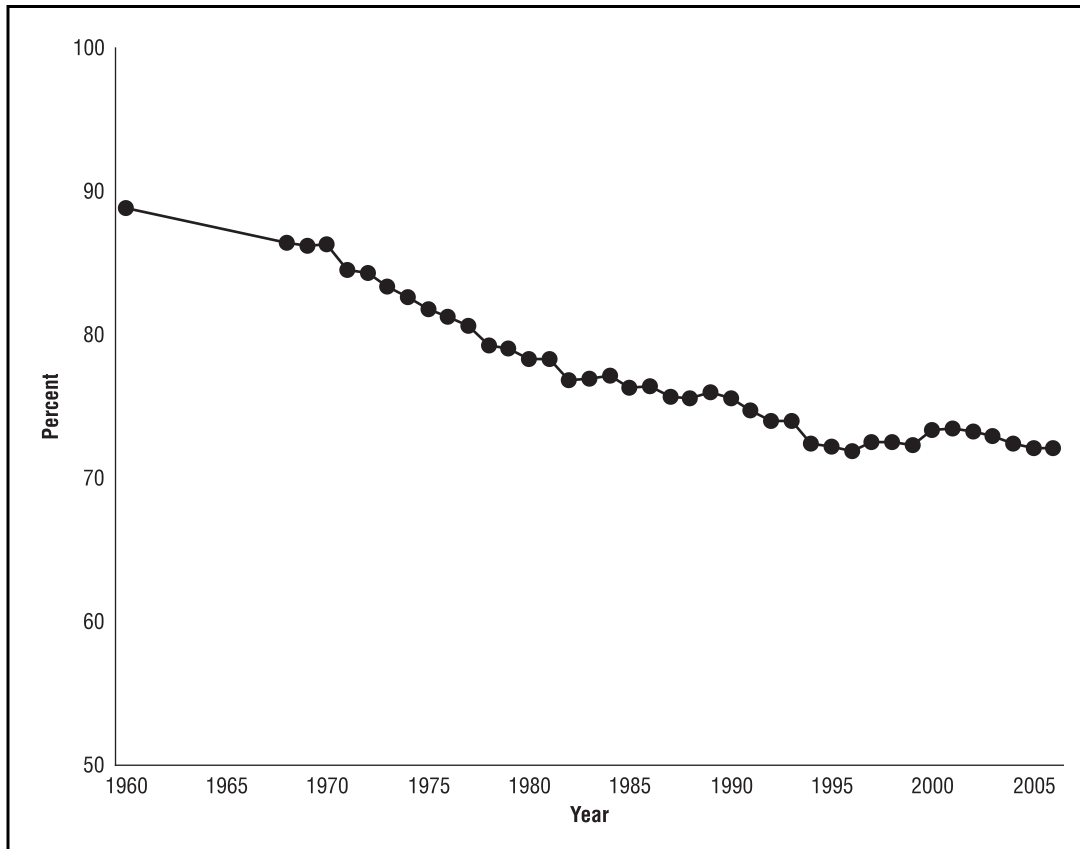

***Figure 2.*** *Children under 18 living with father in U.S.* CENGAGE LEARNING, GALE.

Several researchers have argued that the increase in fathers' involvement should be viewed within the context of mothers' time spent providing childcare to children, which also increased considerably in that period (Sayer, Bianchi, & Robinson, 2004). Married and cohabiting mothers who are employed full-time in the labor force spend about the same amount of time in direct childcare activity per day as did married and cohabiting mothers who were not in the labor force in the 1960s (Bianchi, Robinson, & Milkie, 2006, Gauthier, Smeeding, & Furstenberg, 2004). Annette Lareau (2003) suggested that a culture of concerted cultivation of children explains why parents maximize the time they spend with their children. In addition, critics of research documenting increasing levels of father involvement with children point out that the additional three quarters of an hour per day of childcare is trivial in light of the considerable increase in mothers' participation in the labor force during that period.

The increase in involvement with children has taken place primarily among residential fathers. However, during the same period the proportion of children who do not reside with their fathers has increased (see Figure 2). Approximately 72% of U.S. children under age 18 lived with their fathers in 2006, compared with 89% in 1960 (U.S. Census Bureau, 2006, 2008). Data from the 1999 National Survey of America's Families revealed that 34% of children living with single mothers who were not married at the time the child was born did not visit their nonresident fathers in the previous year (Koball & Principe, 2002). Taken together, the findings suggest an upward trend for residential fathers' involvement with their children and a downward trend for nonresidential fathers' involvement.

Various explanations have been provided for this phenomenon. Ralph LaRossa and colleagues (2000) suggested that cultural norms often change more quickly than does actual behavior. This suggests that there may be some unevenness in behavioral change, with some groups of fathers (residential fathers) showing evidence of increased involvement with their children and other groups of fathers (nonresidential fathers) showing no change or even less involvement. Other researchers have suggested that although the norms for father involvement have changed, situational factors often interfere with fathers' ability to stay involved with their children (Marsiglio, Roy, & Fox, 2005). For example, whether

## STAY AT HOME DADS

Although fathers constitute only a small proportion of primary caregiver parents in the United States (less than 1.5% in 2006), the number of fathers who cared for children at home for a full year while their spouses were in the labor force increased nearly two and a half times between 1995 and 2006—from 64,000 to 159,000 (U.S. Census Bureau, 2007). Primary caregiver fathers challenge traditional ideas about masculinity and gendered family roles. In a study of at-home fathers in Australia, Belgium, Sweden, and the United States, Laura Merla (in press) found that men dealt with their primary caregiving role by adapting traditional definitions of masculinity. Some fathers rejected the importance of paid work and integrated their childcare role into a masculine self-definition. Other fathers developed an alternative form of masculinity that incorporated a feminine side or rejected traditional masculinity in favor of "androgyny." Andrea Doucet (2004) found that many Canadian fathers who were primary caregivers retained close ties to paid work and contributed to the family income, reinforcing their masculinity. In addition to identity issues, at-home fathers face problems such as social isolation. Web sites and blogs attempt to link at-home fathers with one another.

the father ever resided with the child is an important influence on nonresidential father involvement. Fathers are likely to form bonds with their children when they reside in the same household. The father's bond to the child and the child's attachment to the father can have a strong influence on fathers' continued involvement with the child after the father leaves.

On the basis of findings suggesting that a father's residence with a child is critical for his active presence in the life of the child, researchers sometimes have concluded that parental marriage is better for father–child relationships than is cohabitation (i.e., unmarried residential arrangements). Although a substantial body of literature has documented that marital relationships are more stable than cohabiting relationships (Seltzer, 2000), researchers seldom have been able to isolate the effects of these relationship patterns on paternal involvement with children. However, a study using the Fragile Families and Child Well-Being data, a longitudinal study of a cohort of children born in large U.S. cities between 1998 and 2000 primarily to unmarried couples, examined father involvement among a subset of fathers who previously were married or cohabitating with the mother when the child was an infant but no longer were living together or romantically involved when the child was 3 years old (Laughlin, Farrie, & Fagan, 2008). Mothers reported that previously cohabiting fathers were more competent fathers and had more contact with their children after separation. Marriage may benefit families in some ways, but cohabitation may provide unique benefits that are not well understood.

### THEORETICAL APPROACHES

Four theoretical perspectives are important for understanding fathering: life course theory, developmental theory, the ecological perspective, and sociological theory. The life course perspective highlights individuals' trajectories of social roles and transitions and the implications of those trajectories for those individuals (Elder, 1998). In addition to acquiring a major social role with associated expectations and obligations, a man making the transition to fatherhood may experience life-altering changes in other areas of his life, including employment, his relationship with the child's partner, his own social behaviors, and his identity as a father. Depending on social and historical circumstances, these life transitions may be stressful or exciting and may lead to positive or negative changes that can set the father on a trajectory of more or less involved parenting (Elder, 1998). The life course perspective also suggests continuity over time in family relationships. For example, noncustodial fathers' commitment to their adolescent children was associated strongly with father–child relationships in early adulthood (Aquilino, 2006). The life course perspective also emphasizes the ways in which individuals' lives are linked to the lives of others, especially others within the family. Thus, events in a father's life such as losing a job reverberate in the life of his child and affect the child's well-being. In the same way, events in a child's life such as a critical illness affect the life of the child's father.

Central to the life course perspective is the concept of the timing of life events (Elder, 1998). Being involved early in the transition (at birth) gives a man the opportunity to develop a relationship with his unborn child, and that may strengthen his commitment and engagement over time (Cabrera, Fagan, & Farrie, in press). It is also important to consider timing in terms of the age at which a man becomes a father. Fathering a child during adolescence can have detrimental consequences for the father's life experiences, including lower educational attainment (Rhein et al., 1997), higher rates of drug use and engagement in illegal activities (Fagot, Pears, Capaldi, Crosby, & Leve, 1998), and more psychological problems (Vaz, Smolen, & Miller, 1983) compared with

the father's peers. Early fatherhood may have a negative effect on the social and emotional development of the child as adolescent fathers' exposure to these risk factors may lead to decreased involvement with their children over time (Farrie, Lee, & Fagan, 2008).

Developmental theory based on Erik Erikson's (1950) stages of psychosocial development has been used to understand fathering across the life course (Snarey, 1993). In Erikson's theory, a mature young adult is one who has a psychological and social need to nurture the next generation. Fathering is not seen simply as a social role defined by external forces; instead, generative fathering is considered a developmental process that requires continuous efforts to move toward mastery of parenting (Hawkins & Dollahite, 1997). Fathering is viewed as a process of growth and development within the man. The father's sense of well-being is closely tied to his involvement with his children in meeting their developmental needs. The value of the generative fathering framework is that it deemphasizes thinking about fathers as deficient and emphasizes fathers' potentials for growth.

The ecological systems perspective refers to the multiple influences on fathers' behavior and stresses the interrelatedness among those influences (Bronfenbrenner, 1986). A father's behavior is structured by his individual characteristics and his relationships with other members of his immediate social circle as well as by the larger structures (political, economic) in which individuals operate. However, rather than focusing on the interplay among these roles, most research has focused on fathers in relation to their close social relationships. For example, an increasing number of studies have shown the significance of the father–mother dyad relationship in relation to the father–child relationship (Doherty & Beaton, 2004). Recent studies also have addressed structural-level influences (the role of governmental and social policy). For example, research has shown that stricter child support enforcement policies in the United States have been associated with increased father involvement with children in the households of never-married mothers (Huang, 2006). An important contribution of the ecological systems perspective is the finding that fathering appears to be more sensitive to environmental influences (e.g., marital stress) than is mothering (Doherty, Kouneski, & Erickson, 1998).

Sociological theory focuses on fathers' personal and interpersonal resources. A person's set of skills and knowledge, such as educational attainment, personality traits, work habits, and occupational skills, is referred to as human capital (Coleman, 1990). Fathers who have made investments in their personal success have a positive influence on their children's outcomes. Studies have shown that fathers' educational achievement is significantly correlated with children's academic success (Amato, 1998). Social capital theory suggests that the resources that are generated as a result of relationships between people can affect a father's influence on his children (Amato, 1998). Fathers who have a diverse set of friends and acquaintances can expose their children to a wide variety of experiences and perhaps garner resources to aid in their development. Social capital studies have revealed more positive child outcomes when fathers are more engaged with their children and when the quality of their interactions with their children is high (Marsiglio, Amato, Day, & Lamb, 2000).

## FUTURE DIRECTIONS FOR RESEARCH

Early studies of fathers' influences on children made some of the same mistakes that were made in research on mothers' influences on children: The mother–child or father–child relationship was examined without regard for the impact of the other parent or the larger family and social context. Recent studies have begun to address this oversight by including both mothers and fathers (Davidov & Grusec, 2006). The potential for researchers to examine child outcomes within the context of the entire family and the larger social context has increased with the availability of large longitudinal data sets such as the Early Childhood Longitudinal Study: Birth Cohort and the Early Head Start Research and Evaluation Project: Fathers' Study (Cabrera et al., 2004).

Little research has examined fathering across the life course. Few studies have addressed the effects of having children on men from the time when they become fathers though older adulthood. Research on men tends to examine their development in the context of work, relationships, communities, and families (Levinson, 1986) but seldom in relation to fathering; an exception is the work of Rob Palkovitz (2002). For example, there has been little research on how men's development is affected by raising children during adolescence, which can be a difficult time for many parents. Also, little is known about the development of men who do not reside with their children. A fruitful area for research would be the development of men in different types of relationships with their children.

Finally, few studies have examined the ways in which social policies affect fathers' relationships with their children. Fathering-related policies in the United States have focused on low-income nonresidential fathers. The 1996 Personal Responsibility and Work Opportunity Act, which requires parents (mostly mothers) receiving public assistance to be gainfully employed within 2 years after first receiving assistance, specified as one of its major objectives increasing children's access to both parents. The Act allows states to use federal money to develop programs that increase the employability of fathers. One assumption guiding this policy is that low-income

***Fathers Taking Leave.*** *Tim Waddill changes Chase, his newborn twin son's diaper, left, as Stephanie Waddill, back, gives a bottle to their other twin boy, Connor, at their home in Irving, TX.* AP IMAGES.

nonresidential fathers who are more employable are likely to provide financial support to their children, stay involved in their children's lives, and lift their children out of poverty. Research is needed to examine the influence of this policy initiative on fathers and children.

# FLEXIBLE WORK ARRANGEMENTS

The term *flexible work arrangements* describes a number of alternative work options (including flextime and telecommuting) that allow work to be done at times and in places outside the standard workday. These arrangements

are especially important to workers at different stages in the life course, particularly dual-career couples and single working parents with young children. The related term *flexibility*, however, also characterizes the wide range of employment arrangements that exist outside the standard full-time, continuous-employment contract. These arrangements include temporary, contingent, seasonal, and contracting work. Unlike the first type of flexibility, these arrangements benefit not so much employees as the needs of employers to cut labor and benefit costs.

Although it is doubtful that the majority of workers in industrial economies such as the United States ever worked the so-called standard full-time workday, there is evidence that even fewer did so in the period from the early 1980s into the first years of the 21st century. ''Flexibility'' has been called the slogan of the emerging postindustrial economy and associated life cycle. Flexible work arrangements are contrasted with the ''rigid'' work arrangements of industrial economies (e.g., assembly line manufacturing, or clerical office work) and with ''linear'' life-cycle stages—that is, the assumption of lockstep progression through school, work, and retirement. In the new, flexible arrangements individuals may experience all three of these stages simultaneously.

Rigid work arrangements were best suited to the mass production of consumer goods where markets for the goods and for the workers producing them remained relatively stable from year to year, such as the U.S. auto and home appliance industries of the 1950s and 1960s. Such stability led firms to hire workers on a semipermanent basis, thus allowing within-firm career mobility paths and generous health and retirement benefits for workers. In contrast, the postindustrial economy is based on providing rapidly changing consumer services within globally competitive markets with a demographically diverse workforce. Increasing the flexibility of work arrangements, including legal definitions of who is eligible for work, is argued to be better suited for this new system by advocates for both employees and employers, although the two sides emphasize different forms of flexibility.

Employee preferences for more flexible work arrangements are strongly related to one's stage in the life course. The increasing presence of married women, especially those with young children, in the labor force has led many employers to initiate family-friendly work-flexible programs, such as flextime, compressed workweeks, reduced hours, and telecommuting, in order to attract and retain highly skilled and valued workers, especially professional women. Working mothers with young children also are the demographic group that is most likely to prefer nonstandard weekday shifts (e.g., evenings, nights, weekends), for personal and family reasons, such as childcare. The combination of workers retiring at younger ages but living longer has increased preferences among retirement-age workers for jobs that allow them to reenter or continue in the labor force, often on a less than full-time basis.

Some firms have addressed these preferences by allowing workers to ''phase down'' to retirement by reducing their job duties and responsibilities before retirement. Older workers without such arrangements often take new jobs at or after retirement, such as greeters at retail stores. These jobs bridge the financial gap between career and complete retirement. Also, as flatter, less hierarchical organizational structures have reduced traditional ''intra-firm'' (internal labor market) career paths, many younger, Generation X workers, especially those with highly sought-after professional or technical skills, have developed preferences for inter-firm or ''portfolio'' careers as self-employed independent contractors who sell their skills to firms for a set period of time or for a particular product. Flexibility is considered a characteristic of a ''good'' job, when it is sought out as a way for employees to meet their personal and family needs.

The origins of employer preferences for flexible work arrangements are quite different. Although some employers have embraced programs such as flextime and phased retirement to respond to employee preferences, the primary employer motivation for initiating work flexibility has been to better cope with rapidly changing technological changes and consumer preferences that characterize many new product and service markets, such as the computer software and hardware markets. Many firms also seek flexible staffing to cope with the profit squeeze created by increased foreign competition and rising costs of employee health care and pension benefits. In such cases, the flexibility stems from how employers staff jobs, rather than when and where the work is done. Thus, many employers have developed flexible strategies that externalize employee contracts and benefits via the use of temporary agencies or by hiring independent contractors. Other employers have replaced their employees with part-time or contingent workers (or redefined them so), and such workers have no psychological or legal expectations for continued employment.

These trends have been aided by the decline in union membership and influence, which has enabled employers to undo the collectively bargained fixed work rules and defined benefits that were common in industrial production. More flexible staffing arrangements are also consistent with new managerial theories and practices that cut costs by eliminating middle-management positions and thus ''flatten'' organizational hierarchies. In turn, these changes have reduced intra-firm job mobility while making employees more responsible for their own training and career, using the disincentive of job insecurity. In this context, flexibility is associated with bad jobs.

## SHIFT WORK

The most common alternate, if not flexible, work arrangement involves the wide variety of times when workers do their jobs. A worker's job shift defines both the number of hours worked in a week and which hours and days are worked. In the United States, the standard shift is considered to be a fixed daytime, 35 to 40 hours per week, 5 days per week, Monday through Friday schedule. However, according to data from the 1997 Current Population Survey (CPS) of the U.S. Census Bureau and the Bureau of Labor Statistics, by the end of the 20th century fewer than half of adult workers (43%) worked the standard 35 to 40 hours per week. Another 25% worked more than 40 hours, and 22% worked part-time—that is, fewer than 35 hours per week. In addition, in terms of which hours and days one worked, only 3 in 10 adult U.S. workers were employed on the standard weekday shift. Nonstandard shifts include evenings, nights, rotating shifts, being on call, compressed hours, weekends, and multiple combinations of different days and times, including flexible work schedules. The most common nonstandard arrangement was weekend work; 23% of all workers worked at least one weekend day. Weekend work was slightly more common among part-time workers (24%) and was especially common among those working more than 40 hours (30.5%). The most common nonstandard hourly shift was fixed evenings, worked by 6% of all full-time workers and 14% of part-timers.

Men were somewhat more likely than women to work both nonstandard hours (21.1% vs. 18.6%) and nonstandard days (40.3% vs. 38.9%, respectively). Men were more likely to work fixed nights (between midnight and 8 a.m.), weekends, and on rotating shifts in which the shift times change periodically. By contrast, women were more likely to work fewer than 5 days per week because of the higher percentage of women working part-time (30% to 14%). African Americans and Hispanics were more likely than Whites to work nonstandard shifts, whereas increasing age and years of education reduced the likelihood of doing so. Married workers with a coresidential spouse were less likely to work nonstandard shifts than workers in other marital categories. Having school-age or younger children also reduced the likelihood of women, but not men, working nonstandard shifts.

Work shifts, however, are primarily determined by the occupation and industry in which one works. Those working in retail sales and personal services were most likely to work nonstandard shifts, especially waiters/waitresses, cashiers, and supervisors and proprietors in these industries. Well over half of workers in these categories worked nonstandard hours and especially nonstandard days. For example, a full 84% of male waiters and 76% of female waitresses worked weekends. Just 10 specific occupations accounted for one-third of all nonstandard workers, and 8 of the 10 were jobs in the retail and personal services. The other 2 occupations were truck drivers and nurses. Professional and administrative support workers were least likely to work nonstandard shifts (especially hours), particularly if they were government employees.

Most workers—two-thirds of male and half of female employees—cited job requirements as the reason why they held nonstandard shifts. Family considerations and day-care arrangements were also a chief concern among mothers (but not fathers) of preschool-age children. Thus, at least for one sizable segment of the workforce, shift work may be used as a strategy for balancing work and family demands. Likewise, three-fourths of part-time workers kept their reduced hours voluntarily, although an increasing number reported working part-time because they had been unable to find full-time work. For most other workers, shifts appear more fixed than flexible.

Since the 1970s most research on shift work has centered its effects on the well-being of workers and their families. In this area, there is one key question: Is nonstandard work a strategy for balancing work–family demands or a cause of work–family conflict and instability? This question is particularly salient when attempting to understand the work choices of the current cohorts of adults, given the increases in women's labor force participation and the overall number of hours worked by Americans at their jobs. Given these shifts, workers have far less time available for family and leisure activities. The evidence is mixed but does suggest that working nonstandard shifts—especially rotating and weekends—reduces interaction among spouses and their children and interferes with family obligations.

An even longer standing concern, dating back at least to the 1950s, is the health effects of nonstandard shifts. Working nonstandard hours, especially nights and rotating shifts, is thought to create physiological and psychological adjustment problems by disrupting human circadian rhythms and sleeping and eating patterns. As a result, some research shows that workers of nonstandard schedules have elevated risks for cardiovascular and coronary problems, diabetes, gastrointestinal and digestive problems, on-the-job injuries, depression, and alcoholism. The overall results, however, are mixed and inconclusive.

Research is also inconclusive with respect to the prevalence of nonstandard shifts. Although the assumption is that the growth of service industries and the globalization of markets has created a 24/7 economy

***Working at Home.*** *Technology has made it easier for parents to balance time between home and work.* © STEFANIE GREWEL/ZEFA/CORBIS.

necessitating round-the-clock operations, there is no direct evidence that nonstandard shifts are more common in the early 21st century than they were during the 1950s or 1960s. The exception is the expansion of part-time work, which increased from 13% of the workforce in the 1950s to 22% in 1997. Data limitations have prevented the systematic study of nonstandard work over recent decades. Although the CPS has periodically included supplements with questions on work schedules since 1973, the survey questions on specific work hours are not asked consistently. Questions regarding specific workdays were not introduced until 1991. The assumption of increased nonstandard schedules rests primarily on the relative growth rates of jobs with high rates of nonstandard workers and demographic projections for continued rapid growth, such as nursing, food preparation and serving, retail sales security guards, and waitresses/waiters.

## FLEXTIME

Flextime is a type of work schedule that allows employees to vary the times they work on a periodic basis, by starting and ending the workday early or late, or by compressing weekly work hours into fewer days (e.g., working 10 hours per day for 4 days). Flextime may be a formal company policy establishing the limits of flexibility. For instance, workers may have the option of starting work within the 2-hour window of 7 to 9 a.m. and ending the workday between 4 and 6 p.m., provided they put in a full day of work. By contrast, flexible hours may be an informal attribute of a job, such as with college professors, who often choose their own work hours. In both formal and informal flextime there are likely to be core times in which employees must be at their jobs.

Since the early 1990s employers have increasingly adopted flextime policies. According to a 2001 survey, 59% of employers offered flextime to some or all of their employees, an increase of 21% since the early 1990s. In a separate 2001 survey of employees, however, only 29% reported working on flexible schedules. This disparity between employer-reported availability and actual use points to the major issue in the flextime literature: the mismatch between its availability and its use. Many workers who have access to flextime may not need it,

such as older workers who are not caring for young children or elderly parents. Other workers who could use flextime often do not take it because of informal employer or coworker pressures not to, or because they fear it will negatively affect their career advancement by signaling that family obligations are more important than work obligations, as in the case of the "mommy track."

Surveys of employee preferences have consistently found that working a flexible schedule is a highly desired job characteristic, primarily because it helps balance work and family demands. Out of all working parents, 80% regarded it as an important and sought-after job attribute; 80% of those who lacked access to flextime desired it; 25% said they were considering changing jobs or employers in order to work on a more flexible schedule, even if it would reduce their opportunities for career advancement. Conversely, working inflexible schedules is second only to number of hours worked as a reason for not spending more time with family.

Employers also see the benefits of flextime in reducing job stress, employee turnover, absenteeism, and tardiness while increasing satisfaction and morale, as well as the ultimate benefits of recruiting and retaining highly skilled workers, thus improving organizational performance. Nevertheless, although some evidence shows that flextime improves employee morale and reduces absenteeism, there is no consistent evidence that it increases employee productivity or organizational performance. Moreover, flextime may be of limited practical use to employers because, unlike many job benefits such as health insurance or pensions, it is best suited to the idiosyncratic needs of particular individual workers, regardless of job, such as mothers of young children or those caring for elderly parents, rather than all workers in particular jobs, such as all female lawyers.

The result, as pointed out above, is underutilization of flextime and a mismatch between those who would benefit most and those who have access and use it. As with job shifts in general, flextime is characteristic of the job and not of the demographic characteristics of workers. Although women and African American workers express the strongest desire for flextime, those with greatest access include males, especially married males with children; college-educated, professional, managerial, and sales workers; workers in private household and agricultural occupations; and both those working more than 40 hours per week and those working fewer than 40 hours. Actual use of flextime is greatest among married, high-income, professional, managerial, and sales workers. Age, race, and having school-age children, however, did not increase use of flextime, even when available. Finally, and perhaps because of the disparity between preferences for flextime and who has access to and uses flextime, the evidence is only mixed as to whether these work arrangements actually help workers balance work and family demands.

## HOME-BASED WORK AND TELECOMMUTING

Working at home is not a new work arrangement; indeed, it dates back to the old "putting out" or "cottage" system of the late Middle Ages (and much farther back if one considers agrarian economies). What is new and potentially flexible is the form known as telecommuting. This is an arrangement that allows workers to do work from home or other locations away from the normal work site. Advances in technology, such as computers, fax machines, and cell phones, facilitate communications between off-site workers and a central office, or a "virtual office" in the extreme case in which there is no longer a physical central office.

The term *telecommuting* was introduced and first used by firms in 1970s as a way to make them less vulnerable to fuel shortages during the oil embargo imposed by the Organization of Petroleum Exporting Countries (OPEC). Estimates of the number of workers who telecommute in the United States vary greatly, as such estimates depend on the frequency with which an employee works from home. By the early 1990s it was estimated that between 3% and 8% of workers worked from home at least 1 day per week. The raw number of telecommuters had increased from 1 million in the mid-1970s to more than 8 million by the early 1990s and has continued to grow by roughly 20% per year. In 2000 the U.S. Department of Labor estimated that between 13% and 19% of U.S. workers telecommuted on a regular basis.

As with flextime, the benefits of telecommuting for workers are thought to include increased control over job schedules, which helps balance work–family demands. Telecommuting also reduces commute-related stress and time and saves on fuel and other transportation costs. In addition, telecommuting allows the employer to cut costs related to office space and energy use. Also, because employees no longer have to live within physical commuting distance, companies may hire from a wider pool of potential talent. Society also benefits through reduction of air pollution, fuel use, and traffic congestion.

Telecommuting, however, also has potentially serious drawbacks. For the telecommuter, there is the isolation from coworkers and professional networks and the loss of both a social support system and career contacts and mentors. Working from home also may increase family demands, particularly if one has young children, or other competing family obligations. It can also increase work demands. The technology that facilitates

telecommuting also can make the worker "available" to the employer 24/7. For employers, the major drawback is the challenge telecommuting poses for monitoring the work of off-site employees. This is an important issue for employers, especially in the absence of definitive data comparing the productivity of telecommuters with that of on-site workers.

The characteristics of workers who telecommute are generally similar to those who have access to flextime. College-educated, professional, managerial, and sales workers and, to a lesser degree, private household workers were more likely to telecommute, as were married workers, especially if they had a spouse at home. Unlike with flextime, however, women were more likely to telecommute than men, as were both mothers and fathers of preschool children. Working long hours, especially more than 50 per week, substantially increased the likelihood of telecommuting. Such trend data are difficult to interpret, however. It is unclear whether those who work long hours use telecommuting as a strategy for balancing work and family demands or at least meeting work demands, or whether the telecommuting technology makes them available to work longer hours. Telecommuting is also strongly related to working a flexible schedule, particularly having the ability to adjust one's schedule on a daily basis.

## FLEXIBLE EMPLOYMENT STAFFING ARRANGEMENTS

Flexible employment relations, also commonly referred to as nonstandard, alternative, or market-mediated work arrangements, consist of temporary, contingent, seasonal, and contract (consulting) work. These diverse categories share one common factor: Employees are not continuous employees for the firm for which their work is done. For the most part, these arrangements are structured by the preferences of employers and not employees.

**Temporary, Contingent, and Seasonal Employment** In contrast with part-time employment, which may be regular, long-term employment, temporary, contingent, and seasonal employment is by definition short-term employment. Most temporary employment arrangements involve externalization of responsibility and control of labor through third-party temporary help agencies. Although they have been around since the 1920s, it was only after 1972 that employment through these agencies experienced rapid growth, at more than 11% per year, from 0.3% of the U.S. workforce in 1972 to 2.5% by the late 1990s. Since the mid-1990s, however, the growth rate has slowed considerably. The primary impetus for growth appeared to come from employer strategies of meeting cyclical changes in staffing needs; hiring through temporary employment agencies allows firms to add or reduce staff on an as-needed basis. Firms also use temporary agencies to lessen their recruitment and training costs and to externalize employee benefits, which are provided by the agency.

Temporary help agency employees are more likely to be women, Black or Hispanic, and under the age of 35. They are most likely to be hired for work in manufacturing and service industries and in administrative support and labor occupations. Of all temporary employees, 60% are involuntary in that they prefer permanent employment with a firm but have been unable to secure such employment. Some employees use temporary agencies to acquire job skills and experience in order to find permanent employment. Data are mixed as to how successful they are able to do so. One study using national CPS data found that 52% of temporary workers had changed employers 1 year later; the data do not reveal, however, whether they had found permanent employment or changed agencies. Temporary workers are paid an average of one-third less than regular employees; however, temporary engineers and technicians often earn more than their counterparts in regular jobs. Even among higher paid temps, fringe benefits are fewer and more limited than those of regular workers.

The Bureau of Labor Statistics defines contingent employment arrangements, including seasonal and on-call employment, as those having no implicit (or explicit) long-term contract. They involve fixed-term contracts or no contracts at all. Unlike temporary workers who are employed by third-party help agencies, most contingent workers are hired and paid directly by the firm for which they will do the work. Based on these characteristics, in 2001 about 5% of the U.S. workforce was contingent. Almost 40% of U.S establishments use contingent workers, most commonly in industries with low-cost production strategies. The most common reason for hiring contingent workers is to meet seasonal demands, such as retail workers during holiday seasons, summer workers in tourism, or farm workers during harvests. Seasonal farm laborers make up 42% of all contingent workers. Contingent workers also help employers with special projects and unexpected increases in demand and fill in for regular workers who are absent. Although there is a lack of good data on overall trends in contingent employment, a decline in nonfarm contingent workers during the late 1990s appeared to be related to the expansion of the U.S. economy and a tightening of the labor market. The need for seasonal farm labor, in contrast, has remained stable.

**Contracting and Consulting Work** Contracting or consulting workers may be employed by a firm or they may be self-employed. Contracting firms operate like temporary

help agencies except much of the work done for clients may be done off-site, in which case it is labeled "subcontracting." Since the 1980s the use of contract firms has spread throughout U.S. industries, from business consulting firms to data processing to janitorial services, as more firms have sought to externalize labor and production costs by outsourcing these activities.

Contracting may also be done by independent, self-employed workers. Unlike employees, whose work and compensation is defined by the amount of labor expended, independent contractors are generally given specifications for a final product and they decide how best to accomplish it. Thus, independent contractors enjoy greater autonomy over their work, but they bear the economic risk of their employment, while providing their own benefits and being solely responsible for paying Social Security and unemployment compensation taxes. Moreover, many independent contractors are really not that "independent" because much of their work comes from one firm rather than from many.

There are no definitive data on the number of independent contractors in the United States, but according to 1997 CPS data, 7% of workers self-identified as such. Another 5% to 6% of workers identified themselves as self-employed but not as independent contractors. Despite the lack of objective data on employment trends for independent contracting, researchers assume that this type of employment substantially increased since the 1970s because of changes in the U.S. tax code that facilitated and even required some categories of workers, such as real estate agents, to become independent contractors. It has also been assumed that many younger professional and technical workers have been drawn to independent contracting because of the promise of greater flexibility of these work-project-oriented arrangements and portfolio or "boundaryless" careers, especially during a period in which traditional intra-firm career paths were disappearing.

The evidence is mixed, however, as to whether independent contracting is more beneficial than regular employment. Most independent contractors prefer this type of arrangement to traditional employment. Many earn higher wages than comparable workers in traditional employment arrangements. This has been especially true in many professional and technical occupations, particularly during the economic boom and tight labor market of the late 1990s, as epitomized by the software industry in Silicon Valley. Yet, an important disadvantage is that independent contractors are less likely to be covered by health insurance and pensions.

## DIRECTIONS FOR FUTURE RESEARCH

Given the great variety of work arrangements that are defined as flexible, each with its own research gaps and needs, it is difficult to summarize overall suggestions for future research. Nevertheless, researchers are in agreement about the following needs. First, future research would benefit from greater clarification and agreement on terminology with respect to terms such as *flexible*, *alternative*, *nonstandard*, *contingent*, *temporary*, and *contract* work. As noted above, not all alternative or nonstandard arrangements are flexible; examples include shift work or temporary work. Likewise, researchers must clarify how much schedule flexibility constitutes flextime and how much off-site work constitutes telecommuting and, more importantly, who makes the decisions as to where and when to work: Is this a choice of employers or employees? Are flextime and telecommuting considered flexible work arrangements if they occur within strict employer-defined limits? What makes these arrangements flexible is the control employees have over where and when they work.

Second, researchers agree that, once defined, more valid and reliable measures of these work arrangements are needed. Researchers need to go beyond measures that are based on self-identification, as in CPS measures of shift work or independent contracting, yet the measures must still be amenable to survey research. Likewise, because flexible work arrangements are organizational as well as individual, better measures of the organizational characteristics that are associated with both "good" and "bad" flexibility are needed. Such organizational attributes may include departmentalization, formalization, authority structure, and the presence of work teams.

In terms of outcomes, more research is needed that examines the effects of flexible work on the physical and emotional well-being of workers and their families. Outcomes could be expanded to include the distribution of household labor and other responsibilities among dual-earner couples. Research along these lines is most developed in studies of shift work and flextime, but even here more valid and reliable outcome measures are needed.

Other research needs to look at the long-term effects of flexible work arrangements on workers' careers and retirement. Do flexible arrangements hinder upward mobility by creating more interruptions in workers' job histories? What are the implications for postretirement well-being and pension eligibility if workers continually change employers and their employment status? This is an especially critical question in an era of increasing individual responsibility for pensions, as in 401(k) plans.

## POLICY IMPLICATIONS

The major policy implications of flexible work arrangements involve labor, health, pension, and family policies. Current U.S. labor laws were crafted during the early

1930s and 1940s and continue to be premised on standard employment arrangements. Thus, workers in flexible arrangements are less likely to have protections provided by various federal occupational safety and antidiscrimination laws. They are also less likely to be covered by employer-provided medical and pension plans. Indeed, the growth of many forms of flexible work arrangements have been spurred by employer efforts at reducing the regulatory and benefit costs of these programs. Thus, many scholars have argued for the development or expansion of benefit programs that are not funded primarily through employer contributions. These would include universal health care and expansion of Social Security eligibility and credits to cover all workers regardless of changes in employer and employment status.

Rapidly increasing health care and pension costs have also limited employers' offerings of family-friendly benefits, particularly paid maternity leave and on-site day care. As employers cut these benefits, it is likely that employee preferences for less costly alternatives such as flextime and telecommuting will grow. Other pressures that could lead to expansion of these flexible arrangements are an aging population and the increasing need for elder care and increasing energy costs and environmental concerns. As these pressures build, scholars need to develop data strategies that answer employers' concerns about the effect of flexible job arrangements on worker productivity and firm profitability. Policy makers need to develop programs that better target flexible work arrangements to work with families and those relatively deprived of flexibility, such as lower income single mothers, African Americans, and those working standard fixed shifts, especially night and rotating shifts. Likewise, they will need to develop alternatives to meet the needs of workers in jobs such as public safety that are not amenable to flexible scheduling or work-site arrangements.

All evidence suggests that both "good" and "bad" flexible work arrangements will become even more common in the future, whereas workers with standard, full-time arrangements will become an even smaller minority. However, because many social benefits such as health insurance, pension funds, and unemployment compensation are tied to full-time status and the number of years worked for the same employer, the growth of work flexibility could create serious problems for the well-being of workers, especially in later life. One general solution is to "decouple" benefit eligibility from employment status and tie it to more universal characteristics, such as citizenship.

At the same time, employers offering benefits such as flextime or telecommuting to one worker in a particular job category are generally required to offer it to all in that category. However, because the use of these benefits is based on individual, nonwork needs, employers are reluctant to provide them, especially in the absence of data on how these benefits will affect their bottom line. This suggests a solution opposite to the more universal provision of health care and pension benefits: that certain flexible benefits be targeted to individual workers based on their personal, nonwork needs. Beyond this difference, however, future policies that address both more universal and more personalized benefits need to take into consideration how workers' progressions through their life courses affect their needs for different types of benefits and different types of flexible work arrangements.

# FRIENDSHIP, ADULTHOOD

Friendship is one of the few relationships that can begin in childhood and endure for the entire life course. It is also a uniquely voluntary relationship that is influenced by choice more than by ties such as kinship. Nevertheless, social statuses and contexts determine the set of acquaintances from which people choose friends, and so the pool of potential friends usually is constrained by factors such as age, gender, race and ethnicity, social class, geographic location, and personal interests. Like other close relationships, a friendship may change over time, reflecting the developmental characteristics of the friend pair as well as their lifestyle choices. Friendships are subject to the joys and frustrations inherent in any strong emotional bond.

## DEFINITION AND FUNCTIONS OF ADULT FRIENDSHIP

Adults typically define friends as persons with whom one is intimate and caring, whose company one enjoys, and whom one can trust. Friends are people whom one can depend on, who accept one as is, and who share similar interests. Most friends are similar to each other in characteristics such as age, sex, race, and class.

The definition of friendship is tied closely to the purposes friendship serves in adult life. Friends are valued for companionship, practical assistance, and advice. They provide emotional support, affirm one's worth as a social being, serve as role models, and make life interesting. Friends who share a long and meaningful history help sustain one another's self-identity and provide opportunities for pleasant reminiscing. Some people purposely seek out friends who will stimulate them by introducing them to activities they might not try on their own or involving them in different social networks. Research reviewed by Beverley Fehr (1996) shows that those who are socially integrated with friends (and relatives) are happier and healthier—and even live longer—than social isolates.

## HISTORICAL PERSPECTIVES AND DEMOGRAPHIC TRENDS IN ADULT FRIENDSHIP

Interest in friendship dates back to ancient times. Plato, Aristotle, and Cicero described the qualities of ideal friendship, identified categories and functions of friendship, and analyzed the role of friendship in maintaining a stable society. Their conceptions were rooted in philosophical questions about the relationship between social justice and personal happiness and in the conviction that wholesome biological and psychological development results in a spiritual or moral character.

Historical analyses show that until medieval times people spent their daily lives in close association with many community members, not just family members, and presumably found opportunities for friendship across age, sex, and class distinctions in social activity in streets and markets. With the separation of work from the home during the Industrial Revolution and the rise of the nuclear family, friendships became less central to everyday life and tended to be restricted to persons of the same age, sex, and class. Factory and office workers spent more time away from home and had less time for

leisurely pursuits, perhaps diminishing the importance of friendship for some. Nevertheless, friendship is considered an important part of social life for both workers and nonworkers in contemporary society. Spouses are supposed to be friends, employees expect to have friendly relations at work, and most people place a high value on friendship despite the demands of work and family responsibilities.

A 2002 survey of a nationally representative sample of 1,000 American adults revealed some interesting features of adult friendship. Many friendships are long-lasting. In fact, 65% of Americans have known their best friend for at least 10 years and only 15% have known their best friend for fewer than 5 years. (In this survey a spouse was not eligible as a best friend.) Most adults share social characteristics with their best friends. Specifically, 92% of women and 88% of men have a best friend of the same sex, 73% of adults have a best friend within 5 years of their own age, 73% of married adults have best friends who are married, and 70% of unmarried adults have best friends who are unmarried.

The survey also revealed that contemporary adult friends are in frequent contact and enjoy spending time together. Among the respondents 45% meet with their best friend at least once per week, 23% talk to their best friend on the phone daily, 40% of online adults exchange e-mail and 23% exchange instant messages with their best friend weekly, and 41% send letters or cards, although the frequency is less than once a month. The survey also showed that 91% said they would enjoy going on vacation with their best friend. Age and sex influence the mode of interaction. Younger adults are most likely to send e-mail or instant messages to their best friend. Older adults are most likely to send handwritten cards and letters, but younger adults do so more often than middle-aged adults do. Women are more likely to phone their best friend or send e-mail or instant messages, whereas men are more likely to meet their best friend in person.

## STRUCTURAL FEATURES OF ADULT FRIENDSHIP

Friendship structure refers to the characteristics of the people who become friends and of the ties linking individuals to their friends. One structural feature of friendship is homogeneity, that is, whether friends are of the same sex and race and are similar in age and social class. Another is hierarchy. Often friends have equal power and social status, but sometimes people choose to be friends with someone who is more or less influential or of a different status. Friendships also vary in terms of the degree of intimacy (which researchers refer to as solidarity) experienced within them. In addition, personal preferences combined with the context in which friendship occurs influence whether a person cultivates few or many friendships (network size) and whether a person's friends know one another (network density and configuration).

Friendship does not occur in a vacuum; rather, persons who are available to become friends and the functions and activities associated with friendship are influenced by contextual factors that include historical period, social structure, culture, geographic and spatial location, and temporal patterns related to schedules and routines in everyday life. These external elements intersect with one another and change over time, leading to virtually limitless complexity in the range of influences on friendship.

During the high school and college years, many people are friends with others near their age and similar in other personal characteristics because those are the people they know; from this group of available social contacts, they find friends with whom they feel comfortable and share interests. Employment may bring chances to become friends with people from many age groups, as the workplace offers chances to interact with them regularly. Outside work, young adults tend to be close friends with others of the same marital status, and to find friends through sports, church, volunteering, and neighborhood groups. Middle-aged people are sometimes so busy with work and family demands that they have little time for friends and interact mainly with their best friends. Upon retirement, older adults often have time to add to their friendship circle through their leisure pursuits. Many seek friendships with younger persons because they realize they are at risk of losing their same-age friends to old-age-related illness and death.

## ADULT FRIENDSHIP INTERACTION PROCESSES

The interactive aspects of friendship consist of behavioral, cognitive, and affective responses that occur among friends. Behavioral processes include communication, which often takes the form of self-disclosure as well as assistance and advice; shared activities; conflict; and many other forms of interaction. Cognitive processes signify the internal thoughts that partners have about themselves, friends, and friendships. They include evaluations of each person's performance in the friend role, an assessment of the stability of the friendship, perceptions of similarity on psychological attributes, judgments of the friend's character, explanations of events occurring within the friendship, and interpretations of each partner's intentions and needs. Affective processes include emotional responses to friends and friendships. Both pleasant and unpleasant emotions can be involved in friendship, ranging from love and satisfaction to jealousy and anger.

## PHASES OF FRIENDSHIP IN ADULTHOOD

Friendships are not static but have multiple possible phases. Friendships begin when acquaintances have opportunities to know one another better, reveal personal information about themselves, and discover shared interests and values. Friendships continue through a sustaining phase, which can be long-lasting and can encompass increasing, decreasing, or fairly stable levels of closeness and interaction over time. Some friendships end, often by fading as friends drift apart because of changes in lifestyle and interests, geographic separation, or competing demands. On rare occasions people terminate a friendship purposely, typically as a result of betrayal or irresolvable conflict. The phases of friendship are not necessarily linear. For example, high school friends who have drifted apart may renew their friendship in adulthood if they resume regular interaction.

## NEW DIRECTIONS IN ADULT FRIENDSHIP RESEARCH

Although early research on friendship tended to highlight the positive aspects of interactions among friends and the benefits of friendship, later studies documented the potential for disappointment and conflict in friendship as well. Studies show that some adults tolerate characteristics that are less than desirable if the friend and the friendship fill important needs. However, certain behaviors are likely to lead to strife and the dissolution of a friendship, including criticism, jealousy, and disputes over matters such as business affairs. More research is needed on the extent to which adults experience friendship dissolution, the effects of conflict between friends on personal health and well-being, and the strategies adults use to resolve friendship problems.

Research on friendship among college students and older adults is more prevalent than studies of friendships among middle-aged adults and among young adults who do not attend college. A fuller understanding of friendship structure, interactive processes, and phases could be obtained from studies of the latter groups. In addition, comparative studies of friendship across subcultural and national groups are needed for a comprehensive understanding of friendship. In light of the ubiquitous nature of friendship in adulthood and its important contributions to well-being, increasing the range of information would enable professionals to develop plans to foster the establishment of meaningful friendships, advise people about the best ways to sustain satisfactory friendships, and aid those with friendship troubles.

## GAMBLING

Gambling is a behavior in which a person puts something of value at risk. When gambling is offered as a commercial product, a person risks money on the outcome of some event, with the possibility of receiving a monetary return if a certain outcome occurs. Governments at the state level offer some forms of gambling and regulate all others. Casinos typically offer slot machines, video poker machines, and a variety of table games (e.g., blackjack, craps, baccarat). Many state governments in the United States offer lotteries, in which people buy tickets with a very small chance of winning a very large jackpot. Other forms of gambling (e.g., betting on horse racing and greyhound racing) are available in several states. Online casino gambling and poker have become very popular in recent years. Some forms of gambling represent games of skill (e.g., casino table games, poker), whereas others are purely games of chance (e.g., lotteries, slot machines).

People who gamble typically see it as a form of entertainment. Gambling is an *experience good* such as watching a movie or a football game, and not a *tangible product*, such as computers or shirts. People are willing to pay for experience goods because the experience itself provides benefits. For example, casino games may be fun to play, often have a social aspect, and offer a chance to win money. Many casinos are built with amenities such as hotels, live theater shows, and restaurants that gamblers also can enjoy. Lotteries offer a chance to win a very large amount of money (usually millions of dollars); many people enjoy thinking about what they would do if they won a large jackpot.

However, by their nature, gambling products have a negative *expected value* for the player. This means that, on average, the players of such games are expected to lose. Casino games typically have an expected value of around -5%, depending on the game, whereas lotteries have an expected value of around -50%. This means that for each $100 bet placed at a casino, the casino keeps an average of $5; for each $100 of lottery tickets purchased, the government selling the lottery keeps an average of about $50. Typically the Website hosting a poker game will keep a small percentage of each hand's total bets. The *house* is able to keep these amounts, on average, and this represents the income they receive for providing the games, facilities, and other costs of doing business. Some players *will* win, but most gamblers understand that casino games and lotteries have, on average, a negative expected value. For people to be willing to gamble, then, they must expect the benefits of playing (e.g., the chance of winning, the enjoyment, any social interactions) to exceed their expected losses, which can be thought of as the *price of gambling.* Just as a person must pay $10 or more to watch a movie at the theater, he or she expects to lose some money to the casino for playing its games.

### GAMBLING OVER THE LIFE COURSE

Research by psychologists has focused on gambling among adolescents, adults, and senior citizens. This research is still in its infancy, but rates of gambling participation are a major focus of researchers. Lifetime participation rates are often estimated at more than 70% for all age groups—a majority of people, including adolescents, have gambled at some point in their lives. The gambling participation rate varies by demographic group, geographical location, legal restrictions, and other variables. For example, in Australia, gambling is a much more common and acceptable form of

***Slot machines.*** *Casino games are an "experience good" because they may be fun to play, often have a social aspect to them, and offer a chance to win money.* FIELD MARK PUBLICATIONS.

entertainment than in the United States. Therefore, the participation rate in Australia is expected to be higher than in the United States where casino gambling is a relatively new phenomenon except in New Jersey and Nevada.

Many adolescents gamble but not always in market-based gambling such as casinos and lotteries. Students may bet on sporting events, play poker, or other social forms of gambling. Such activities are counted in participation rates. Few adolescents develop gambling problems, but still, such gambling is viewed with concern, to the extent that it may lead to problem gambling as an adult. However, for most people, gambling represents a harmless form of entertainment.

## PROBLEMATIC GAMBLING

A small portion of gamblers develop what has been termed *pathological gambling*, in which an individual damages his or her personal and professional life because of an unhealthy amount of or a preoccupation with gambling. In 1994, the American Psychiatric Association (*DSM-IV*) suggested that the prevalence of pathological gambling was around 1% of the population. Psychologists, psychiatrists, and medical researchers are interested in understanding the causes of problematic gambling behavior. Among the issues related to pathological gambling are the rate of the affliction (prevalence), how it affects different demographic groups differently, different rates of severity, and the types of behavior that result from or characterize it. Some researchers have focused on youth gambling behaviors and effects, whereas others have focused on gambling among members of minorities, gambling in various cultures, and society as a whole. Different samples of the population may be affected by pathological gambling in different ways.

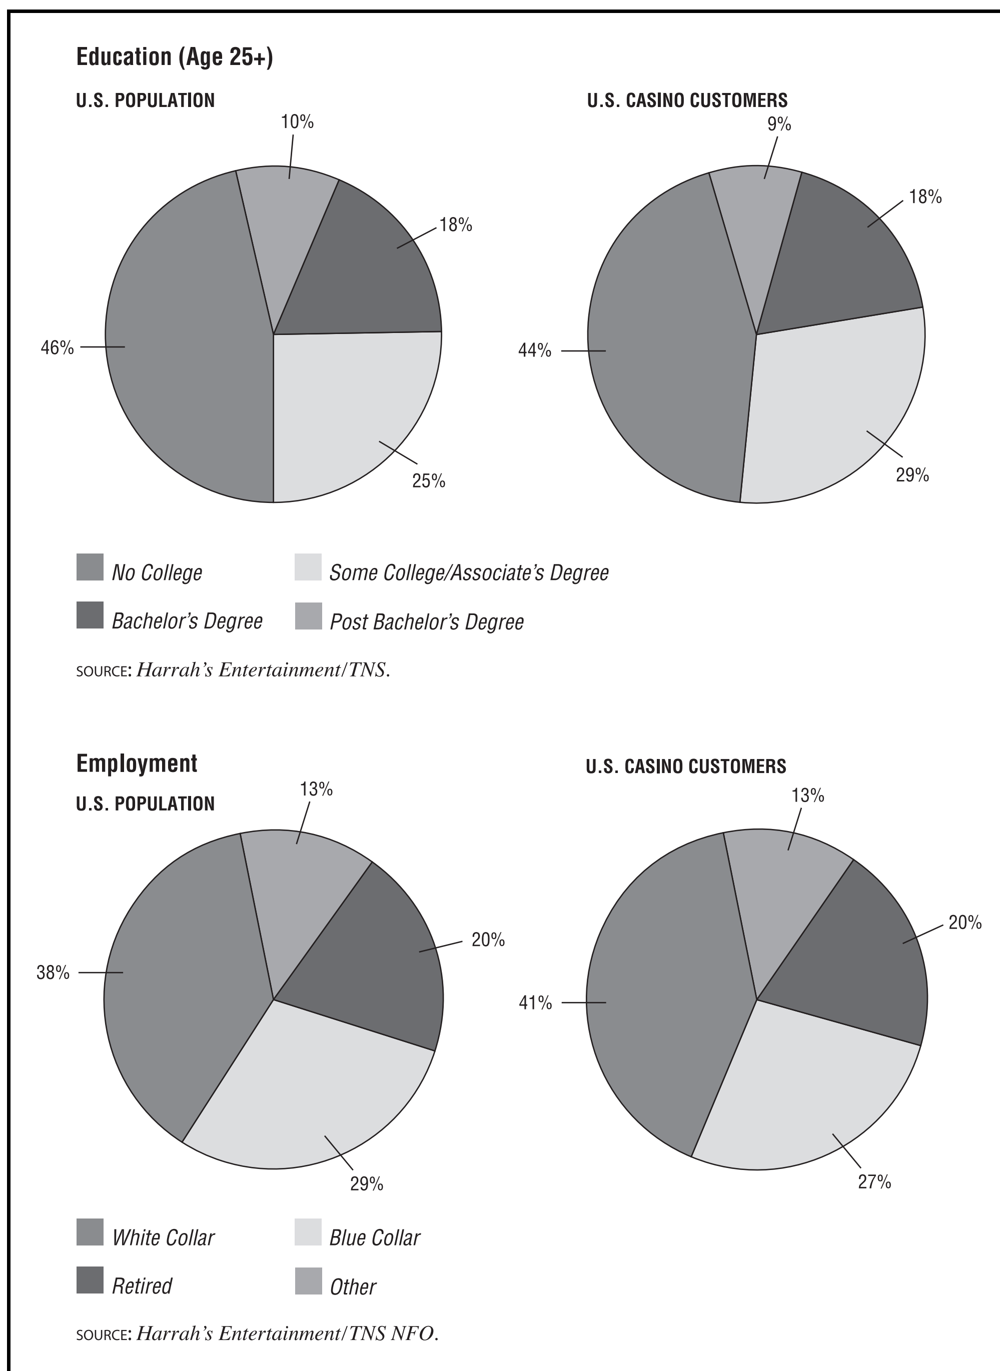

***Figure 1.*** *The average U.S. casino customer is more likely to have attended college and hold a white collar job than the average American.* CENGAGE LEARNING, GALE.

The results of such studies depend on the sample being studied, cultural idiosyncrasies, legal restrictions, research methodology, and other factors. The newest and most promising area of research related to pathological gambling deals with the neuroscience of addiction (Ross, Sharp, Vuchinich, & Spurrett, 2008). This research examines the role of processes inside the brain in initiating and sustaining addiction and promises to improve prevention and treatment strategies. This area of research overlaps with research on other addictions, such as alcoholism and drug abuse. Some researchers have suggested that all forms of addiction, and related behaviors, are not

medical issues, but are instead nothing other than very strong preferences (Becker 1996; Schaler 2000).

### CONSEQUENCES OF THE GAMBLING INDUSTRY

The other major research interest with respect to gambling is involved with the social and economic effects of the gambling industry. Many governments (local, regional, and national) have either adopted or are considering the adoption of gambling as a public policy tool, primarily to raise tax revenues. Economic studies of the effects of gambling have become more common in recent years, focusing on cost-benefit considerations.

On the *cost* side of gambling adoption are issues of pathological gambling and related behaviors. As psychologists, sociologists, and others attempt to measure the prevalence and severity of such behaviors, economists attempt to quantify these costs. This area of research has been fraught with methodological problems, particularly related to how to define *social costs* and how to measure them in monetary terms (Walker, 2007). No reliable estimates of the social costs of pathological gambling yet exist.

On the benefit side of the equation, most advocates of legalized gambling argue that there are significant consumer benefits, tax benefits, and economic development effects, particularly owing to large casinos. Perhaps the most important and sizable of these benefits is the consumer benefits received from the availability of gambling. If consumers did not enjoy gambling, they would not do it. The facts that casinos earn profits and lotteries continue to raise revenues indicate that people do enjoy gambling. Aside from these consumer benefits, the most common benefits derived from legalized gambling appear to be tax revenues from lotteries and casinos, and economic development, in the case of casinos.

Overall, results of existing research suggest that the economic benefits of legalized gambling (including consumer benefits, development and tax effects) probably outweigh the costs of pathological gambling. However, such economic and medical research is still in its infancy. Before researchers can develop reliable monetary estimates of costs and benefits, many conceptual and methodological issues need to be sorted out. As gambling expands, the gambling industry and government are beginning to offer more help for problem and pathological gamblers. Such programs will become more effective as researchers develop a better understanding of problem gambling behaviors.

## GAYS AND LESBIANS, ADULTHOOD

The adult life course of men and women who report same-sex attraction must be considered in the context of social and historical change. Following social theorist Karl Mannheim (1993 [1928]) and sociologist Glen Elder (2002), persons born within adjacent birth years comprise a generational cohort and are subject to many of the same social influences at about the same ages. At the same time, there is considerable intra-cohort variation based on such factors as geography, social status, ethnicity, or sexual orientation. This entry focuses on the interplay of social change and the life course among men and women in contemporary American society who seek others of the same sex for social and sexual ties. Social and historical change interplay with life history in determining the meanings that men and women construct about their sexuality and this is reflected in the distinct identity cohorts that have emerged from the context of social change.

Discussion of the life course of men and women expressing same-sex desire must be understood in terms of three aspects of their sexuality: sexual orientation, sexual behavior, and sexual identity (Savin-Williams, 2005). Sexual orientation refers to awareness of a preponderance of desire for social and sexual encounters with others of the same sex. Desire must be distinguished from sexual behavior, which is the realization of desire in action. Sexual orientation and behavior must in turn be differentiated from sexual identity, that is, the label that men and women use in portraying their sexuality. Biologist Alfred Kinsey et al. (1948), psychologist Ritch Savin-Williams (2005), and philosopher of science Edward Stein (1999) maintain that sexual attraction cannot be viewed as either straight or gay but that sexual attraction instead ranges from complete affinity for the opposite sex to that for one's own sex. This perspective has been supported in Lisa Diamond's (2006) study of young adult women and in Stein's (1999) careful review of quantitative findings regarding homosexuality.

Across generational cohorts in contemporary American society, the narrative of sexuality told by men is most often that of an awareness of same-sex desire that reaches back into childhood or early adolescence and that remains fixed across the life course. Women are more likely than men to portray a variable sexuality across the course of life, involving partners of both the same and the opposite sex. Reviewing findings regarding the expression of same-sex awareness among men and women, Phillip Hammack (2005) has described the life course of women with awareness of same-sex attraction as one of sexual fluidity in which the primary focus is on relationships and a "sex-unspecific pattern of erotic preference" (p. 271).

Understanding of self and sexuality among men and women coming to adulthood and aware of same-sex desire varies across generations because it is closely tied to social and historical change. As historian George Chauncey (1994) has shown in his discussion of the definition of same sex-desire across the past century, the very terms used to portray this desire have changed over time. Within contemporary European and North American society, men and women presently entering late life and aware of same-sex attraction were born in the years preceding World War II (1939–1945) and came to adulthood in the conservative postwar era. With same-sex desire stigmatized by the larger society, to the extent that these men and women even sought social and sexual contact with others of their own sex, meetings were furtive in bars and other venues and were always in danger of exposure with the possibility of criminal sanctions.

Some men aware of their same-sex desire joined the clandestine Mattachine Society, while women seeking same-sex ties joined the Daughters of Bilitis. These homosocial groups were increasingly active in the advent of the civil rights movement in the 1960s. These men and women had often chosen solitary or low-key occupations, such as that of an accountant or librarian, where they could keep "below the social radar," and be able to avoid discussion of their personal life with work colleagues. These men and women often define their sexual identity as *homosexual*, a term common in a time that still viewed same-sex desire as evidence of personal maladjustment.

Sexual orientation, conduct, and identity within generational cohorts born later in the 20th century have been significantly influenced by social and historical change. Men and women born in the immediate postwar period came to adulthood in the turbulent years of the 1960s and 1970s. Often aware from childhood of same-sex desire that was regarded at the time as a source of shame and stigma, many of these men and women were emboldened by the civil rights movement and the tentative social activism of the preceding decade to seek tolerance from the larger society. This generation came to adulthood at a time of dramatic social change and at a time when membership in a sexual minority group was becoming recognized as one of a number of sexual lifeways. Much of this activism was mobilized in the aftermath of patron resistance to a June 1969 police raid on the Stonewall Inn, an establishment frequented by men and women seeking same-sex camaraderie. This raid galvanized young adult patrons and their friends to demand an end to police raids and inspired visible social activist groups nationwide across the following decade. This activism marked the advent of the gay rights era and resulted in ordinances prohibiting discrimination on the basis of sexual orientation in many cities nationwide. For the first time it was possible for men and women to enjoy same-sex companionship in now visible bars and other spaces. It was also possible to publish newspapers reporting on the activities of the community, which included advertisements for bars and for men and women seeking others as social and sexual partners. Men and women within this cohort often chose the label *gay* and *lesbian* to describe their identity. This generation eschews the term *homosexuality*, because to them it associates awareness of same-sex attraction with psychiatric illness.

The very social changes that made possible socially visible spaces in which to find other men and women with same-sex desire led to anonymous and casual sexual partners. These practices increased the possibility of transmitting a virus that silently destroyed the immune system over a number of years, which became manifest in the following decade as a fatal disease. First reported in the *New York Times* in the summer of 1981 as a rare cancer striking a group of men in San Francisco acknowledging same-sex conduct, the means of transmission and tests for AIDS were available by the mid-1980s. Between 1980 and 1995, when the first medications were discovered that would turn AIDS into a chronic rather than life-threatening illness, several hundred thousands of men had died from complications associated with AIDS. By the mid-1980s most school sex education programs featured the importance of practicing safer sex; men and women coming to adulthood, then, better understood the implications of risky sexual practices.

This young adult generation of self-identifying gay men and lesbians made their community through their activism, and later assisted by the Internet, were able to help other men and women aware of their same-sex desire to learn that they were not alone. Even in high school these young adults had been able to "come out" without the opprobrium that had greeted previous generations. Forming an identity cohort characterized by demand for respect for their sexuality, this generation now in middle adulthood presumes their right to make their own life free from stigma or legal restriction.

The most recent generation of adults coming to adulthood, who follow the activism of preceding generations, presumes that there is little relationship between sexual orientation or sexual desire and conduct and other aspects of their life as they emerge into adulthood. Many of these men and women maintain that their sexual preference for same- or opposite-sex partners has little relevance to who they are as persons. These young adults either identify themselves as *queer* or as *spectrum* (meaning other than completely heterosexual on the six point Kinsey scale of same-sex attraction) or, more often, explicitly reject any sexual or other identity labels (Cohler & Hammack, 2007). Whereas Anthony D'Augelli (2002) has portrayed the struggle of young adults in previous generations to deal with their same-sex desire when faced with shame or hostility at home and in the community, Bertram Cohler and Hammack (2007) observe that changing social circumstances have shifted the narrative of young adulthood among more recent young adults from a narrative of struggle and suppression to a narrative of emancipation. To an even greater extent than youths in the preceding generation, these young adults presume that their sexuality is not relevant to their accomplishments at school and work or their participation in the larger community. Research confirms this presumption: There are few socio-demographic differences in sexual orientation (Badgett, 2001), although these findings are based largely on studies of convenience samples.

***AIDS Quilt.*** *A view from the Washington Monument on Oct. 11, 1996, shows the huge AIDS Quilt laying on the ground, stretching from the monument to the U.S. Capitol.* AP IMAGES.

Accompanying the social and historical change that has been the background for personal development across these generational cohorts in American society, each generational cohort has been challenged by unique developmental tasks that may not be generalized to later cohorts moving across the course of life from early adulthood to later life. Further reciprocal socialization means that cohort effects across generations shaped the subsequent course of life for each generation in a manner unique to a particular time and place. For example, the very success of current young adult and middle-aged generations in charting a new path in society has led many formerly hidden elders to come out and to found new homophilic organizations such as Senior Action in a Gay Environment (SAGE), which lobbies for quality senior housing for older same-sex attracted men and women no longer able to live alone. A lifetime of increasing competence in dealing with stigma has equipped these older adults to manage the dual prejudices of their aging and their sexuality. At the same time, the lifelong experience of sexual minority stress and stigma has taken its toll on the morale of members of this generation (Meyer, 2003), a toll that is unique to this generation of elders with same-sex orientation and cannot be assumed to characterize later cohorts of men and women with same-sex attraction. It is important to distinguish between the effects due to aging from those due to membership in a particular cohort.

The present generation of men and women in settled adulthood has participated in much of the social change since the emergence of the gay rights era of the 1970s. Many of these adults still grieve the death of romantic partners and friends from the AIDS pandemic. Viewing the AIDS Memorial Quilt composed of squares memorializing the lives of those who died from AIDS, it is striking how many of these squares are for men born in the 1950s and dying in the time between the mid-1980s and the mid-1990s. Members of this generation experienced loss and mourning more characteristic of later life within the heterosexual world. Despite these experiences of grief, Cohler and Robert Galatzer-Levy (2000), in their review of studies of the association of sexual orientation and mental health, report few differences in well-being among persons who report primarily same- or opposite-sex attractions. However Ilan Meyer (2003)

has shown that greater prejudice due to sexual minority orientation experienced in childhood and adolescence is associated with lower morale experienced across the adult years.

Current cohorts of midlife adults also belong to the first generation for which the normative adult role transitions of legally recognized romantic relationships or marriage and parenthood are available as choices. While the desirability of same-sex marriage as an option continues to be controversial among both men and women with same-sex attraction and also within the larger community, several states have accorded legal protection for two men or two women entering into long-term sociosexual relationships. The state of Massachusetts and entire countries such as Canada and the Netherlands explicitly sanction same-sex marriage (see sidebar).

Chauncey (1994) views both legal protection for same-sex romantic unions and legal protection for parenthood among men or women open about their same-sex attraction as the outcome of a process of social change over the postwar period. This is nowhere more evident than in the enhanced opportunity for men and women open about their same-sex desire to adopt children. About one-third of women forming a same-sex relationship have children from a previous heterosexual relationship. Most states permit single men or women to become foster parents and to legally adopt the children in their case. Advances in reproductive technology have made it possible for women to share biological parenthood in which the baby is the product of one partner's egg, sperm donation from either a man who is a friend of the couple or an anonymous donor, and carried to term by the other partner. The birth mother in these same-sex couples reports less stress than her heterosexual counterparts as the other partner is much more involved in child care than men in traditional heterosexual marriages. Men may call upon a friend to serve as a surrogate mother with sperm from either or both partners fertilizing the egg.

Early studies of the effect of parental sexual orientation on child outcomes were based on convenience groups using same- and opposite-sex parents agreeing to a comparative study of children in the classroom and the playground. More recent studies have been based on large-scale national surveys. Taken together, these studies reveal that children raised by same-sex couples do not differ in their adjustment and subsequent life course from children growing up in traditional heterosexual families (Patterson, 1995), although they tend to be particularly tolerant in their social attitudes. When same-sex couples, particularly men, elect to adopt, agencies may still offer the most desirable children to heterosexual couples. Children offered for foster parenthood or adoption for either single men or same-sex men couples may he at higher developmental risk resulting from foreign birth or biological parental pregnancy and childbirth than children raised by heterosexual couples. These children may be born with some developmental infirmity such as fetal alcohol syndrome or may have such developmental disabilities as developmental delay. However, the motivation for generativity or the need to care for the next generation means that these children get unusually good care and may be helped to overcome these developmental problems.

The current young adult generation of men and women aware of same-sex attraction is unique in two respects. In the first place, the generation of youth or emergent adulthood is itself a generation that was not explicitly recognized in American society until the postwar period. In the second place, while previously stigmatized by peers and teachers, adolescents and young adults aware of same-sex attraction have empowered themselves

## SAME-SEX MARRIAGE

Same-sex (or equal) marriage refers to a union between two persons of the same sex that provides the same legal status and protection that is provided to married heterosexual couples. Belgium, the Netherlands, Canada, Spain, and South Africa currently recognize same-sex unions as a marriage. Some nations such as Israel offer formal recognition for same-sex unions. Whereas one state in the United States (Massachusetts) allows same-sex marriage and eight states provide the same protection for same-sex domestic partnerships as for heterosexual unions, 26 other states explicitly ban using the term *marriage* to refer to the union of a same sex couple. Historian George Chauncey (2004) traces the demand for same-sex marriage to the gay rights era beginning in the 1970s, which by the 1990s led both to many employers offering domestic partnership benefits, and to a series of court decisions regarding the protection of privacy. Opponents of gay marriage maintain that marriage presumes procreation and that persons of the same sex cannot produce offspring (Sullivan, 1997). However, that presumption is not a part of federal or state law regarding heterosexual marriage.

with the support of both peers and adults. They have been supported in their ability to overcome prejudice—prejudice that in earlier youth cohorts led to sexual minority stress by groups at school and college and even in the workforce—with resources available on the Internet and provided by other questioning and same-sex defined peers and elders.

As a consequence, the life story of members of this generation has shifted from one of struggle to overcoming prejudice to one of emancipation with issues of struggle largely irrelevant in urban America. The change is reflected in the reluctance of these youths to adopt identity labels such as *gay* and *lesbian* or even *queer*. The concern of this generation is with their own success in education and work and perhaps with finding a relationship with a like-minded man or woman aware of his or her own same-sex desire. It is common for these men and women aware of same-sex desire to have close friends and to be part of social groups varying in their commitment to same- and opposite-sex social and romantic relationships. For members of this generation of emergent adulthood, concern with issues of sexual identity appears to be much less of a concern than finding satisfying work and meaningful relationships. Cohler (2007) has illustrated this shift in discussing the blog of a Midwestern college student writing about his boyfriend, his straight fraternity friends, and their views regarding work, relationships, and their future prospects.

The life course of present generations of men and women from youth through middle age aware of their same-sex attraction is increasingly similar to that of their heterosexual counterparts. From the experience of social isolation and sexual minority stress due to stigma characteristic of the oldest generation of same-sex attracted men and women, generations of same-sex attracted men and women within present cohorts across the first half of life have become virtually indistinguishable from their opposite-sex attracted peers. Further, this social change is leading to backward socialization among older adults who now see new possibilities for their life as they embrace social activism. Whereas conservative commentator Andrew Sullivan (1996) celebrates this change, radical social commentator Michael Warner (1999) decries the loss of the vibrant culture created by minority sexuality men and women following the gay rights revolution. However, it is clear that sexuality cannot be discussed apart from social change and the impact of this change upon the life courses of the various generational cohorts born in the 20th century.

## GENDER DISCRIMINATION

SEE Volume 2: *Sexism/Sex Discrimination.*

## GENDER IN THE WORKPLACE

Women's rapid movement into the paid labor market over the past century has had an impact on childrearing, marriage, gender equality, and the labor market itself. Whereas in the past most women devoted their time to caring for their families, women's life courses are now shaped by the combined influences of family and work. In the early 21st century, women in the workplace experience many opportunities, but there are still key issues and challenges.

### TRENDS IN WOMEN'S LABOR FORCE PARTICIPATION IN THE UNITED STATES

Women's participation in the paid labor market increased dramatically during the 20th century. In 1890 only 18% of women were in the labor force. Women's labor force participation rose slowly but steadily through the early 1900s, reaching 28% in 1940. During World War II women were actively recruited into jobs that supported the war effort, with the result that their labor force participation rates jumped to 36% in 1945. When soldiers returned home after the war, some women returned to homemaking, but the decline in women's labor force participation rates was short-lived. By 1960, 38% of women age 16 and older were in the labor force, and this participation rate increased every decade until it reached 58% in 1990. Women's overall labor force participation rate hovered between 58 and 60% until the early 2000s (Blau, Ferber, & Winkler, 2006). These numbers are even higher among women who have completed their schooling and have not yet retired. For instance, in 1998, 76 to 78% of women age 25 to 34, 35 to 44, and 45 to 54 participated in the labor force (Fullerton, 1999). The rise in women's employment occurred in most racial groups. For example, Bart Landry (2000) documented that the percentage of married African American women in the labor force increased from 1940 until 1994. The percentage of African American married women in the labor force was higher than that of White married women in each decade among both upper and lower middle class women. In addition to greater financial need, Landry explained that the Black–White difference was due to Black women, particularly Black middle-class wives, embracing a different version of "true womanhood" that included a commitment to both family and career. These racial differences in employment among married women are still evident in the 21st century. Among young single women, however, White women are working at higher rates than both Blacks and Latinas (see Taniguchi & Rosenfeld, 2002).

Women's roles as wives and mothers have typically had an impact on their participation in the paid labor market, but women's approaches to navigating work and family across the life course have changed substantially over time. In the early part of the 20th century, women typically worked when they were young and single, exiting the labor force when they married or had children—if they could afford to live on only their husband's income. However, labor force participation rates for women with young children have increased rapidly since the 1950s. For instance, only 17% of women experiencing their first birth between 1961 and 1965 were working 12 months after the birth. In contrast, between 2000 and 2002, nearly two-thirds (64%) of new mothers were working 12 months after the birth (Johnson, 2008).

The reasons for this dramatic shift have been studied extensively. Economists argue that women's labor market decisions are based on a comparison of the value of market time (or time at work) to the value of nonmarket time (or time at home). According to this theory, people's decisions are based on *opportunity costs*, that is, an assessment of the costs of making one choice relative to the costs of choosing something else. Over the course of the past century, the value of women's market time increased greatly and the value of women's nonmarket time decreased greatly, leading women to spend a larger proportion of their lives employed (Blau et al., 2006).

Increases in women's educational attainment are an important factor underlying shifts in the value of women's market and nonmarket time (Blau et al., 2006). In 1940 only 4% of women had completed a college degree, but by 2007 this had risen to 28% (U.S. Department of Education, 2007). Men's educational attainment also rose over this period, but women closed, and even

## OPTING OUT

Since the 1980s, the media have disseminated stories about professional women opting out, or leaving the workforce, to care for their children. The claim that society is experiencing an opt-out revolution (Belkin, 2003) has spurred debates about whether mothers with professional jobs really are opting out and, when they do, about their motivations for doing so. Evidence on the extent of the opt-out revolution is mixed. Studies examining the work decisions of all women tend to show little evidence of an opt-out revolution (Boushey, 2008; Cotter, England, & Hermsen, 2007), but one study indicated that college-educated women in their late 20s are spending less time in the labor market than did earlier cohorts of young educated women (Vere, 2007). Although some mothers who leave their jobs express a clear preference for staying at home, many others feel pushed out of work by the competing demands of an inflexible workplace and motherhood (Stone, 2007).

reversed, gender gaps in educational attainment. In 1900 only 19% of college degrees were awarded to women, whereas in 2006 women earned more than half (58%) of all college degrees (U.S. Department of Education, 2007). These changes in educational attainment have led more women to aspire to professional careers than in the past and mean that women face clear losses in earned income and professional advancement if they exit the labor market when they have children.

Indeed, despite the common impression that women with low education and limited labor market skills (who are more likely to be single or partnered with a low earner) are the most likely to work because they need the income, in reality women with higher education levels are most likely to work when they have young children. Of women experiencing their first birth between 2000 and 2002, 62% of women with less than a high school education did not work within a year of their child's birth compared to 40% of women with a high school degree and 27% of women with a college education or higher (Johnson, 2008). In addition to the career aspirations of women with higher education, researchers have identified multiple barriers to the employment of low-educated women. High childcare costs, low childcare quality, lack of access to a car, and health limitations of the mother or the child all contribute to the challenges that mothers with low education and wages face when trying to combine work and family (Roy, Tubbs, & Burton, 2004; Scott, London, & Hurst, 2005).

A second factor pulling women into the labor market may be changes in the availability of other sources of income, such as their partners' earnings or welfare and other government benefits. Peter Gottshalk (1997) indicated that since the 1970s the earnings of men with the weakest labor market positions (e.g., low education levels, limited job skills) have declined. The level of welfare payments and the ability to collect welfare without working have also declined (Committee on Ways and Means, 2004). These changes should push more women into the paid labor market, particularly women with low education levels and single mothers. Although mothers with low education levels are still less likely to work when their children are young than mothers with higher education levels (Johnson, 2008), in the late 1990s there was a sharp increase in the labor force participation rates of single mothers (Blau et al., 2006).

In addition to the forces increasing the value of women's time in the market, many forces have reduced the value of women's nonmarket time (Blau et al., 2006). Moving from an agrarian society to an industrial society reduced families' dependence on women's domestic labor as families became less likely to produce their own food and clothing. Domestic responsibilities continued to decrease with the advent of dishwashers, laundry

machines, and precooked meals readily available for purchase. Families are smaller than in earlier centuries, reducing the time that women spend pregnant or nursing infants. Additionally, the rapid increase in nonmaternal childcare options provides parents with more opportunities to enter the labor market.

## KEY ISSUES AND CHALLENGES FACING WOMEN IN THE WORKPLACE

Some of the key issues and challenges facing women in the workplace include the gender wage gap, discrimination, the glass ceiling, and sexual harassment.

**The Gender Wage Gap** Despite women's increased educational attainment and strengthening attachment to the labor force, women working full-time still earn less than men working full-time. Estimates of the gender wage gap differ somewhat based on whether researchers compare men's and women's annual earnings or hourly wages, because men tend to work more hours than women. Regardless of the measure used, the gender wage gap has closed over time but has not disappeared. From 1979 to 1998 the ratio of women's to men's hourly wages increased from 63% to 80% (Blau & Kahn, 2006). Several factors explain the gender wage gap, including differences in what women and men choose to study in school, the occupations that women and men enter, the number of years women and men spend employed, and discrimination.

As noted earlier, women are now more likely than men to complete a college degree. However, this trend masks variation that is key to understanding the gender wage gap: Women and men choose very different academic majors. In 2000–2001 women earned just 28% of the bachelor's degrees awarded in computer and information sciences, 20% in engineering, and 34% in economics. In contrast they earned 78% of the degrees in psychology, 77% in education, and 84% in health (Blau et al., 2006). Among those with college degrees, these differences in educational choice translate into women and men holding very different jobs—with very different earning trajectories.

Among those without college degrees, women and men also hold different jobs. Different jobs translate into different pay, authority, and social status (Reskin & Padavic, 1994, p. 31). Jobs that are primarily filled by women and/or minorities tend to require lower level skills and, in turn, provide low wages (Tomaskovic-Devey, 1993). In 2000, women represented more than half of the workers in several major occupational groups such as sales and office work, service (Gist & Hetzel, 2005). A greater percentage of men (58.1%) than women (41.9%), however, held management, business, and financial jobs, which are generally more lucrative and require more training than sales and service positions. Even after controlling for skill demands, "female occupations" (i.e., jobs comprised of mostly women) pay less than "male occupations" (England, Allison, & Wu, 2007; Huffman, 2004). Pay discrepancies rooted in gender-typed career choices are not easily remedied by public policies. The Equal Pay Act of 1963 requires equal pay for equal jobs. This law does not, however, prohibit employers from paying less to all workers in predominantly female occupations than workers in predominantly male occupations (Reskin & Padavic, 1994).

Jobs that women typically hold have been referred to as *women's work*, a derogatory label emphasizing the low status of these jobs (Tomaskovic-Devey, 1993). In particular, care work, which includes jobs such as childcare provider, nurse, and teacher, is synonymous with women's work. Childhood socialization, in which girls and boys are taught normative gender roles, likely plays a large role in the ultimate educational and occupational choices of women and men. Women do the majority of both paid and unpaid care work, because it meshes with gender roles emphasizing women's capacity for nurturing. The low pay and support for these workers, despite the large skill set required for these jobs, leads many to argue that care work is devalued (England, 2005). Despite continuing gender segregation in care work, other industries showed a decline in segregation between 1996 and 2003. This decline was due in part to the rise in service sector jobs, which are less segregated than jobs in other industries (Tomakovic-Devey et al., 2006).

A second factor that explains the gender wage gap is the amount of time men and women spend in the labor force. The time invested in paid employment, in terms of gaining work experience as well as skills relevant to one's own employer, is often called *human capital*, those skills and experiences that a worker "sells" on the market. Men and women follow very different employment trajectories, with men more likely to work continuously and women more likely to follow a variety of paths that include transitions to and from the labor market as well as spells of part-time employment (Hynes & Clarkberg, 2005; Moen & Han, 1999). Researchers estimate that about 11% of the gender wage gap is due to differences in labor force experience (Blau et al., 2006).

Parenting demands are among the key reasons why women have more discontinuous work histories than their male peers, but children play a role in women's earnings beyond differences in labor force participation. Researchers have begun to study differences in earnings between mothers and nonmothers and have found what they now call a *motherhood wage gap*. Compared to

nonmothers, mothers experience a wage penalty of about 7% per child. Here too, labor market entrances and exits explain only part of the gap in pay between mothers and nonmothers (about one-third), leaving the remaining two-thirds of the gap unexplained (Budig & England, 2001). Research in this area is still underway, but some of the hypothesized explanations for the unexplained gap include differences between mothers and nonmothers in their productivity and energy while at work, their decisions about whether to take demanding jobs or to select more family-friendly jobs, and discrimination (Budig & England, 2001).

**Discrimination** Most researchers acknowledge that discrimination is likely to account for some of the gap that remains between men's and women's wages after factors such as occupation and experience are taken into account (Blau & Kahn, 2006; Budig & England, 2001). The Civil Rights Act of 1964 prohibits employers from discriminating on the basis of gender during hiring, promotion, and job assignment. The Equal Employment Opportunities Commission was created to enforce this act, but given the subtlety of many employers' intentional and unintentional actions, Joan Williams (2000) points out, it can be difficult to prove gender discrimination.

In addition to gender-based discrimination, evidence suggests that caregivers also experience discrimination, such as being terminated or denied promotion due to family responsibilities. In one case, female grocery clerks were not promoted to management because their employer believed the clerks' childcare responsibilities would prevent them from working long hours (Williams & Segal 2002). Although caregiving discrimination can happen to men, it is more likely to happen to women as they typically assume more caregiving responsibilities.

Employers may also discriminate by offering women lower wages than men. Although illegal, there are still cases in which employers pay women less than men for performing the same job (see examples in Reskin & Padavic, 1994). For example, in 2001 six women filed a lawsuit claiming, among other issues, gender discrimination in pay decisions at Wal-Mart and Sam's Club. In 2004 the federal court made it a class action lawsuit applying to all female employees at Wal-Mart in the United States. The case has not been tried or settled out of court. Pay discrimination occurs at all levels of the occupation hierarchy and is partly responsible for the increasing gender wage gaps over the life course (Maume, 2004). Pay differences and differences in hiring and promotion can have a cumulative effect over time, with small differences early in a career adding up and leading to larger differences later in the life course (Maume, 2004).

Unfortunately, estimating how much of a pay gap is due to discrimination versus other factors is a difficult task as researchers rarely have information on all factors influencing wages, such as individual productivity, job experience, and whether jobs require comparable skills (Reskin & Padavic, 1994). Experimental studies can help eliminate these challenges by examining how job applicants are rated when the only substantive difference between two workers is their gender or parental status. For instance, Shelley Correll, Steven Bernard, and In Paik (2007) asked college students to rate the application materials of two job candidates for a high-level position. The students were told that their comments would be passed on to a hiring committee and may influence actual hiring decisions. The researchers constructed resumes and other materials making the applications equally qualified for the job, but they experimentally manipulated the parental status of the applicant. Their results showed that mothers were perceived as less competent and less committed to their jobs than nonmothers and that these perceptions translated into lower proposed starting salaries and higher required achievement standards for mothers.

**The Glass Ceiling** A *glass ceiling* metaphor has been commonly used to describe the invisible barrier that prevents women, particularly minority women, from advancing in organizations (Williams, 2000). Although many women have management positions, the number of women holding top-level positions, such as chief executive officer of an organization, is very small. In 1995 the Federal Glass Ceiling Commission published a report documenting a stark contrast in the number of male and female senior managers in Fortune 1500 companies: 95% of senior managers were men. Furthermore, when Mary Noonan and Mary Corcoran (2004) examined gender differences in promotion among University of Michigan law school graduates from 1972 to 1985, they found that women were less likely to be promoted to partner in law firms than were men, even after accounting for differences between men and women in factors such as grade point average in law school, number of years they had practiced law, and amount of time taken off, if any, from work to raise children. The Federal Glass Ceiling Commission identified three barriers that account for the glass ceiling: (a) societal barriers (differential opportunities for educational attainment, prejudices), (b) structural barriers within the business (initial placement in noncareer track jobs, lack of mentoring), and (c) governmental barriers (lack of consistent monitoring, inadequate reporting; U.S. Department of Labor, 1995).

Although women may have a difficult time "cracking" the glass ceiling, mothers tend to have an even more

difficult time, given the time constraints and responsibilities associated with managing a job and motherhood simultaneously. As noted earlier, mothers with low education and few financial resources often struggle to remain attached to the labor market, which can have immediate negative consequences for their own and their children's financial well-being. Taking time out of the workforce can also have consequences for career advancement. For instance, lawyers who took time out of the labor force to care for children were less likely to make partner and earned less if they did become partners (Noonan & Cochran, 2004).

Some accommodations for working mothers, such as reduced work hours, have led to concerns that they place women onto a "mommy track" that then prevents them from maintaining their previous status or from advancing further. Indeed even mothers who are not interested in these accommodations may be viewed differently once they have children and may experience changes in their work arrangements that move them into less prestigious jobs. For instance, the Federal Glass Ceiling Commission reported that upon returning to work after maternity leave, women often received less desirable assignments than they did before giving birth (U.S. Department of Labor, 1995).

**Sexual Harassment** As women have become a larger part of the American workforce, many have faced sexual harassment in the workplace. The Equal Employment Opportunity Commission (2007a) defines sexual harassment as "unwelcome sexual advances, requests for sexual favors, and other verbal or physical conduct of a sexual nature . . . when this conduct explicitly or implicitly affects an individual's employment." Although sexual harassment is illegal, a 1994 survey by the U.S. Merit Systems Protection Board (1995) found that 44% of women reported experiencing some type of harassing behavior at work during the previous two-year period. The most common behaviors reported are sexual teasing and jokes, but 10% of survey respondents indicated that they received letters, calls, or other sexual material, and 7% reported being pressured for sexual favors. Of those who reported experiencing some type of sexual harassment, only 6% reported making a formal complaint. Only half of those who made complaints reported that this improved the situation (U.S. Merit Systems Protection Board, 1995). It is unclear why more complaints were not filed, but possible reasons include fear of retaliation or job loss.

Sexual harassment can have negative consequences for health, workplace morale and productivity, and victims' career trajectories. For instance, Chelsea Willness, Piers Steel, and Kibeom Lee (2007) show that harassment has been linked to a reduction in mental wellness for female victims and an increase in rates of posttraumatic stress disorder. Sexual harassment has also been linked to heightened stress and physical illness (Rospenda, Richman, Ehmke, & Zlatoper, 2005), which can lead to frequent absences from work, strained coworker relationships, and limited productivity (Willness et al., 2007). Sexual harassment can also have lasting effects on women's careers. Victims are more likely to be dismissed or lose promotions due to absences from work (Willness et al., 2007).

## FUTURE DIRECTIONS FOR RESEARCH ON GENDER IN THE WORKPLACE

One of the most promising avenues for future research on gender in the workplace asks the question: What can be done to address the challenges that women are facing? Many scholars have outlined suggestions to eliminate the glass ceiling, reduce sexual harassment, reduce gender inequality in pay, and help individuals meet their work and family responsibilities (e.g., Catalyst, 2000; Moen & Roehling, 2004; Rapoport, Bailyn, Fletcher, & Pruitt, 2002). A wide variety of interventions and changes have been proposed, ranging from workplace policies about flexible scheduling and sexual harassment to government policies about maternity leave and childcare.

One of the challenges in this area is philosophical. A debate has existed for generations about how to define equality between women and men and what the goal of related policies should be (Loutfi, 2001; Vogel, 1993). Does equality mean that women have the same opportunities as men and receive the same penalties as men for factors such as reduced time in the labor market, or does equality mean that women and men have the same outcomes on issues such as time spent in caregiving and occupational attainment?

This controversy is still apparent in policy debates about how to address employees' needs to balance their work and family responsibilities (Lewis & Guillari, 2005). Jennifer Glass (2004) categorizes commonly proposed work–family policies into three groups. The first set promotes reductions in work hours, allowing workers (typically mothers) to reduce their time in the labor market in order to perform caregiving at home. The second set promotes schedule flexibility (adapting the timing and location of work), allowing workers to meet their caregiving responsibilities without minimizing their overall time in the labor market. The third set provides assistance to workers (such as on-site childcare or assistance finding elder care) and helping workers pay others to provide care when it is needed. These policies reflect very different choices (providing care oneself vs. purchasing care in the market) and may have very different

effects on the career trajectories and the well-being of workers and their families.

Although addressing the challenges that women face in the workplace involves grappling with the philosophical question about ultimate policy goals, research can greatly inform these debates by providing concrete information about the costs and benefits of various workplace and government policies. These studies need to be complex, because interventions with positive impacts in one domain (e.g., career attainment) may have negative impacts in another (e.g., individual or child well-being). They also need to reflect the reality that policies that are plausible and beneficial to one group of workers (e.g., professional workers, married workers) may be unfeasible or not beneficial to others (e.g., workers in less skilled occupations, single parents).

# GENETIC INFLUENCES, ADULTHOOD

One of the most influential developments in science is the growing understanding of genetics. During the last half century, the body of knowledge about genes and their consequences has flourished. As scientists' understanding of genetics has increased, the relevance of genetics to the study of a wide variety of issues has been highlighted. In this vein, understanding adult life trajectories requires taking into account individuals' genetic inheritances and their interplay with the social and physical environment.

## GENES AND EVOLUTIONARY HISTORY

A gene is a single coding segment of DNA, which is the hereditary material in all organisms including humans. The hereditary directions in DNA are stored in 3 billion bases. The order of these bases provides the blueprint for building and maintaining an organism. Genes are grouped onto chromosomes, of which humans have 23 pairs. The pairing of chromosomes means that humans have two copies of all genes, with the exception that males have only one copy of sex-linked genes (those that occur on the X chromosome and those that occur on the Y chromosome; females have two X chromosomes, males only one). Different forms of a gene are referred to as alleles, and the combination of allele forms for a particular gene are known as a genotype. A genotype corresponds to a particular set of gene products, whereas a phenotype is the observed end result of the gene process.

To understand the nature of genes as well as how they influence human lives, it is important to recognize their evolutionary past. Genes are passed along from parents to child, so a gene's "success" is measured in the number of copies it transmits to future generations. To pass genes on, an individual must reproduce offspring. Thus, genes that increased the reproductive success of an individual were more successful in the course of evolution and are more prevalent today. Conversely, genes that are present today must have been selected for reproductive advantage over evolutionary history. Because the modern world differs dramatically from the circumstances under which these genes were selected, characteristics that were advantageous then may not be advantageous today. For example, humans have evolved excellent physiological mechanisms to store energy when food is abundant, so as to sustain them in times when food is in short supply. Contemporary humans can be considered as selected for genes that favor energy storage and that defend against weight loss. Contemporary industrialized societies, however, are characterized by low levels of physical exercise and abundant food supply. It is this misfit between one's primeval genes and modern lifestyles that accounts for the current U.S. epidemic in obesity at the population level. Individuals differ considerably in the risk of obesity, however, because they are exposed to different sets of genetic and environmental factors. This evolutionary perspective is a helpful way to interpret research on genes and the life course, because it frames the narrative on the origin of a genetic effect.

The effect of genes on complex phenotypes, such as behaviors, has been explored in a number of ways that have evolved as scholars' understanding of biology has increased. Studies on twins and adopted children allowed researchers to explore the heritability (i.e., the degree to

which a characteristic is passed from parents to children via genes) of behaviors using known levels of genetic similarity between individuals to disentangle genetic and social effects. For example, in twin studies, differences between pairs of identical (monozygotic) twins and fraternal (dizygotic) twins are compared; because the identical twins are known to share the same genetic material, smaller average differences in behavior between identical twins than fraternal twins suggest that the behavior is influenced by genetics. In adoption studies, adopted siblings are biologically unrelated to any others raised in the same household, so the effect of the family social environment can be observed by comparing the extent to which adopted siblings resemble others raised in the same family. These models do not isolate any particular gene responsible or associated with behaviors; they simply indicate that there is a genetic component to the observed behaviors.

With advances in genetic technology, more sophisticated methods have become available to researchers. Clinical research using animals enables researchers to ascertain the effects of specific genes. The biochemical effects of these genes can be determined, so researchers are able to observe what the genes do and what the consequences of their actions might be. Drawing upon results of these animal experiments to identify genes that may affect some outcome, scientists can then collect both social and genetic data from humans, which allow them to test for associations between these candidate genes and behaviors. Most recently, the development of genome wide association scans has allowed scientists to use large amounts of information from points along the entire genome in order to examine genetic bases of disease and behaviors.

## GENETIC INFLUENCES ON THE ADULT LIFE COURSE

Genes play a part in several aspects of the adult life course, including physical and mental health, fertility, and criminal behavior. However, individuals' statuses and trajectories at the start of adulthood are shaped by a vast array of influences, including genetic influences, experienced at younger ages. Thus genes also have an impact on the adult life course through their effects on development during youth and adolescence. Genetic influences highlight the long-term, cumulative view of life events and processes inherent to the life course perspective.

Evidence suggests that genetics shape health during adulthood. The most obvious cases are genetic diseases such as Huntington's disease, sickle-cell anemia, and hemophilia. These diseases are Mendelian in nature; that is, there is a simple, almost deterministic relationship between a certain genotype and having the disease. However, most diseases are complex and involve a number of genes and nongenetic factors. For example, in most cases, obesity is not caused by a single gene. Rather, many genes and a large number of factors related to dietary patterns, exercise, and other health behaviors appear to be involved. Using several large genome wide association studies, work has produced evidence that the FTO gene is associated with an individual's propensity to obesity (Frayling et al., 2007). As alluded to earlier, a genome wide association study is a method used to identify genes involved in human disease by searching the genome for small variations that occur more frequently in people with a particular disease than in people without the disease. The data is then used to pinpoint genes that may contribute to a person's risk of developing various diseases.

Genes also are implicated in alcohol use (Nurnberger & Bierut, 2007). Facial flushing, drowsiness, and other unpleasant symptoms from even light alcohol use are observed much more frequently among East Asians than Europeans. Such symptoms mainly occur to those possessing the ALDH2*2 allele, which is prevalent in East Asians and encodes inactive forms of the ALDH2 gene. ALDH2. Research also shows that the presence of the ADH2*2 allele, which is also more prevalent in East Asians and encodes superactive forms of ADH2, can trigger the responses. Probably because of the unpleasant flushing responses, the ALDH2*2 and ADH2*2 alleles tend to protect those who possess the alleles from developing alcoholism. GABA-A receptors are believed to be involved in alcoholism. Studies suggest that the GABRA2 gene is associated with alcohol dependence (Soyka, Preuss, Hesselbrock et al., 2008).

Reproductive behavior, whether a person has children and, if so, when they have their first and how many they ultimately have, is another area of adult life that appears to have a genetic basis. In addition to fecundity, the biological ability to have children, there are a number of crucial steps that lead to childbearing, each of which could also be influenced by genetic factors. Age of sexual debut has been shown to be related to the dopamine D4 receptor gene (DRD4), a gene that has been hypothesized to be related to risk-taking behavior (Guo & Tong, 2006). Another important component of reproductive behavior, a person's number of sexual partners, has been found to be related to the DAT1 gene among males (Guo et al., 2007).

Preliminary work suggests that a number of genes (DAT1, DRD2, and MAOA) are associated with involvement in delinquent and criminal acts during adolescence and early adulthood (Guo, Ou, Roettger et al., 2008). However, even if a gene does have an effect on a

human outcome, the effect is almost never deterministic. Typically, it increases or decreases the probability of an outcome by a moderate amount just like a nongenetic factor. Sometimes, the effect of a gene depends on environmental factors. Avshalom Caspi and colleagues (2002) investigated the role of genotype in violent behavior among individuals who were maltreated in childhood. Males who were maltreated early in life are at risk of becoming violent offenders, but not all males respond to maltreatment in the same way. The study found that a functional polymorphism in the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) modifies the effect of maltreatment. Only maltreated children with a genotype generating low levels of MAOA expression tended to develop the violent behavior problem.

The above examples highlight some specific areas in which researchers are working to untangle the connections among adult outcomes, genes, and social circumstances. However, there are other possible ways to look at the effects of genes on the adult life course. Genetic effects are not necessarily static, as the effects of genes are known to vary across the life course. Because most genes have a number of consequences, a phenomenon called pleiotropy, which aspect of their work that is important can change over time. For example, a gene called p53 suppresses cancer by limiting the proliferation of stem cells (Rodier et al., 2007). Early in life, the consequences of this gene are helpful—a reduced likelihood of developing cancer. However, as the individual ages, the consequence of suppressing the growth of stem cells is a more rapid aging process.

Changes in social environments over the life course also may lead to temporal variation in the effects of genes on behavior. Over time, an individual is exposed to different circumstances, as a result of their age, historical forces, or a combination of the two. These circumstances can alter the way in which genes are expressed. For example, while there appear to be genes associated with drinking behavior, the importance of these genes varies with life course stage. During adolescence, when the individual is subject to strong peer influences about drinking, there is little genetic association between genes and drinking behavior. But later in life, peer group influences are no longer the dominant force in the person's life and the genes become an important predictor of alcohol use (Guo et al., 2007).

## FUTURE DIRECTIONS FOR RESEARCH

This entry has examined a number of paths by which genes could affect the life of an individual, and it may seem that scientists are beginning to understand how genes affect the adult life course. However, current understanding is limited by a number of methodological and conceptual concerns.

First, the relationship between genes and behavior is complex. Some of the relationships between genes and behavior discussed above were direct (e.g., a gene variant raises or lowers the probability of having a disease), whereas others were moderated (e.g., a gene product leads to a particular outcome only under certain circumstances, as in Caspi et al. [2002] about maltreated children.). When the circumstances under which a gene leads to a particular outcome are external to the individual, this situation is referred to as a gene-environment interaction. An example is the case of phenylketonuria (PKU), a condition that develops when individuals born with specific genetic markers are exposed to phenylalanine (an amino acid) in their diet (Khoury, Adams & Flanders, 1988). In a gene-environment interaction, the environment may influence how sensitive individuals are to the effects of a genotype and vice versa (Hunter, 2005). The existence of such complicated interactions makes understanding the effects of genes even more difficult for researchers.

Second, researchers lack the data necessary to research the links among genes, environment, and behavior. To unpack all of the complexity of genes and environments, large-scale collection of both social and genetic information is needed. Because certain genotypes are exceedingly rare, large samples are necessary to analyze their effects. To date, no study has been sufficiently large and detailed to truly capture the nuances of genes and environments. Even with such a data set, methodological issues arise, as the sheer volume of information makes the possibility of false positive results very real.

Third, the outcomes that have been studied thus far are limited in scope; there is room to explore what these genetic factors might mean for career and marriage trajectories, for example. However, with complicated outcomes, more genes and environmental factors will be involved. Thus career trajectories will be much more difficult to study than the trajectory of a person's blood pressure. In addition, research thus far has also examined only a small number of candidate genes. Because researchers rely on previous work to establish a plausible mechanism by which a gene leads to behavioral differences, this gap in knowledge has limited the avenues of exploration. Thus further study is needed on the biological effects of genes and how these effects then translate into observed behaviors.

Finally, the adult years represent the longest span of the life course, yet it remains one of the most understudied areas with regards to genetics and their effects on

the life trajectories of individuals. Further research in this area is critical.

While a number of paths are open to future research, there are also a number of ethical, legal, and social issues related to genetic research. The implications of understanding an individual's genetic inheritance and the consequences of what that knowledge can shed light on about the person and their life are immense. An obvious example is the effect on insurance and access to health care, should genetic predispositions be known—a concern that drove the passage of the Genetic Information Nondiscrimination Act of 2008, which protects Americans against discrimination based on their genetic information. For example, this Act prohibits health insurers from denying coverage to healthy individuals who may be predisposed to developing certain illnesses in the future and also bars employers from factoring in a person's genetic makeup into hiring, firing, and promotion decisions. At the same time, within the medical community there has been a persistent hope that, with knowledge of a person's genome, medicine might be personally tailored in order to more accurately and safely deal with health problems (Guttmacher & Collins, 2005).

More attention is needed to the ways in which information about individuals is safeguarded to protect the individual. In addition, genetic testing reveals information not just about an individual, but also about his or her family. For example, if a young person was tested and found positive for Huntington's disease, the test result would also provide disease information on his or her siblings. With the current medical and scientific system built on informed consent, how does one deal with the fact that by testing an individual, you indirectly test family members, who may not have consented to having their genes tested?

Knowledge of a link between genes and behaviors could lead to targeted social programs. Given the policy necessity of targeting resources where the leverage is greatest, this could mean that an individual could warrant intervention on the basis of genetic heritage, even when others in similar social situations may not. Most fundamentally, as it is learned how genes influence the way in which people live their lives, people have to ask what it means to be "created equal" if there are inherent differences in people that cannot necessarily be overcome by environment or conscious effort.

# GIDDENS, ANTHONY

***(1938–)***

Born in London, Anthony Giddens is a social theorist with an international reputation. In 1985 he was awarded a professorship from Cambridge University and later became the director of the London School of Economics (1997–2003). He was the cofounder of Polity Press, which is now one of the world's foremost publishing companies for the social sciences and humanities. In

***Anthony Giddens.*** JASON BYE/AFP/GETTY IMAGES.

1999 he was invited to present the British Broadcasting Corporations (BBC) Reith Lectures, which he subsequently published in *Runaway World* (1999). He became a member of the House of Lords in 2004. Over the course of his career, he has been awarded 15 honorary degrees. He continues to add to his substantial body of academic writing, which includes more than 40 books. His work has been translated into more than 40 languages.

The theme in much of Giddens's writing is the tension between structure and agency, which culminated in the development of *structuration theory*. This theory was developed incrementally in Giddens's writings that distinguished it from other theoretical approaches such as positivism, interpretivism, structuralism, and functionalism. Giddens (1984) presented a summary in *The Constitution of Society: Outline of the Theory of Structuration*. He proposed that structures consisted of rules and resources, which the agent uses to reproduce social life. *Agency* refers to the ways in which individuals continually monitor, rationalize, and create their social world. Structuration theory moves beyond the polarized positions held by objectivist and subjectivist approaches to understanding the social world and provides a new way of understanding the basic elements of social reality. It describes the production and reproduction of social structures through social practices across time and space, reconceptualizing structure and agency as a duality. For Giddens, structures do not have an independent existence outside of the individual but are always partially internal to the agent, mediated by experience, and continuously produced and reproduced through social interaction.

Giddens's later work applied structuration to the way in which large-scale historical forces such as globalization, modernity, and politics shaped the perceptions and experiences of individuals, with particular emphasis on the implications for self and identity. In *Modernity and Self-Identity* Giddens (2001) claimed that "modernity radically alters the nature of day-to-day social life and affects the most personal aspects of our experience" (p. 1). The primary characteristics of late modernity that Giddens observes include increasing technological advances, multiplicity of choice, a decline in traditions, and a reorganization of time and space as systemic social activities are "lifted out" from localized contexts. The centrality of experts and symbols in the coordination of social relations, in a way that is disembedded from traditional communal ties, radically alters the nature of experience.

Despite the advances of late modernity, Giddens does not consider these features of modernity as signs of increasing order and stability. Conversely, he views them as responsible for an increasing sense of living in an out of control or runaway world. Late modernity's attempt to gain control and mastery over the external environment relies on individuals' reflexivity and their knowledge of their social world; however, knowledge is itself constantly questioned and potentially revisable. The consequent existential experience of anxiety, uncertainty, and risk, Giddens argued, is also evident in people's relationship with their own bodies and identities. One can see this in the increased significance, prominence, and preoccupation with the body, particularly in regards to its appearance and performance.

Furthermore, anxieties emerging from a perception of increased risk have become a particular feature of late modernity, related to associated declines in tradition, increases in choice, and subsequent self-awareness and reflexivity of lifestyles. Reflexivity involves individuals' ability to rationalize and reason about their actions. Allied to this, Giddens (2001) suggested that lifestyles consisting of the repetition of taken-for-granted practices, serve to maintain a sense of *ontological security*. This psychological mechanism of ontological security plays a fundamental role in creating a "protective cocoon" (p. 3) from existential anxieties threatening the individual's self-identity and the effective functioning of society in general.

In *The Transformation of Intimacy,* Giddens (1992) applied the concepts of choice, control, and self-identity in modernity to the arena of intimate relationships. In conceptualising what he called "the pure relationship," Giddens contended that intimacy, like self-identity, is a reflexive practice no longer defined by tradition and that "plastic sexuality" represents the emancipation of sexual expression from the traditional reproductive constraints. This has led to a restructuring and democratization of intimate relationships, which increasingly become mechanisms for exploration of self-identity. Moreover, changes in intimacy also reflect the increasing uncertainty, risk, and meaning creation in late modernity.

Research and theory on the life course have been significantly influenced by Giddens's contributions. In particular, lifestyle projects involving self-actualization have a major impact on the way individuals subjectively experience aging, the choices they are faced with as they age, and the intimate relationships they encounter. In navigating the life course, the individual is increasingly exposed to a multiplicity of choice about the cultivation and reconstruction of the body and self-identity. The resulting ethical dilemmas are the grounds for a new life politics about how people should live in a post-traditional order.

# GLOBALIZATION

Globalization has become a central point of reference for the media, politicians, academics, and policy makers to understand social change. Life course studies therefore increasingly focus on the impact of globalization on life courses in various modern societies.

The term *globalization* summarizes four interrelated structural shifts (Blossfeld, Mills, Klijzing, & Kurz, 2005): (a) the swift internationalization of markets after the fall of the Iron Curtain (which divided Europe into two separate areas from the end of World War II until the end of the 1980s) at the end of the Cold War and the growing integration of cheap manufacturers in eastern Europe, China, and India into the world economy; (b) the rapid intensification of tax competition among nation-states, forcing them to introduce labor and welfare state reforms (such as deregulation, privatization, and liberalization); (c) the accelerated diffusion of knowledge and the spread of networks that are connecting global markets and decision-makers via new information and communication technologies (ICTs); and, (d) the rising vulnerability of local markets because of their dependence on random shocks—such as scientific discoveries, political upsets such as wars and revolutions, economic crises, or price shocks—occurring elsewhere on the globe.

Together these changes are generating an unprecedented level of global competition with resulting structurally based uncertainty for individual actors. In short, globalization is making life courses more insecure. For example, layoffs have become increasingly socially acceptable in the corporate world. Major companies have used the threat of relocating jobs to other locations or countries as a way to secure pay and benefit cuts. Weak unions have little choice but to accept wage cuts or else lose jobs by the thousands. Thus falling wages, reduced benefits, and rising job insecurity seem to be increasingly entrenched features of the new uncertain life courses across most of Western Europe, the United States, and other parts of the developed world. In addition, unemployment and the number of insecure freelance positions are rising while stable jobs with good benefits are being cut. Large numbers of laid-off workers do not get their old jobs back; instead, they are having to look for new work, often in entirely new fields. Those who still have jobs are working longer hours with little prospect of meaningful raises.

Although there is increasing uncertainty in the economic and social spheres of advanced economies, it does not affect all individuals and social groups to the same extent. There are institutional settings and social structures that determine the degree to which people are affected by rising uncertainty (see Figure 1).

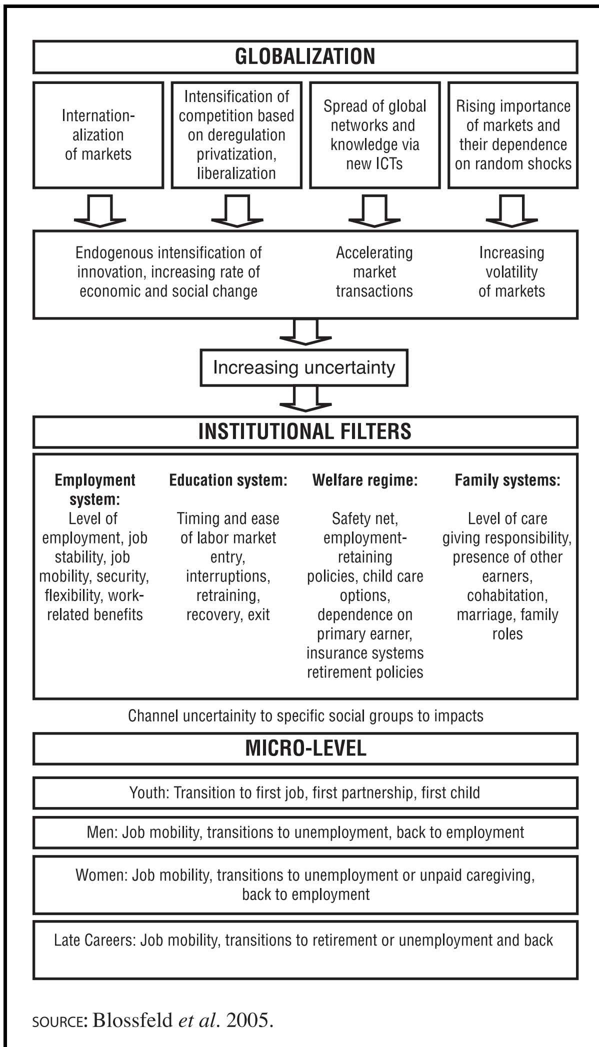

***Figure 1.*** *How globalization creates increasing uncertainty, is filtered by domestic institutions, and impacts life course transitions.* CENGAGE LEARNING, GALE.

## FORCES UNDERLYING GLOBALIZATION

The concept of globalization used here summarizes four interrelated structural forces (see Figure 1). First, globalization refers to the internationalization of markets and subsequent decline of national borders. This is connected with changes in laws, institutions, and practices that make various transactions (in commodities, labor, services, and capital) easier or less expensive across national borders. Taxes on imports, for instance, have been greatly reduced under the General Agreement on Tariffs and Trade (GATT), between member states in the European Union (EU), and via the North American Free Trade Agreement (NAFTA). Capital flows are facilitated by new political agreements. In economic terms, the internationalization of markets is particularly reflected in the rising number of firms conducting business in more than one country, through the presence of multinational corporations (MNCs) and foreign direct investment (FDI). In fact, MNCs are a driving force of the globalization of production and markets because they account for around two-thirds of world trade, 20% of the world's total amount of goods and services, and play a primary role in the diffusion of technology. However, increasingly small and medium-size businesses are also expected to take advantage of cheaper labor in eastern European or Asian countries.

Second, globalization relates to the intensification of competition among nation-states (i.e., the notion that capital and labor, but capital in particular, is increasingly mobile and forcing national economies to compete in attracting global money). Governments are reducing taxes for companies and introducing policy measures designed to improve the functioning of markets, such as the removal or relaxation of government regulation of economic activities (deregulation). Governments are also shifting their policies toward relying more on markets to coordinate economic activities (liberalization), and to transfer the control of assets or enterprises to private ownership that were previously under public ownership (privatization).

A third feature of globalization is the spread of global networks of people and firms linked by ICTs, such as microcomputers and the Internet. These ICTs, together with modern mass media, transmit messages and images instantaneously from the largest city to the smallest village on every continent and allow a faster diffusion of information and knowledge over long distances (Castells, 1996). They increasingly allow people to share information and to connect and create an instant common worldwide standard of comparison. Modern ICTs influence communications between individuals, organizations, and communities by effectively rendering physical space and distance irrelevant. Thus, although the introduction of technology is not unique in itself, recent ICTs have fundamentally altered the scope, intensity, velocity, and impact of technological transformations.

Finally, due to the intensification of competition, globalization also increases the relevance of markets in the coordination of decisions in all modern societies. These developments inherently strengthen the worldwide interdependence of decision-making. As a consequence, market prices and their changes increasingly convey information about the global demand for various goods, services, and assets, and the worldwide relative costs of producing and offering them. These prices increasingly set the standards to which individuals, firms, and nation-states then try to comply. However, globalization does

not only mean that actors are increasingly in the hands of anonymous global markets. What is equally important is that the changes in these markets are becoming more dynamic and less predictable. First, the globalization of markets intensifies competition between firms, forcing them to be innovative, to use new technological developments, or to invent new products. This in turn increases the instability of markets.

Second, modern ICTs and deregulation and liberalization measures allow individuals, firms, and governments to react faster to observed market changes and simultaneously accelerate market transactions. This in turn makes long-term developments of globalizing markets inherently harder to predict. Third, global prices tend to become more liable to fluctuations because worldwide supply, demand, or both are getting increasingly dependent on *random shocks* caused somewhere on the globe. Random shocks may include wide-ranging occurrences, such as major scientific discoveries, technical inventions, new consumer fashions, major political upsets such as wars and revolutions, or economic upsets. The accelerated market dynamics and the rising dependence of prices on random events happening somewhere on the globe produce a higher frequency of surprises. In other words, the increasing dynamics and volatility of outcomes of globalizing markets makes it more difficult for individuals, firms, and governments to predict the future of the market and to make choices between different alternatives and strategies.

## GLOBALIZATION AND DOMESTIC INSTITUTIONAL FILTERS

Increasing uncertainty is not the most important consideration when studying the consequences of globalization for life courses; rather, it is how rising uncertainty is "institutionally filtered" and channeled toward specific social groups in various countries (Blossfeld et al., 2005). Increasing uncertainty does not affect all regions, states, organizations, or individuals in the same way. There are institutional settings and social structures, historically grown and country-specific, which determine the degree to which people are affected by rising uncertainty (see Figure 1). These institutions have a tendency to persist and act as a sort of intervening variable between global macro forces and the responses at the micro level (Nelson, 1995).

Some have argued that globalization undermines the authority or even heralds the fall of the nation-state. However, new research clearly demonstrates that the nation-state and, in particular, institutions that shape life courses do not lose their significance, but generate country-specific problems that call for country-specific solutions and transformations. Thus, one cannot expect that increasing uncertainty leads to a rapid convergence of life courses across all modern societies, as claimed, for example, by neo-institutionalists (social scientists who discuss the way modern societies interact and influence each other, e.g., Meyer, Ramirez, & Soysal, 1992) or the proponents of the modernization hypothesis (who describe the mechanisms which contribute to the social progress of modern societies, e.g., Treiman, 1970). Rather, life course research shows that there are unique developments within countries. The institutions that most impact life courses are employment relations, educational systems, national welfare state regimes, and family traditions.

## GLOBALIZATION, INCREASING UNCERTAINTY, AND LIFE COURSE DECISIONS

Many decisions in the life course have long-term implications. People choose educational and professional tracks, enter and exit job careers, and make long-term binding family decisions. However, higher levels of uncertainty due to globalization generate insecurity and potential conflict and make it increasingly difficult for individuals to make such choices in ways that maximize their best interest and the best interest of their families. A central issue in modern life course research is therefore to understand how people make life course decisions under conditions of increasing uncertainty. For example, it is important to understand how individuals cope with growing uncertainty in their everyday life and the extent to which their (long-term) decisions are shaped by a specific local social context. As Mario Regini (2000) states: "The institutional context, in fact, provides actors with a set of resources and constraints that they must necessarily take into account when choosing among different alternatives and consequently shapes their actions" (p. 8).

## SOME RESULTS FROM THE GLOBALIFE PROJECT

The Globalife project is the first international comparative research project to study the impact of globalization on individual life courses in 23 European and North American societies. It is organized into four volumes that cover the transition from youth into adulthood (Blossfeld et al., 2005), mid-career changes for both men (Blossfeld, Mills, & Bernardi, 2006) and women (Blossfeld & Hofmeister, 2006), and the transition from employment to retirement (Blossfeld, Buchholz, & Hofäcker, 2006) (see Figure 1).

First, this research shows that globalization has influenced young people's ability to establish themselves as independent adults in the workforce, to form romantic partnerships, and to become parents (Blossfeld et al.,

2005). Youth in all studied countries were exposed to dramatically increasing uncertainty at labor market entry in the form of more precarious, lower quality employment (e.g., fixed term contracts, part-time work, lower occupational standing, freelancing, and lower wages). This study also shows that nation-specific institutions clearly shield or funnel uncertainty in unique ways to particular groups of youths. For example, in Italy precarious forms of self-employment among young people have been rising dramatically, or in Spain and Germany the proportion of fixed-term employed young people has been exploding.

The experience of uncertainty is therefore quite unequal among young people, with risk disproportionately accumulating among those in lower-skilled occupations that require little education. There were also clear implications of uncertainty for family formation. Economic, temporal, and employment uncertainties translate into a higher likelihood of postponing or forgoing partnership and parenthood. Thus, globalization contributes to marriage and fertility declines.

Second, Globalife research demonstrates that men in the middle of their careers in countries such as the United Kingdom and the United States, where the labor market is highly deregulated, are also strongly affected by globalization (Blossfeld, Mills, & Bernardi, 2006). In contrast, midlife men in Sweden, Germany, Italy, Denmark, and to a lesser extent Spain and the Netherlands, were more insulated from the negative impacts of globalization. These so-called insider-outsider countries have a history of centralized wage bargaining and restrictions on businesses that mainly protect mid-career men.

Third, Globalife findings demonstrate that globalization has mixed implications for women's employment, largely depending on the welfare state and the country-specific employment regime (Blossfeld & Hofmeister, 2006). In some countries, such as in Germany and the Netherlands, globalization fosters women's employment by allowing more women to (re)enter the labor market than in the past. In these countries, more flexible jobs bring a large group of midlife women into the labor market who previously had no or only marginal difficulty reconciling paid work with unpaid care duties. Yet in other countries that already have achieved higher levels of women's full-time secure employment (e.g., the United States or the Scandinavian countries), employment restructuring due to globalization has the potential to jeopardize that security.

Finally, the Globalife project reveals that older workers are particularly vulnerable in globalized societies because the new type of knowledge-based work in globalized countries puts a huge premium on innovation speed as well as on new technology. New technology and outsourcing renders many established job positions obsolete, in particular the unskilled ones. However, an employer's willingness to invest in retraining older employees is often low because these employees are generally expected to leave the company soon, either due to retirement or poor health. The Globalife project demonstrates great cross-country differences for older workers. In neoliberal countries such as the United Kingdom or the United States, low levels of employment protection foster a relatively high level of labor market mobility among older workers. Low levels of income security provided through public pensions leads to continuous employment even beyond the formal retirement age. In social-democratic countries such as Sweden or Denmark, labor market policies and high emphasis on continuous lifetime education foster older workers' connection to the labor market, while pension systems, to some extent, allow work patterns to remain more flexible. Finally, in conservative and southern European countries, there are relatively high rates of labor market exits through early retirement.

Because of relatively regulated employment relations systems, economic restructuring of work can hardly be achieved by dismissing workers (the so-called insiders). In addition, rigid labor market boundaries created by standardized occupational systems, as in the case of Germany, do not allow the older workforce to move to other jobs easily. In these so-called insider-outsider countries, pension systems therefore provide incentives for an early retirement.

## UNRESOLVED ISSUES REGARDING GLOBALIZATION AND THE LIFE COURSE

Globalization is critical to understanding changes in life courses in modern societies. It forces researchers to develop a multilevel conception that links global transformation to impacts at the institutional and individual level. Different experiences and behaviors in these countries led to several interesting findings in the Globalife study. However, one must concede that life course research that incorporates global changes into its analysis is only just beginning. Much more empirical research is necessary because of the complexity of causal mechanisms that work their way through institutions and labor markets to the individual level. However, the results of the Globalife project stimulate discussion, modifications, and new approaches to study these complex and drastic transformations of modern societies. In particular, more life course research in non-Western nations such as India and China would be necessary in the future. Little is known about the life courses of individuals outside the developed world; in addition to having an impact on the life

course in developed nations, globalization highlights the importance of considering the contours of life courses throughout the world.

## HEALTH BEHAVIORS, ADULTHOOD

There is growing recognition that the U.S. population is well below the level of health possible given the advanced state of U.S. medical technology. This gap is attributed in part to individual behaviors that contribute to a relatively high population-level risk of disease and ill health (McGinnis, Williams-Russo, & Knickman, 2002). Certain health behaviors may contribute to increases in various cancers, stroke, heart disease, and functional impairment. The two most important negative behaviors for adult health are smoking, which is declining over time, and obesity, which is on the rise. A key positive health behavior is regular exercise. Other important behaviors include diet (as related to body weight) and drinking. In addition, research indicates that health behaviors are interrelated and in particular that negative health behaviors cluster together. For example, individuals who are more sedentary are also more likely to engage in other less healthy behaviors such as smoking (Carlsson, Andersson, Wolk, & Ahlbom, 2006). With adjustments in health policy and medical and educational interventions, these behaviors may be changed to improve health and reduce medical costs.

### HEALTH BEHAVIORS AND THE LIFE COURSE

The cumulative impact of lifelong health behaviors on adult health is well established. Many health conditions and mortality in late-middle adulthood are thought to be at least partially the result of the cumulative impact of poor health behaviors (excessively drinking alcoholic beverages, smoking, sedentary lifestyle, high-fat diet, etc.). Many argue that this connection between negative health behaviors and poor health is also true for older adults. Others argue, however, that poor health and old age mortality are unaffected by current or future health behaviors. In this view, once a person has reached old age, poor health behaviors have little bearing on overall health and mortality. Individuals who have survived despite engaging in poor health behaviors are especially robust or physically strong and resilient. It is likely that both of these scenarios are true, with the latter argument true for only a small fraction of the population.

Health behaviors can be shaped by major life course events. For example, as with many other major historical events, the effects of the Great Depression were felt long after the economy rebounded. Elder (1974) notes that the economic hardship experienced during the Depression "had enduring consequences for life course and values" (p. 3). In particular, those who grew up during this time of uncertainty and deprivation placed high value on the stability of the family as they became spouses and parents. Aside from influencing values about the family, constrained family finances and societal resources not only contributed to poor nutrition during this period but also may have shaped long-term values attached to food and weight management. Research suggests that poor prenatal care or poor childhood nutrition and health conditions may have negative effects on health in adulthood (Johnston, 1985), in particular increased risks of chronic diseases such as coronary heart disease, diabetes, hypertension, and stroke. This negative health impact may have been countered somewhat to the extent that experiencing the Depression led to moderate ideas about food intake and thus better weight management.

Other major life events also impact health behaviors; for example, marriage may have a beneficial effect in smoking cessation (Franks, Pienta, & Wray, 2002).

## HEALTH BELIEF MODEL

The Health Belief Model (Becker, 1974; Rosenstock, 1974) provides a framework for understanding why some individuals participate in positive health behaviors (healthy diet, moderate alcohol consumption, exercising, and abstaining from smoking) and others do not. A premise of the model is that individuals' decisions to engage in positive health behaviors (or to change their health behaviors) are based on their evaluation of the possible threat posed by a health condition and the perceived benefits and barriers of taking action to prevent getting the health condition. Two factors influence an individual's assessment of the potential threat posed by a health problem: the perceived seriousness of the problem and the perceived susceptibility to it. In the perceived seriousness dimension, the individual considers the potential social, psychological, and physiological ramifications of the problem if left untreated. The greater the perceived severity, the more likely they are to take preventative action. Concerning perceived susceptibility, an individual evaluates the chances of developing the health problem. The greater the perceived susceptibility, the more likely they are to take preventative action. Factors influencing the assessed benefits of taking action include reducing the risk of experiencing negative effects associated with the disease and of contracting the disease, while the perceived barriers include lack of time or resources.

If the sum of the potential threats outweighs the sum of the benefits and barriers to taking action, positive health behavior is likely (Glanz & Rimer, 1997). From this perspective, research on health in adulthood should focus on identifying interventions effective in enhancing perceived benefits and reducing perceived barriers to healthy behaviors. Understanding these determinants has the potential not only to increase the well-being of the adult population but also to decrease the societal costs associated with poor health in this population.

## DIET AND BODY WEIGHT

Diet is defined as the quantity and quality of food consumed by an individual. A common way to assess healthy body weight (in part the result of diet) is the body mass index (BMI), an index of the relationship of body weight to height, calculated as weight in kilograms divided by height in meters squared. BMI may be assessed using self-reports of height and weight or by taking physical measurements. The National Heart, Lung, and Blood Institute (NHLBI) has developed a BMI classification scheme commonly used by medical practitioners for the clinical assessment and treatment of problems associated with body weight: underweight = BMI $< 18.5$; normal weight = BMI 18.5 to 24.9; overweight = BMI 25.0 to 29.9; and obese = BMI 30.0 and over (NHLBI, 1998). Where body fat is stored on the body is also an important predictor of disease and poor health. The waist to hip ratio is a way to assess healthy body fat and can be defined as the ratio of the distance around the waist to that of the hips.

Although BMI is widely used as a measure of obesity and underweight, it is not a perfect measure. First, although self-reported measures of height and weight are considered legitimate ways of defining body weight, they may also result in underestimating BMI because people of short stature tend to overreport height and heavy individuals tend to underreport their weight (Black, Taylor, & Coster, 1998; Kuskowska-Wolk, Bergström, & Boström, 1992). Therefore, self-reported measurements may produce conservative estimates of how obese a society may be. Second, BMI is a measure of excess body weight rather than excess body fat. Because body composition varies with age, race, and gender, people at the same BMI do not necessarily have the same percentage of body fat or the same risk for adverse outcomes (Flegal, 2000). Third, BMI does not indicate how weight is distributed over the body, which may also be an important and independent health risk. For example, previous research suggests that older women with a low BMI but a high waist–hip ratio (abdominal obesity) have a higher risk of death than heavier women who have a lower waist–hip ratio (Folsom et al., 2000).

**Rationale for the Study of Diet and Body Weight in Adulthood** Social science research on the effects of body weight and health among adults has flourished since the late 1990s. An important health trend has spurred research in this period: Average body weight in the United States has significantly increased over time (He & Baker, 2004), and obesity has become a growing and costly problem. Obese adults have a twofold increase in disease conditions. Disease conditions more prevalent among obese adults include heart disease, diabetes, and certain types of cancers. These national increases in body weight, obesity, and obesity-related health problems likely contribute to elevated medical care costs. One study found that an individual's health care costs are 44% higher when they are obese (Sturm, Ringel, & Andreyeva, 2004). Thus, learning more about body weight, particularly excess weight, could be fruitful in improving quality of life and reducing medical costs among adults.

**Life Course Patterns in Weight** Individuals tend to gain weight through middle adulthood into early old age and then plateau or decline in weight at very advanced ages,

perhaps as a result of disease (Jenkins, Fultz, Fonda, & Wray, 2003). This suggests that middle age is a time of life in which weight management is particularly important to overall health, and especially to health concerns associated with excess weight. In contrast, older age is often marked by weight loss—suggesting a morbid weight loss sometimes related to disease.

**Patterns by Sociodemographic Characteristics** Body weight in adulthood differs substantially by social and demographic characteristics such as race and ethnicity, gender, and socioeconomic status. A review of studies on body weight patterns among African Americans, Mexican Americans, and other Hispanic groups (versus White Americans) indicates that White men and women have lower average body weight than other racial and ethnic groups, but they tend to gain more weight over their lives. In terms of gender, women tend to gain more weight over the life course than do men (He & Baker, 2004). Although on average women's BMI is lower than men's, at the 75th percentile and above of the BMI distribution, women have higher BMIs than men (Williamson, 1993). That is, the prevalence of BMI >= 25 is higher for men than for women, whereas the prevalence of BMI >= 30 is higher for women than for men (Flegal, 2000). That BMI varies by race and ethnicity more so for women than for men suggests a stronger association between weight and women's social and cultural roles. Where body fat is typically stored can also vary by certain socioeconomic characteristics such as gender (Flegal, 2000). For example, men tend to carry their weight around their abdomen and women on their hips and thighs.

Socioeconomic factors play a role in body weight, with the incidence of excess weight and obesity generally higher among those with lower education levels and incomes. The educational differential in obesity tends to be highest among young adults and varies by race at older ages. For example, while obesity is more prevalent among older White Americans with lower education, it does not vary systematically by education among older African Americans. Current older cohorts of African-American adults are in general more poorly educated than upcoming cohorts. Because there is little variability in education among current cohorts, the lack of variability in level of education makes it difficult to see changes in obesity by one's education level (Himes, 1999).

Work transitions in adulthood can contribute to a reduction in economic status, resulting in larger weight disparities in adulthood than in other phases in life. Conversely, excess weight related to health declines, which is more common in adulthood, may contribute to the inability to work, resulting in larger economic effects in adulthood than in childhood or retirement. In other words, body weight may be an important predictor of economic advantage or disadvantage in adults, yet these patterns may vary by gender. For older men, obesity may be related to higher socioeconomic status (Fonda, Fultz, Jenkins, Wheeler, & Wray, 2004). Among more recent cohorts of adults, excess weight among men may be a sign of success or a strong work ethic that could provide them with more resources or opportunities (e.g., higher paying jobs).

In sum, excess body weight, a growing concern in the U.S. population, varies by race, gender, age, and education level, with obesity being more common among some subgroups of non-White persons, women, middle-age adults, and the less educated. In addition, sociocultural groups have differing norms about healthy body weights (Chang & Christakis, 2001), and body composition itself suggests the need for varying interpretations of excess weight. To be effective, programs for prevention and treatment of obesity must take into account these differences in developing and targeting interventions (NHLBI, 1998).

**Patterns in Diet and Body Weight Internationally** Differences exist between lower and higher income countries in the factors associated with body weight. In the United States, lower socioeconomic status is associated with higher BMI, especially among women. In many lower and middle-income countries, the opposite relationship is observed. In these nations, economic development has been accompanied by a transition to a diet high in red meat, saturated fat, sugar, and refined foods—and low in fiber—essentially the "Western diet." This dietary shift emerged after 1950 in East Asia, where an epidemic in excess body weight is starting to emerge. In a lower income country, expanding people's access to money and Western food may actually boost average BMI. For example, in urban India, the affluent are adopting Western dietary patterns and consuming larger quantities of fats, oils, and sugars than are the poor (Chatterjee, 2002). With this nutrition transition (Popkin, 2004) taking hold in lower and middle-income countries, the poorer populations continue to be the most underweight, whereas the affluent have a growing incidence of excess body weight.

**The Relationship of Body Weight with Disease, Functional Impairment, and Mortality** Both too-low and too-high BMI are associated with health problems that can decrease longevity and quality of life. A too-low BMI (commonly defined as a BMI of less than 18.5) has been suggested as one indicator, along with muscle weakness (Shlipak et al., 2004) and improper immune function (Walston & Fried, 1999), of frailty (Fried et al., 2001), a condition characterized by wasting and a decrease in the

body's reserves. Past research indicates that frailty may be a predictor of inability to perform common daily activities such as bathing, eating, and dressing.

Body weight, along with its association with disease, can also affect one's ability to perform basic tasks. Being obese or having a too-high BMI is a contributing factor to a number of chronic medical conditions (Jenkins, 2004) such as hypertension, heart disease, diabetes, stroke, arthritis, and urinary incontinence. Side effects and symptoms of these obesity-related diseases and conditions may themselves contribute to difficulties in doing such things as walking up stairs or getting up from a chair (Himes, 1999; Jenkins, 2004). Being underweight, however, may suggest a concealed disease that would subsequently lead to the diagnosis of a health condition (such as cancer) at a more advanced stage. Side effects and symptoms of certain health conditions can ultimately contribute to impairments.

Even though adults at either extreme in body weight are more likely to have one or more chronic diseases, the same relationship does not hold true for mortality. Individuals who are underweight in middle age and older adulthood are more likely to die than older adults of normal weight. Overweight and obese middle-aged adults are more likely to die than their normal weight counterparts (Adams et al., 2006). In contrast, older adults who are obese have a similar life expectancy to those who are not obese (Reynolds, Saito, & Crimmins, 2005). This finding suggests that there is something unique about older obese adults. They may be particularly robust given that they lived to older age being obese. It is important to remember, however, that their quality of life may still be affected (i.e., they may be more likely to be living with disease and functional impairments) even though their life expectancy may not be affected. Another possibility is that poorer health in midlife contributes to being underweight that then leads to even further health declines.

Several studies have shown that high body weight—beyond its association with debilitating conditions—impairs physical functioning (Clark, Stump, & Wolinsky, 1998; Damush, Stump, & Clark, 2002; Jenkins, 2004). Excess body weight may inhibit functioning in several ways (Launer, Harris, Rumpel, & Madans, 1994). First, excess body weight typically contributes to inflammation of the joint tissues, making walking painful and difficult (Walford, Harris, & Weindruch, 1987). Second, it increases the amount of mechanical stress placed on body joints, elevating the risk for and severity of osteoarthritis (Clark & Mungai, 1997) and increasing functional impairment. Third, excess weight is associated with a sedentary lifestyle, which negatively affects muscle strength and cardiovascular fitness and may eventually result in difficulties with physical functions such as walking several blocks or climbing flights of stairs (Himes, 2000).

The relationship between diet and body weight and smoking, drinking, and exercising is complex in that body weight may interact with these health behaviors in affecting health and functioning. For example, obesity can contribute to the onset of impairment by restricting one's activities making one less likely to experience the beneficial effects of exercise, and in turn making simple activities difficult. In addition, having a lower BMI is associated with smoking cigarettes (Molarius, Seidell, Kuulasmaa, Dobson, & Sans, 1997), perhaps because smoking acts as an appetite suppressant (Perkins et al., 1991). Smoking, however, can also hamper the body's ability to use oxygen, making daily activities, and indeed breathing, difficult (Stuck et al., 1999). Some research indicates that side effects and symptoms of these obesity-related diseases and conditions may themselves contribute to difficulties in doing such things as walking up stairs or getting up from a chair (Himes, 1999; Jenkins, 2004).

Researchers examining the health status of adults must be attentive to the complex interrelationships among body weight, disease, and functional impairment in this age group. Interventions to encourage healthy weight maintenance and weight management are essential, especially for African-American and Latino adults. Targeting obesity is particularly vital to prevent or delay the onset of disease and functional impairment and thereby improve the quality of life of the adult population.

## SMOKING

Smoking in the United States most commonly refers to the consumption of tobacco via cigarettes, but it may also include the use of cigars or a pipe. Like obesity, smoking contributes to a variety of diseases (particularly many cancers and respiratory illnesses), life-threatening health conditions such as heart disease, functional difficulties decreased longevity and higher health care costs. Yet, despite public knowledge of these risks, more than a quarter of the U.S. population continues to smoke (Lahiri & Song, 2000). The proliferation of smoking bans since the late 1990s is likely to have a beneficial effect on the long-term health of society. Among Americans, however, smoking is still considered the most avoidable cause of death (National Cancer Institute, 2007).

**Theories about Why People Smoke** Given the high incidence of smoking in the face of known health risks and public campaigns against smoking, an important

question for researchers and health professionals alike is: What factors motivate people to stop smoking? According to the Health Belief Model (discussed above), an important factor in motivation to change unhealthy behavior is the perceived threat posed by the behavior. Individuals who view their smoking behavior as a threat to their health or life span may be much more motivated to quit smoking than those who do not understand or who underestimate how detrimental smoking is to their lives (Schoenbaum, 1997). Research has shown that smokers know, but tend to underestimate, the dangers of smoking (Schoenbaum, 1997; Smith, Taylor, & Sloan, 2001). A small fraction of smokers may accurately assess the threat posed by smoking, but choose to smoke regardless because they have a high tolerance for risk in this and other areas of their lives (Barsky, Juster, Kimball, & Shapiro, 1997).

**Smoking Internationally** With the bans on smoking in public areas enacted since the late 1990s, particularly in the United States, smoking in higher income countries is steadily becoming more socially unacceptable. With the loss of revenue from these countries, tobacco companies are more heavily marketing in lower income countries to offset the loss. Compared to higher income countries, the health impact of the increased smoking rates may be even greater in lower income countries, where more highly infectious diseases, such as tuberculosis, are still common. It is projected that by 2030 approximately 80% of annual tobacco use deaths will be from lower income countries (Mathers & Loncar, 2006). Aside from the tremendous health impact that tobacco can have on adults from lower income countries, it also takes a severe economic toll. Individuals from these countries may spend already limited resources on tobacco rather than on education and food (World Health Organization, 2007).

**Relationship with Sociodemographic Characteristics** Adult smoking varies by education, race/ethnicity, gender, age, and income. Level of education may be particularly useful in helping practitioners to understand patterns and trends in smoking behavior and aiding health professionals in targeting critical subgroups for smoking cessation programs. Adults with lower educational attainment and income are more likely to smoke compared to adults with higher socioeconomic status (Lockery & Stanford, 1996). Smoking also varies by race and ethnicity, with African-American adults having similar smoking rates as White adults, and higher rates than Hispanic and Asian/Pacific Islander adults (Henry J. Kaiser Family Foundation, 2006). In regard to age and gender, adults in their mid-20s have the highest smoking rates, after which rates tend to decline, and men are more likely to smoke than women.

**Smoking Cessation** Given that smoking contributes to disease, disabling conditions, and decreased longevity, a substantial and growing body of literature addresses smoking cessation. More specifically, one question that is important to study is: What factors may motivate someone to quit smoking? Being diagnosed with a serious chronic condition may motivate an adult to quit smoking. Many older adults do not easily alter lifelong poor health behaviors (Franks et al., 2002). Rather, major health events or transitions spur such changes. This is evidenced by long-term smokers quitting following a cardiac event, such as a heart attack. Higher levels of education may make an older adult even more likely to quit smoking following a health event (Wray, Herzog, Willis, & Wallace, 1998). For example, once an individual is diagnosed with diabetes, they have a higher probability of smoking cessation if they have a college degree compared to having 9 years of education or less (Kahn, 1998). Other life course events, such as having a child, may also prompt an individual to quit smoking.

Another factor that may motivate an individual to quit smoking is the notion that after a number of years, former smoker's health outcomes become similar to those of adults who have never smoked. Smokers are more likely to live more years in failing health. An interesting and optimistic finding, however, is that in regard to the years of healthy life remaining, former smokers (those who stopped smoking 15 or more years ago) were similar to those who never smoked. In order to encourage smoking cessation, health professionals may want to inform patients of the association of smoking with a decrease in living better (Østbye & Taylor, 2004) and educate them on the notion that quitting smoking increases the chances of a healthier life.

Spousal support may also facilitate smoking cessation. At its best, the marital relationship is uniquely intimate and supportive. Individuals also tend to marry people similar to themselves in regard to educational attainment, socioeconomic status, and racial and cultural backgrounds. Thus it is plausible that beneficial changes in smoking behavior may be more likely to be initiated or maintained when both spouses participate in the effort. Clearly, this notion of spousal participation and support has important implications for smoking cessation efforts (Franks et al., 2002).

## ALCOHOL CONSUMPTION

Drinking is defined as the consumption of alcoholic beverages such as beer, wine, or liquor. Researchers and medical professionals consider both the quantity and frequency of alcohol consumption in assessing drinking behavior. Moderate alcohol consumption is defined as no more than one drink per day for men 65 years of age and older and for women of any age and no more than two

drinks per day for men under 65 years (National Institute on Alcohol Abuse and Alcoholism (NIAAA, 1992). The *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition, revised (1987), defines alcohol dependence as positive responses to any three of the following four CAGE (derived from the operant word in each of the four screening questions) assessment questions: (a) Have you ever felt that you should cut down on your drinking? (b) Have people ever annoyed you by criticizing your drinking? (c) Have you ever felt bad or guilty about drinking? and (d) Have you ever taken a drink first thing in the morning to steady your nerves or get rid of a hangover? (Ewing, 1984). A positive response to any one of the four CAGE questions could be indicative of an alcohol problem.

Another definition of heavy or problem drinking commonly used in social science and medical research is binge drinking. The NIAAA's National Advisory Council defines binge drinking as behavior that produces a blood alcohol concentration of 0.08-gram percent or above, which is typically having five or more drinks (men) or four or more drinks (women) in about 2 hours. Heavy drinking, a related term, can be defined as five or more drinks per day for men and four or more drinks per day for women.

**Historical Patterns in Alcohol Consumption** Alcohol use was socially acceptable and increased in popularity starting in the mid-1880s until the prevalence of alcohol-related accidents and illnesses become so widespread and problematic that the social acceptability plummeted, culminating with Prohibition in 1919. Prohibition was revoked in 1933, and a dramatic upswing in the use of alcohol occurred after World War II, followed by a more gradual increase through the 1970s with a peak in 1975 (Nephew, Williams, Stinson, Nguyen, & Dufour, 1999). Recognition of the increase in certain morbidities associated with excessive alcohol use led to a gradual decline in alcohol use until around the late 1990s. Population-based estimates of alcohol use among adults show an increase since the late 1990s (Lakins, Williams, & Yi, 2007).

**Characteristics Influencing Alcohol Consumption** At the population level, patterns of alcohol use vary by societal, cultural, familial, and sociodemographic factors in part because societies and cultural subgroups vary in their social acceptance of alcohol use. For example, cultural conventions about who consumes alcohol and under what circumstances may at least partly explain why men have a higher percentage of heavy alcohol use than women and why Latino and African-American adults have higher percentages of problem drinking than White adults. Within subgroups, families (via family values) further differentiate individual alcohol behavior (Zucker, 2000).

Biological traits that predispose an individual to alcohol use or abuse further differentiate drinking behavior and should not be ignored when attempting to understand patterns in alcohol use (Anderson, 1998a & b). Someone with a biological predisposition to problem drinking who lives in an environment that has more liberal attitudes about alcohol may be more likely to develop problems with alcohol than someone surrounded by more conservative alcohol attitudes (Elder & Caspi, 1989).

Among individuals, drinking behavior remains relatively stable throughout life. Alcohol consumption can often change, however, in response to major life events. Hospitalization and disease onset can lead to a reduction in alcohol consumption, as side effects of medication, treatment, or the disease itself may make an individual feel too ill to drink. On the other hand, retirement, job loss, and widowhood may result in increased consumption (Perreira & Sloan, 2001). In general, stressful life events are thought to be associated with increased drinking behavior, although marital transitions (getting married or divorced) both increase and decrease alcohol consumption (Perreira & Sloan, 2001). Individuals' perceptions of and the lifestyle changes associated with these marital transitions may influence how an adult may use alcohol (either increasing or decreasing consumption) in managing the transition (Perreira & Sloan, 2001).

Socioeconomic and demographic characteristics also influence alcohol consumption. Adults who have lower educational attainment and reside in more rural areas have higher rates of drinking problems (Dawson, Grant, Chou, & Pickering, 1995). Race and ethnicity also influence alcohol consumption. Specifically, in more recent years, a greater percentage of African-American and Latino adults are abstaining from alcohol, but at the same time a greater percentage among those who drink are drinking heavily (Galvan & Caetano, 2003). Factors such as access to health care and racial discrimination are thought to be important explanations for the racial and ethnic differentials in alcohol use. Health insurance status is thought to be another socioeconomic factor linked to drinking behavior. Individuals with health insurance may be more likely to receive primary, secondary, and tertiary forms of treatment for illness and disease than those without. Regular care is thought to translate into better health and potentially less problem drinking behavior. This insurance–drinking connection is supported by two findings: Compared to adults who are either continuously or intermittently insured, adults who are continuously uninsured are more likely to either drink heavily or abstain from alcohol (Baker, Sudano, Albert, Borawski, & Dor, 2001)—both of which are typically related to poorer health and adults who are continuously uninsured tend to have higher CAGE scores.

**Drinking and Health** Although the effects of alcohol use on mortality have long intrigued social scientists, health professionals, and policymakers, until more recently, the effects of drinking on disease and morbidity has received much less attention, with the exception of its impact on cardiovascular and liver disease (Perreira & Sloan, 2002). Nevertheless, excessive alcohol use has been shown to have deleterious effects on various aspects of health and functioning in adulthood. Negative health effects include increased risk of onset of functional impairment and increased amount of impairment; greater likelihood of developing depression and disease (particularly some cancers); and increased risk of occupational injury (Ostermann & Sloan, 2001; Perreira & Sloan, 2002; Zwerling et al., 1996). Yet moderate alcohol consumption (not simply red wine consumption) in adulthood may have some beneficial effects on health, particularly cardiovascular disease. Albeit controversial, there is also growing evidence for a beneficial effect of moderate alcohol consumption on cognition, functional limitation, and disability (Kutty, 2000; Ostermann & Sloan, 2001).

In sum, the growing body of work on alcohol consumption's connection with other aspects of health finds that drinking heavily is related to the onset of functional impairment. Having a history of drinking problems is related to the onset of various mental health conditions such as depression. Other studies find that persons who drink in moderation have the lowest rates of disability, with heavy drinkers and those who abstain from drinking each having a greater likelihood of disability. Those who drink heavily, however, also have a greater amount of impairment on their existing activities (Ostermann & Sloan, 2001). To improve overall health and extend active life expectancy, more research is needed in this area to better understand if a relationship exists between moderate alcohol consumption and beneficial health outcomes in various domains of health. It is also important to note that heavy alcohol consumption can have negative effects on other aspects of life besides health, such as marital disruption and unemployment.

## ILLICIT DRUG USE

Illicit drug use can be defined as the intake of substances for nonmedical purposes, used solely for recreation and the feeling the substance (or substances) provides. Illicit drugs are typically classified into categories. There are several categories in which governmental organizations and the like commonly collect information. These include prescription-type sedatives, pain relievers, tranquilizers, and stimulants (again used for nonmedical purposes); hallucinogens (e.g., LSD, PCP, and MDMA [also know as Ecstasy]), cocaine (including crack), heroin, marijuana (including hashish), and inhalants (e.g., gasoline, glue, and paint).

**Characteristics Associated with Drug Use** Drug use varies considerably by socioeconomic characteristics. Age, geographic area, gender, educational attainment, race and ethnicity, and employment status are all characteristics in which trends in drug use vary. More specifically, adults who are employed full-time (versus unemployed or employed part-time), live in metropolitan areas, male, American Indian or Alaskan Natives (compared to individuals who are classified as Asian, of two or more races, Black, White, Hispanic, or Native Hawaiian or other Pacific Islander) are more likely to be currently involved in illicit drug use. Interestingly, though, drug use is highest among adults 18 to 20 years of age followed by adults 21 to 25 years of age; after that there is a gradual decline in illicit drug use with increasing age. College graduates have the lowest rate of current illicit drug use (compared to other individuals classified with lower educational attainment). Yet, compared to adults who did not complete high school, college graduates are more likely to have tried an illicit drug at some point in their lives (SAMHSA, 2006).

**Gateway Hypothesis** The general premise of the gateway hypothesis is that initiation into "harder" classifications of drugs (e.g., cocaine and heroine) is derived from first use (usually in adolescence) of "softer" drugs such as alcohol and cigarettes. There is general support for the gateway hypothesis in the research community. Yet it appears to not be generalizable to all subgroups of the population (e.g., homeless individuals). Certain subgroups seem to follow different substance use trajectories.

Social scientists examine this hypothesis through various lenses, and each contributes unique insights. Economists, for example, typically examine adolescent substance use through the lens of consumer decision-making rather than deviant behavior (Kenkel, Mathios, & Pacula, 2001). Two important economic constructs that contribute to economic modeling of consumer behavior, with alcohol and drug consumption behavior being no different, is the price and availability of goods. Economic theorizing of these two constructs, in regard to the gateway hypothesis, suggests that alcohol and tobacco may serve as gateway drugs in part because of their lower user cost and relatively easy access compared to harder substances. Economic theory argues that the use of these substances varies by gender, race, and ethnicity in part because of accessibility (Kenkel et al., 2001). More specifically, the gateway drug of choice is different for males and females; the two differential initial steps toward illicit drug use appear to be alcohol (for males) and tobacco (for females) (Kandel & Yamaguchi, 1993).

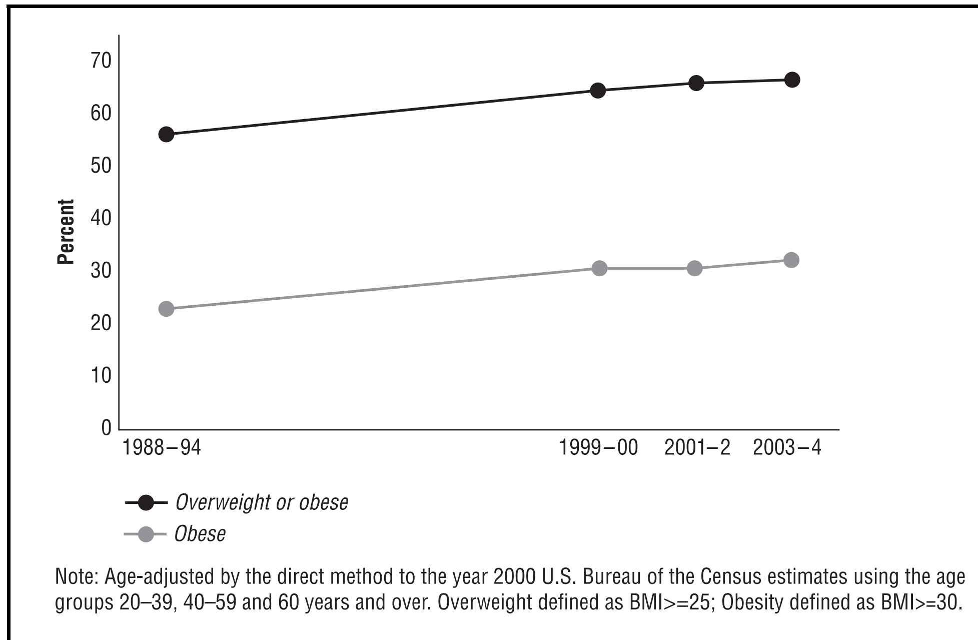

***Figure 1.*** *Trends in adult overweight and obesity, ages 20 years and older.* CENGAGE LEARNING, GALE.

The price and availability of goods as foci in economic modeling of the gateway hypothesis also has important policy implications, particularly in regard to taxation and restrictions of alcohol and drug use. One outstanding policy question for which economic modeling can be particularly useful is: Does a reduction in the use of alcohol or tobacco lead to a reduction in the use of other drugs? There is some evidence to support that indeed higher prices of gateway substances reduce the use of other substances (DeSimone, 1998; Pacula, 1998). With that in mind, taxing the purchase of alcohol and cigarettes and creating stiffer penalties for persons who sell these substances to underage individuals may be some tangible policy-driven methods to reduce substance use problems (Kenkel et al., 2001).

## EXERCISE

Defining exercise is complex. One traditional definition of exercise is to physically exert oneself with the intention of benefiting one's health. There are also various dimensions of exercise that one might consider when discussing a definition: frequency, length of participation, and the type of activity in which one engages (e.g., light or vigorous activity). More recently, researchers, health professionals, and policymakers have taken on a more expansive view of exercise and discuss it in terms of being more physically active or having an active lifestyle. This more modern definition deviates slightly from the more traditional one in that the traditional definition of exercise can be thought of as structured and done with the main purpose of benefiting one's health (e.g., running, bicycling, or swimming), whereas physical activity may or may not be structured and done with the main purpose of having a health benefit. Examples of being physically active are heavy housework, gardening, or dancing. The current recommendation for most adults is 30 minutes of physical activity each day.

The shift from more labor-intensive agricultural and factory jobs to more information management and technical jobs over the past century has contributed to adults being more sedentary. This lack of daily activity on the job is a problem of great public health interest and has made leisure-time physical activity much more important. Lack of exercise is a multifaceted problem that affects many aspects of mental and physical well-being. It has been associated with functional impairment (Jenkins, 2004), depression, survival (Richardson, Kriska, Lantz, & Hayward, 2004), and various diseases such as heart disease, hypertension, cancer, diabetes, and stroke. Because a sedentary lifestyle is an increasing threat to health and longevity, understanding how to incorporate physically active tasks into daily life may prove beneficial in targeting interventions to increase physical activity levels and improve the health of adults.

**Differential Patterns in Exercise** Evidence suggests that women, racial and ethnic minorities, persons with lower socioeconomic status (Crespo, Ainsworth, Keteyian, Heath, & Smit, 1999), married persons (Pettee et al.,

2006), and rural residents (Arcury et al., 2006) are less likely to participate in physical activities. These are the subgroups most important to target for effective exercise interventions. Research on the determinants of exercise has generally found significant positive effects of both early life and adult socioeconomic status, as measured by parents' education, own education, and economic resources (Wray, Alwin, & McCammon, 2005). Spousal relationships impact health in part because of similarities in both partners' environments. Married couples reside together and therefore are exposed to the same environmental toxins and neighborhood stressors and share household income. With that in mind it is not so surprising that their health behaviors are often very similar. If a husband participates in moderate exercise it is likely that his wife will too. This has important implications for encouraging active lifestyles. Encouraging activities that appeal to both spouses may aid in maintaining health-promoting behaviors (Wilson, 2002).

**Exercise, Disease, and Functioning** Exercise provides many mental and physical health benefits, and these occur through a variety of mechanisms. Lack of exercise contributes to decreased muscle strength and cardiovascular fitness, which can increase the risk of disease and decrease the ability to perform basic daily activities such as walking or dressing oneself. Adults who participate in regular vigorous physical activity are less likely to experience various diseases and the onset of functional impairment.

Physical exercise has also been shown to have beneficial effects on diverse mental health outcomes, particularly depression (Ruuskanen & Ruoppila, 1995), and has been suggested as a possible treatment for this condition (Barbour & Blumenthal, 2005; Blumenthal et al., 1999). Among adults (60 years of age and older), those who did not need to give up any physical activities and those who found a satisfying replacement for them had lower levels of depressive symptoms (Benyamini & Lomranz, 2004). Several possible linking mechanisms have been suggested for this association including both physiological mechanisms (e.g., central monoamine theory) and psychological factors (e.g., improvements in self-efficacy) (Barbour & Blumenthal, 2005).

Health-promoting behaviors such as exercise are assumed to have the potential to improve quality of life and thus decrease health care costs by preventing disease. Even among older adults this is generally the case—light and heavy long-term exercise does show a slight decrease in health care use (Lee & Kobayashi, 2001). Some empirical evidence, however, supports the opposite patterns for short-term exercise. Short-term light exercise is related to a slight increase in the use of the health care system (e.g., doctor visits or hospital days). One possible reason for this finding is that older adults who initiate only a light exercise regimen but do not maintain it for longer periods may be less healthy. They may view themselves as unhealthy and, knowing the health benefits of exercise, try to engage in a more active lifestyle. Because they do not maintain their exercise regimen, however, they do not reap the health benefits.

It is important to recognize the negative health effects that arise from a sedentary lifestyle. Encouraging routine daily exercise is a significant goal in the effort to improve the health and quality of life of adults. It is also important for policymakers and persons engaged in clinical practice to remember that individuals are more apt to spend time doing what they enjoy and to make time to do such activities, so it is especially important to make physical activities more appealing to certain subgroups of adults who are among the least physically active. More knowledge on the barriers of routine exercise and having an active lifestyle might help both policymakers and researchers target interventions and resources most cost-effectively.

## CONCLUSION

Encouraging positive health behaviors early in life is important because health behavior change over the life course is difficult. Positive behavior change, however, even in later life, can be beneficial to overall health. With chronic diseases with long etiologies being common in the United States, a long-term commitment to a healthy lifestyle is encouraged in order to prevent rather than manage such illnesses.

The study of health behaviors is a fruitful area of research for both public health practice and policy. With poor health behaviors, particularly lack of physical activity and excess body weight, being commonplace in the United States, insight on the characteristics that may assist in the development of interventions and educational tools to encourage active and healthy behaviors for adults is important. A better understanding of the relationship between barriers to participating in exercise, maintaining a health body weight, smoking cessation, and responsible drinking will also allow public health policymakers more effectively target resources and interventions to reduce the life-threatening health problems associated with behaviors and improve the health and quality of life of adults.

# HEALTH CARE USE, ADULTHOOD

Health care can be defined as any product or service designed to prevent, treat, or manage illness, or maintain mental and physical well-being. Health care has gone from a relatively minor part of the world's economy, to a sizable proportion of the economies of most developed nations. The United States, for example, spent about $1.9 trillion on health care in 2004, or 16% of its gross domestic product (GDP) (Stanton & Rutherford, 2005). Though the United States spends far more both in absolute and relative terms than any other country (Schoen et al., 2007), the increasing prominence of health care in people's lives and in national budgets is a worldwide phenomenon.

## THEORIES OF HEALTH CARE USE

Various aspects of health care, including the determinants and consequences of utilization, are studied across a variety of disciplines, including sociology, economics, and public health. This interdisciplinary field is often referred to as health services research, and several scientific journals are dedicated to the topic. In this literature, two theoretical models, the Health Belief Model (Rosenstock, 1966) and the Behavioral Model of Health Care Use (Andersen, 1968), are commonly used to understand patterns of health care utilization. The Health Belief Model was developed to explain health behavior and use of preventive care, and focuses on one's perceptions, beliefs, and other psychological characteristics that determine whether individuals perceive themselves to have a health problem or are willing to change their behavior or seek care to ameliorate it. The Health Belief Model asserts that the decision to use health care, or to change any health related behavior, is determined by perceptions across the following four dimensions: (a) severity of the illness; (b) susceptibility to the illness; (c) the benefits associated with preventive use or behavioral change; and (d) the barriers to use or behavior.

In contrast, the Behavioral Model takes a systems approach to understanding health care use, categorizing the determinants of use into three groups: (a) factors that predispose individuals to use health care; (b) factors that enable individuals to get care, or impede them from doing so; and (c) factors that relate to the need for health care. Demographic variables such as age, gender, and race are examples of variables usually considered *predisposing* factors; insurance coverage and income are examples of important *enabling* or *impeding* factors; and the presence or absence of specific chronic conditions are examples of *need* factors. Note that the Behavioral Model tends to lump all the social and psychological factors central to the Health Belief Model into the predisposing category.

Though developed in the 1960s, both the Health Belief Model and Behavioral Model are widely used in health services research in the early 21st century. Both are, nonetheless, subject to several critiques. Critics of the Behavioral Model suggest that it places too little emphasis on social, cultural, and psychological factors that contribute to health care use, whereas critics of the Health Belief Model suggest that it places too little emphasis on individual and organizational barriers to obtaining needed health care. Both theoretical frameworks are criticized for being little help in understanding issues regarding the timing of health care utilization, the quality of care, and the continuity of care—all issues that are of growing importance in health services research. It has also been suggested that both the Behavioral Model and the Health Belief Model place too much emphasis on individual decision making, while underemphasizing how social context and social interaction affect beliefs on health and illness and, also, what actions are appropriate and desirable in response to different health conditions (Pescosolido, 1991; Pescosolido, 1992).

From these criticisms, new models are emerging. One example is the Network Episode Model (Pescosolido, 1991; Pescosolido, 1992). Its main focus is how social interaction, structured by social networks, influences the ways individuals recognize and respond to illness. Rather than viewing decisions regarding health care as one-time choices, the Network Episode Model views health care use to be a dynamic process, informed by social interaction both in families and communities and in formal health care settings. Utilization models, like the Network Episode Model, that move away from examining single choices are promising because health care use is increasingly driven by chronic, age- and lifestyle-related conditions. Such conditions often require long-term reliance on formal and informal health care and, therefore, decisions regarding health care use are not one-time occurrences.

## COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine (CAM) is a diverse set of approaches and therapies for treating illness and promoting well-being that generally fall outside of standard medical practices. These approaches are usually not taught in medical schools, and not practiced by physicians or other professionals trained in medical programs. Examples of common CAM therapies include chiropractic, massage, homeopathy, and acupuncture. Complementary medicine is distinct from alternative medicine in that the latter is meant to be used in place of standard medical procedures, while the former is meant to be used in conjunction with medical procedures to increase their efficacy or reduce side effects.

Use of complementary and alternative medicine is common, even in industrialized countries with modern medical systems. For example, a survey in the United States shows that the number of individuals using some form of CAM during 2002 was over 62% (Pagan & Pauly, 2005). Furthermore, the use of CAM has been increasing for at least the late 1980s (Eisenberg, Davis, Ettner, & Appel, 1998).

### DATA ON HEALTH CARE USE AND ACCESS

Data on health care use generally come from two sources: surveys and administrative records. In the United States, for example, the National Health Interview Surveys (NHIS) and the Medical Expenditure Panel Surveys (MEPS) collect information on health insurance coverage, use, expenditures, and attitudes about health care for the noninstitutionalized population; the Medicare Current Beneficiary Survey (MCBS) collects information on enrollees in the Medicare program. The second source of data on health care use, administrative records, makes use of data from hospital discharge records and other records kept by medical practices and institutions. Both survey and administrative data sources have advantages and disadvantages. The advantage of administrative records is that they usually provide accurate information on the exact type of service used, the date of use, how much was paid, and the source of payment. The disadvantage of this type of data is that detailed information on the characteristics of individuals and households such as income, education, and attitudes about health is limited or nonexistent. Surveys, in contrast, can provide very rich data on individuals, their families, and their attitudes about health, but rely heavily on self-reports for information on health care use and expenditures.

Access to health care, or the ability to obtain needed medical services in a timely manner, is an important

concept in health services research, but is difficult to measure. It is frequently measured by health care use, but this is not ideal because use is strongly linked to the need for health care. For example, healthy individuals with jobs that provide generous health benefits may have excellent access to health care, but little or no use. In contrast, unhealthy individuals with poor health insurance coverage may have very high levels of health care use out of medical necessity, but still not be able to get all the care they truly need. Several indicators of access are frequently used to avoid this problem. One approach is to consider hospitalizations for what is termed *ambulatory care sensitive conditions* (Ansari, Laditka, & Laditka, 2006). The underlying idea is that a hospitalization for a condition that could have been avoided or managed better in an outpatient setting is a sign of having poor access to quality health care. This approach to studying health care access often uses administrative records. Other commonly used measures for access are whether someone has a usual source of care, and subjective assessments of the ability to obtain needed medical care (Kirby, Taliaferro, & Zuvekas, 2005; Zuvekas & Taliaferro, 2003). These measures usually come from survey data.

## PATTERNS OF HEALTH CARE USE OVER THE LIFE COURSE

Though the amount and intensity of health care use varies widely across individuals, there is a definite pattern of use seen in a typical lifetime, at least in industrialized societies. Health care use is high at the beginning of life, as many births in industrialized countries are now in hospitals and attended by physicians, and continues at a fairly high level into adolescence. Standard medical practice in most industrialized countries consists of frequent visits for very young children, with declining frequency as children age. Health care use declines thereafter and young adults beginning their careers tend to have the lowest health care use of any age group, as they tend to be the healthiest, and are least likely to have the time or money to spend on physician visits. In the United States, these are the years in which individuals are least likely to have health insurance. For women, childbearing prompts an increase in health care use. For both men and women, individuals begin to use more health care services starting in their 40s and 50s and this increases steeply and in a nonlinear fashion with age. Thus, the shape of the health care utilization curve resembles a mortality curve, in that the incidence of use is high at very young ages, declines until early adulthood, and increases thereafter.

A noteworthy characteristic of health care use across the life course is the extent to which it is concentrated toward the end of life. For example, data from the MCBS in the United States suggest that around 27% of all health care expenses among older people go toward care received in the last year of life (Hogan, Lunney, Gabel, & Lynn, 2001). This frequently cited statistic is, however, somewhat misleading. The concentration of usage in the last year of life is often considered the main cause of the high cost of care, but this is debatable. The proportion of medical expenses incurred in the final year of life has not changed much since the 1970s (Hogan et al., 2001), despite the rapid development of expensive new medical technology. Use of inpatient hospital services, the most expensive type of health care, by the terminally ill actually declined beginning in the late 1980s and 1990s (Hoover, Crystal, Kumar, Sambamoorthi, & Cantor, 2002). It is possible that initiatives to promote the use of hospice care and advance directives may have held down end of life expenses. When expenses for decedents are compared to that of survivors with similarly severe conditions, differences in expenses are minimal (Hogan et al., 2001). Thus, what is often termed the *high cost of dying* is really just the high cost of being severely ill.

## DISPARITIES IN HEALTH CARE USE AND ACCESS

Health services researchers have documented large and persistent disparities in health care use and access to quality health care by race, ethnicity, and various socioeconomic characteristics, even in nations with universal health care coverage. Racial and ethnic minorities and the poor generally use less care, report more problems with getting care, and have less favorable outcomes from the care they get than others (Agency for Healthcare Research and Quality, 2006). In the United States, for example, Blacks and Hispanics are less likely to have any ambulatory care during a year, are less likely to have a usual source of care, and more likely to report barriers to obtaining care than non-Hispanic Whites (Kirby, Taliaferro, & Zuvekas, 2005). Differences emerge for many specific services too. For example, in the United States, Black children are less likely to have up-to-date vaccination coverage than Whites (Chu, Barker, & Smith, 2004), and Black adults at risk of sudden cardiac death are less likely to have an implantable defibrillator (Stanley, DeLia, & Cantor, 2007). Socioeconomic disparities in access and use are as large as or larger than racial or ethnic disparities. These disparities in health care regarding socioeconomics and race or ethnicity are still not fully understood by researchers. Individual, family, and community characteristics currently thought to affect disparities explain only a fraction of the differences observed (Kirby, Taliaferro, & Zuvekas, 2005).

## HEALTH SERVICES RESEARCH AND LIFE COURSE CONCEPTS

Developing a system that organizes, finances, and distributes health care in a financially sustainable and equitable

way is a goal that motivates much health services research. To achieve this, a basic understanding of how people perceive and respond to health and illness, and how they interact with various actors in modern health care systems, is essential. To date, life course concepts have been notably lacking in this effort, and have been lacking in health services research in general. This is unfortunate because as populations age and health care utilization is increasingly driven by conditions related to chronic diseases, life course concepts become increasingly relevant. For example, the life course concepts of timing, sequence, and duration applied to different health-related experiences, including interactions with health care systems, could shed light on some of the questions important in health services research. *Linked lives* is another important life course principle that is relevant in the study of health care use. Attitudes about health and health care, and about how best to respond to illness, are formed and influenced by interactions within complex social networks. These and other concepts from the life course perspective are powerful and largely untapped resources in health services research.

# HEALTH DIFFERENTIALS/ DISPARITIES, ADULTHOOD

The term *health disparities* refers to differences in measured mental health, physical health, and death rates (often termed *outcomes*) across meaningful social and demographic groups within a population. While a population can be defined at many different levels (e.g., a hospital population, a clinic population, a city population, or a state population), this entry focuses on health disparities within the working-aged (ages 25 to 64) population of the United States as a whole. Because of the very wide range of health outcomes that can be examined, only the most general of those outcomes will be dissected here. Similarly, because of the breadth of sociodemographic groups for which disparities are measured, this entry will focus on health disparities in adulthood by gender, race and ethnicity, and educational attainment, while recognizing that there are also well-documented U.S. health disparities across income groups, occupational groups, geographic regions, and more.

## THE SIGNIFICANCE OF HEALTH DISPARITIES

One of the two overarching goals of the U.S. government's *Healthy People 2010* initiative is to eliminate health disparities among different segments of the population. Specifically, the goal refers to differences that occur by gender, race or ethnicity, education or income, disability, geographic location, or sexual orientation (U.S. Department of Health and Human Services, 2000). The *Healthy People 2010* initiative and the health disparities goal, in particular, have helped create enormous scientific

and policy interest on this topic. Scientifically, health disparity studies range across academic disciplines, from public health, medicine, nursing, and biology to economics, geography, sociology, and demography. Indeed, it would be impossible for any review to cover the massive amount of literature on this topic that has been produced in many disciplines since the early 1990s. Policy-wise, the goals and objectives of *Healthy People 2010* have, perhaps most notably, led to significant increases in funding at the federal level for research and programs specifically dedicated toward the better understanding of why health disparities exist and how to eliminate them.

The significance of U.S. health disparities is at least threefold. First, documented health disparities indicate inequalities in well-being across subgroups of a population. Thus, in a society that is striving for both overall excellence as well as excellence in health within all subgroups of the population, disparities in measured outcomes symbolize systematic, unequal access to some of society's most important resources, including the length of life itself. At issue, then, is fairness across population subgroups. Second, continued health disparities in a nation as wealthy as the United States serves as a reminder that even though the overall level of health achievements over the last century or more has been extraordinary, there is still much room for improvement if all groups are to be as healthy as the most advantaged group. Third, individuals in the subgroups who have less favorable health and higher mortality rates experience substantial amounts of human suffering, increased health care costs, and loss of economic productivity that could potentially be alleviated if health disparities did not exist. Together, these add up to some of the most critical social, health, and ethical issues in the 21st-century United States.

Beyond the general significance of health disparities, the topic's significance among the U.S. working-aged population may be especially important. While a great deal of research—and justifiably so—focuses on health disparities among the older population (i.e., age 65 and older) of the United States, measured health disparities by gender, race or ethnicity, and education have often been found to be wider during the working-aged years in comparison to the older adult years (Rogers et al., 2000). Moreover, thinking about health disparities from a life course perspective makes clear that what happens during the working-aged years—such as marriage or divorce, parenting, career trajectories, income trajectories, access to health insurance, and preparation for retirement—is a very important determinant of later life health. Thus, the working-aged years help to structure health disparities during middle and old age. Moreover, life course approaches to health disparities should step back even further—to adolescence, childhood, and even previous generations—to best understand how disparities in the working ages and older adult ages develop.

## CURRENT HEALTH DISPARITIES WITHIN THE U.S. WORKING-AGED POPULATION

In this section, disparities will be briefly documented in two general but very important measures of health during the working-aged years—self-reported health and mortality rates—by gender, race or ethnicity, and education. The reasoning for the focus on these two common health outcomes is that, first, self-reported health has been found to be a very strong predictor of subsequent mortality risk, even when other physical health conditions are statistically controlled. Further, it is a standard item on many health surveys. In this case, people who report either fair or poor health are compared to those who report excellent, very good, or good health. Second, mortality rates provide a useful summary indicator of the overall health of a population and its subgroups. There are, of course, many other indicators that could be examined (e.g., activity limitations, presence of hypertension or diabetes, cancer prevalence, measures of mental health, and more). Further, this entry's examination of sociodemographic disparities will be limited to gender, race or ethnicity, and education. The U.S. population clearly continues to be stratified across categories of these sociodemographic factors and this stratification has significant consequences for health outcomes. A more comprehensive documentation would include a full analysis of other sociodemographic characteristics including, but not limited to, sexual orientation, religion, marital status, income, occupation, immigration status, and geographic location.

Nationally representative and publicly available data collected and made available by the federal government are often used to document these disparities. This entry's documentation of disparities in self-reported health specifically draws on nationally representative survey data from the 2004 National Health Interview Survey (NHIS), collected and processed by the National Center for Health Statistics. This annual survey of the U.S. population has collected data from tens of thousands of noninstitutionalized U.S. adults each year since 1957 and is considered to be the nation's core source of information for population-level health and health care trends and disparities. This entry's documentation of disparities in mortality within the working-aged population specifically draws on published data from the National Vital Statistics System, which is also a product of the National Center for Health Statistics. The calculation of mortality rates in this system relies on death counts, taken from U.S. death certificates, as the numerator in the mortality rates and population estimates,

***Table 1.*** *Percentage of U.S. working-aged adults who report fair/poor health in 2004 by sociodemographic group.* CENGAGE LEARNING, GALE.

taken from the U.S. Census Bureau, as the denominator of the mortality rates.

Turning first to self-reported health, Table 1 shows the percentage of U.S. working-aged adults who report being in fair or poor heath, by sociodemographic group and by age. Across each sociodemographic group examined, the percentage of individuals reporting fair or poor health is higher in older age categories, as might be expected. By gender, women report worse health than men for all age groups except between 55 and 64; in that interval, there is no statistically significant difference in the percentage of men and women reporting fair or poor health. The overall gender difference in reporting poor or fair health in the full age range of 25 to 64, 12.1% for women versus 10.1% for men, while statistically significant, is not nearly as wide as the disparities by race or ethnicity and educational level.

Table 1 next shows self-reported health disparities across seven self-identified racial or ethnic groups. American Indians have the highest percentage of all the racial and ethnic groups of reporting fair or poor health in each of the 10-year age categories shown, as well as for the entire working-aged population. For the entire age range, 23.8% of American Indians reported poor or fair health, compared to just 9.4% among non-Hispanic Whites. In contrast, there are no significant differences between Asian Americans and non-Hispanic Whites in reporting fair or poor health. Both non-Hispanic Blacks and Mexican Americans have significantly higher percentages of persons reporting fair or poor health than do non-Hispanic Whites within each 10-year age category, as well as for the entire age range. Puerto Ricans have significantly higher percentages of persons reporting fair or poor health than non-Hispanic Whites for ages 35 to 44 and 55 to 64; these percentages are also higher than those for non-Hispanic Blacks and Mexican Americans.

Table 1 further shows that educational disparities in self-reported health are substantial. Nearly all education levels for all age groups are characterized by a higher percentage of individuals reporting fair or poor health when compared to the reference category of 17 or more years of education; the only exception is that the health reports of persons with 16 years of completed education do not differ from those with 17 or more years in the 25 to 34 age group. Looking within the 10-year age categories, some of these self-reported health disparities by education are very large. For example, within the 35 to 44 age group, 18.3% of people with 9 to 11 years of education reported poor or fair health, compared to just 1.4% of those with 17 or more years of education. Even

***Table 2.*** *Age-specific mortality rates for US working-aged adults by sociodemographic group.* CENGAGE LEARNING, GALE.

at the highest levels of education, there are significant differences between 16 years of education (which is synonymous with attaining a bachelor's degree) and 17 years or more of education (which is any education beyond a bachelor's degree); for example, 4.9% of working-aged adults with 16 years of education reported poor or fair health compared to 3.3% of those with 17 or more years of education.

Table 2 displays age-specific mortality rates (number of deaths per 100,000 persons) for U.S. working-aged adults by sociodemographic group. For all categories of each sociodemographic factor, mortality rates consistently are higher among older age groups, as might be expected. Within each 10-year age category, females have much lower mortality rates than their male counterparts. At the youngest age group (ages 25 to 34), for example, the male mortality rate is more than double that of females. Higher male rates of mortality across the life course result in a life expectancy for men (74.7 years) that is currently more than 5 years less than that of women (80.0 years). This life expectancy disparity by gender is lower than the 8-year disparity observed in the 1970s, but is still very wide (Arias, 2007).

Table 2 next shows age-specific mortality rates for six racial and ethnic groups. Non-Hispanic Blacks experience the highest mortality rate within every age group as well as within the entire 25 to 64 age range. Among the Hispanic ethnic groups, Puerto Ricans experience the highest mortality rates, whereas Mexican Americans and other Hispanics experience relatively similar and much lower age-specific mortality than Puerto Ricans and non-Hispanic Blacks. Within each age group, Puerto Ricans are the only Hispanic ethnic group to experience a higher mortality rate than non-Hispanic Whites. However, for all ages combined, the Puerto Rican mortality rate is lower than that of non-Hispanic Whites. This reflects the younger average age of the Puerto Rican population compared to the non-Hispanic White population and the fact that mortality rates are lower for younger people.

Mexican Americans and other Hispanics, by contrast, experience mortality rates that are lower than non-Hispanic Whites within each 10-year age group, as well as within the entire working-aged population. The relatively low mortality rates of these Hispanic ethnic groups, in combination with their relatively high rates of poverty and low levels of education, have been termed an *epidemiologic paradox* (Markides & Coreil, 1986). This is in contrast to the very strong correlation between the high rates of poverty and high mortality rates experienced by non-Hispanic Blacks. The epidemiologic paradox among U.S. Mexican Americans is a topic of much scientific research. Current work suggests two clear reasons why Mexican Americans exhibit relatively low rates of mortality in the United States: (a) They are characterized by a high percentage of recent

immigrants, who tend to be very healthy when they migrate to the United States; and (b) they exhibit very low levels of negative health behaviors, such as cigarette smoking, heavy alcohol use, and use of illegal drugs.

Turning to educational disparities, it is clear that mortality rates have an inverse relationship with education for each 10-year age group. That is, individuals who attain higher levels of education have much lower rates of working-aged mortality in the United States. For example, the mortality rate for individuals aged 25 to 34 with 0 to 11 years of education is about 4 times as high as the rate for individuals with 13 or more years of education in that age group. Moreover, it is evident that education can protect health not only within a particular age group, but across all age groups. For example, the mortality rate for persons aged 55 to 64 with 13 years or more of education is lower than the mortality rate for persons aged 45 to 54 and 55 to 64 with either 12 or 0 to 11 years of education.

## CAUSES OF HEALTH DISPARITIES

Research suggests at least four general sets of factors leading to the development of U.S. health disparities by gender, race or ethnicity, and educational level during the working-aged years: (a) biological factors; (b) behavioral causes; (c) psychosocial factors; and (d) differential access to health-promoting resources across sociodemographic groups.

Biological factors, for example, have been linked to health disparities by gender (Waldron, 1983). The most obvious example is that women are exposed to both common and severe health-related risks associated with pregnancy and childbirth, whereas men are not. Historically, mortality rates among women during the childbearing ages were strongly influenced by risks associated with pregnancy and childbirth; fortunately, this is no longer the case. Women are also protected, in part, from some infectious diseases and circulatory diseases during early adulthood because of the presence of estrogen, whereas men are more likely to be characterized by the harmful effects of the accumulation of fat in the abdominal region (Waldron, 1993). Biological factors are thought to have much less of an impact on either racial and ethnic or educational disparities in health during the working-aged years.

Behavioral factors across sociodemographic groups can also produce health disparities. Cigarette smoking is an excellent example. Convincing research shows that heavier smoking by men than women had a major impact on gender-specific health disparities in the United States, resulting in much higher male mortality when compared to female mortality throughout the 20th century. The impact of smoking on male-female mortality disparities peaked in the 1970s and has been declining since (Preston & Wang, 2006). At the same time, smoking is becoming increasingly concentrated among persons with lower education in the United States. Correspondingly, some U.S. health and mortality disparities among the working-aged population appear to have widened quite considerably in more recent years; that is, smoking-related illness and deaths are now much less frequent among the higher educated than the lower educated. Such wide health and mortality differences by educational level are reflected in Tables 1 and 2.

An array of psychosocial factors also affect health disparities during the working-age years. One important example is the experience of racial or gender discrimination—whether racism and sexism are encountered at the individual level, within U.S. social institutions, or both—which can influence the health of racial or ethnic and gender groups. The loss of resources associated with racism and sexism (e.g., lower income) and the psychological stresses of dealing with racism and sexism have been shown to be important in the development of health disparities across U.S. sociodemographic groups (Krieger, Rowley, Herman, Avery, & Phillips, 1993). Another important psychosocial factor that influences health disparities is that higher educated individuals perceive a greater sense of control over their lives than lower educated individuals. A greater sense of control assists highly educated persons in making healthier decisions and in dealing more effectively with life's stresses in comparison to individuals with lower levels of education (Mirowsky & Ross, 2003).

Differential access to health-promoting resources is the fourth set of causal factors underlying U.S. working-aged health disparities (Link & Phelan, 1995). Persons with low levels of education, for example, are less likely to have access to steady, high-paying jobs with health insurance benefits in comparison to persons with low levels of education. Thus, stresses associated with bouts of underemployment or unemployment, less income with which to purchase nutritious food and live in a safe neighborhood, and the lack of health insurance can all lead to lower levels of health and higher levels of mortality among the less educated. Further, differential access to health-promoting resources does not begin in adulthood. For example, non-Hispanic Black, Hispanic, and American Indian children are much less likely to grow up in affluent neighborhoods than non-Hispanic White and Asian-American children in the United States (Massey, 2001). This residential segregation structures the later educational, occupational, housing, and health care opportunities that different sociodemographic groups experience and, thus, can have very important impacts on the development of health disparities throughout the life course.

### CONTINUED RESEARCH NEEDS

There is a continuing need to better understand and address U.S. health disparities within the working-aged population. Using the most general measures available, health disparities by gender, race or ethnicity, and education continue to be wide in the United States and have been stubbornly resistant to closing in spite of the priority of this topic set by the U.S. Department of Health and Human Services. Perhaps the greatest challenge for both future researchers and policy makers is not to approach health disparities on an outcome-by-outcome or disease-by-disease basis, but as disparities that are structured in fundamentally social ways, both across generations and over the life course. Given that gender, race or ethnicity, and educational attainment all continue to structure opportunities and constraints in very important ways throughout the life course and even across generations, research and policy priorities in this area might best be focused on how and why these sociodemographic factors continue to have the social impact that they do and what, in turn, can be done to minimize or eliminate the constraints faced by groups that are the most disadvantaged.

## HEALTH INSURANCE

Health insurance refers to protection against the costs of health care arising from illness or injury. The specific expenses covered by health insurance differ widely, but in general the costs to individuals and families of routine, emergency, and critical health care are covered all or in part by the insurer. In most developed countries, this coverage is mandatory. It can be provided by private companies (operating for profit or not) or by government programs; most countries' health systems rely on a mix of both sources of coverage. Payment for insurance depends on the provider: Private insurers generally collect premiums from individuals and employers, whereas public insurance is often funded through general taxation or salary deductions.

Since the advent of the British National Health Service in 1948, the role of health insurance in producing or ameliorating socioeconomic inequities in health has been of great interest. Based on the widely held assumption that a great part of social inequities in health stemmed from unequal utilization of modern medical care, the most obvious solution to reduce these inequities appeared to be the elimination of inequities in access to medical institutions (Robert & House, 2000). As such, universal, mandatory health insurance coverage and, in certain cases, national health systems were the prime ways by which societies hoped to mitigate the effects of social inequalities on health (Acheson, 1998). While it has since

been recognized that health insurance is not a sufficient condition to eliminate socioeconomic inequities in mortality (Townsend, Davidson, & Whitehead, 1992) evidence indicates it keeps them in check. Indeed, in countries such as the United States that still do not guarantee health insurance coverage to all their citizens, social inequalities in health are often amplified, with dire consequences for health across the life course.

## PUBLIC AND PRIVATE HEALTH INSURANCE AND INEQUALITIES IN HEALTH

At the national level, the organization of health insurance can affect social inequalities in health through two interrelated mechanisms: whether health insurance is mandatory and the methods for setting rates. By definition, mandatory insurance ensures that no individual is left uninsured, with two important implications for equity: Sick individuals cannot be denied health insurance, and healthy individuals cannot remove themselves from the risk pool. The United States constitutes an exception among developed countries because it does not provide mandatory insurance. Globally, however, the question of how insurance costs are established is the most salient issues for insurance equity across the life course.

The most equitable situation occurs when the cost of health insurance is a function of one's income or salary. This progressive taxation policy favors the most deprived segments of the population, by providing them with the same (or more) services for less money than the wealthiest segments (O'Donnell, van Doorslaer, Wagstaff, & Lindelow, 2008). This is particularly important considering that deprived groups also tend to accumulate the most heath problems and therefore have the greatest need for health services. This type of cost setting is characteristic of public insurance schemes.

At the other end of the spectrum are costs established on the basis of competitive risk rating—that is, according to the relative risk of ill health of the person to be insured. For all but those with the lowest risks, this practice leads to the "inverse coverage law" whereby those who need coverage the most get the least or must pay more for it out of pocket (Light, 1992). Finally, given equal risk, the breadth of coverage can often be increased with higher premiums, meaning that coverage is a function not only of medical characteristics but also of socioeconomic factors. This type of cost setting is characteristic of private insurance schemes.

As such, compared with public insurance, private insurance may contribute to social differentials in health by compounding the positive effects of socioeconomic position on health. In contrast, coverage through public means should mitigate socioeconomic differentials in health as it can remove—and even reverse through progressive taxation—one pathway whereby advantaged socioeconomic positions may contribute to better health. Theoretically, public insurance should therefore reduce the total effect of social position on health.

## EMPIRICAL EVIDENCE

Very few studies have explicitly contrasted the impact of risk rating versus other costing methods on health and social inequalities in health. This question poses the empirical challenge of obtaining data before and after—that is, a "natural experiment" involving a radical change in national health system policy. Unfortunately, there are scant data on such transitions, and they typically are limited to aggregate-level contrasts, as these policies tend to affect whole populations, thus precluding analysis at the individual level. Thus, attributing causality to this specific health policy change is difficult, as it rarely occurs in isolation from other social changes.

The Black Report (Townsend, Davidson, & Whitehead, 1992) probably constitutes the most well-known study to shed some light on this topic. This landmark report revealed that social inequalities in health and mortality had not diminished since the implementation of the National Health Service in the United Kingdom, but had instead increased (Townsend, Davidson, & Whitehead, 1992). Yet part of this growing gap was attributable to improvements in mortality among the wealthier classes, and not to declines among the lower socioeconomic groups. This suggested that the upper classes were making greater (or somehow "better") use of the improved access to medical resources. Note, however, that the Black Report was measuring socioeconomic

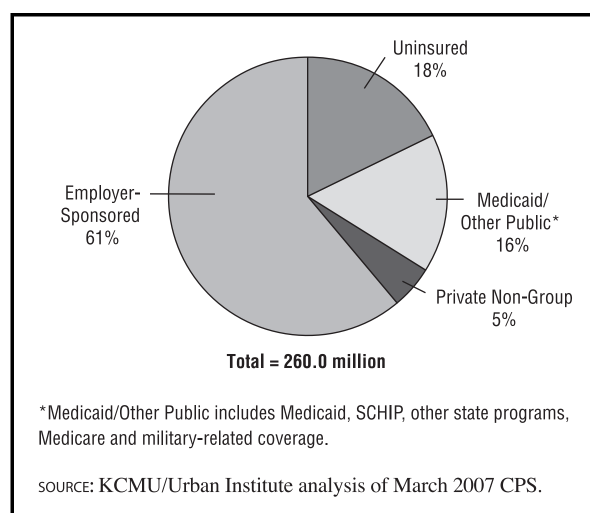

***Figure 1.*** *Health insurance coverage of the nonelderly population (under the age of 65), 2006.* CENGAGE LEARNING, GALE.

status through an occupational class schema, and not through income, which precluded the estimation of the aforementioned hypothesized redistribution effects.

In contrast, other studies that made use of the Canadian experience in developing a one-payer public system found that access to care among the poor increased substantially after the introduction of national health insurance (Enterline, Salter, McDonald, & McDonald, 1973; McDonald, McDonald, Salter, & Enterline, 1974). Moreover, it appears that this increase in access also translated into improved health outcomes. Hanratty (1996) found that the introduction of national insurance was associated with a 4% decline in infant mortality rates, coupled with a decrease in the incidence of low birth weight that was particularly marked among single parents. Infant mortality is more sensitive to social inequalities in health than is general, all-cause mortality (Gwatkin, 2001), suggesting that the introduction of a national health insurance system did disproportionately benefit the most destitute in Canada.

Since then a substantial international literature has developed to examine income inequities in access to medical care, to the point where the scholarly journal *Health Economics* even devoted a whole issue to this topic in 2004 (Volume 13, Issue 7). These studies generally found income inequities in access to medical care whereby low-income individuals were less likely to access specialist services, even in countries with universal coverage. The most comprehensive such study found that whereas access to general practitioners was equitably distributed in Organisation for Economic Co-operation and Development (OECD) countries, access to specialists exhibited such a pro-rich gradient that overall access to physicians appeared to favor the wealthiest segments of the population (van Doorslaer, Masseria, & Koolman, 2006). Moreover, this relationship was exacerbated in countries with private health insurance. As the authors themselves point out, however, this research speaks only to access to care, and more research remains to be done to show whether these inequities in access also translate into health differentials.

## IN THE ABSENCE OF MANDATORY HEALTH INSURANCE: THE CASE OF THE UNITED STATES

The U.S. health insurance system is unique among developed countries by not providing a guarantee of universal health insurance coverage for its citizens (Fried & Gaydos, 2002). Indeed, the vast majority of the adult population in the United States relies on private coverage through employers, and "holes" still exist that create a substantial—and increasing—uninsured population. Thus, privately insured, publicly insured, and uninsured adults coexist, but the risk of being in any of those groups is not equally distributed in the population; this has important implications for equity of access to care, and, ultimately, for the elimination of health disparities.

**A Growing Uninsured Population** After more than half a decade of stable uninsurance rates, the U.S. Bureau of the Census's Current Population Report on health insurance in 2001 reported an increase in the proportion uninsured (Holahan & Pohl, 2002; Mills, 2002), a trend that has since continued unabated (DeNavas-Walt, Proctor, & Smith, 2007). This subgroup continued to grow from 2005 to 2006, reaching an estimated 15.8% of the population, or 47 million Americans (DeNavas-Walt et al., 2007).

Most significantly, these increases were due primarily to a drop among individuals covered by employment-based health insurance (DeNavas-Walt et al., 2007; Mills, 2002; Mills & Bhandari, 2003). Finally, 90% of the growth in the number of uninsured during the early 21st century occurred among low- and middle-income households (Hoffman & Wang, 2003; Holahan & Wang, 2004).

**The Unequal Distribution of Risk of Coverage** Privately insured individuals are more likely to be employed, to be in good health, and to report higher levels of education and of income (DeNavas-Walt et al., 2007; Institute of Medicine, 2002; Mills & Bhandari, 2003). In contrast, because of the eligibility requirements for this coverage, publicly insured individuals are more likely to have incomes below $25,000 per year (Mills & Bhandari, 2003), and they are often in poor health as well (Institute of Medicine, 2002). The uninsured are a heterogeneous group, composed of a variety of individuals: those just above the eligibility requirements for public insurance, people who would qualify for public insurance but either do not know about it or do not feel that they need it, people temporarily unemployed or working part-time, and those who are working full-time in "bad jobs" that do not offer health insurance (Kalleberg, Reskin, & Hudson, 2000) or in small firms (fewer than 100 employees) that cannot afford health insurance for their employees.

Thus, the young (persons ages 18 to 24) and racial and ethnic minorities are overrepresented among the uninsured (Mills & Bhandari, 2003), chiefly as a consequence of their unfavorable position in the labor market. Nearly two-thirds of the uninsured have low family incomes (i.e., below 200% of the poverty line)—even though about 70% of the uninsured count at least one full-time worker in their household (Hoffman & Wang, 2003). Moreover, the risk of long spells (more than 12 months) uninsured is not uniformly distributed, as it is greater among individuals with low incomes, those in fair or poor health, Hispanics, and young adults (Haley & Zuckerman, 2003).

**The Relation between Health Insurance and Health** Longitudinal and cross-sectional studies of the effects of health insurance demonstrate a clear link between private health insurance coverage—especially when it is continuous—and more timely and appropriate access to care, better self-rated health, and lower mortality (Ayanian, Weissman, Schneider, Ginsburg, & Zaslavsky, 2000; Baker, Sudano, Albert, Borawski, & Dor, 2002; Hadley, 2003; Institute of Medicine, 2002; Quesnel-Vallée, 2004; Short, Monheit, & Beauregard, 1989; Sudano & Baker, 2003). Uninsured Americans receive fewer services and have lower utilization rates than insured individuals because they generally cannot afford either private health insurance premiums or out-of-pocket medical care costs (Seccombe & Amey, 1995; Short et al., 1989). Moreover, the length of time uninsured is also associated with increasing barriers to access to care (Haley & Zuckerman, 2003).

Thus, it appears that the U.S. exception of not mandating health insurance for all its citizens has a strong potential to put an increasingly large proportion of Americans at risk of ill health. Moreover, as the uninsured tend to come disproportionately from groups that are already socially disadvantaged, this policy also has the potential to contribute to social inequalities in health in the United States.

## GAPS IN RESEARCH KNOWLEDGE AND POLICY IMPLICATIONS

The limitations of this emerging body of literature point toward directions for future research. With regard to the contribution of private and public insurance to social inequalities in health, a first limitation is the widespread use of data for countries or geographic units within countries, which limits causal inference and does not usually permit the measurement of within-country inequities. Additionally, many of these studies measure income quite crudely, and often stop at classifications above or below the median country level (e.g., Blendon et al., 2002). This limits the comparison of fine-grained associations between countries as well as the assessment of individuals' life course income trajectories. Another limitation is the tendency to rely on mortality or access to care as measures of health outcomes, instead of morbidity or health-related quality of life. Finally, as highlighted by van Doorslaer and Jones (2004), even state-of-the-art research on these issues has lacked comparative individual-level longitudinal data that would enable the assessment of causal relationships and the evolution of these processes over the life course of individuals.

While the evidence on the public/private mix of insurance and its impact on social inequalities in health has global policy implications for equity, the United States faces the special challenge posed by its lack of mandatory coverage. Indeed, as mentioned earlier the young (ages 18 to 24) and racial and ethnic minorities are overrepresented among the uninsured (Mills & Bhandari, 2003), and this is likely to have a substantial impact on their health. Keppel (2007) identified the ten largest health disparities in the United States, finding that the bulk were related to social inequalities and lack of access to monitoring or testing. Given that the second goal of the federal government's "Healthy People 2010" program is the elimination of health disparities, it appears that ensuring equitable access to care for the uninsured is not simply a lofty ideal, but a pressing necessity.

# HOME OWNERSHIP/ HOUSING

Several key life course transitions, such as leaving home and beginning to cohabit with a partner, also can be considered household transitions because they involve movements between households, the creation of a new household, or the dissolution of a household. Because a household typically is defined as a group of individuals who share a dwelling space, these household transitions are also housing transitions for at least some of the individuals involved. Those persons relocate physically from one housing unit (e.g., an apartment, house, or mobile home) to another. They also may change their housing tenure, that is, whether they own the dwelling, pay rent to live there, or have another arrangement.

In addition to the close practical link between household transitions and housing transitions, housing has a reciprocal relationship with other life course transitions, such as having a child, in that a life course transition may require a change in housing (e.g., to get more space) or may not occur until appropriate housing has been secured. Finally, transitions between housing situations can be considered life course transitions in their own right because they enhance or limit people's opportunities.

## HOUSING CHARACTERISTICS

Housing circumstances are differentiated by a variety of characteristics that are influenced strongly by local and national housing policies. One distinction is between institutional or group housing (military barracks, college dormitories, jails, hospitals, monasteries, etc.) and housing that consists of private households. Transitions into and out of group housing can mark important events in the life course, but these transitions usually involve either relatively small proportions of the population or relatively short periods in the life course. In the North American context most housing transitions involve private households.

**Tenure** Housing consisting of private households can be differentiated by tenure, structure, and neighborhood

characteristics. Tenure reflects the social organization of property and establishes rights regarding housing. In North America tenure mostly is divided between rental housing and owner-occupied housing, though there are other categories, including cooperative housing. Those living in rental housing are tenants who pay rent to landlords in exchange for their housing. Depending on local regulations, renters often have limited rights with respect to privacy and few guarantees regarding the stability of their living quarters. However, moving between rental dwellings is relatively easy, leaving renters with more flexibility to move than owners have. Rental housing usually is controlled by the private sector in North America, with considerably smaller ownership by the public (government-run) and nonprofit sectors.

Households that live in owner-occupied housing serve as their own landlords; these owners typically have greater rights to privacy and more stability in their living circumstances than do renters. However, because buying and selling real estate is a much more involved process than renting, there are higher transaction costs associated with moving for owners and correspondingly less flexibility. In the North American context transitions into ownership usually are financed by arranging a loan, or mortgage, from a lender. The dwelling serves as collateral for the loan and may be repossessed if the owner falls behind on the payments (Lea, 1996). Mortgage payments are often higher than rental payments but eventually act as investments, whereas rent does not. As a result of building equity in their housing investment, home owners usually attain wealth faster than renters do. In the United States tax advantages are provided to home owners, further increasing their ability to accumulate wealth relative to renters (Chevan, 1989).

**Structure** Housing also can be differentiated by structure. Key distinctions based on structure typically relate to the number of households that share the same building and walls. Thus, housing can be detached (or single-family), with one household completely separated from all others; attached or semiattached (e.g., town houses, row houses, duplexes), where dwellings share walls but are otherwise freestanding with separate street-level entrances; or multiunit (apartment buildings). Apartment buildings usually are differentiated into low-rise and high-rise buildings, depending on the number of floors they contain. Other aspects of housing structure also vary, including total floor space, number of bedrooms, number of bathrooms, age, state of repair, and presence and characteristics of kitchens. Some of these aspects, such as number of rooms, are particularly important for the measurement of household-level concepts such as residential crowding (Myers & Baer, 1996).

**Neighborhood** Housing also can be differentiated by neighborhood. Neighborhood 1ocation is a key factor in most housing decisions because neighborhoods differ in distance from work and availability of services and amenities (Dieleman & Mulder, 2002). The structure and costs of different types of housing vary by location, and housing transitions frequently involve movement between neighborhoods. Overall, housing structure is closely related to housing tenure in North America, so that most detached single-family housing is owner-occupied (Rossi & Weber, 1996). Structure of housing also is linked to neighborhood. Roomier single-family housing often dominates low-density rural and suburban neighborhoods, and smaller apartments in multiunit buildings typically predominate in higher-density urban neighborhoods (Rossi & Weber, 1996).

## HOUSING, SOCIAL STATUS, AND HISTORICAL TRENDS

Housing structure, tenure, and neighborhood are closely related to social status both in North America (Gans, 1967; Perin, 1977) and elsewhere (Rowlands & Gurney, 2000; Bourdieu, 2005). C. Perin (1977) remarked on the implicit existence of a housing ladder. Individuals are presumed to enter a rental market after leaving the parental home, thus starting at the base of the ladder. Then they gradually climb the ladder, building wealth and status as they obtain owner-occupied housing and move to more desirable neighborhoods. Owner occupation of a detached single-family home in a residential neighborhood is considered the most desirable housing situation (Rossi & Weber, 1996). Consequently, owners often are considered more trustworthy, stable, and responsible than renters (Rowlands & Gurney, 2000). Despite popular perceptions, a review by P. Rossi & E. Weber (1996) found few consistent social benefits (meaning benefits to society) to home ownership.

As a result of the associations between housing and social status, the transition into home ownership is significant for many people. It frequently is viewed as one of the transitions that define responsible adulthood (Henretta, 1984). Policymakers in a variety of contexts also have taken an interest in encouraging home ownership. In the United States tax policies and policies regulating the extension of credit have encouraged transitions into home ownership (Chevan, 1989). Nevertheless, sharp distinctions in access to home ownership remain, separating the economically advantaged from the disadvantaged (Lauster, 2007).

**Improvements in Housing** Housing conditions and trends differ from place to place, but a few broad historical trends can be identified. Average household size has

declined dramatically in North America and Europe over the long term, leaving fewer people sharing the same amount of housing space. According to U.S. Census data, average household size decreased from approximately 4.5 people per private household in 1900 to 2.5 in 2005 (Ruggles, Sobek, Alexander, Fitch, Goeken, Hall et al., 2004). In that period home ownership rose, with an estimated 46% of households owning in 1900, compared with 67% in 2005 (Ruggles et al., 2004). Most of the increase in home ownership in the United States occurred after World War II (Chevan, 1989). The proportion of households living in roomier dwellings and in detached dwellings also rose during that time (Lauster, 2007). All these trends suggest a gradual improvement in North American housing standards, with fewer people living in crowded housing and more people living at the top of the housing ladder.

**Unequal Distribution of Housing** Improvements in housing standards have not been distributed equally. In the market-dominated model of housing provision that prevails in North America, households with little savings or income have been left without access to more valued forms of housing. Several trends have combined to widen housing disparities since the 1970s. Rising income inequality coinciding with rising housing prices has contributed to widening disparities in access to housing (Piketty & Saez, 2003; Lauster, 2007). At the same time incentives for developers to build new rental housing largely have disappeared, leaving little new housing stock available to those at the lower end of the income range (Erikson. 1994). These trends, coupled with a movement toward deinstitutionalizing those with mental and physical disabilities, have led to a marked rise in substandard housing and homelessness for those marginalized by the market (Burt, 1991).

Estimates of the number of homeless in North America range from hundreds of thousands to several million (Erikson, 1994; Shlay & Rossi, 1992). As the number of homeless people has increased, the composition of the homeless population has changed (Rossi, 1989; Phelan & Link, 1999). Whereas the homeless once were mainly White middle-aged single men (Erikson, 1994; Swanstrom, 1989; Hoch & Slayton, 1989; Cohen & Sokolovsky, 1989), they have become more diverse and include women, children, and families of various ethnic backgrounds (Shlay & Rossi, 1992). The homeless are also more visible throughout cities (Rossi, 1989) as well as being poorer and younger and are affected by various medical, criminal, and social problems (Erikson, 1994; Gelberg & Linn, 1989; Lee & Schreck, 2005). Various life course events influence the likelihood of becoming homeless, but analysts emphasize that the primary cause is the inability of people to compete for housing in the face of a shrinking supply of low-cost housing (Erikson, 1994). The disadvantages created by homelessness, including loss of opportunities, feelings of helplessness, and general social stigma, have long-term implications for the life course of homeless individuals.

In addition to the ways in which the poor have been disadvantaged by the market provision of housing, other groups have been disadvantaged by direct discrimination. In the United States, historically, Black Americans in particular were often prevented from living outside designated Black neighborhoods. Black Americans also often were denied loans to purchase housing, the major route for building wealth in North America. The Fair Housing Act of 1968 penalized discrimination on the basis of "race, color, religion, or national origin," but few means of enforcement were included in the act (Schill & Friedman, 1999). In 1988 a set of amendments strengthened the act and also barred discrimination against "families with children and ... persons with physical or mental disabilities" (Schill & Friedman, 1999).

Despite efforts to reduce discrimination in housing in North America and elsewhere, neighborhood segregation is widespread, especially by ethnicity and race (Massey & Denton, 1993; Wilkes & Iceland, 2004). L. Freeman (2000) provided three explanations for the persistence of segregation: the spatial assimilation model, which links segregation to impoverishment and broader lack of housing opportunities (Massey 1985); the place stratification model, which states that direct discrimination continues to limit opportunities for minority group members (Alba & Logan, 1993); and the residential preferences model, which argues that much of segregation can be explained by minority households choosing to live near one another (Schelling, 1971). Freeman found evidence for each of those models.

## HOUSING AND LIFE COURSE TRANSITIONS

Housing characteristics, including tenure, structure, and neighborhood, can influence a number of specific life transitions. These effects are often reciprocal, so that life course transitions also influence housing transitions (Mulder & Wagner, 1998; Lauster & Fransson, 2006).

Neighborhood effects on life course transitions have received increased attention (Sampson, Morenoff, & Gannon-Rowley, 2002). For example, neighborhoods influence the likelihood of risky behavior and exposure to violence (Kowaleski-Jones, 2000; Sampson et al., 2002), the timing of first sex (Baumer & South, 2001), and family formation (South & Crowder, 1999).

Life course events also can influence neighborhood choice. For instance, coming out in the life course of gays and lesbians often is accompanied by a choice to live in

gay enclaves (Weston, 1991). These communities allow gays and lesbians to share stories and develop histories, feel accepted, exert political and social power, and meet others who are similar (LeVay & Nonas, 1995; Sutton, 1994; Weeks, Heaphy, & Donovan, 2001; Weston, 1991). This process is similar to the residential preference model of segregation discussed by Freeman (2000). In this case the gay community is not necessarily created to separate homosexuals and heterosexuals but is a method for protecting individuals' quality of life.

Similarly, having school-age children can influence neighborhood choice, at least for those with the ability to choose. In addition to neighborhood moves based on minimizing the risks children face, parents may move to further educational achievement and improve social status (Croft, 2004). As J. Holme (2002) noted, these moves often are based on social constructions of school status, combining perceptions of neighborhood class and racial composition with measurements of performance. In turn, neighborhood school status boosts the price of local housing (Kane, Staiger, & Samms, 2003; Croft. 2004), and that also limits neighborhood choice.

Research shows that access to housing, housing tenure, and housing structure are reciprocally related to life course transitions. Access to housing seems to influence both the likelihood that new households will be formed and the form new households take (Mutchler & Krivo, 1989; Hughes, 2003). Some authors argue that limited access to housing increases the likelihood of nontraditional living arrangements, including extended family living and nonmarital cohabitation (Mutchler & Krivo, 1989). Other authors have found evidence that securing high-quality housing serves as a culturally important prerequisite for both traditional (Hughes, 2003) and nontraditional (Lauster & Fransson, 2006) forms of family formation. Increased access to all forms of housing may allow more people to live alone (Kobrin, 1976; Lauster & Fransson, 2006). Securing access to a detached roomy dwelling also may be linked to childbearing in the United States (Lauster, 2007). Conversely, marrying or having children before owning a detached roomy dwelling makes individuals more likely to move to this type of housing (Chevan, 1989; Mulder & Wagner, 1998; Clark, Deurloo, & Dileman, 1997; Lauster & Fransson, 2006).

Although the overall level of mobility between dwellings varies widely across countries, the age pattern of moves is broadly the same (Dieleman & Mulder, 2002). Most housing transitions occur during young adulthood, reflecting the relative instability of the transition to adulthood and its many life course transitions. Rates of residential mobility begin to taper during middle age (Dieleman & Mulder, 2002). Nevertheless, important relationships between housing and later life course transitions remain.

Some researchers have provided evidence that home ownership reduces the risk of divorce, at least on the individual level, because ownership represents a shared investment in a marriage (Murphy, 1985). Others argue that the likelihood of separation is increased in contexts in which single-family homes dominate, preventing the development of supportive communities (Bratt, 2002; Lauster, 2005). Late in life transitions in housing circumstances usually reflect retirement or changes in caregiving arrangements (Dieleman & Mulder, 2002). The move from independent housing to retirement communities or assisted living facilities can be particularly traumatic (Adams, Sanders, & Auth, 2004), leaving many people to age in place (remain in their own homes as they age). However, aging in place may result in deterioration of the dwelling if individuals are unable to make repairs (Golant & LaGreca, 1994).

Housing transitions may lead to or result from a variety of household transitions. Housing serves as one of the key links between life course transitions and the economy. Access to housing is also heavily influenced by policy makers. As a result, housing policy can have large effects on how people proceed through a host of life course transitions. By placing individuals, housing also links the life course to neighborhoods and to the environment. This is important for understanding neighborhood effects on the life course as well as the impacts of life course transitions on the environment. Overall, although most housing transitions take place early in the life course, housing intersects with and shapes the life course at all ages.

## HOMELESS, ADULTS

Completely accurate and comprehensive documentation of the pervasiveness of homelessness is nearly impossible for many reasons. Not only is the number of individuals who are homeless a matter of contention, but defining homelessness also is a contentious matter. Many studies measure only the *literal homeless*, defined as persons who live in emergency shelters or transitional housing, or those who sleep in places not meant for human habitation (e.g., streets, parks, abandoned buildings, and subway tunnels). Other researchers include in their counts of the homeless those persons who are *precariously housed* or on the brink of homelessness. They may be doubled-up with friends or relatives or may pay extremely high proportions of their resources (more than one-third of monthly income) for rent—thus, they are often characterized as being at imminent risk of becoming homeless (U.S. Department of Housing and Urban Development, 2007). In addition, the population of homeless referred to as the *hidden homeless* further complicates scholars' understanding of the extent of homelessness. The hidden homeless are those who are living in automobiles, campgrounds, abandoned structures, or boxes—that is, places that it would be extremely difficult for researchers to locate.

Enumeration of the homeless is difficult and is usually conducted in one of two ways. One way that the number of homeless persons has been documented is a point in time (PIT) count. The PIT count occurs when the number of persons who are sheltered (in a shelter or transitional housing) or unsheltered (living in the streets, automobiles, or other public or private place not designed for regular sleeping accommodations) are counted. The problem with this method of documenting homelessness is that a PIT count is representative of individuals and families who were homeless for one specific night and excludes those who may be homeless the next night or the next. Another method of documenting the homeless that is often used is period prevalence counts (PPC). PPCs are counts that determine the number of people who are homeless over a given period of time, utilizing longitudinal data. Longitudinal data are data that are collected over a predetermined amount of time and document unduplicated numbers of persons who have used emergency and/or transitional housing during this time period. This type of enumeration of the homeless provides a more accurate portrait of homelessness than the PIT estimates, because whereas PIT data do capture a higher share of homeless individuals and families who use shelters or transitional housing for long periods of time, PIT estimates underrepresent people whose homelessness is episodic. Using PPC is more costly and takes longer to obtain data, however. So although PPC does provide more information, this method also has limitations.

Despite the many challenges of enumeration, researchers estimate that over the course of a lifetime, approximately 9 to 15% of the U.S. population will experience homelessness (Ringwalt, Greene, Robertson, & McPheeters, 1998; Robertson & Toro, 1999). Homelessness is an event that may occur at any point along the life course with each stage offering a unique set of challenges, depending on how or where one views him/herself on the life-course trajectory. Each year, more than 3 million people are believed to experience homelessness, including 1.3 million children (National Law Center on Homelessness and Poverty, 2008).

### WHO IS HOMELESS?

Researchers estimate that on average, single men comprise 53% of the sheltered homeless population (compared to 14% of the U.S. population), single women 17% (compared to 16% of the U.S. population), unaccompanied youth 3% (compared to 5% of the U.S population), adults in households with children 10% (compared to 47% of all U.S. households having children), and children in households with adults 17% (compared to 23% of the U.S. population). Single men, then, are highly overrepresented among the homeless. The sheltered homeless population is estimated to be nearly 44% African American (African Americans represent 13% of total U.S. population), 34% White non-Hispanic (White, non-Hispanic persons represent 66% of total U.S. population), 13% White, Hispanic/Latino (Hispanic and Latino persons represent

15% of total U.S. population), and 9% other (others represent 6% of total U.S. population; U.S. Bureau of Census, 2008b; U.S. Department of Housing and Urban Development, 2008).

### SINGLE MEN

Single men (i.e., men who have never been married, divorced, or widowed) who are poor may be particularly vulnerable to homelessness because the largest social programs are targeted toward families, especially mothers and children (Temporary Assistance to Needy Families), or toward the elderly (Social Security). Single men are more likely to have substance abuse problems that make it less likely that friends or family will take them in. Single men also may feel less vulnerable on the streets or in shelters, so they may be less likely to be doubled-up with friends or family to avoid living on the street (U.S. Department of Housing and Urban Development, 2008). Single men also have been found to be socially isolated, transient, and homeless for longer periods of time than other subgroups of homeless (Roth & Bean, 1986). They often have histories of legal problems and marital trouble (First & Toomey, 1989) and often are veterans (U.S. Department of Veterans Affairs, 2008).

About one-third of the adult homeless population in the United States has served their country in the armed services. Current population estimates suggest that about 154,000 veterans (male and female) are homeless on any given night and perhaps twice as many experience homelessness at some point during the course of a year (U.S. Department of Veterans Affairs, 2008). Almost all (97%) homeless veterans are male (just 3% are female); the majority are single, and most come from poor, disadvantaged backgrounds. About 45% of homeless veterans suffer from mental illness and slightly more than 70% experience alcohol or other substance abuse disorders. Currently, the number of homeless Vietnam veterans is greater than the number of service members who died in the Vietnam war. Additionally, a small number of Desert Storm veterans have appeared in the homeless population. The U.S. Department of Veterans Affairs has developed several initiatives to provide services to this population, one of which is the Grant and Per Diem Program, which is offered annually by the U.S. Department of Veterans Affairs to fund transitional housing or service centers for homeless veterans.

### SINGLE WOMEN

Another recognized subpopulation of the homeless is single women (17% of sheltered homeless). Single women are generally older, White women with relatively high levels of individual dysfunction such as mental illness, substance abuse, or physical disability (Johnson, 1995; U.S. Conference of Mayors, 2007). Compared to women with children, single childless women are more likely to have been homeless for a longer period of time, more likely to have received mental health services, and more likely to admit to substance abuse problems (Robertson, 1991).

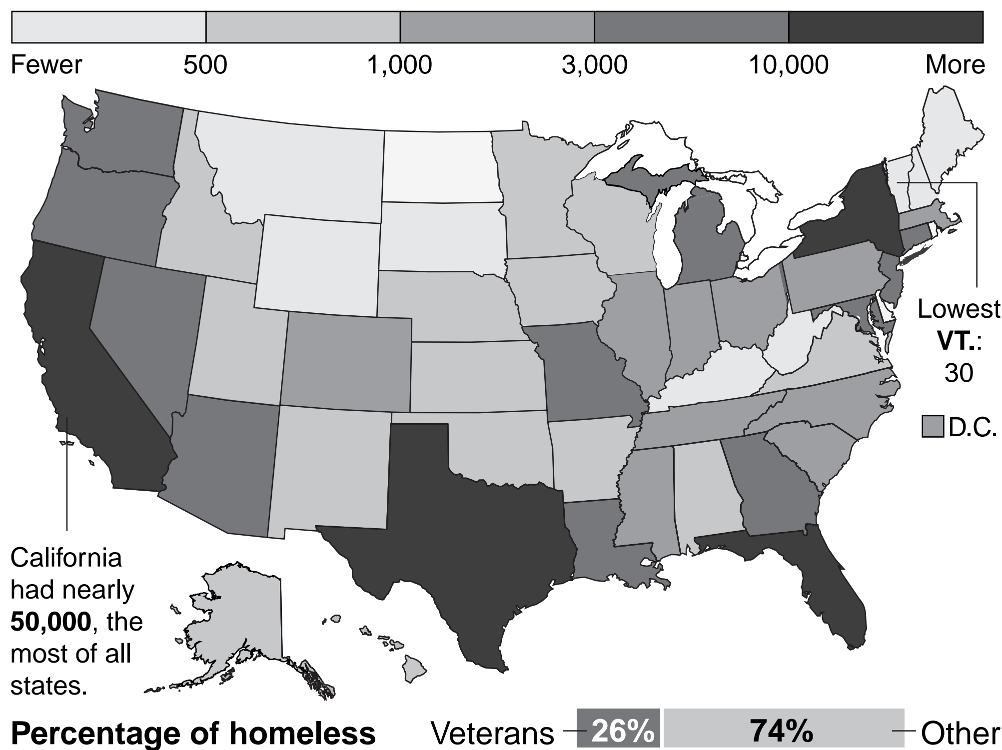
### WOMEN WITH CHILDREN

Women with children are considered the fastest growing subgroup of the homeless (National Alliance to End Homelessness, 2007; National Coalition for the Homeless, 2007; U.S. Conference of Mayors, 2007). One of the factors that contribute to this growing subpopulation of the homeless is the poverty rate. Beginning in 2000, the poverty rate rose for 4 consecutive years, from 11.3% in 2000 to 12.7% in 2004. The poverty rate then began to decline slightly, to 12.6% in 2005 and 12.3% in 2006. So although there was a decline in the poverty rate from 2005 to 2006, the change from 12.6% (2005) to 12.3% (2006) was not statistically significant (U.S. Bureau of Census, 2008).

Other characteristics that may contribute to the vulnerability of women include declining wages, a slowing economy, declining welfare rolls (more likely due to the time limits placed on benefits in 1996, rather than an indicator of improvement in the economic well-being of low-income women), loss of social benefits, loss of health insurance, and the limited availability of both affordable housing and subsidized housing. Subsidized housing is so limited that fewer than one in four Temporary Assistance to Needy Families nationwide lives in public housing or receives a housing voucher to assist with rent (National Coalition for the Homeless, 2007). Finally, domestic violence also contributes to homelessness among families. When women leave abusive relationships, often they have no place to go. Due to the lack of affordable housing and limited supply of subsidized housing, many women are forced to choose between the abusive situation or living on the streets. Estimates of rates of domestic violence for homeless women with children range from 12% to 50% (Homes for the Homeless, 2008; National Coalition against Domestic Violence, 2001; U.S. Conference of Mayors, 2007).

### CHRONICALLY HOMELESS

Chronic homelessness is described as an unaccompanied homeless individual with a disabling condition who has either been continuously homeless for a year or more or has had at least four episodes of homelessness in the past 3 years. To be considered chronically homeless, a person must have been on the streets or in emergency shelter (i.e., not in transitional or permanent housing) during these stays (U.S. Department of Housing and Urban Development, 2008). The U.S. Department of Housing and Urban Development estimates that approximately

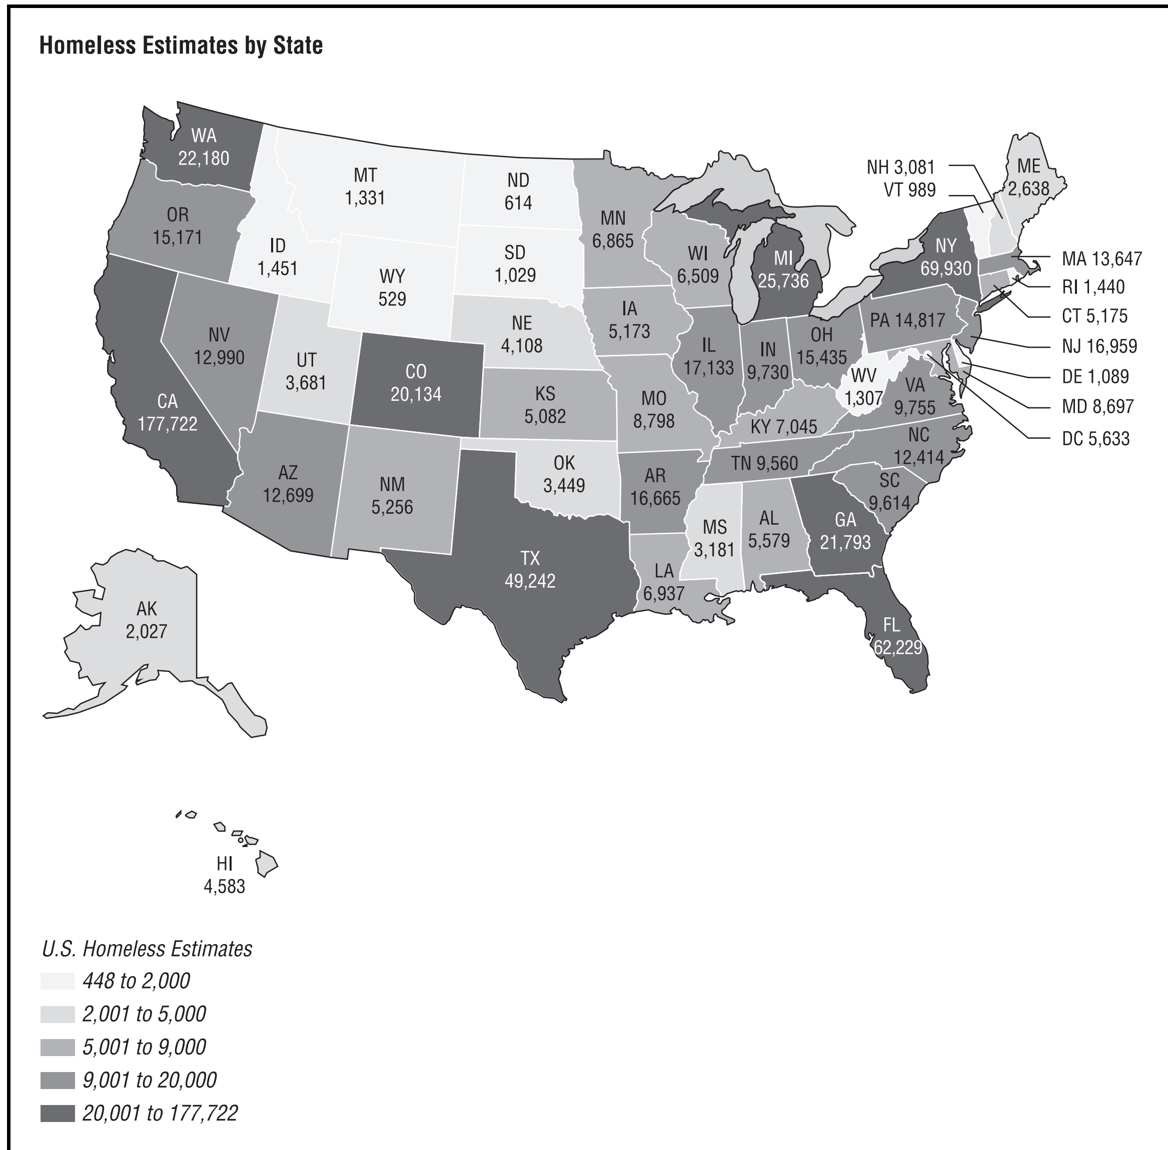


*Homeless Veterans.* *U.S. map shows the number of homeless veterans in 2006.* AP IMAGES.

20% of all homeless persons could be considered chronically homeless. Communities are working to end chronic homelessness by providing services to help meet the needs of this vulnerable population. However, these services—including mental health treatment, substance abuse treatment, intensive medical care, and incarceration—tend to be very expensive.

## HOMELESS OLDER ADULTS

The growing consensus is that homeless persons ages 50 and older comprise the "older homeless" category. Homeless persons ages 50 to 65 frequently fall between the cracks in that they are not old enough to qualify for Medicare, therefore many suffer from poor physical health given that they most likely have experienced poor nutrition and severe living conditions (National Coalition for the Homeless, 2007). Increased homelessness among older adults is largely due to the declining availability of affordable housing. Throughout the nation, there are at least nine seniors waiting for every occupied unit of affordable elderly housing (HEARTH, 2008). Many elderly are retired and on fixed incomes, or dependent on Supplemental Security Income for support in their retirement. Still, homeless persons are far less likely than their housed peers to survive until later life. People who experience homelessness for long periods of time do not survive to age 62 as often as persons in the general population; this may account for older adults' relatively small percentage (16%) among the homeless (U.S. Department of Housing and Urban Development, 2008). The average life expectancy of a person without permanent housing is estimated to be between 42 and 52 years, far below the United States' average life expectancy



***Map 1.*** *Homeless estimates by state.* CENGAGE LEARNING, GALE.

of 80 years. A study by O'Connell (2005) indicated that premature death for older homeless persons most often resulted from acute and chronic medical conditions aggravated by homeless life rather than by either mental illness or substance abuse.

## STRUCTURAL FACTORS CONTRIBUTING TO HOMELESSNESS

**Lack of Affordable Housing** Since the 1970s or so, much of the affordable housing and single room occupancy (weekly or daily rental of economy motel rooms) housing that had been located in the central part of larger cities has been lost to development or gentrification (e.g., the conversion of rental units to condominiums, historic preservation). Funding for public housing programs has been inadequate. Historically, when money is tight the first programs and services that are cut or eliminated are social service programs. Currently, because housing is not seen as an entitlement, only one in four eligible individuals and families are receiving services from programs such as Housing Choice. Housing Choice, formerly known as Section 8, is a program administered by U.S.

Department of Housing and Urban Development that provides housing vouchers that can be used in partial rent payment for housing. These vouchers may be used for apartments, homes, or mobile homes of the family's choice as long as basic criteria are met. The vouchers also may be used for public housing units (i.e., public housing units are apartment complexes that house large numbers of low-income individuals and families exclusively).

**Foreclosure/Subprime Mortgage Crisis** Related to the lack of affordable housing is the current foreclosure/subprime lending crisis. Nationally, more than 2 million home foreclosures were reported in 2007. A home foreclosure occurs when an owner is unable to keep up with his or her monthly home payments, which include mortgage, property taxes, and interest. The resulting spiral has resulted in the decline in home values of up to 20%. This decline has perpetuated a plummet in local tax revenues that are based on property taxes (National Coalition for the Homeless, 2007). Congress and state governments are scrambling to provide some stability to the economic crisis that has ensued by crafting legislation to reinforce banks, lenders, and other financial institutions to hold off a recession. Few proposals have been made to provide relief for the homeowners who have lost their homes. Foreclosure has forced many families to move in with friends or relatives, and others have moved into emergency shelters. The National Coalition for the Homeless (2007) conducted a survey of state and local homeless coalitions and asked if they had seen an increase in individuals and families seeking shelter since the crisis began in 2007: 61% of the agencies (71 out of 117) replied that they had indeed seen an increase, which they attributed to the foreclosure crisis. Only five coalitions replied that they had not seen an increase in their area; the remaining respondents were unsure.

**Poverty** The official poverty rate in 2006 was 12.3%, slightly but not significantly down from 12.6% in 2005. Homelessness and poverty are inextricably linked. Poor people are frequently unable to pay for housing, food, childcare, health care, and education. Difficult choices must be made when limited resources cover only some of these essential necessities (National Coalition for the Homeless, 2007). Often, because housing typically comprises such a high proportion of income, it is at high risk of being dropped from an individual/family's budget. Being poor often means that a person is just a single illness, accident, or a paycheck away from living on the streets.

**Health Care** The final key issue related to the problem of homelessness is health care. Poor health is both a cause and consequence of homelessness. For individuals and families who are struggling to pay the rent, a health crisis (such as a serious injury or disability) can cause a freefall into homelessness. If an individual is unable to work, once savings (if any) are depleted to pay medical bills or rent, the next step is to double-up, find an emergency shelter, or resort to the streets. Rates of both chronic and acute health problems are extremely high among the homeless population. Conditions that require regular, continuous treatment such as tuberculosis, HIV/AIDS (estimated between 3% and 20% of the homeless population), diabetes, hypertension, addictive disorders, and mental disorders are all extremely difficult to treat or control for those with inadequate housing. Illness may cause homelessness; chronically mentally ill persons or alcoholics who are noncompliant with treatment may be cast out by their families. Alternatively, illness may be a consequence of homelessness and may result from the tough conditions of the street (e.g., inadequate shelter, inadequate diet, or possibly selling sex for money).

In 2006 nearly 47 million Americans under age 65 (15.7%) had no health insurance coverage, an increase of 2.1 million from the previous year (Kaiser Family Foundation, 2007). Further, 38 million people from working families were uninsured in 2005 because not all businesses offer health benefits, not all workers are eligible for health benefits, and many employees cannot afford their share of the health premium.

## WHAT THE FUTURE HOLDS

As the number of homeless individuals and families increase in the United States—whether as a result of mental health issues, substance abuse, disability, access to health care, inadequate education and job preparation, or domestic violence—it is clear that the problem of homelessness is a heterogeneous one. However, with all the diversity within this population, there is one thing all members have in common: lack of housing. Since the late 1990s, many pilot programs have been established throughout the United States that advocate a "housing first" approach to eradicating homelessness (Beyond Shelter, 2008). "Housing first" is an alternative to the current system of emergency shelter/transitional housing, which tends to prolong the length of time that families remain homeless. The premise of service delivery is based on the belief that vulnerable and at-risk homeless individuals and families are more responsive to interventions and social services support after they are in their own housing, rather than while living in temporary/transitional facilities or housing programs. With permanent housing, these individuals and families can begin to

regain the self-confidence and control over their lives they lost when they became homeless.

# HORMONE REPLACEMENT THERAPY

**SEE** Volume 2: *Menopause*.

# HOUSEWORK

Housework is defined by social scientists as unpaid labor that contributes to the maintenance of the household. Studies frequently include as housework tasks such as laundry, cooking, dishwashing, cleaning, shopping for household goods and groceries, and making house repairs. Tasks that involve direct caretaking of family members, such as childcare, are not usually considered housework, even though the distinction between housework and other forms of care is somewhat artificial. Studies of housework not only provide an important window into gender relations in families, housework performance has also been linked to factors including wages, mental health, and relationship quality.

## THE EMERGENCE OF MODERN HOUSEWORK

Under the system of subsistence agriculture that was common throughout the world over the past several thousand years, the majority of productive work took place in or near the household. The emergence of the contemporary understanding of housework as distinct from paid employment is the direct result of the separation of paid labor from the household under systems of industrial production. The rise of industrial production during the past two centuries was accompanied by a supporting ideology of "separate spheres." This ideology emphasized the belief that women and men were fundamentally different, and it valorized women in their roles as domestic caretakers and moral guardians. Men, by

contrast, were viewed as responsible for the public sphere, and especially market work. A fundamental insight of housework research has been the realization that these two spheres are not separate, but rather are intricately interconnected. Increases in women's employment since the 1950 have heightened awareness of the linkages between paid and unpaid work and collectively demonstrated the false dichotomy that the idea of "separate spheres" represents.

A vast amount of work was required to support families in the pre- and early industrial period. Susan Strasser (1982) points out that this work frequently included making clothes by hand or sewing machine, collecting water, washing clothes by hand, gathering fuel for heating and cooking, producing meals for family members, preserving and storing food, producing sources of lighting, cleaning the house, and a substantial number of related tasks. The sheer volume and physical burden of this work has been gradually reduced by a combination of products available for purchase in the market and the spread of electrical and gas-powered appliances. At the same time, it seems likely that standards of cleanliness rose alongside the availability of such externally powered devices. For example, in 1974 Joann Vanek found little change in the amount of time spent on housework in the United States between 1925 and the mid-1970s despite the increased availability of household appliances over that time.

Although housework is frequently cast as burdensome and unpleasant, scholars increasingly recognize that it serves a dual role. As Marjorie DeVault (1991) explained, housework simultaneously produces goods for individuals and families, such as clean homes and nourished family members, and facilitates the expression of human connection. This dual meaning of housework is reflected in the emergence of the concept of "care work." Despite this dual nature, much housework research has focused on the unpleasant work that tends to be repetitive, to have a relatively rigid schedule for completion, and to be physically demanding. To the extent that such work is unpaid, many scholars have suggested that it is also undervalued socially. Indeed, the purpose of much of this research is to both highlight and recognize the crucial value of such work for the reproduction of families and larger social groups.

## STUDYING HOUSEWORK

Two related areas of social research take housework as a central focus. The first is the study of time use. Time spent on domestic labor is a central concern among researchers such as Jonathan Gershuny (2000) and John Robinson and Geoffrey Godbey (1999) who are interested in the contours of human activity across the day, the week, the year, and the life course. Along with paid employment, leisure, and self care, housework constitutes one of four key areas into which researchers generally divide human time use. The second area of research in which housework is examined is the study of gender. In this area, scholars are interested in the role of housework in defining and reflecting role differences between women and men. This second area of study has driven a remarkable increase in research on housework since the 1980s. Housework serves as both a central manifestation of gendered family roles and as a key marker of status. As a result, understanding the factors associated with performing household work as well as the consequences of its performance provides an important indicator through which changes in gender relations may be assessed.

Most studies of housework draw on one of three methodological approaches. The first, and arguably most reliable, technique relies on the completion of "time diaries" by representative samples of specific populations (see Bianchi, Robinson, & Milkie, 2006). With this technique, respondents most commonly report the activities of the previous 24 hours in small time increments. Using this methodology, respondents are generally allowed to report multiple activities performed at the same time (multi-tasking). The disadvantage to this approach is that it is highly resource intensive and is burdensome to study participants, so the collection of data that could be used to explain patterns of time use has often been limited. In the United States the time diary has been utilized to study changes in time use from 1965 into the early 2000s. A growing cross-national time use archive is also available (see Gershuny, 2000).

Two less costly but more common methods for collecting data about time use include "hours estimates" and "stylized" questions about responsibility for household tasks. With the hours-estimates approach, respondents are asked to state the amount of time they spend on particular tasks (laundry, cooking, etc.) in a given day or week. The greatest drawback to this measurement strategy is that respondents tend to overestimate the time they spend on tasks. Among other problems, this approach frequently produces data in which respondents' estimates sum to more than 24 hours per day. With the stylized approach, respondents are asked to describe whether they or their spouses usually perform specific tasks. Although such data may be useful for studies of the way household tasks are divided by gender, they are less useful for studying time allocation.

## FINDINGS FROM RESEARCH ON HOUSEWORK

**Who Does the Housework?** The two most definitive findings to emerge from studies of housework based on time-diary data from the United States are (a) that women spend more time on housework than men, and

(b) that women have substantially reduced the time they devote to housework since the late 1960s (Bianchi et al., 2006. The former finding is reported in almost all studies of housework, and the latter pattern has also been documented in a large number of wealthy nations besides the United States (Gershuny, 2000). Figure 1 presents trends in time spent on meals and cleaning by married mothers and fathers from the United States between 1965 and 2000. This change has occurred over a historical period in which women's rates of employment increased dramatically. Arlie Hochschild (1989) was among the first to note the potential emergence of a "second shift" if women do not reduce their housework time in direct proportion to their time spent in the labor market. Although Bianchi and colleagues (2006) report an hour-for-hour exchange between housework and paid work in the United States, Gershuny (2000) finds that British women reduce their time spent on housework and childcare by only 30 minutes per each additional hour they spend in paid employment. This implies that in Britain women have increased their total working time as their rates of employment have risen.

***Figure 1.*** *Trends in hours per week spent on housework tasks by married mothers and fathers in the United States, 1965–2000.* CENGAGE LEARNING, GALE.

Closely connected to the debate about the combined burden of paid and unpaid work for women is the issue of the time men spend on housework. In her qualitative study, Arlie Hochschild (1989) framed her findings as reflecting a "stalled revolution" in which men's behavior with regard to unpaid labor had not changed nearly as much as had women's involvement in paid employment. Results from time-diary data suggest, however, that husbands in the United States have increased both the absolute amount of time they spend on housework as well as the amount they spend relative to their spouses. The time married fathers spent preparing meals more than tripled between 1965 and 2000 (from 36 to 126 minutes per week), and their time spent on housecleaning increased by a factor of six (from 18 to 108 minutes per week) (Bianchi et al., 2006). Gershuny, Michael Godwin, and Sally Jones (1994) argue that family behavior can be characterized as reflecting a process of "lagged adaptation" in which men's domestic behaviors are slowly coming in line with contemporary patterns of paid work among women. Nonetheless, with an average of 19.4 hours per week, married mothers now spend just over twice as much time on housework per week as do married fathers (Bianchi et al., 2006).

Children's responsibility for housework declined as education replaced family-based production as the principal use of time during childhood and adolescence. Data on children's housework are scarce, but a study by Bianchi and Robinson in 1997 estimated that children spend an average of 22 minutes per day on housework. Time spent on housework is greater among older children, among girls, and among children from larger families. One study by David A. Demo and Alan C. Acock published in 1993 reports that children from single-parent families perform more housework than children living with two parents. In support of the life course concept of "linked lives," there is evidence that children's observations of how their parents divide household labor influence their own division of housework in adulthood.

**Housework and Life Transitions** Participation in housework is closely linked with central transitions in the life course. The transition to marriage is associated with increases in the amount of time women spend on housework and decreases in the amount of time men spend on housework. Although some studies report greater housework sharing among cohabiting couples than married couples, this finding is not universally supported. The transition to parenthood increases time spent on housework for both mothers and fathers (Berk, 1985;), but many studies find that a more strongly gendered division of housework emerges when couples become parents. Couples who become parents at older ages appear to divide housework more equally than couples who have children at younger ages (Coltrane & Ishii-Kuntz, 1992). This finding appears to be the result of greater investments in the father

role by men and greater bargaining power among women who delay entry into parenthood.

Changes in women's paid employment are central to explanations of housework allocation, and wives' earnings have frequently been characterized as a resource with which they can bargain to reduce their responsibility for housework. Several researchers suggest that housework serves as an opportunity for the display of gender in addition to the production of household goods (Berk, 1985; Brines 1994). This line of reasoning holds that women who earn more than half of a couple's income may attempt to neutralize this gender "deviance" by performing a larger share of housework, and their husbands may cut back on housework in a similar effort. Recent work by Sanjiv Gupta (2007) casts doubt on this argument by demonstrating that housework performance is best explained by women's absolute earnings, rather than their earnings relative to their spouses'. In addition to women's earnings, several studies have shown that women's employment histories are positively related to their male partners' participation in housework. Research has also demonstrated that causality may move in the other direction, with responsibility for housework decreasing wages (Noonan, 2001). Retirement is another life course transition with implications for housework, and most research suggests that the division of labor remains highly gendered even after both spouses have retired.

A substantial body of research has documented the consequences for individuals of performing housework. For instance, Michelle L. Frisco and Kristi Williams (2003) showed that perceptions of inequity in housework are associated with a higher risk of divorce among women. Housework performance has also been linked to poor mental health, and cross-national studies have recently expanded the understanding of the cultural context of housework (Hook 2006). This research demonstrates how country-level characteristics such as measures of gender empowerment, women's employment, and welfare state policies directly influence the division of labor between spouses and also how they moderate the influence of individual-level characteristics on patterns of housework allocation.

Studies of housework have made important contributions to our understanding of power and exchange in couples' and individuals' time use. Work done at the turn of the 21st century points to the study of the mental, emotional, and even spiritual dimensions of housework. In addition, scholars are paying increasing attention to issues such as paid help for housework, the growing prevalence of shift work, and the emergence of global migration as a significant factor in housework allocation.

Studies of housework continue to document substantial changes in individuals' performance of housework and their perceptions of appropriate patterns of housework for women and men. As such, research on housework will continue to provide important insights into gender and class dynamics across the life course for the foreseeable future.

## IMMIGRATION, ADULTHOOD

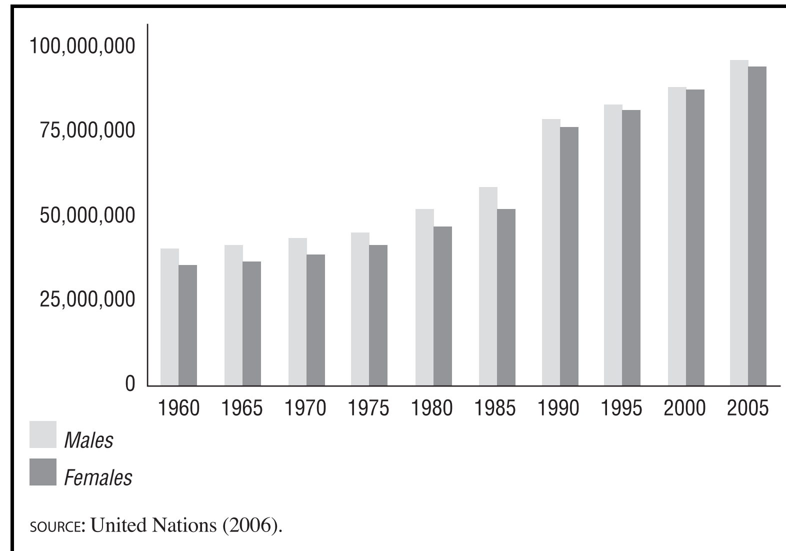
Entering the 21st century, the world is becoming increasingly mobile. People frequently cross international borders on daylong excursions or on longer trips as tourists. A few people, who may lack a fixed place of residence and are often referred to as nomads, move across borders in well-established patterns of territorial mobility. Others cross borders, sometimes returning on a daily basis or after a period of time stretching over years, to work or to study abroad. Others cross borders to seek asylum, to exercise their right to establish residence in the receiving country, or to join relatives. All countries of the world are experiencing the movement of people across their borders and available evidence suggests that the phenomenon has been increasing in volume, possibly because of the growing ease of long-range travel.

The complexity of movements across borders and the consequent difficulties in describing and understanding migration flows, monitoring changes over time, and providing governments with a solid basis for formulating policy has led the United Nations to draft several sets of recommendations about the measurement and description of international migration. The United Nations (2006) has recommended that an "international migrant" be defined as "any person who changes his or her country of usual residence" (p. 17). Unlike previous recommended definitions, it does not include a specific time frame. Instead, the United Nations recommends that migrants be classified as *long-term* if they are in the country of destination for at least 1 year and *short-term* migrants if they are in the country of destination between 3 and 12 months.

Much of the data on international migration are gathered at the time migrants enter their destination country via entry and exit permits or visas; by the processing of requests for asylum (thus ignoring what happened before or happens after the crossing of the border); or through population registers, issuance of residence permits, cross-sectional surveys, and censuses of migrants after they arrive in their country of destination (thus including only those who remained there). Unfortunately, these data constraints mean that much of the knowledge about international migrants remains static, ignores how decisions to migrate depend on or vary by life course stage, and ignores how the consequences of migration for the migrants, their families, and the countries involved vary by life course stage. In addition, shifts in the volume and character of international migration and new phenomena, such as remittances, new destinations, and transnational linkages, mean that much of the story is still unfolding.

### DEMOGRAPHY OF INTERNATIONAL MIGRATION: TRENDS, GENDER, AND AGE

After compiling the data from national censuses and surveys, the United Nations estimates that there were about 75 million migrants in the world in 1960. By 2005 the number had increased to 190.5 million (see Figure 1). In 1960 about 42% of all migrants were found in the more developed regions of the world. Since then the percentage has been steadily growing; by 2005, 60% of all migrants were living in the more developed regions of the world (United Nations, 2006). The major receiving regions in 2005 were Europe with more than 64 million migrants, Asia with more than 53 million migrants, and North America with 44.5 million migrants. The top three receiving countries in 2005 were the United



SOURCE: United Nations (2006).

***Figure 1.*** *Estimated numbers of male and female international immigrants in the world.* CENGAGE LEARNING, GALE.

States (38.4 million migrants), the Russian Federation (12 million), and Germany (10 million). The three top sending countries were China (35 million), India (20 million), and the Philippines (7 million).

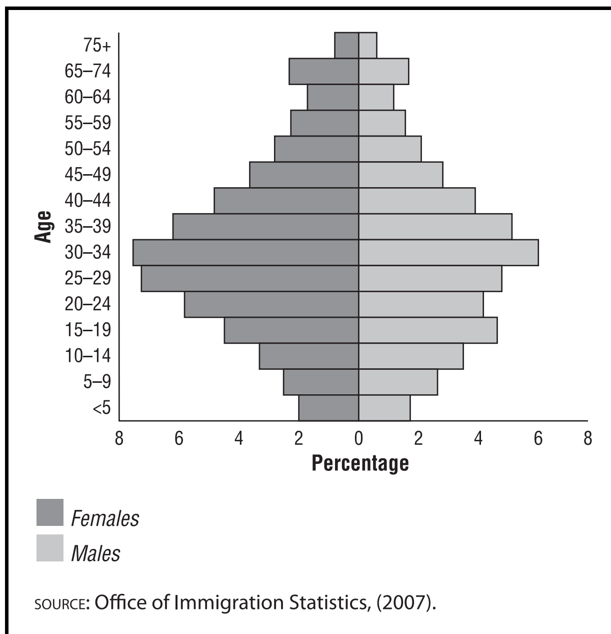
Because of the overwhelming emphasis on economic and occupational incentives and conditions in theories of international migration, typical migrants are often explicitly presumed to be young adult men; yet almost half of the international migrants in 2005, 95 million, were female. In many countries, especially the more developed countries, women constitute the majority of immigrants. In the United States, for example, 57% of the immigrants legally admitted during 2006 were female (see Figure 2). Moreover, although more than half of the newly admitted immigrants were adults in the prime working ages (20–44), about 16% of the newly admitted immigrants were minor children below the age of 15 and about 8% of newly admitted immigrants were over the age of 60 (Office of Immigration Statistics, 2007).

## NATIONAL POLICIES

The volume and character of the migration streams reaching across the world lie, to a large extent, under the control of nation-states. A few countries—such as the People's Republic of China and North Korea—limit the emigration (out-migration) of their citizens. In contrast, some countries have reached agreements that allow free movement across their borders. In 1985 five European countries (Belgium, France, Germany, Luxembourg, and the Netherlands) signed the Schengen Agreement, which allowed free movement of persons and commerce across their borders. By December 2007 the agreement had expanded to include 24 European states and now covers almost all of Europe. (Notably, the United Kingdom and Ireland have only partially implemented the agreement.) The implementation of this agreement means that structure of international migration across almost all European national borders has changed: The movement of people across the shared borders within the Schengen area can no longer be considered international migration. One result is that the focus in European Union countries is now on immigration from countries outside of the Union rather than on what is now being recast as internal migration.

Most countries, however, limit in some way the numbers and characteristics of in-migrants, while not imposing constraints on the emigration of their citizens. Major immigrant-receiving countries, such as Australia, Canada, and the United States, all have immigration policies in place that limit, or attempt to limit, in some way the numbers and types of immigrants allowed into the country. In general, the policies of immigrant-receiving countries focus on numbers (e.g., calculating how many in-migrants the country needs or how many the country can absorb); the potential economic contributions of immigrants; and the social costs (such as the anticipated burdens on the welfare system, health system, and the educational system). However, the details of immigration policies differ greatly from country to country and even within countries across time.

Canada's current immigration policy, for example, uses a point system to rank prospective immigrants with extra points given to those who are younger, well-educated, and know one of the country's official languages. Australia's current system also strongly emphasizes youth, specific occupational skills, and knowledge of English. In the



SOURCE: Office of Immigration Statistics, (2007).

***Figure 2.*** *Percentages of newly admitted immigrants by age and sex (U.S.).* CENGAGE LEARNING, GALE.

United States, the 1965 Hart-Cellar Act lifted the quotas dating from the 1920s for immigrants from selected countries and established family reunification as the major rationale for the admission of immigrants to the country. But after 1990 the United States immigration policy shifted toward admitting skilled and professional labor and immediate family members. (American immigration policy also includes a provision for admitting citizens from countries that have been less likely to send immigrants to the United States.) At a global level, more and more countries are adjusting their immigration policies to overtly court highly skilled young adult immigrants.

The flip side of encouraging highly skilled immigrants is the discouraging of immigrants who lack the designated educational, occupational, or linguistic skills. Individuals who cannot migrate to specific countries under the auspices of the current policy often resort to migration without appropriate documents. Many immigrant-receiving countries, especially the North American and European countries, have been struggling with the growth in the numbers of undocumented or unauthorized migrants. Unauthorized migrants include those who enter the country without receiving the appropriate visa or official permission under the country's immigration policy and those who enter the country with authorization to stay for a limited time, perhaps as a tourist or student, and then overstay. Estimates in 2006 suggest that about 11 million of 30 million foreign-born people who entered the United States after 1980 are unauthorized migrants (Hoefer, Rytina, & Campbell, 2007) and that at least 5 million of the 56 million migrants in Europe crossed international borders without authorization (Global Commission on International Migration, 2005).

## THEORIES OF INTERNATIONAL MIGRATION

The millions of migrants in the world, who comprise about 3% of the world's population, are engaged in large and patterned flows. Numerous theories of international migration—varying across academic discipline, level of analysis, and data sources—attempt to explain these flows. Economists, for example, focus on wage rates and labor market conditions and thus view migrants, especially young adult males, as prospective workers. Political scientists focus on the role of the state and thus consider how policy shapes the attributes of the incoming migrants. Sociologists focus on the assimilation and integration of immigrants in the country of destination and thus investigate how immigrant children and the children of immigrants fare in the receiving societies. More recently, social scientists are considering global forces shaping international migration.

Neoclassical macroeconomic theory is the oldest and still best-known approach to understanding why some people move from one country to another. The basic assumption is that international migration is caused by national differences in the supply of and demand for labor. Individuals change labor markets if the prevailing wages and other employment conditions are better in the destination country. Neoclassical microeconomic theory presumes that rational actors migrate because they expect an increase in some positive reward, usually higher wages, after taking into account the costs of migration, which include the difficulties of adjusting to a new labor market and a new social environment. The new economics of migration focuses on households rather than on individual workers. Here households are viewed as managing their economic well-being by diversifying the allocation of household resources (and thus minimizing risk) by, for example, sending one or more household members to work in a different economy.

Dual labor market theory, by contrast, argues that international migration is caused by a permanent demand for immigrant labor that is inherent to the economic structure of the more developed nations. The demand for immigrant labor is fed by the need of employers, who have capital at their disposal, to hire workers only when labor is needed to satisfy demand. Immigrants satisfy capitalists' need for temporary labor because immigrants, especially less educated immigrants, are more apt to be satisfied with low-level and unstable jobs than native-born workers.

Doug Massey (2004), a sociologist, offered the theory of cumulative causation to explain why international

migrations continue after the initial conditions triggering a migration flow disappear. The basic argument is that the social networks and social institutions that emerge along with a migration stream serve to perpetuate the flow. Scholars such as Alejandro Portes (1999) have argued that contemporary international migration is too complex to be explained by one overarching grand theory. He suggests that scholars consider at least four important dimensions: the origins of immigration, the directionality and continuity of migrant flows, the use of immigrant labor in destination countries, and the integration of immigrants in the receiving societies.

The available theoretical frameworks are limited in many respects. Few consider how gender, age, and life cycle considerations play out in decisions and opportunities to migrate; which migrants countries prefer to encourage under their policies; and how immigrants fare in their country of destination. In particular, there are only piecemeal explanations seeking to understand the migration of people who migrate before or after young adulthood. Young migrant children, for example, are almost always assumed to have migrated with one or both of their parents. Yet this assumption omits the role of international adoption in the migration of orphans, the migration of children who join other family members, and the migration of children who are sent to other countries by their guardians for educational or other reasons. The presumption that minor children always accompany their migrant parents also cloaks the corollary assumption that migrant parents always bring their minor children with them to their country of destination, which is almost certainly not the case. Meanwhile, the preponderance of young adults among recent migrants means that little attention has been paid to the smaller but growing numbers of migrants who move later in adulthood.

Similarly, women are often assumed to migrate with their husbands or other family members but many, in fact, migrate independently of family members. Although many women migrate for economic reasons, some women (and a few men) embark upon cross-national relationships and migrate to join their partners or spouses. This phenomenon, which is fed by countries' worldwide military operations, the growth of multinational businesses, the consequent traveling of employees across borders, and the increasing presence of Internet matchmaking organizations fostering cross-national relationships, appears to be responsible for a growing number of international migrants.

## OUTCOMES OF MIGRATION

The effects of international migration are complex, pervasive, and occur at several different levels of analysis. International migration affects both the sending and receiving nations. The lives of migrants are affected by which country they were born in, the timing and reason for migration, and by their country of destination. In addition, migration streams between countries forge social and economic linkages that affect people in both societies.

Between 1990 and 2000, for example, migration accounted for more than half (56%) of the population growth in the developed world, and an astonishing 89% of the population growth in Europe. Many of the major immigrant-receiving countries such as the United States and several countries in the European Union, which are experiencing increases in racial, cultural, and religious diversity because of high levels of immigration, are engaged in heated political discussions about the integration of migrants. In a tightly related phenomenon, because many migrants move in young adulthood, a life stage marked by childbearing and childrearing, migrants in low-fertility regions such as the European Union and North American countries are the parents of a disproportionate number of children. Immigrants in the United States, for example, constitute about 12% of the general American population, but are the parents of about 23% of the nation's children. Many immigrant-receiving countries are thus also engaged in discussions about the added educational needs of the children of immigrant parents—for example, bilingual programs.

Increasingly, international migration is responsible for strong financial linkages between countries. This is clearly seen in the significant growth of remittances from migrants (especially those in the more developed countries) to families in their countries of origin. In 2006 the World Bank estimated that remittances reached a worldwide peak of $258 billion U.S. dollars, most of which was sent to developing countries. These flows of money are widely recognized as among the most stable external sources of money for developing countries and, in the case of countries such as Mexico, the Philippines, and most recently India, constitute a significant fraction of the country's gross domestic product (Chishti, 2007). It is unclear to what extent the levels of remittances are driven by the sheer numbers of international migrants or whether remittances submitted by migrants increase as they age in the destination society (and presumably earn more) or drop as migrants' ties to the sending country fade over time.

Social scientists, especially economists and sociologists, are concerned about the welfare of individual migrants after they arrive in the new country. Economists often track trajectories of earnings over the remainder of the migrants' life cycle in the new country; sociologists have done the same for occupational careers. This research often shows that after controlling for educational attainment and other forms of human capital, migrants' labor force careers are disrupted shortly after migration but often recover as they adapt to the new society.

However, most of this work has concentrated on male migrants who arrive in early adulthood.

Sociologists have also considered how those who migrate in childhood fare in the new society. Very little research has compared how the timing of migration in a migrant's life course, whether in childhood, early adulthood, middle adulthood, or late adulthood, differentially affects a migrant's life trajectory and well-being in the country of destination. But some processes of acculturation may be much more difficult for people who migrate later in life to a new country than for those who migrate earlier in life. The *critical period hypothesis* in second language learning, for example, suggests that age at migration is a potentially important predictor of how well a migrants eventually learn their host society's language and thus of how well they then fare in the labor market (Bleakley & Chin, 2004).

# INCARCERATION, ADULTHOOD

This entry discusses both incarceration and imprisonment. Individuals are considered imprisoned when they have been convicted of a crime and sentenced to more than 1 year. Although some imprisoned individuals are held in local jails, most are transferred to state or federal prisons to serve their sentences. The median sentence for state prisoners, who comprise more than 85% of the American prison population, is 36 months, and the median time served is 17 months. Although an individual must have been sentenced to more than a year to become a prisoner, all an individual must do to be considered incarcerated is be held in a jail—even just for 1 day. The term *incarceration* covers everything from people serving life sentences for murder to people who have been jailed overnight because of disorderly conduct. The term *incarceration* therefore covers a broader range of confinement than does the term *imprisonment*.

## THE ERA OF MASS IMPRISONMENT

For the first three-quarters of the twentieth century, the American imprisonment rate hovered around 100 persons per 100,000. Over this period, American imprisonment was noteworthy mainly for its stability; in 1973 the imprisonment rate appeared so immune to social change that researchers doubted it would deviate significantly in the near future (Blumstein & Cohen, 1973). Even the coming and going of two great wars—World War I (1914–1918) and World War II (1939–1945)—had little effect on the imprisonment rate. Starting in the mid-1970s, however, American imprisonment rapidly increased. As of 2008, the imprisonment rate in the United States was more than 500 per 100,000. America's rate of incarceration is closer to those of South Africa, Malta, and the former Soviet Union than to Great Britain, Canada, or other comparable democracies. A high rate of imprisonment has become a distinctive feature of American society since the mid-1980s.

Although researchers debate the causes of the dramatic rise in American imprisonment, there is considerable agreement that the prison boom had political and economic antecedents. Following the presidential campaign of Barry Goldwater (1909–1998) in 1964, crime became a national political issue as it never before had been. For the first time,

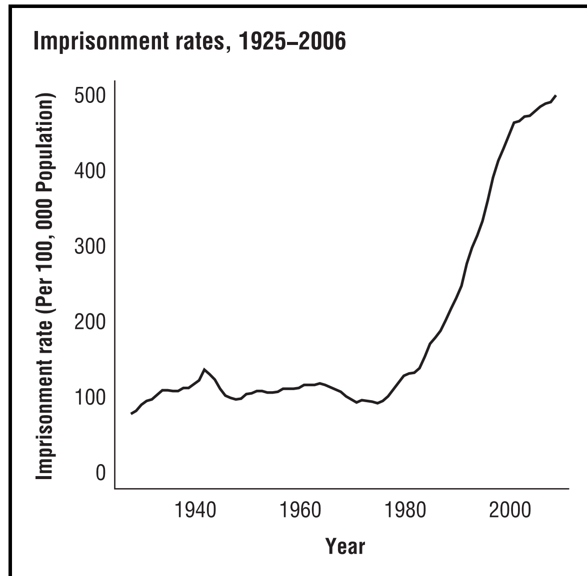

*Figure 1.* *U.S. Imprisonment rates, 1925–2006.* CENGAGE LEARNING, GALE.

politicians on a grand scale began solidifying public support by sponsoring punitive legislation that was often as predictive as it was reflective of public opinion (Beckett, 1999). The national manufacturing decline and the flight of jobs and people from poor urban neighborhoods to predominantly White suburbs also altered the landscape of opportunities available to the nation's worst off. Crime rates during this period rose, but the connection between rising crime and the use of incarceration is not overwhelmingly strong. The drug trade—and the War on Drugs beginning in the 1980s—hold a particularly important place in the story. Increasing rates of incarceration for drug-related crime explain 45% of the increase in the state prison population (Western, 2006).

The causes of mass imprisonment have received substantial research attention since the 1990s, the consequences of incarceration have also been examined. Rather than focusing solely on the effects of incarceration on crime, this research considers a wider variety of impacts of incarceration on individuals, their families, and society more broadly.

## RISKS OF INCARCERATION

The risk of being incarcerated is unequally distributed in America, as elsewhere. The risk of entering prison or jail is highest during the period between a person's late teens and early 30s; before and after this age span, the risk is relatively low (Pettit & Western, 2004). Men are much more likely to be incarcerated than women, although the risk of imprisonment has grown faster for women since the 1980s (Bonczar, 2003). The lion's share of the growth in female imprisonment is attributable to changes in convictions for drug-related offenses. Individuals with low levels of education—and especially individuals who have not finished high school—are more likely to enter jail or prison than individuals with higher levels of education. Racial inequality in the risk of imprisonment is also substantial: Black men born between 1965 and 1969 were around seven times more likely to have been to prison by 1999 than comparable White men (Pettit & Western 2004, pp. 161–162). Latinos are also at higher risk of imprisonment than Whites, but their risk is much lower than that of comparable Blacks (Bonczar, 2003). Black men who did not finish high school have a 60 percent chance of going to prison in their lifetime (Pettit & Western, 2004, p. 161).

The mass imprisonment of Black men has significant life-course implications. As Table 1 indicates, Black men are more likely to be imprisoned at some point in their lives than they are to earn a college degree or enter military service. The same cannot be said for White men, only about 3% of whom will ever be sent to prison. For Black men with little education, marriage is not even twice as common as imprisonment. White men, by contrast, are 12 times more likely to get married than go to prison.

Large racial and class inequalities in the risk of imprisonment suggest that, even prior to incarceration, the life chances of prisoners are more limited than those of the average individual. Inmate surveys bear this out: Prisoners are more likely than the average citizen to have been abused as children, to suffer some form of mental illness, to have been homeless, and to be addicted to drugs or alcohol (Mumola, 2000). Coupled with histories of criminal activity, unemployment, and residence in poor neighborhoods, most prisoners began life at a significant disadvantage to the general population.

## CONSEQUENCES OF INCARCERATION

Research suggests, however, that having been incarcerated may further impede the life chances of formerly incarcerated individuals. Studies conducted since 2000 point to four areas in which incarceration may have consequences for the lives of former prisoners: (a) the labor market, (b) family life, (c) health, and (d) civic participation. This entry does not discuss the effect of imprisonment on crime—a topic that is the subject of much debate—in any detail. One study estimates that the growth in imprisonment rates explains only about 10% of the decline in serious crime at the end of the 1990s, but estimates range from no effect to 40% (Western, 2006).

Of all the consequences of incarceration, its economic effects have probably received the most scholarly attention. Research in this area has focused on three labor market outcomes: (a) getting a job, (b) earnings, and (c)

| Life Event | White Men (%) | Black Men (%) |
|---|---|---|
| All Men | | |
| Prison Incarceration | 3.2 | 22.4 |
| Bachelor's Degree | 31.6 | 12.5 |
| Military Service | 14.0 | 17.4 |
| Marriage | 72.5 | 59.3 |
| Noncollege Men | | |
| Prison Incarceration | 6.0 | 31.9 |
| High School Diploma/GED | 73.5 | 64.4 |
| Military Service | 13.0 | 13.7 |
| Marriage | 72.8 | 55.9 |

***Table 1.*** *Percentage of non–Hispanic Black and White men, born 1965–1969, experiencing life events and surviving to 1999.* CENGAGE LEARNING, GALE.

wage growth. The most methodologically rigorous study to date of the effects of incarceration on the probability of getting a job showed that having a criminal record drastically reduced the likelihood of receiving a positive response from an employer seeking to fill an entry-level position (Pager, 2003). The study also showed that Black men with criminal records did much worse than White men. White men with criminal records received a positive response 17% of the time; comparable Black men received a positive response 5% of the time (Pager 2003, p. 958). Research on earnings draws similar conclusions, showing that having ever been incarcerated diminishes earnings by as much as 40% (Western, 2006). Other studies suggest that because time out of the labor force may diminish the probability of getting a career job, and thus having substantial wage growth, incarceration may increase economic inequality (Western, 2002). Yet these findings are not without dispute; research using administrative data shows that an additional year of incarceration does not diminish earnings (Kling, 2006).

For individuals attached to families, the experience of imprisonment also appears to weaken family ties. Men who go to jail or prison experience much higher risks of divorce and separation than otherwise comparable men; they also experience much lower rates of marriage than other men when they are incarcerated (Lopoo & Western, 2005). Families of the incarcerated often shoulder burdens of visitation, diminished household earnings, and stigma; mothers tend to suffer psychological distress as a consequence of having their adult sons incarcerated. One study suggests that romantic partners have higher levels of stress and depression because of the incarceration of a loved one (Braman, 2004). Other research, however, reports that the removal of a violent, drug-addicted man from a household may provide temporary respite for women (Comfort, 2008). Substantial differences in interpretations of the effects of incarceration on romantic partners illustrate the need for more research on the collateral consequences of incarceration.

Imprisonment, however, affects more than the life course of incarcerated adults and their families. High levels of imprisonment also have consequences for children. As imprisonment has become common for adults, so also has parental imprisonment become common for children. Christopher Wildeman (in press) estimates that one in four Black children born in 1990 had a parent imprisoned by their 14th birthday; for Black children of high school dropouts, parental imprisonment was modal. These risks are about twice the risk of those for children born 12 years earlier—and drastically higher than the risk for comparable White children. One consequence of high levels of imprisonment—especially female imprisonment—is an elevated risk of children being placed in foster care. Changes in the female incarceration rate account for 30% of the drastic increase in foster-care caseloads between 1985 and 2000 (Swann & Sylvester, 2006). Although other consequences of parental incarceration for children are uncertain, there are reasons to suspect that parental incarceration further disadvantages children. If so, mass imprisonment would contribute not only to social inequality among adults but also to that among children.

Incarceration may additionally worsen the health of former prisoners. Ex-offenders have higher death rates than those who have never been incarcerated after adjusting for age, sex, and race (Binswanger et al., 2007), although it is unclear whether this relationship is causal or spurious. In the latter case, the association may reflect other factors associated with both higher risk of death and incarceration, such as drug abuse. Even if incarceration does not increase mortality risk, research shows that incarceration increases the risk of certain acute health conditions (Massoglia, 2008)—especially those related to stress—and has contributed to racial inequality in HIV and AIDS infection rates for both men and women (Johnson & Raphael, in press). To the degree that mass imprisonment may harm the health of prisoners—and, potentially, their families and children—it is not only a criminal justice concern but also a public health concern.

Finally, incarceration poses formidable legal barriers to political participation, the retention of parental rights, and the receipt of welfare, public housing, and financial aid (Travis, 2002). In all but two states, incarcerated individuals are not allowed to vote, and ex-felons are not allowed to vote in many states. The 1997 Adoption and Safe Families Act speeds the termination of parental rights for children who have been in foster care for 15 of the last 22 months—a duration far shorter than the median prison sentence. An often-overlooked provision of welfare reform permanently prohibits individuals with

drug-related felony convictions from receiving federal assistance and food stamps. Statutes enacted in the 1990s give public housing agencies the authority to deny housing to individuals with a wide array of criminal convictions. Also, the Higher Education Act of 1998 renders any individual convicted of a drug-related offense ineligible for student loans. Together, these legal barriers present formidable challenges to individuals seeking to return safely from prison—particularly given their diminished pre-incarceration resources (Travis, 2002).

## DOES INCARCERATION REALLY DIMINISH LIFE CHANCES?

Although research on the effects of incarceration on the life chances of individuals points to consistent, negative effects, it is also possible that the poorer life chances of the ever-incarcerated are due to something other than incarceration. The logic for this argument is simple: Because researchers know that individuals likely to go to prison already suffer from diminished life chances, how can they be sure that differences between formerly incarcerated individuals and other individuals are due to incarceration and not something else, such as living in poverty or partaking in crime? Most studies in this area use observational data and therefore have difficulty isolating causal relationships between incarceration and life chances. In order to increase confidence in the foregoing conclusions about the consequences of incarceration, more studies should use experimental or quasi-experimental research designs. Although this type of research is typically more difficult, expensive, and time-consuming to conduct than other types of research, the potential rewards are greater because these experimental studies have less trouble dealing with many of the biases that hinder studies based on observational data.

## FURTHER RESEARCH

There are many important areas for future research in the study of incarceration, but two merit special attention because of their potential policy implications. First, researchers should consider situations in which incarceration may *improve* the life chances of incarcerated individuals and those around them. Current research tends to consider incarceration as having only negative effects on the life course of individuals and their loved ones—indeed, this entry suggests just that—but one recent study casts doubt on the claim that incarceration only diminishes life chances (Comfort, 2008). This study is quick to note, of course, that many of the benefits of incarceration exist solely because prisons are one of the only places in which basic social services are readily available to the poor. In order to have a better idea of what the consequences of incarceration are, however, researchers should attempt to determine with greater precision when incarceration harms, helps, and has no effect on individuals.

Second, more research should evaluate programs to help formerly incarcerated individuals successfully return to civic life after leaving prisons and jails. To find out what works, more research should be conducted on which programs—both during and after incarceration—help diminish the probability of recidivism. Research should also consider early intervention programs aimed at decreasing an individual's risk of incarceration. Although the evaluation of programs should not be the sole focus of policy interventions, researchers of the penal state should nonetheless spend more of their time and resources considering how to keep individuals away from crime and out of prison.

# INCOME INEQUALITY

Income inequality can be defined as the amount of variation in the value of goods and services received by individuals in a defined population at a given time. That is, income inequality refers to how income is distributed among members of a population at a point in time. For instance, in the United States, according to Census Bureau estimates for 2006, the poorest 20% of households (those earning $19,178 annually or less) earn just 3.4% of all income earned by households in the United States, whereas the richest 20% of households (those earning over $91,705 annually) earn 50.5% of all income earned by households in the United States. The significance of income inequality for the life course and life course research is difficult to overstate, because life course processes are related to both the causes and the consequences of income inequality. For instance, the degree of variation in income within a society establishes a structure of economic opportunity that constrains economic achievement, and the pursuit of economic well-being itself helps to establish the level of income inequality observed at a particular historical moment. Broadly, the amount of income inequality makes up a central part of an individual's sociohistorical context as that individual navigates the life course.

## MEASUREMENT

Researchers have developed a wide array of methods to measure income inequality. One of the most popular is the Gini coefficient, which quantifies the difference between an observed income distribution and a perfectly equal income distribution. The Gini coefficient ranges from a minimum of 0 (or perfect equality, where all income-receiving units receive an equal share of the income produced in a society) to a maximum of 1 (or perfect inequality, where one income-receiving unit receives all the income produced in a society).

The first step in calculating the Gini coefficient and other summary measures of income inequality is thus to define the income-receiving unit. Because incomes are typically shared within households, empirical researchers often designate households as the unit of analysis. The next step is to define income. For instance, one commonly used income measure is *disposable income*, or the sum of all wage and salary income and government income transfers, less direct tax contributions, that is available for spending or saving. Thus disposable income includes income from many sources, not just income from employment. This highlights the important distinction between *income inequality* and *wage inequality*. Income inequality, a broader concept, in addition to wages and salaries also includes money from self-employment; property income; pension, sickness, disability, and unemployment benefits; child support transfers; and a wide range of other government benefits. Because income inequality incorporates information on government taxes and transfers, it is also referred to as *post-fisc inequality*, in contrast to *pre-fisc inequality*, or inequality generated only by the market.

Once the income-receiving unit and income are clearly defined, the Gini coefficient, and other measures of income inequality, can be calculated. The Gini coefficient itself is based on the Lorenz curve, which plots the cumulative share of total income (on the y-axis) against ranked income-receiving units (on the x-axis). For instance, in a society with perfect income equality, the Lorenz curve would be shaped like a straight line tilted at a 45-degree angle, as the lowest 20% of households shared 20% of society's income; the lowest 50% shared 50%; the top 20% shared 20%; and so on. Again, in this perfectly equal society, the Gini coefficient would be 0. By contrast, in the United States, where the bottom 20% of households garner 3.4% of total U.S. income and the top 20% of households garner 50.5% of total U.S. income, the Gini coefficient equals 0.464 (based on Census Bureau estimates for 2006 data).

Other popular summary measures of income inequality include (a) the variance of logged incomes; (b) the coefficient of variation; (c) the Theil index; (d) the Atkinson coefficient; and (e) the relative mean deviation. One popular measure that is especially easy to interpret is the percentile ratio, or the ratio of income received by a household at a percentile rank high in the income distribution to the income of a household at a lower rank. One's location in the income distribution thus refers to how their income ranks relative to others in the United States. For example, a household in the 80th percentile of income distribution is a household whose income is higher than 80% of households in the United States.

In the United States, the ratio of income earned by a household at the 80th percentile of the income distribution

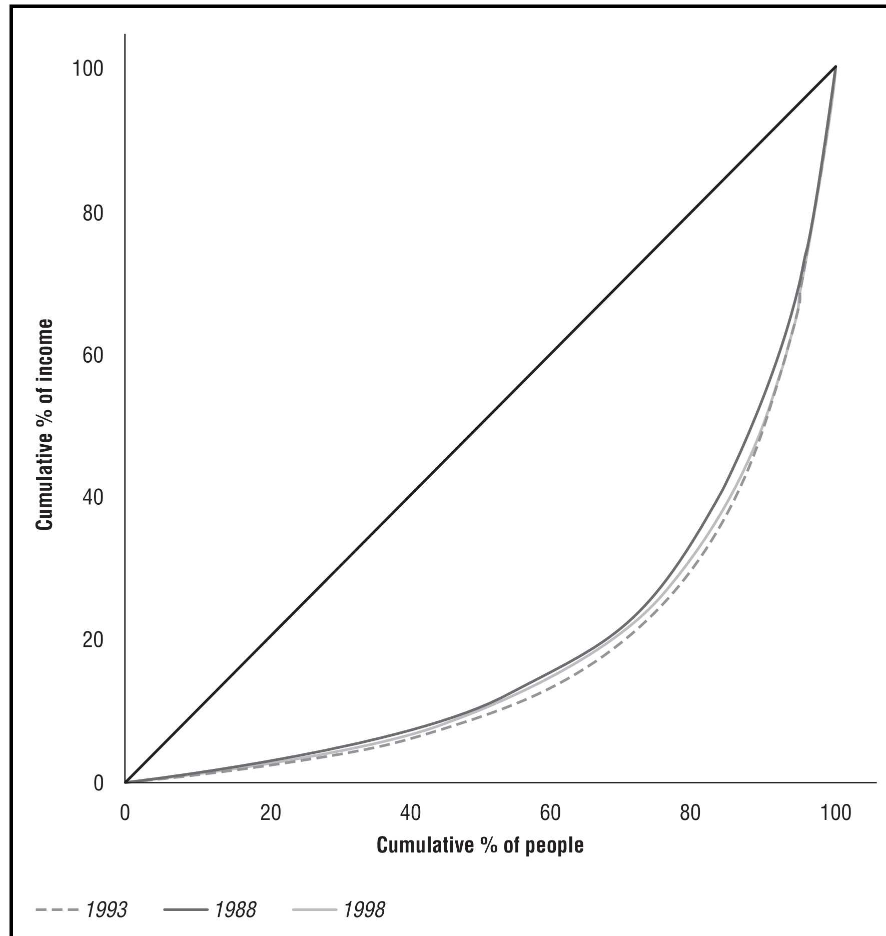

***Figure 1.*** *Global Lorenz curve (world individuals).* CENGAGE LEARNING, GALE.

to income earned by a household at the 20th percentile (the 80-20 percentile ratio) was 2.996 in 2000, according to the Luxembourg Income Study (LIS). By contrast, the 80-20 ratio in Canada was 2.524, and in Sweden it was 2.012. The 90–50 percentile ratio—the ratio of the 90th percentile household income to the median household income—was 2.104 in the United States, 1.933 in Canada, and 1.684 in Sweden.

## TRENDS

There is a consensus in research literature that income inequality within advanced industrial societies such as the United States has grown since the 1970s. For instance, again according to the LIS, the Gini coefficient for the United States has grown from 0.301 in 1979 to 0.372 in 2004, which is a very large increase as income inequality generally does not exhibit strong trends. (The difference between the LIS estimate and the Census Bureau estimate reflects differences in how the indices are calculated; LIS data are calculated for cross-national comparability.) Even in egalitarian Sweden, though, the Gini coefficient grew from 0.197 in 1981 to 0.252 by 2000. However, whereas many accept that income inequality has increased in societies such as the United States, there is more debate over (a) the specific timing of the increase; (b) the extent of the increase; (c) the causes of the increase; and (d) the consequences of the increase (Neckerman & Torche, 2007). Arthur Alderson et al. (2005) used LIS data on 16 advanced industrial countries to clarify how inequality has changed. They show that the largest increases in income inequality have been driven more by the rich getting richer (upper polarization) than by the poor getting poorer.

There is also a consensus in this literature that income inequality varies substantially across countries, with the highest levels generally observed in the developing countries of Latin America and sub-Saharan Africa, and the lowest levels generally observed in the advanced industrial countries of Scandinavia and western Europe. Anglo countries such as the United States, the United Kingdom, Canada, and Australia currently exhibit levels of income inequality that are significantly higher than

those in western Europe. The trends also differ, with income inequality growing more rapidly in the United States than in western Europe. Of course, whether data are comparable across nations is a key concern when comparing levels of income inequality, but great strides have been made in this regard by data collection and dissemination efforts such as the LIS and the Pitt Inequality Project, which collect comparable data from many nations and make them available to researchers.

If there is general agreement that income inequality has increased in many advanced industrial societies, and has increased especially strongly in the United States, there is much less agreement on how total world income inequality is evolving. (See Kathryn Neckerman's and Florencia Torche's "Inequality: Causes and Consequences" [2007] for an overview addressing this matter and references to key works on the subject.) Total world income inequality is the broadest measure of income inequality, because it is composed of between-country differences in national economic development, and within-country income inequality among individuals. In one influential line of research, sociologist Glenn Firebaugh (2003) argues for a "new geography of global income inequality" based on evidence that total world income inequality is on the decline, because rising income inequality within countries is vastly outweighed by decreasing economic inequality between countries. In direct contrast, economist Branko Milanovic argues that global inequality rose sharply from 1988 to 1993, then declined modestly from 1993 to 1998, based on new evidence from household survey data. This debate is marked by a number of measurement controversies and differences of interpretation, creating a significant opportunity for further research. Moreover, few studies have examined the difference this possible change in the global social context makes for the lives of individuals as they move through the life course.

## CAUSES

The relationship between economic development and income inequality has long been a puzzle. In the 1950s, economist Simon Kuznets (1901–1985) conjectured that income inequality has an inverted U-shaped relationship to economic development, rising in the early stages of industrialization and falling at later stages, as people move from the agricultural sector, where wages are lower, to the industrial sector, where wages are higher. This sector dualism causes income inequality to increase at first, purely as a function of the changing composition of the labor force by economic sector. Two other changes associated with economic development can also help to account for the Kuznets curve: the expansion of mass schooling, which decreases the wages of the highly educated by creating a larger pool of highly educated labor, and the demographic transition from a high-fertility, high-mortality regime to a low-fertility, low-mortality regime, which increases income inequality as population growth expands the labor supply at the low end of the income distribution (Alderson & Nielsen, 2002).

Because wage inequality is clearly a significant proportion of income inequality, researchers also look to other aspects of the labor market beyond sectoral composition, skill composition, and demographic composition to explain cross-national differences and trends in income inequality. For instance, a large body of evidence shows that where labor is better organized, inequality will be reduced. Antilabor corporate restructuring and government policies in the United States in the 1980s are often blamed for part of the increase in income inequality in the United States, and cross-national investigations show that unionization rates are highly correlated with income inequality (Alderson & Nielsen, 2002). On the demand side of the labor market, one controversial explanation of increased income inequality in places such as the United States is skill-biased technological change: The argument is that technological shifts have substantially raised the wages of the most highly educated segment of the labor force, which has raised income inequality by increasing inequality in the upper end of the income distribution.

National governments are also critical to any examination of the causes of income inequality. National economic policies, for instance, produce and reproduce social cleavages, as tight monetary policy restricts inflation and benefits the privileged classes, whereas full employment policy benefits the disadvantaged classes. Social policy also affects income inequality directly through income transfers. Other national policies and institutions also affect income inequality: In the United States, laws restricting labor organization, tax policies, infrastructure programs, the declining real value of the minimum wage, and education policies all affect the level of income inequality, by shaping who has access to education and helping to determine which jobs receive what rewards, among other mechanisms.

In response to explanations that center on forces within nations, world systems theory redirected scholarly attention toward international forces during the 1970s and 1980s. World systems theory argues that income inequality in developing countries is worsened by dependence on foreign capital, as (a) the occupational structure is distorted in an expansion of the working class and an internationally oriented elite, and (b) the nation directs its economic and social policy to the advantage of multinational corporations (Chase-Dunn, 1975). In work on advanced industrial societies, there is also evidence that globalization is associated with the recent increase in income inequality that has been dubbed "the Great U-Turn" (Alderson & Nielsen, 2002). New research also shows that other international forces, including the regional integration in western Europe, are also associated with rising income inequality, over

and above any relationship between inequality and globalization (Beckfield, 2006). This suggests that regional integration, or the construction of regional political economy that has enjoyed a resurgence around the world, itself may be an important new dimension of the social context that influences the life chances of individuals.

## CONSEQUENCES

Whether income inequality has important consequences is an enduring controversy. Neckerman (2004) presents evidence from the Russell Sage Foundation's research program on inequality, focusing on the relationship between growing income inequality in the United States and several other aspects of social inequality, including family and neighborhood life, education and work, health, political participation, public policy, and wealth, while Stephen Morgan, David Grusky, and Gary Fields (2006) review research on the connections between income inequality and social mobility. Although each of these topics is clearly relevant to life course scholarship, the debate over health has been particularly contentious and policy-relevant, and thus warrants a detailed treatment.

Since Richard Wilkinson's pioneering work in the early 1990s, researchers from various disciplines have debated the provocative claim that the level of income inequality in a society is related to the health of its population (Beckfield, 2004; Wilkinson & Pickett, 2006). The theoretical arguments for a negative health effect of income inequality are straightforward. Perhaps most prominently, Wilkinson pursues an approach based on the work of French sociologist Emile Durkheim (1858–1917) that emphasizes social integration. For Wilkinson (1996), income inequality produces social disintegration, which causes unhealthy societies. Disintegration translates into poorer population health as individualism dominates social life and undermines the beneficial health effects of social support. Wilkinson claims that to live in a society characterized by inequality and social disintegration is to "feel depressed, cheated, bitter, desperate, vulnerable, frightened, angry, worried about debts or job and housing insecurity; to feel devalued, useless, helpless, uncared for, hopeless, isolated, anxious and a failure" (1996, p. 215), and that these feelings harm health. This social psychological mechanism may help to account for high correlations between income inequality and measures of population health that are sometimes observed in samples of advanced industrial societies.

Poor health in high-inequality societies has also been explained as a result of societal underinvestment in pro-health physical, human, and cultural capital, including medical services, education, and cultural activities (Lynch & Kaplan, 1997). These claims overlap with Wilkinson's, because they argue that this underinvestment hurts health, in part, because it undermines social cohesion. However, John Lynch and George Kaplan (1997) focus instead on conditions experienced in everyday life and deemphasize the emotional experience of inequality. Some theorists consider relative deprivation the link between income inequality and health. Relative deprivation theorists generally argue that the perception that one has less than others causes psychological stress, which produces ill health. This reasoning suggests that income inequality harms population health because it intensifies this relative deprivation. Some researchers emphasize both social cohesion and relative deprivation as important determinants of health. Controversies surround the finding of a correlation between income inequality and health, with some researchers questioning the generality of the correlation (Beckfield, 2004; Wilkinson & Pickett, 2006).

Research on income inequality is enjoying a renaissance, and there are a number of opportunities for further work in this theory-rich and policy-relevant area. Research that addresses the debates above is clearly needed, as is further work to address two major gaps in the literature: (a) an inadequate understanding of how inequality among groups within national societies relates to the overall level of income inequality, and (b) an inadequate understanding of how international forces affect income inequality among and within national societies. First, although early-21st-century research on inequality within the United States has focused on the roles of gender discrimination (Correll et al., 2007), racial discrimination (Pager, 2003), social networks (Mouw, 2003), and cultural dynamics of child-rearing strategies (Lareau, 2003) in explaining economic outcomes for different groups within the United States, this work is rarely connected to the level and trend in income inequality. Second, the ongoing formation of international economic and political networks raises new questions about how changes in the scale of social action and institutions affect and are affected by patterns of income inequality.

# INDIVIDUATION/ STANDARDIZATION DEBATE

Social scientists have a long-standing interest in the structure of the life course, that is, in the occurrence, timing, and order of social roles over people's life spans and how these patterns are shaped by sociohistorical conditions. Such interests are two-fold. In one respect, variation in whether, when, and how people move into adult social roles has implications for social achievement, social standing, social experience, as well as one's identity, attitudes, and emotions. For example, the often contentious issue of teen parenthood typically reflects concern about the implications of a major life transition occurring at too young of an age, prior to other life transitions (such as finishing school), or in the absence of potentially complementary transitions (such as marriage). Yet in another respect, the variable unfolding of human lives is informative about the societies around them. Different societies foster distinctive pathways through life and thus reveal the presence of cultural norms, scripts, and sociostructural contexts that shape how lives unfold. In this regard, the life course is often examined as a window into the modernization and development of societies.

Although analysis of the life course extends back to the 19th century, the dramatic social changes of the 20th and early 21st centuries set the stage for volumes of research. The central issue at hand was how core changes in the nature of society restructured, perhaps even radically so, the individual life course. The empirical aspect of this work is simple in the sense that researchers are largely interested in how, if at all, the life course differs from that of earlier societies or varies across cultures. Yet, the study of the life course is also complex in that there is little agreement on how such comparisons should be made. Available data are often sparse and not well-suited to comparison, and the technological advances in statistical methodology that would allow for systematic comparison are in their infancy.

Nevertheless, contemporary research has done much to increase understanding of social change and the life course and has led an important debate. On one side, some scholars argue that the life course is increasingly *individualized* as pathways through life are increasingly diverse and unanchored from mainstream social institutions and social locations (Buchmann, 1989). Such an argument challenges long-held views that human lives were *standardized* in the 20th century by the increasing importance of institutions such as formal education, work, and law and the emergence of a world society. A number of other terms are used to describe the sides in this debate, including *institutionalization*, *deinstitutionalization destandardization*, *differentiation*, *dedifferentiation*, and *pluralization*, but their distinction from the ideas of individualization and standardization is more subtle than substantive (Bruckner & Mayer, 2005).

## THEORIES OF STANDARDIZATION AND INDIVIDUALIZATION

In many respects, arguments for the standardization of the life course are a logical extension of broader arguments about the modernization of societies and their implications for personal and social behavior. Martin Kohli (1986), for example, argued that the modern organization of public services and employment opportunities by age creates a more orderly and homogenous life cycle. Laws regarding age at marriage, mandatory participation in education, and employment establish generic starting lines for life transitions. Likewise, the

increased rationality of education and employment in Western nations helped to standardize exits from schooling and thus created similarity in transition ages. Although the evidence to date is thin, there are also grounds to expect that cross-national variation in the life course has diminished with increasing globalization and the emergence of a one-world society linked through shared economies, politics, and social institutions.

The idea of a standardized life course was highly prevalent in the late 1970s and 1980s. This is not surprising given that researchers of the time were typically considering data from the first half of the 20th century and referencing the profound changes in culture and economy that accompanied the post–World War II (1939–1945) era. Specifically, the postwar economic boom led to the regulation of the life course in that males, White males in particular, could finish secondary education (or not), could move into jobs that paid a living wage, and could earn enough to both purchase a house and support a wife and children. Given the emergence of a strong middle class, at least among Whites, it is not surprising that the economic conditions of the era produced a highly regulated life course. Sociologist Dennis Hogan (1978) was among the first to empirically document this *orderly* or *normative* life course whereby people finished school, entered full-time employment, and then proceed to get married and have children, all of which was seen as a rational, almost taken-for-granted response to the economic and cultural conditions of the day.

A view that located the life course in the economic, cultural, and political contexts of society was a logical way of making sense of changes in lives over the 20th century. However, this perspective produced a new set of arguments to accompany the changing conditions of the late 20th century. These arguments emphasized the individualization of the life course and ultimately challenged the earlier standardization thesis. It is difficult to locate exactly where the individualization argument first arose, but it was clearly a reaction to the changing nature of society. Sociologist Michael Shanahan (2000) suggested that an individualization argument had its roots in the decline of family and community, which increasingly freed people from traditional sources of social control and thus allowed them to exercise greater agency in structuring their lives. Likewise, Marlis Buchmann (1989) suggested that the standardized trajectories of the past were "shattered" by structural and cultural change. Among the most significant of these were the increased disconnect between educational attainment and occupational standing, the diminished value of occupational training and expertise, changes in the family involving increased rates of cohabitation and parenthood outside of marriage, and an increase in cultural emphases on emotional well-being through individuality. These forces unanchored the modern life course from regulated and regulating institutions and increased the significance of flexibility, choice, and personality in shaping life paths.

## THE STATE OF THE EVIDENCE: WHAT IS KNOWN AND WHAT SHOULD BE KNOWN

Adjudicating among these different arguments is complicated by the fact that there is no agreed-on standard of evaluation and a variety of data has been brought to bear on the issue. Ideally, one would like longitudinal data that covers a number of historical periods. Such data are rare and in many cases nonexistent. As a result, researchers have marshaled data from a wide variety of sources to speak to the key issues. Based on such data, several conclusions can be drawn and several questions remain.

First, it seems clear that the time line for the transition to adulthood became compressed and that standard transitions increased in prevalence through much of the 20th century. John Modell, Frank Furstenberg, and Theodore Hershberg (1976), for example, showed that the time it took 80% of the population to leave their family of origin (i.e., their parents' home), marry, and establish their own household declined significantly between 1880 and 1970. Consistent with this, other research shows that increasing proportions of the population followed a typical or normative life course pattern through the 19th and 20th centuries (Hogan, 1981).

Second, life courses in the late 20th century did have some seemingly unique features. First, the pursuit of higher education became much more prevalent, and thus education characterized a longer period of the life course for a larger percentage of people. Movement into full-time, career-type work was delayed as people increasingly pursued college educations in the hopes of securing better jobs. Yet the labor market itself was less accommodating, which made job entry an even longer and more tenuous process. One corollary to this was an increased overlap between schooling and work, such that full-time students also spent long hours working for pay. At the same time, the age at which people married for the first time increased, in part due to the changes in education and work. In some cases, this produced a re-nesting effect whereby single men and women returned to their parents' home after graduating from college (Goldscheider & Goldscheider, 1999). Coupled with advances in contraceptive technology, later marriage meant that childbearing also occurred later in the life course, creating a phenomenon that sociologists Claude Fischer and Michael Hout (2006) characterized as people having their "third and fourth child" without having their first and second. In addition, new family arrangements became more common—notably cohabitation and nonmarital childbearing—and divorce rates increased sharply. When all these factors are put together, the lockstep, sequential, and

orderly life course of the past has given way to an increasingly elongated, increasingly disorderly, and increasingly variable and differentiated process.

Although the demographic reality of the contemporary life course is not strongly disputed, the weight of the evidence supports neither a pure standardization nor a pure individualization perspective. To some extent, this may be because adjudicating between theories, both of which may be partially correct and which concern historically contingent processes, is an unrealistic goal. At the same time, future study could greatly increase understanding of how life courses are constructed, how life courses vary across gender, racial, ethnic, and social class subgroups in society, and whether and how life courses have changed over time. For example, relatively few studies have linked the social psychological processes integral to the individualization thesis to the demographic behavior of the individuals. Future research should focus on opening the "black box" of human agency in the construction of the life course. Several studies have been attentive to the variety of life course pathways, both within and across social groups, yet future research should seek to formally model heterogeneity in pathways through the life span. In the latter respect, social demographer Elizabeth Fussell (2005) has pioneered techniques to systematically document variation in the life course over time, techniques that should lead the way for a new generation of scholarship. Accompanying such work should be systematic comparisons of longitudinal data from comparable samples from different historical periods. Although the latter approach may require unique data collections, as well as creative use of existing data, it could greatly enhance understanding of the past, present, and future of the life course.

Ultimately, the debate over standardization and individualization highlights changes in the life course and provides concepts for making sense of broad and multifaceted change. More research is needed to show how, if at all, the life course has changed and whether it has changed in the ways that individualization advocates argue. Still, it is difficult not to recognize the complexity of contemporary life paths and treat them and their consequences as an important area of study. As Frank Furstenberg, Sheela Kennedy, Vonnie McLloyd, Rubén Rumbaut, and Richard Settersten (2006) provocatively suggest, the contemporary life course, whether truly "individualized" or not, is a time when "growing up is harder to do."

# INFERTILITY

Infertility is defined as the inability to obtain and sustain a pregnancy after 12 months of regular, unprotected intercourse. Fertility problems are estimated to affect between 15% and 20% of couples of reproductive age (Tierney, McPhee, & Papadakis, 1999, p. 913). Infertility generally affects women and men equally, with approximately one-third of fertility problems in couples being attributed to female factors, close to one-third to male factors, and one-third to both male and female factors or remaining unexplained (Tierney et al., 1999, p. 913).

Infertility is fundamentally physiological, although the physiological condition may have social precursors. In males, the most common fertility problems are *oligospermia*, a deficiency in the number of sperm in the seminal fluid, or *azoospermia*, the absence or near absence of sperm. Until the late 20th century, fertility problems in females were primarily caused by endocrine imbalances or anatomical impairments, such as blocked fallopian tubes or endometriosis. However, since the late 20th century an increasing number of men and women have been choosing to delay parenthood well into their thirties and forties—attempting to fulfill their educational and career aspirations prior to becoming parents.

Despite the growing number of women and men having children at later ages, many who delay parenthood find that they cannot achieve a viable pregnancy. Fertility typically begins to decline for women in their 30s due to changes in endocrine functioning and aging eggs. Also, as a woman ages the risk of spontaneous miscarriage and congenital abnormalities increases, further compromising her chances of a successful pregnancy. There is evidence that as a man ages, his fertility declines as well due to diminished quality of the sperm (Tierney et al., 1999). When the male partner is older, his female partner has a greater risk of miscarriage and there is also a greater risk of genetic disorders in the child (Sloter, Nath, Eskenazi, and Wyrobek, 2004). These facts have contributed to an increase in the number of individuals and couples in their thirties and forties who turn to medical technology in their efforts to produce a child.

The advancement of reproductive knowledge and technologies in the 20th and 21st centuries has provided many couples with an explanation of, and treatment for, their infertility. These technologies include the use of fertility drugs, *in vitro* fertilization (IVF), intracytoplasmic sperm injection (ICSI), egg-freezing, the use of donor sperm and/or eggs, surrogacy, and gestational care (Tierney et al., 1999). The American Society for Reproductive Medicine (ASRM) reported that as of 2002 almost 300,000 babies were born in the United States alone as a result of advancements in reproductive technologies (American Society for Reproductive Medicine, 2008). Despite these advances, medical intervention results in a viable pregnancy for only 30% to 60% of couples using such treatments, depending on the cause of their infertility (Tierney et al., 1999). For a significant number of infertile individuals and couples medical treatment fails, so they face the difficult task of coming to terms with permanent biological childlessness.

## THE PSYCHOSOCIAL IMPACT OF INFERTILITY

Most individuals assume they are fertile and have control over if and when they will become parents. Consequently, a diagnosis of infertility is usually met with disbelief. Initially couples may be surprised that they are not getting pregnant, but after several months the idea that they might be infertile seeps into their awareness and they seek medical care. When a diagnosis of infertility is confirmed, couples need to decide whether they want and can afford to pursue fertility treatments, which can cost more than $10,000 per treatment cycle (Garcia, 1998). Because multiple attempts are often required to produce a viable pregnancy, couples must also decide how many treatment cycles they are willing and financially able to undergo and when treatment must be abandoned. They may also face ethically and morally difficult decisions about which treatments they are comfortable pursuing, particularly in the case of third-party options such as donated embryos or surrogacy. In an attempt to make sense of their infertility, many turn inward and wonder what they could have done to cause their infertility.

In most cultures, parenthood is seen as an important benchmark of healthy adult development. Fertility also is associated with femininity and masculinity. Consequently, infertility is a major life crisis for most couples—one that is characterized by multiple losses. Feelings of sadness, grief, anger, inadequacy, and depression are common in response to infertility, according to Judith C. Daniluk (2001b). Caren Jordon & Tracey A. Revenson (1999) indicate this is particularly the case for women, whose bodies bear the primary burden of medical testing and treatments and who tend to be held socially accountable for a couple's infertility. Russell E. Webb and Daniluk (1999) point out that men also struggle with coming to terms with infertility—feeling powerless in being unable to give their partner a child

## WOMEN WAITING TOO LONG TO BECOME MOTHERS

Increasingly, women in developed nations are delaying motherhood to pursue their educational and career goals and attain stability in their finances and relationships. However, concerns have been raised about the higher risks of birth defects, prenatal complications, and premature births for older mothers, leading some to suggest that delaying motherhood is not advantageous to mothers or their children. Early 21st century advances in reproductive technology, which appear to offer solutions to some of the fertility problems associated with age, may offer women a false sense of security, leaving many to face infertility and childlessness in the future. There has also been considerable debate in the media about the motivations of women who elect to become mothers in their 50s and 60s and about the potential health of these mothers who may not be able, or available, to raise these children. As this debate rages, reproductive technologies continue to advance. Such is the current state of the brave new world of reproductive technologies.

and questioning their own masculinity when faced with a diagnosis of male factor infertility.

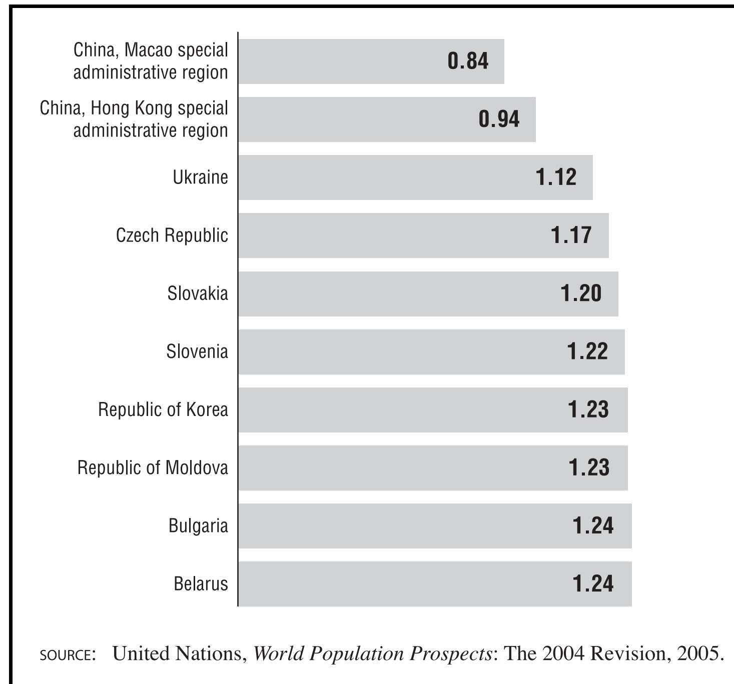
Research, such as that done by Frank M. Andrews, Antonia Abbey, and L. Jill Halman (1991), indicates that men's and women's psychosocial distress increases during what are often very time-consuming fertility treatments. The invasiveness of medical tests, assessments, and treatments is emotionally and physically taxing and frequently places considerable stress on both members of the couple and on their relationship (Daniluk, 2001b; Leiblum, 1997). Couples refer to the "emotional rollercoaster" of infertility treatment—feeling hopeful and optimistic at the start of each menstrual and treatment cycle, followed by overwhelming sadness and even despair when they face another month without becoming pregnant. Infertility also takes a tremendous toll on a couple's sexual relationship as sex for pleasure is replaced by sex for procreation, and a once satisfying, spontaneous, and intimate act becomes paired with repeated failure (Leiblum, 1997; Pepe & Byrne, 2005). Patients also describe feeling a loss of control given that fertility investigations and treatments are focused on the most intimate and private parts of their lives and bodies.

If treatment fails or couples reach the end of their emotional or financial resources, they must make the painful transition to biological childlessness (Daniluk, 2001a; Daniluk and Tench, 2007; Leiblum, Aviv, and Hamer, 1998). For Americans this transition occurs in a context where parenthood is seen as central to constructing meaning in one's life and is viewed as a key milestone in adult development. There are few acceptable alternative models of healthy and normative female development for women who are childless, Mardy S. Ireland (1993) explains. In a society where *family* is defined by parental status, those whose biological childlessness is permanent must construct a healthy identity and a meaningful life that does not include the norm of biological parenthood (Daniluk, 2001a). Once treatment fails and the option of parenting their biological progeny is exhausted, couples also must determine which, if any, other parenting options—such as adoption—are available and acceptable to them. Research suggests that in time most couples come to terms with their biological childlessness and live satisfying lives, whether or not they elect to pursue other parenting options such as adoption (Daniluk, 2001a).

### POLICY ISSUES

The creation of life outside of the private act of intercourse carries with it considerable ethical, moral, and legal consequences and raises important questions. Reproductive science and technology have advanced and continue to advance at a rate that outpaces society's ability to respond proactively to the potential implications of these newly created family forms. Children can now be born after one or both of their genetic parents have passed away, families can be intentionally created with only one parent, children can be born into families with no knowledge of or information about their genetic fathers or mothers, parents can have their embryos screened to ensure that their children have particular desired characteristics (e.g., gender), children can be created for the express purpose of being tissue or organ donors for a sick sibling, women can gestate and give birth to a child to whom they have no genetic connection, mothers can carry children for their infertile daughters, and women in their fifties and sixties can give birth to children through the use of donated eggs and sometimes sperm. While the governments in many countries of the world (e.g., Australia, the U.K., and Canada) have imposed regulations on the fertility industry, no such national regulations existed in the United States in the early 2000s. Each state had its own laws regarding the acceptability of particular treatments—resulting in reproductive tourism, couples traveling to other states to access treatment options not available to them in their home state.

The issue of cost is also problematic, given that insurance coverage for reproductive treatments is not available through the majority of managed health-care plans. In



***10 Places with the Lowest Total Fertility Worldwide.*** *Average number of children per woman, 2000–2005.* CENGAGE LEARNING, GALE.

1998 Garcia estimated the cost of a live birth through in-vitro fertilization (IVF) to be $66,000, meaning that advanced reproductive technologies are restricted to the economically privileged. Although some fertility centers offer couples who cannot afford treatment the option of cost reduction or deferral if the patient agrees to donate a percentage of her eggs to another couple, serious concerns have been raised about the ethics of this exchange.

Questions also have been raised about the rights of children who are conceived using third-party reproduction to know the circumstances surrounding their conception and to have information about their medical and genetic histories. There is ambiguity and lack of regulatory laws concerning suitable compensation for surrogates and gestational carriers and concern about the economic coercion of young women to become egg donors to offset their personal debts or educational costs. The birth of twins in 2006 to a 67-year-old single woman in Spain has also reignited the worldwide debate about the upper age at which women, and in some cases their male partners, should be able to use technology to pursue a pregnancy. At the heart of the debate is concern about the health and mortality of these older mothers, which may preclude their ability to raise their children to adulthood.

Although the American Society for Reproductive Medicine has created best practice guidelines for the provision of fertility treatments, physicians and health care providers who are not members of ASRM are not bound by these guidelines. Clearly there is much work to be done to deal with the immediate and long-term ramifications for the individuals and families involved in these treatments and for the children created as a consequence.

## JOB CHANGE

Over the course of their working lives, individuals often change jobs. Sometimes this mobility is involuntary, as when workers are permanently laid off or fired and must seek new employment. More commonly, workers choose to change jobs in search of better pay or benefits, more interesting work, or to find an arrangement that better accommodates family responsibilities. Job changes play an important role in shaping workers' career trajectories over the life course.

### JOB CHANGES OVER THE LIFE COURSE

Job changing is particularly common during the early career. Economic models suggest that workers will look for new jobs when they believe they can offset the costs of the search by finding a new position that offers higher wages, better working conditions, or other benefits. ''Job shopping'' is particularly useful for workers who lack experience in the labor market because it helps them discover which jobs will be most rewarding. Over time, workers should improve the quality of their job matches, reducing the likelihood of making gains by switching (Burdett, 1978).

In the period after World War II, ultimately settling down and staying with an employer offered important advantages to a substantial share of workers. Robert Althauser and Arne Kalleberg (1981) explained that in exchange for investing in skills and training of value to their current employer, but not necessarily of value to a wide array of other potential employers, workers were rewarded for seniority, gaining job security and regular pay raises. The ideal-typical pattern of job mobility over the life course was thus one of early job changes succeeded by long-term stable employment with a single employer.

### TRENDS IN JOB CHANGING

In recent years, there has been concern that changes in the U.S. economy have weakened bonds between employers and workers, with more and more workers experiencing multiple spells of short-term employment (Baron & Pfeffer, 1998). Studies assessing this possible phenomenon typically measure the flip side of job changes—how long jobs last (job stability). Most commonly, researchers measure trends in job stability by studying changes in tenure distributions (the share of workers who have remained with their employers for different lengths of time) or retention rates (the likelihood that jobs will last for a specified period of time). Although stability has declined in some industrialized countries, a study by the Organisation for Economic Co-operation and Development (1997) showed that this is not a universal trend. In the United States, overall job stability declined between the 1970s and early 1980s, was relatively stable between the 1980s and 1990s, and then declined between the late 1980s and mid-1990s (Neumark, Polsky, & Hansen, 1999).

Although job stability has not declined substantially overall, research by David Neumark, Daniel Polsky, and Daniel Hansen (1999) revealed differences among subgroups. Between the 1970s and 1990s, job stability in the United States declined most sharply for Black workers, both male and female. At the same time, job stability rose

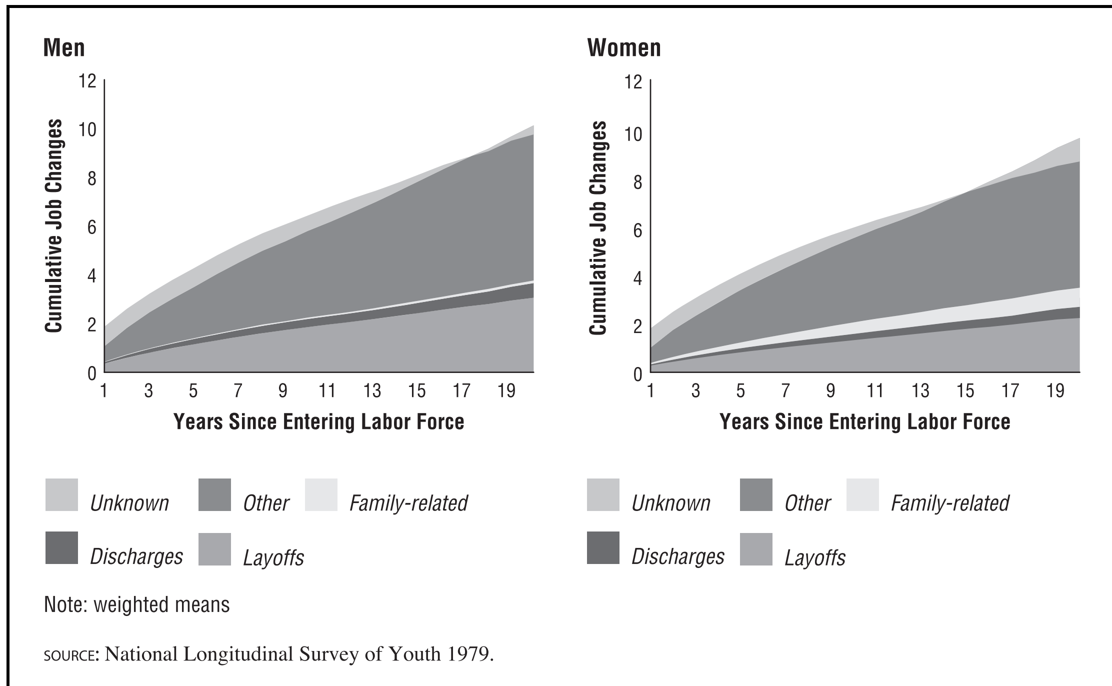

***Figure 1.*** *Cumulative job changes of American workers during the first 20 years in the labor force (1979–2004).* CENGAGE LEARNING, GALE.

among White women as their attachment to the labor market increased. Throughout the 1980s younger workers and those who had started their jobs relatively recently experienced declines in stability, but in the first years of the 1990s job stability declined more among workers who had held their jobs for a relatively long time.

## JOB CHANGE PATTERNS

Not all workers follow the same job change trajectories. Workers in European countries and Japan tend to change jobs less frequently than their North American counterparts (Organisation for Economic Co-operation and Development, 1997). Industry, occupation, and worker characteristics all shape the likelihood of job changes in each country. Employers have less incentive to reward worker loyalty with job security or wage premiums when their jobs are not perceived to require specialized skills. In the United States, according to Paul Ryscavage's analysis in 1997, workers are most likely to stay with the same employer in public administration, manufacturing, transportation, communication, and other utilities and least likely to stay with the same employer in entertainment, recreation services, agriculture, forestry, fisheries, personal services, and business services. Worker characteristics are also associated with differences in job change patterns. On average, younger workers, the less educated, and women are more likely to leave their jobs (Ryscavage, 1997).

Workers also differ in the types of job changes they undergo. The best information about these patterns is based on longitudinal data from surveys of younger workers. Among young men, Hyunjoon Park and Gary Sandefur (2003) found that higher turnover among Black and less educated workers is largely a function of their higher likelihood of involuntary job changes. Gender differences in cumulative voluntary job changes and layoffs are not large among younger workers, but Sylvia Fuller (2008) indicated that women are more likely to leave jobs for family-related reasons and are less likely to be discharged. Overall, younger women are less likely than younger men to leave employers for a better job but more likely to experience a period of nonemployment between one job and the next. These differences largely reflect the behavior of less educated women, particularly African Americans and Hispanics (Alon & Tienda, 2005).

## CONSEQUENCES OF JOB CHANGES

The consequences of job changes are not inherently positive or negative. Worker flows between jobs are an important mechanism by which labor markets adjust as some occupations, industries, and regions experience faster job growth than others. For employers the ability to change the size of the workforce by hiring or laying off workers provides an important source of flexibility. Changing jobs offers workers the possibility of finding more desirable work. Indeed, for young workers in

particular, studies by Robert Topel and Michael Ward (1992) reported a substantial share of wage growth occurs via job mobility.

At the same time, job changing can have a darker side. Whereas voluntary job changes and those whereby a worker moves directly from one job to another typically raise wages; layoffs, discharges, family-related job changes, and changes that involve an intervening period of unemployment or labor force withdrawal usually result in wage losses. Moreover, even the threat of job loss is stressful. Perceptions of job insecurity can negatively affect physical and mental health according to Magnus Sverke, Johnny Hellgren, and Katharina Näswall (2002).

Work by Audrey Light (2005) showed that the outcomes of mobility are also worse for workers who change jobs more frequently. In part this is because workers who experience frequent mobility tend to spend more time not employed (Light, 2005). There is also some evidence for a high-mobility penalty, suggesting that workers who change jobs frequently are stigmatized by employers (Fuller, 2008). High-mobility workers may also experience less social protection because regulatory and welfare systems have been built on a normative model of employment that presumes a relatively stable career. In the United States, for example, job changes commonly result in a loss of employer provided health insurance (Ryscavage, 1997).

### FUTURE DIRECTIONS FOR RESEARCH

Contemporary research on job changing largely focuses on isolated or one-time events. More research that investigates patterns and consequences of different types of job changes over the course of workers' careers is needed. Closely attending to how institutional contexts shape job changes is also needed to clarify reasons for cross-national differences in job mobility patterns and trends. Further research is necessary to understand how variation in job mobility norms across occupational and industrial sectors shapes the consequences of job changes.

Job change patterns and their consequences reflect institutionalized opportunity structures arising from the organization of labor markets and households, as well as normative expectations about how careers should unfold for men and women over the life course. For individuals, they are often turning points in career trajectories, shifting the pace or direction of economic mobility.

# JOB CHARACTERISTICS AND JOB STRESS

For most individuals, working for pay is an important social role during adult life. However, the experiences people have on the job and over the working career vary considerably, due in part to differences in the characteristics of their jobs. Particular job characteristics can contribute to job stress and in turn affect individual well-being and family functioning. Differences in job characteristics and job stress thus help to explain differential life trajectories between socially advantaged and disadvantaged groups.

### DEFINING AND MEASURING JOB CHARACTERISTICS AND JOB STRESS

Jobs have been characterized on a variety of dimensions. A key conceptual distinction is between what could be

labeled *objective* or *structural* job characteristics—those easily visible to an outside observer and similar for all incumbents in a particular occupation—versus more *subjective* or *psychosocial* job characteristics—those that depend on a worker's interpretation of working conditions. Objective job characteristics that have been linked to job stress include physical and environmental exposures (i.e., heavy labor, hazardous conditions, exposure to loud noise, heat, or fumes), scheduling of work hours (i.e., night hours and shift work), number of hours worked (i.e., part time, full time, or overtime hours), and the type of employment contract held—standard (full time, with expectation of continued employment) versus nonstandard (part-time, temporary, independent contracting, etc.). Robert Karasek's (1979) model of job strain, which posits that jobs that combine low control over tasks with high demands are more hazardous to health than jobs that have one or neither of these conditions, is central to analyses of the psychosocial characteristics of jobs. A related model is Johannes Siegrist's (1996) conceptualization of effort-reward imbalance, which characterizes jobs for which workers expend high effort but receive low rewards. Another important subjective stressor is perceived job insecurity.

Most of these job characteristics can be classified as chronic, or ongoing, stressors. When an individual faces a threatening stressor, the brain and body respond by releasing both adrenaline and adrenocortical hormones in the so-called fight-or-flight response. In the short run, this response can help a person to respond to a stressful situation. However, if a person is persistently exposed to a stressor and does not have the means to cope with it, dysregulation of the body's response system can occur, leading to health problems (McEwen & Seeman, 1999). While the physiological stress response is the same for everyone, it is clear that people exposed to the same job characteristic are not necessarily affected in the same way. Workers appraise conditions differently, and have differential access to coping resources, social support, and mastery (a global sense of control), all of which could protect against negative consequences of job stress (Pearlin & Skaff, 1996). In addition, whereas some negative job characteristics are relatively normative for certain phases of the life course, such as greater job insecurity early in the career, these work-related stressors may be more harmful to well-being if they occur at nonnormative points in the life course, such as among older workers.

Two main approaches have been used to study job characteristics and job stress. Some studies have relied on more objective observational data about the job characteristics of specific occupations, collected by employers reporting on the characteristics of their workers' jobs (i.e., how many are temporary employees); by governments recording occupational exposures, accidents, or fatalities; or by expert raters who observe a job and report on its characteristics (i.e., the degree to which a worker must work under pressure of time). Other studies have used survey self-reports by workers themselves about their working conditions, such as their perceived job strain, job insecurity, or work-life conflict.

A debate remains about whether objective observational data, collected by an outsider, or more subjective self-reports, collected from surveys of workers, are a better source of information for understanding the consequences of job stress. Workers' self-reports are the most sensitive measures of an individuals' actual experience on the job because conditions vary considerably even within the same occupation, and because workers also have different levels of coping resources, social support, and mastery. However, self-reports are also vulnerable to a worker's reporting style. Some individuals may report negatively about both their job characteristics and their well-being for other reasons, creating an artificial association between the two. For example, people with high levels of neuroticism may evaluate both their job characteristics and their well-being negatively. Using information about job characteristics obtained from someone other than the worker avoids this problem of spurious association, but provides only a rough estimate of conditions experienced by the many different workers in a given occupation. Furthermore, measures based on outsider observation are costly to collect and the information can become out-of-dateif it is collected infrequently because working conditions in a given occupation often change over time.

## TRENDS AND PATTERNS IN JOB CHARACTERISTICS

Job characteristics change as economies transition from agricultural, to industrial, to postindustrial forms of production. The relative importance of physical and environmental hazards at work declines as fewer individuals hold agricultural and manufacturing jobs, whereas the importance of psychosocial stressors rises as the dominance of the service sector grows. When wealthier countries transition toward service-based economies, they often export physically and environmentally hazardous jobs to nations with fewer regulations and more workers willing to perform these jobs for low pay. For example, maquiladoras on the Mexico side of the U.S.-Mexico border employ manufacturing workers who earn ten times less than their counterparts in the United States (Frey, 2003). However, increasing globalization also means that psychosocial stressors, notably perceived job insecurity, may rise for workers in wealthier countries. This is true even for higher-status workers, whose job security falls as technological innovation and the push for enhanced flexibility and competitiveness lead to organizational restructuring and layoffs.

The United States labor market at the turn of the 21st century has seen the creation of new jobs that can be divided roughly into a smaller group of *good* jobs with favorable characteristics and a larger group of *bad* jobs with less favorable characteristics and a higher risk of generating job stress. Many so-called bad jobs in the growing service sector are in customer service occupations (i.e., fast-food restaurant worker), and can be characterized by high strain and low pay, job insecurity, nonstandard employment contracts, and few traditional employment benefits. Ethnic minorities, immigrants, and less-educated people are overrepresented among those in bad jobs, perpetuating inequalities over the life course that these groups face. The gap between advantaged and disadvantaged workers in terms of job characteristics appears to be widening in the United States, though risks such as job insecurity are increasing even for many better educated and higher status workers (Sweet & Meiksins, 2008).

## CONSEQUENCES OF JOB CHARACTERISTICS AND JOB STRESS

Considerable research has assessed the consequences of job characteristics and job stress for health outcomes or impaired family functioning among workers across the globe. For example, hard physical work and environmental stressors such as noisy surroundings and dangerous conditions are associated with a variety of outcomes, including increased risk of retiring due to disability among Norwegian employees (Blekesaune & Solem, 2005) and greater risk for work-related injuries among Canadian workers (Karmakar & Breslin, 2008). Jobs involving physical labor and noxious environmental stressors often are held by less-educated workers who have fewer options on the labor market, and these experiences contribute to the poorer health profiles overall for people with low education.

Work schedules, hours, and types of contracts are also linked to worker health. For example, shift work is associated with depressive symptoms among Swedish workers (Bildt & Michelsen, 2002), and overtime hours have been associated with poorer perceived health, more work-related injuries and illnesses, and even increased mortality for U.S. workers (Caruso, Hitchcock, Dick, Russo, & Schmit, 2004). Nonstandard contracts have been linked to a higher risk of traumatic and fatal occupational injuries among temporary workers in Spain when compared to their counterparts with standard contracts (Benavides, Benach, Muntaner, Delclos, Catot, & Amable, 2006). However, the consequences of work scheduling, hours, and nonstandard employment contracts may vary depending on the resources and preferences of the job incumbent. In postindustrial economies, for example, overtime work is increasingly performed by highly-educated professionals, so future research is needed to understand how socially advantaged workers manage these conditions.

Turning to the psychosocial stressors, job strain has been linked to higher risk for cardiovascular disease in an array of studies (Belkic, Landsbergis, Schnall, & Baker, 2004), to musculoskeletal symptoms (Smith & Carayon, 1996), and to poorer mental health (Van der Doef & Maes, 1999). Effort-reward imbalance is associated with a similar array of negative outcomes, including increased risk of cardiovascular disease, depression, alcohol dependence, and poor self-rated health (Siegrist & Marmot, 2004). Finally, perceived job insecurity has been linked with self-rated health and psychiatric morbidity in a variety of contexts (Ferrie, Shipley, Stansfeld, & Marmot, 2002). While job strain appears to be more common for less skilled workers, this and other psychosocial stressors are reported by socially disadvantaged and advantaged workers alike.

Work-family conflict is associated with a variety of clinically significant mental health consequences among U.S. workers, but more attention has been directed at the consequences for family functioning. Either mental distress arising from negative job characteristics or a sense of conflict between work and home roles—work and family strains are mutually influential—can lead to poorer family relations and functioning. In particular, work-family conflict has been linked to lower marital dissatisfaction and various measures of family strain (Allen, Herst, Bruck, & Sutton, 2000). Specific job characteristics are also associated with poorer family functioning. Job strain, for example, is associated with more frequent marital disagreements among U.S. workers (Hughes & Galinsky, 1994), and nonstandard schedules are associated with depressive symptoms in parents, hostile and ineffective parenting, and children's emotional and behavioral difficulties in Canadian dual earner families (Strazdins, Clements, Korda, Broom, & D'Souza, 2006). Finally, some studies suggest that families headed by military personnel may be particularly affected by extreme and unusual job stress, such as that arising from exposure to war (Malia, 2007).

Ample evidence reveals that job characteristics and job stress have meaningful consequences for the well-being of workers and their families, yet gaps in understanding persist. First, many studies have relied on data collected at a single point in time. Life course experiences are dynamic, and point-in-time estimates cannot capture the accumulation of exposure to job characteristics that differentiate careers. For example, some individuals stay employed consistently and proceed on a trajectory of improving job characteristics and rewards, whereas

others are unable to escape conditions of high job stress. Some studies have showed that stressors such as job strain have a stronger effect when experienced persistently (Chandola et al., 2008), but more longitudinal data collection on a variety of job characteristics is needed to understand how they accumulate and change over the life course. Longitudinal data with repeated measurements of a variety of negative and positive job characteristics would also be useful for understanding whether and how individuals act to change jobs or adjust their careers in response to these stressors, what kinds of workers are able to do so, and how this might affect health and family functioning.

## SOCIAL AND POLICY ISSUES

The workplace and the labor force are continuously evolving, and important issues of social inequality and public policy remain. First, social inequality in the distribution of negative job characteristics and job stress has persisted even though labor force composition and workplace organization are changing. Men with high levels of education and skills are generally exposed to fewer onerous job characteristics, whereas many women, ethnic minorities, and people with less education are exposed to more objective or psychosocial stressors on the job. Moreover, people with more education and financial resources may have more stable levels of mastery or other social supports under stressful conditions than people with lower levels of these socioeconomic resources, helping them to manage the stressors they do face. The consequences of these social inequalities in the distribution of desirable jobs are heavily influenced by social contexts. For example, many western European nations provide relatively generous social safety nets and have higher levels of unionization, providing some level of protection for workers from across the social spectrum. By contrast, the United States provides few institutionalized supports for workers, even those in undesirable jobs.

Second, as populations age and life expectancies rise, some older workers are remaining in the workforce longer, whether because they choose to, or because they cannot afford to retire. This will increase their life course exposure to job stress as they reach ages at which health typically begins to decline. Individuals with heavy caregiving responsibilities for children or aging parents are also increasingly working for pay, leading to heightened work-family conflict for many dual earner families and single parents, and perhaps especially for women. These and other contemporary labor force conditions are a poor fit with work policy and social practices developed in the post–World War II (1939–1945) U.S. context of the male breadwinner, manufacturing-centered economy, with a standard retirement age. For example, access to unemployment insurance and health insurance coverage, on-the-job training, retirement benefits, and other benefits is often limited or absent for the growing number of workers with nonstandard employment contracts. Policies such as the Family and Medical Leave Act (FMLA) of 1993 were enacted to meet the challenges faced by working families in the United States, but many workers are not eligible because of the size or characteristics of their employer, or cannot afford to take advantage of unpaid leave even if they are eligible.

Finally, research must continue to address the issues of intervention and regulation. While the Occupational Safety and Health Administration (OSHA) and similar governmental bodies regulate some of the gross physical and environmental hazards that characterize some jobs, regulatory capacity has weakened in the United States. Moreover, there are few, if any, regulations on psychosocial stressors in the workplace. The appropriate interventions for stressors such as job strain are not entirely clear. Some have argued that it can be difficult to show that psychosocial stressors have a causal effect on well-being, whereas material resource deficits, such as low education or poverty, are more strongly linked to health and well-being. Because in most cases high levels of psychosocial stressors are the burden of people who also have relatively low material resources, this argument suggests that intervention may best be directed at improving the material resources of disadvantaged workers. Such policies would likely include wealth redistribution through progressive taxation. Others argue that restructuring and reorganizing work to reduce job stress could be a useful public health intervention, even apart from supports to improve material conditions for workers (Singh-Manoux, Macleod, & Smith, 2003). Issues of social inequality and questions about appropriate public policy will continue to be central to an understanding of the importance of job characteristics and job stress across the life course.

## LEISURE AND TRAVEL, ADULTHOOD

The theme of consistency and change underlies the study of leisure over the life course. Individuals start building their leisure repertoires in childhood, and many of these activities remain consistent as people encounter different life stages, even as new ones are added (Kelly, 1982). The everyday definition of leisure is either free time (i.e., time that is not spent at work) or participation in enjoyable activities such as sports, hobbies, or watching television. However, the concept is actually remarkably slippery and complex. As a result, scholars have been debating the definition of leisure for more than 30 years. Leisure, along with work and family roles, is an important aspect of successful adult development and has implications for well-being over the life course.

### WHAT IS LEISURE?

Leisure has been defined as free time or, more specifically, residual time, the time left over after all of an individual's daily obligations are met (Neumeyer & Neumeyer, 1958). Some argue that the concept of residual time does not allow for freedom of choice, a central component of leisure, and question whether time is ever completely free from obligations. Thus, the term *discretionary time* was adopted (Murphy, 1974). Over the years, defining leisure in terms of time use worked, because measures of time use are easily quantified. Using time-budget studies, researchers documented differences in time use between men and women (Shaw, 1985), across occupational categories (Burdge, 1969), across countries (Zuzanek, Beckers, & Peters, 1998), and across historical periods (Schor, 1991). However, in the 1980s scholars increasingly recognized that the concept of leisure as the opposite of work might not be relevant for everyone, particularly the unemployed, stay at home mothers (or fathers), and retired persons. Researchers initially assumed that those not engaged in paid work did not have time off from work and, therefore, could not experience leisure. Thus, scholars moved away from defining leisure as free time.

The definition of leisure as activity, particularly pleasurable activity, developed in parallel with definitions that emphasized time use. This meant that leisure activities were non-work and encompassed such pursuits as hobbies, sports, travel, and outdoor recreation. Defining leisure as activity makes it easy to quantify, so researchers could develop activity inventories to document the most popular activities (Havighurst, 1957) and study participation by gender (Shaw, 1985), race (Floyd, et al., 1994), and age (Witt, 1971). However, if the freedom to choose is a central dimension of leisure, then defining leisure solely in terms of activity obscures the meaning behind the pursuit. This meaning may vary over time and situation. John R. Kelly (1982) points to the differences between playing basketball in a physical education (PE) class as opposed to playing pick-up basketball after school with friends. For some, basketball in a PE class is not leisure because of the obligation associated with it. Feminist scholars also questioned defining leisure in terms of activity, particularly for mothers who are responsible for organizing family activities. Are these family "leisure" activities perceived as leisure by women who organize them, or are they underpinned by a strong sense of obligation? (Shaw, 1992).

***Pleasure Cruise.*** *Ann Duprey feeds squid to sting rays during a shore excursion to Sting Ray City from the cruise ship Norwegian Pearl in the Atlantic ocean during a western Caribbean cruise.* AP IMAGES.

Taking the lead from several classic books in the 1960s in which leisure was described as "a state of being" (de Grazia, 1964, p. 5) or "a mental and spiritual attitude" (Pieper, 1963, p. 40), Neulinger (1974) suggested that the central elements of leisure were the *perceived* freedom to choose an intrinsically motivated experience. He proposed that this perception of freedom and motivation could be measured by assessing one's attitudes. In contrast, Kelly (1982) argued that the full array of meanings associated with leisure could not be captured by perceptions and attitudes alone. Rather, he suggested that leisure reflects the quality or meaning of the activity, intrinsic motivation, and *relative* freedom. This latter criterion reflects the recognition that no choice is ever truly free from influence of social constraints or contexts. The concept *relative freedom* was adopted by feminist scholars, such as Erica Wimbush and Margaret Talbot (1988), who felt that it described women's experiences of leisure in relation to the social forces shaping and constraining their lives.

With the advent of the 24-hour, global, technologically-driven society of the 21st century, Kelly (1999) continued to refine his definition of leisure. In postindustrial society, he reasoned, the boundaries between work, family, and leisure were often hard to distinguish. Moreover, psychologists such as Mihály Csikszentmihalyi (1990/1991) found that people often experience "flow" (i.e., a state of feeling fully immersed in and energized by what they are doing) in the work place. To reconcile these psychological and social perspectives, Kelly suggested that leisure as action is existential (in that it is meaningful and produces meaning) and social (in that it is influenced by society as well as frequently experienced with others).

Thus, the dominant definition of *leisure* used by scholars in the early 21st century encompasses more than activity or free time. It is an experience characterized by

freedom and meaning that also has social aspects. British scholars of leisure tend to critique this definition as being too individual and psychological. Many U.K. scholars are sociologists, whereas in the United States, social psychology has been the dominant paradigm guiding leisure scholarship (Coalter, 1999). However, a framework that includes both the existential and social qualities captures the essence of leisure and provides a foundation for understanding the role and place of leisure in societies where traditional assumptions about time, space, social structure, and social roles are increasingly blurred.

## RESEARCH ABOUT LEISURE

Leisure scholars around the world have amassed a large body of knowledge about leisure as a central life domain as well as its interactions with other life domains such as work or family (Kelly & Freysinger, 2000). In the 1970s and 1980s, researchers examined leisure over the life cycle (Kleiber & Kelly, 1980; Osgood & Howe, 1984), life course (Parker, 1976), or family life cycle (Kelly, 1982; Rapoport & Rapoport, 1975; Witt & Goodale, 1981). A consistent theme in this work is that leisure is characterized by stability and change. Leisure facilitates the completion of specific socio-psychological life tasks, such as finding a partner or maintaining connections with one's community during retirement. At the same time, leisure is shaped by the responsibilities and demands of life stages, events, and transitions. For example, after the birth of children, leisure tends to become more home-centered, and participation in risky activities, particularly adventure sports, is often curtailed.

Some scholars have adopted specific models from life span developmental psychology to examine stability and change in both leisure (Carpenter, 1992; Iso-Ahola, Jackson & Dunn, 1994) and travel choice (Gibson & Yiannakis, 2002). However, whereas some scholars are still proponents of using a life span or life course perspective, most scholars have moved away from this focus and now examine specific life stages such as adolescence (Shaw, Kleiber, & Caldwell, 1995), where leisure provides a context for individuation, identity formation, and experimentation and midlife, where leisure is a context for family bonding and stress relief (Freysinger, 1995).

In addition to investigating leisure in reference to age or life stage, a number of other research foci are evident. In the 1970s and 1980s motivation was a dominant theme. A number of scales were developed, such as Jacob G. Beard and Mounir G. Ragheb's (1983) Leisure Motivation Scale, which identified four sub-dimensions of leisure motivation: competence/mastery, social, stimulus avoidance, and intellectual. The motivations that guide leisure choices are believed to depend on the individual's socio-psychological needs. Conversely, Seppo E. Iso-Ahola (1980) viewed leisure motivation in terms of optimal level of stimulation (OLS); thus, individuals who are stressed and operating above their preferred OLS seek experiences for escape. By contrast, individuals who feel understimulated may seek out activities that provide challenge, novelty, and social interaction.

Around the world, the study of leisure has been integrally tied to recreation and parks provision and management. In North America much of this research uses a benefits framework. Rather than focusing on motivation, the benefits approach looks at outcomes as a philosophy (i.e. the belief that leisure is positive), a framework for empirically demonstrating these outcomes, and a management strategy (Driver & Bruns, 1999). Four types of benefits have been identified:

1. Personal Benefits are both psychological (e.g., identify affirmation) (Haggard & Williams, 1991) and psycho-physiological (e.g., physical fitness). For example, James F. Sallis and Neville G. Owen (1999) found that people who live in communities with a larger number of recreation facilities are more likely to be physically active.
2. Social and Cultural Benefits are linked to social bonding in families (Orthner & Mancini, 1991) and community satisfaction (Allen, 1990).
3. Economic Benefits, which include monetary gain or value, have been documented by a myriad of economic impact studies. For example, John L. Crompton (2001) found that people who live near parks and trails profit in the form of added value to price of their home.
4. Environmental Benefits take the form of additional green spaces in communities, a justification for conservation, particularly if economic benefits accrue from a park in the form of tourism (Sellars, 1997).

Another issue driven by both academic and practical concerns is access to leisure via public parks, both at the local municipal level as well as at state and national parks and other federal lands. This issue has received attention on both sides of the Atlantic, but from different perspectives. In the United Kingdom research focused on social class differentials in access (Coalter, 1998), whereas in North America, research focused on barriers or constraints to leisure participation. Duane W. Crawford and Geoffrey Godbey (1987) in a seminal paper identified three types of constraints that affect leisure participation: intrapersonal (e.g., attitudes, motives, values), interpersonal (e.g., preferences shaped by family, friends), and structural (e.g., time, money). Prior to this the focus had been largely on structural constraints such as time and money, when in fact researchers found intrapersonal

and interpersonal constraints more powerful in shaping leisure participation patterns for both participation or non-participation. This thinking was formalized in the hierarchical model of constraints whereby the three sets of constraints were assumed to be encountered sequentially (Crawford, Jackson, & Godbey, 1991).

However, the hierarchical nature of constraints received little empirical support, particularly as researchers such as Susan M. Shaw, Bonnen, and McCabe (1991) found that the persons with the most constraints participated in leisure activities more frequently and that socio-structural variables were more powerful than previously thought in shaping choices. These findings were supported by others; for example, Tess A. Kay and Guy A. Jackson (1991) found that individuals participate in leisure activities despite constraints, so the idea of constraint negotiation emerged, meaning that "where there is desire an individual will find the way" to take part in preferred leisure activities (Jackson, Crawford & Godbey, 1993). Hubbard and Mannell (2001) established empirically that constraint negotiation has a positive relationship with motivation to participate. This idea receives support from Diane Samdahl and Nancy Jekubovich's (1997) work that indicated people change their routines, such as work schedules, to take part in their favorite activities. In the early 2000s researchers generally believe that constraints are not experienced equally by everybody. While time and money constraints are consistently cited over the life span, this relationship is U-shaped, with people aged 30 to 50 being particularly constrained, whereas cost of participation shows a negative relationship with age, cost being the most important constraint for the younger age groups (Hinch et al., 2006).

Constraints in the form of gender-based inequalities have been the focus of feminist leisure scholars. From the 1980s on, in response to the invisibility of women in previous leisure research (Henderson, 1994), scholars began to identify gender differences in access to leisure, primarily within the context of the family. In North America, working primarily from a symbolic interactionist perspective, researchers suggested that women's leisure was determined by socialization practices, which shaped their activity choices and tended to perpetuate traditional gender roles (Henderson & Bialeschki, 1991). The reinforcement of traditional gender roles was also used to explain why women who are mothers did not enjoy the same assess to leisure as men in terms of time. Shaw (1992) found that women in dual income families spent more time on domestic tasks than their partners, their leisure tended to be family centered, and family leisure was more often work-like than leisure-like. Bella (1992) in a study of family Christmas celebrations found that women often felt obligated to ensure that all of the Christmas rituals were performed, while simultaneously caring for family and children. The ethic of care has been frequently used to explain women's attitudes towards leisure. Learned through socialization, the ethic of care, which emphasizes care of others before self care (Gilligan, 1982), explains why many women do not feel entitled to their own leisure and feel guilty when they take time for themselves (Henderson & Bialeschki, 1991). As feminist research progressed through the 1990s, a shift in thinking focused on leisure as a space where women can resist structural forces and can exercise more control over their lives (Shaw 1994; Wearing, 1998).

Current threads in leisure research reflect recent concerns among both scholars and the public. As immigration becomes a global challenge, the role of leisure in adjustment to life in a new country has received more attention (Stoldolska, 2000). Likewise as different racial and ethnic groups become more prominent in the United States, researchers have begun to examine them. For example, studies have focused on Hispanic leisure (Allison, 2000), whereas in the past most work examined the leisure and recreational experiences of African Americans and whites (Floyd et al., 1994). Another debate centered on the loss of social capital (Putnam, 2001) and stimulated research on the role of leisure and recreation in building social capital (Glover & Hemingway, 2005). A related issue is whether people lack time for leisure and civic engagement (Robinson & Godbey, 1997; Schor, 1991).

This line of research returns to definitions of leisure as free time with all of its disadvantages. However, by providing information that can be compared across different countries and socio-historical periods, time budget data is a good starting point for understanding time pressures and how people deal with them. A portion of this research examines vacation patterns and attitudes to work (de Graaf, 2003). Leisure philosophers studying attitudes towards leisure in different countries and historical periods note that the pervasiveness of the Protestant work ethic explains U.S. attitudes towards leisure and vacation time (Sylvester, 1999); the United States is often cited as one of the most "vacation starved" countries. Taken together, leisure research shows how personal pursuits are molded by larger social, cultural, and economic contexts. Understanding the ways that macrosocial influences and individual preferences shape leisure over the life course is a critically important question that will occupy leisure scholars for decades to come.

## LIFE EVENTS

Life events are objective experiences that have definable starting and ending points. Formal changes in social roles—for example, getting married, becoming a parent, or retiring from work—represent one type of life event. These are often referred to as *life transitions* because they signal passage from one recognizable social status to another (Moen and Wethington, 1999). Changes in social roles act as markers or placeholders in the life course, positioning individuals at different stages of life (Chiriboga, 1997). Another type of life event is a commonly experienced social milestone, for example, obtaining a driver's license or getting a first job.

Life events may require changes in daily routines and behaviors to accommodate new roles and responsibilities, even those that are an anticipated part of normal daily life. These adjustments may increase the risk of mental or physical illness (Holmes and Rahe, 1967). In addition to physical or behavioral adjustments, life events may initiate psychological adjustments, particularly those that are unexpected; for example, divorce or death of a loved one may initiate changes in the way people see themselves or the world around them. Life experiences that initiate a reevaluation of one's current circumstances or purpose in life are referred to as *turning points.* A turning point alters the way people perceive themselves, their social roles, and their relationships (Wethington, Brown, & Kessler, 1997). The impact of life events on well-being is often greater when events are perceived as undesirable. *Traumas* are an extreme example of undesirable life events. Traumas are particularly disruptive and shocking life events, for example, experiencing a violent crime, combat duty, or a life-threatening illness. The magnitude and suddenness of these events may disrupt a person's mental and physical well-being long after the occurrence of the event (Pearlin, 1999).

### ASSESSING EXPOSURE TO LIFE EVENTS

Checklists are the predominant method for measuring exposure to life events. One of the earliest checklists, the Social Readjustment Rating Scale (SRRS), was developed by stress researchers Thomas Holmes and Richard Rahe (Holmes and Rahe, 1967). Life event checklists consist of an inventory of potentially life-changing situations that may have occurred over a specified period of time, typically over the past 6 months or past year.

Respondents indicate which of the events they have experienced. Some checklist measures tally the responses to estimate total exposure to potentially life-changing events and thus total impact on a person's life. Other checklists weight life events by their normative severity (the degree of disruption for an average person), for example, weighting death of a loved one as more severe than changing employment. This approach, however, does not account for individual circumstances that may alter the impact of the event: For example, death of a loved after a long illness may be experienced as less severe than an unexpected job loss. To account for individual circumstances, some checklists ask the respondent to rate the severity of the event. In this approach, however, respondents may be rating the severity of *consequences* of the event in addition to or instead of the event, for example, financial or relationship difficulties following a job loss. This approach makes it difficult to separate the effects of an event and the response to it.

A limitation of the checklist approach is the need to restrict the number of possible life events that respondents could have experienced. The original SRRS scale, for example, consisted of 43 events. Using the SRRS as a model, life event checklists have been refined to include events relevant to particular life stages, such as adulthood (Paykel, Pursoff, & Uhlenhuth, 1971), or to a common health condition, such as pregnancy (Barnett, Hanna, and Parker, 1983). Another limitation is the inability to distinguish between events and ongoing difficulties that precipitate an event, for example marital strain preceeding a divorce or leading to a job change. Despite these limitations, checklists are a

popular and inexpensive way to examine exposure to life events in large and diverse populations.

Investigator-led interviews are an alternative approach to assessing exposure to life events. A personal interview approach involves one-on-one discussions between an investigator (interviewer) and the respondent (the study subject). The interviewer typically begins by asking questions about the respondent's recent experiences in varying domains of life (e.g., births, deaths, employment, health). The investigator probes the respondent for additional information about the circumstances surrounding each event experienced using open-ended questions to obtain in-depth narrative information. The investigator then uses the information to classify experiences into appropriate categories (e.g., life event, health issue, ongoing difficulty), to pinpoint the timing of the event (e.g., June of last year vs. within the past 12 months), and to assess the perceived severity or impact of the event within the context of the respondent's life. The interview approach offers a way to obtain information on a broader range of life events respondents may encounter over the life course. With this approach, the investigator assesses the occurrence of an event and the perceived severity of its impact. Because the interview approach is both expensive and time-consuming, it is most often used in smaller studies, studies that require more accurate timing of events (e.g., for predicting onsets of serious illness), and studies focusing on variations in response to exposure to a specific life event (e.g., death of spouse, retirement) (see Wethington et al., 1997 for a more complete discussion).

## THE IMPACT OF LIFE EVENTS ON HEALTH AND WELL-BEING

The foundation for life events research began more than 50 years ago. Early animal laboratory experiments established a biological pathway through which external stimuli initiated a physiological response, commonly referred to as the *fight or flight response* (Cannon, 1939). Subsequent laboratory experiments with human subjects demonstrated that in addition to physical stimuli (e.g., hot, cold, shock), exposure to psychological stimuli (e.g., anticipation of shock) could also initiate physiological changes (Selye, 1956). Life events research emerged from an interest in studying people's responses to the situations of everyday lives (Sapolsky, 1999).

Studies examining the impact of life events on health and well-being may be separated into three types of outcomes: psychological disturbances, physical disorder and disease, and maladaptive behaviors.

*Psychological disturbances* include a range of effects from minor psychological distress or negative affect, to acute affective disorders, for example, major depression or anxiety disorder. Studies based on both general and clinical populations reveal a strong link between life events, particularly undesirable and uncontrollable events, and increases in psychological disturbances, including distress (Paykel, 1979) depression (Brown & Harris, 1978) (see Tennant, 2006 for a more complete review). The majority of these studies find that it is the perceived severity or significance of an event, rather than the objective occurrence of a particular type of event, that accounts for the impact. Thus, undesirable events impact psychological well-being by threatening individuals' self-image, or sense of control such as unanticipated medical expenses or physical discomfort after a car accident (Thoits, 1983). Consistent findings can be found in studies of older adults (Clémence, Karmaniola, & Green, 2007) and children (Bouma, Ormel, Verhulst, & Oldehinkel, 2008), as well as in international epidemiological (Marmot, Davey Smith, Stansfeld, Patel et al., 1991) and clinical samples (Rojo-Moreno, Livianos-Aldana, Cervera-Martinez, Dominguez-Carabantes et al., 2002).

Studies on the relationship between adverse life events and onset of depression provide the most compelling evidence that exposure to life events directly provokes psychological disturbances (Brown, Harris, & Hepworth, 1994). However, not everyone exposed to a life event, even a very serious event or trauma, responds in the same way. Previous exposure to life events, ongoing life difficulties, and available resources, lifestyle, and genetic factors all contribute to both the risk of experiencing a life event and individual variability in responses to life events as well as to overall vulnerability to subsequent life experiences. Experiencing a major depressive episode, for example, appears to predispose individuals to subsequent depressive episodes, without the occurrence of a subsequent life event (Kendler, Thornton, & Gardner, 2001).

The pathway between exposure to life events and *physical disorder and disease* is more indirect, as changes in physical health occur over long time intervals. Whereas severity of unexpected and undesirable life events most often precede psychological disturbances, total amount of change or cumulative change are more important determinants of disease and physical disorders (McEwen & Seeman, 1999). Recent exposure to life events has been shown to trigger physical disturbances, such as heart attack (Tennant, 1987). Exposure to life events is also associated with increased symptoms of existing physical disorders such as coronary heart disease (see Tennant, 1999 for a review). Exposure to more negative life events is associated with diminished physical functioning and health (Surtees & Wainwright, 2007). Because it takes time for diseases and disorder to develop, life events are not typically the immediate cause of physical disease or disorder but may precipitate acute physical (e.g., heart attack) or mental (e.g. depression) reactions in vulnerable populations.

Exposure to life events may initiate *changes in behavior* to response to changing life circumstances (Cohen & Herbert, 1996). Studies have demonstrated associations between exposure to life events and alcohol addictions (Lloyd & Turner, 2008), eating disorders (Steinhausen, Gavez, & Metzke, 2005) and sleep disturbances (Vahtera, Kivimäki, Hublin et al., 2007). While life events may precipitate behavioral changes, behavioral and life choices may also increase the likelihood of experiencing life events, for example, drinking and driving.

## POLICY IMPLICATIONS AND FUTURE DIRECTIONS

Exposure to life events, particularly adverse life events, is not random. Age, gender, and social status influence the type, the frequency, and the impact of life events (Pearlin, 1982), with individuals of lower socioeconomic status at-risk for increased exposure to adverse life events. Without adequate resources to address life's adversities, these individuals are also at increased risk for exposure to subsequent adverse events. This erosion in daily life experiences contributes to the disparity in physical health status and mortality rates by socioeconomic status (Marmot et al., 1991).

The impact of adverse life events on health and well-being is well established, ushering in a new phase in the study of the relationship between exposure to life events and physical and mental health. Health and well-being in adulthood does not result from a single adverse life event; each stage of life is both the consequence of prior experiences as well as the antecedent for subsequent life experiences (Spiro, 2001). A single event may also trigger related stresses that carry additional emotional/physical costs, such as financial difficulties or marital strain following a job loss. The impact of early exposure to adverse life events, such as abuse or parental divorce, may persist well into adulthood.

In addition to the lingering effects of early life events, people's daily lives consist of balancing the demands of interrelated social roles, particularly in adulthood. Disruptions in spouse/partner relationships, parenting, and employment may lead to disruptions in another domain (Pearlin, Menaghan, Lieberman, & Mullan, 1981). The loss of a job, for example, may be followed by ongoing financial instability and subsequent loss of possessions (e.g., car, house) or relationship difficulties leading to an accumulation of difficulties as a consequence of the initial event (Pearlin, Aneshensel, & LeBlanc, 1997). Thus, there is increased need to consider the cumulative impact of life events and other life experiences across the life course (Elder, George, & Shanahan, 1996). Thus, physical and emotional well-being across the life course requires a more complete assessment of both episodic and recurring circumstances of social and environmental of life.

## MANNHEIM, KARL

***1893–1947***

Karl Mannheim, a European sociologist, developed the field of the sociology of knowledge. His theoretical work on how people's understanding, ideas, and knowledge of the world are influenced through their membership in generations (or birth cohorts) was an important contribution to the sociology of the life course.

Mannheim was born into a Jewish family in Hungary, where he studied and then taught at the University of Budapest. During his tenure there, Hungary experienced political turmoil from 1918 to 1920: A short-lived Communist government was followed by a military uprising, violence, and the restoration of the monarchy. Mannheim left Hungary, initially moving to Austria and then to Germany, where, in 1921, he married a Hungarian psychologist, Juliska Lang. Mannheim held academic posts in Germany at the universities of Heidelberg and Frankfurt. The rise of Nazism forced Mannheim to leave Germany in 1933. He spent the rest of his academic career in England, working as a lecturer in sociology at the London School of Economics and, later, as a professor of education at the University of London.

Mannheim's (1952) theoretical essay on generations is the most relevant publication for understanding his contribution to the sociology of the life course. For Mannheim, knowledge (defined by him as a style of thought or worldview) is socially conditioned by membership in a generation (or birth cohort). People of different generations therefore have distinct and "definite modes of behaviour, feeling, and thought" (p. 291).

For Mannheim (1952), a person's generational membership arises from the "biological rhythm in human existence—the factors of life and death, a limited span of life, and ageing" (p. 290). Mannheim emphasized, though, the overriding and ultimate influence of social factors, so that biological aging must be understood as embedded within social and historical processes. This view became a foundation of the life course perspective.

In Mannheim's (1952) analysis, it is during the life course stage of youth that experiences, ideas, and impressions gel together, stabilize, and form "a natural view of the world" (p. 298). Individuals then carry this with them throughout the remainder of their life course. People are therefore crucially influenced by the sociohistorical context that predominated during their youth. In this way, adult generations are formed, each with distinctive historically determined worldviews. Mannheim therefore suggests that, at a given point in time, adults in different life course stages will not share the same view of the world because of different formative experiences during their youth.

Mannheim proposed that in order to share generational location in a sociologically meaningful sense, individuals must be born within the same historical and cultural context and be exposed to particular experiences and events during their formative years. More specifically, Mannheim argued that not every member of a generation will be exposed to exactly the same experiences because of variations in geographical and cultural locations during youth. He also recognized that whereas some groups within generations will actively participate in the key social and cultural events of their time, other groups will not. Moreover, among actual (or active) generations, responses to

social and cultural events can differ in that they may be oppositional or supportive.

Mannheim's (1952) work on generations also illuminates links between the life course and social change. Mannheim proposed that the likelihood of a youthful cohort developing a distinctive worldview (i.e., of becoming a generation) is dependent on the pace of social change. In turn, generations are regarded by Mannheim as a key element in the production of social change. The "fresh contact" of new adult cohorts with the preestablished social and cultural heritage always means a "changed relationship of distance" and a "novel approach" to doing things (p. 293). The progression of social change is made smoother by the presence of intermediary generations, which act as a buffer between those generations with the greatest difference in worldviews or styles of thought. In times of accelerated social change, however, when the tempo of change quickens, the new generations have even greater opportunity than the natural, gradual changeover allowed by the aging and eventual death of all members of a birth cohort.

Beyond his contribution to life course studies via his work on generations, Mannheim writings engaged more broadly with the social conditioning of knowledge, including the structural positioning of intellectuals and their role in society. Linked to this, Mannheim's work increasingly became concerned with the planned social reconstruction of societies through the application of social policy (including education) to counter both totalitarianism and individualism and sustain democracy.

## MARRIAGE

Marriage is a legal contract or socially recognized agreement between two individuals and their families to form a sexual, productive, and reproductive union. Through marriage, a union is recognized by family members, other members of society, religious institutions, and the legal system. Marriage defines the relationship of the two individuals to each other, to any children they might have, to their extended families, to shared property and assets, and to society in general. It also defines the relationship of others, including social institutions, toward the married couple.

The key features of most marriages include a legally binding, long-term contract or socially recognized agreement; sexual exclusivity; coresidence; shared resources; and joint production. In polygamous societies, the circle of sexual exclusivity expands to include multiple spouses, who might have separate residences. Spouses acquire rights and responsibilities with marriage, enforceable through both the legal systems and through social expectations and social pressure. Marriage differs from other, less formal relationships primarily in its legal status and social recognition. Because marriage is a legally or socially recognized contract, the treatment of marriage in the law and custom shapes the institution, and recent changes in family law in some societies appear to have made marriage less stable.

Historically, in the United States and many other countries, both secular and religious law generally viewed marriage vows as binding and permanent. The marriage contract could only be broken if one spouse violated the most basic obligations to the other and could be judged at fault in the breakdown of the marriage (Regan, 1996). Beginning in the mid-1960s, however, states in the United States substantially liberalized and simplified their divorce laws. One of the key features of this change was a shift from divorce based on fault or mutual consent to unilateral divorce, which requires the willingness of only one spouse to end the marriage. Most states also adopted some form of no-fault divorce, which eliminates the need for one spouse to demonstrate a violation of the marriage contract by the other.

The shift to unilateral or no-fault divorce laws was accompanied by a surge in divorce rates in the United States. At least some of the increase in divorce rates appears to have resulted directly from the shift in the legal environment in which couples marry and decide whether to remain married (Friedberg, 1998). The link between divorce rates and laws that permit unilateral divorce has lead several states to develop alternative, more binding marriage contracts, such as covenant marriage, in which partners agree to seek help for marital problems and to a mandatory period of separation prior to the consideration of getting divorced.

Its status as a legal contract and the features of permanence, social recognition of a sexual and childrearing union, coresidence, shared resources, and joint production lead to some of the other defining characteristics of marriage. Because two adults make a legally binding and socially supported promise to live and work together for their joint well-being, and to do so, ideally, for the rest of their lives, they tend to *specialize*, dividing between them the labor required to maintain the family. One person may become an expert at cooking and the other at cleaning or money management. This specialization allows married men and women to produce more than they would if they did not specialize. Any division of

labor tends to increase productivity; couples do not need to divide family work along traditional gender lines to reap these benefits. The coresidence and resource sharing of married couples lead to substantial economies of scale; at any standard of living it costs much less for people to live together than it would if they lived separately. Both economies of scale and the specialization of spouses tend to increase the economic well-being of family members living together.

The institution of marriage assumes the sharing of economic and social resources and coinsurance. Spouses act as a small insurance pool against life's uncertainties, sharing responsibility if things go wrong and reducing their need to protect themselves by themselves against unexpected events. Marriage also connects spouses and family members to a larger network of help, support, and obligation through their extended family, friends, and the community. The insurance function of marriage also increases the economic well-being of family members, and the support function improves their economic and emotional well-being.

The institution of marriage builds on and fosters trust. Because spouses share social and economic resources, and expect to do so over the long term, both gain when the family unit gains. This reduces the need for family members to monitor the behavior of other members, increasing efficiency.

The vast majority of adults marry at some point in their lives, both in the United States and in other countries. Most young adults in the United States plan to marry and rank a happy marriage and family life as one of their most important goals (Thornton & Young-DeMarco, 2001). Thus, marriage is a key component of the life course, and one around which other important transitions, such as moving into the workforce and residential and financial independence, are positioned.

## TRENDS, PATTERNS, AND DIFFERENTIALS

**Age at Marriage** In the United States, age at marriage declined in the first half of the 20th century, but then rose dramatically. Entering the 21st century, men and women in the United States are marrying later than at any other time in past decades (Fitch & Ruggles, 2000). Between 1970 and 2000 the median age of first marriage for women increased by almost 5 years, from 20.8 to 25.1, and for men the median age increased by almost 4 years, from 23.2 to 26.8 (Fields & Casper, 2001). In this same time period, the proportion of women who had never been married increased from 36% to 73% among those 20 to 24 years old and from 6% to 22% among those 30 to 34 years old. Similar increases occurred for men (Fields & Casper, 2001).

For African Americans, the delay of first marriage has been especially striking. The median age at first marriage increased to 28.6 for African-American men, and 27.3 for African-American women (Fitch & Ruggles, 2000). This represents a 6-year increase from about 22 for African-American men and a 7-year increase from about 20 for African-American women since the 1960s. And, in 2000 among those 30 to 34 years old, 44% of African-American women and 46% of African-American men had never married (Fields & Casper, 2001).

Similar changes in marriage patterns have taken place in most European countries; cohorts reaching

adulthood recently are marrying at older ages and over a wider range of ages than in the past. However, European countries differ substantially in marriage ages. The Nordic countries of Sweden, Denmark, and Iceland show the highest average ages at marriage for women (around age 29), primarily because these countries have high rates of cohabitation, and the eastern European countries of Bulgaria, the Czech Republic, Hungary, and Poland show the lowest (around age 22). Because societies with a relatively high age at marriage also tend to be those in which many people never marry, this diversity suggests that marriage is a more salient component of the family in some European countries than others.

Marriage typically takes place at substantially younger ages in Africa, Asia, and Latin America than in North America and Europe. The average mean age at marriage among countries in the developed regions is almost 28 for men and 25 for women, compared to 25 for men and 21 for women in the less developed regions of the world. Young average ages at marriage are common in some parts of Africa (such as Uganda, Chad, and Burkina Faso), in some parts of Asia (such as India, Nepal, and Indonesia), in the Middle East, and in eastern Europe. Within regions of the world, women and men in developed countries tend to marry at older ages than those living in less developed countries. For example, in Southeast Asia women's age at first marriage is about 27 in Singapore and about 22 in Indonesia. Men tend to marry at older ages than women, but the gender gap in average age at marriage varies quite substantially both within and between regions. The gap tends to be the largest where women marry relatively early (United Nations, 2000), perhaps because in these countries women are less likely to work for pay and thus depend on their husbands for financial support.

**Proportion Married** In the United States, age at marriage has risen substantially, divorce rates are high and stable, and rates of remarriage have fallen, so that a larger proportion of adults are unmarried now than in the past. In the United States in 1970, unmarried people made up 28% of the adult population. In 2000, 46% of adults were unmarried. In fact, the shift away from marriage has been so dramatic for Blacks that only 39% of Black men and 31% of Black women were married in 2000, compared to 59% of White men and 56% of White women (Fields & Casper, 2001).

Countries in Europe show a great deal of variation in the proportion of women in marital unions. Marriage is most common in Greece and Portugal, where more than 60% of women ages 25 to 29 are married, and least common in the Nordic countries, Italy, and Spain, where one-third or less are married (Kiernan, 2000).

In spite of increases in the age at first marriage in some countries, the vast majority of adults marry at some time in their lives, with the proportion of those who were ever married by age 50 reaching more than 95% of both men and women. Relatively high proportions of men and women have not married by their late 40s in the Nordic countries, where cohabitation is common, and in Caribbean countries such as Jamaica and Barbados, countries characterized by a long history of informal unions or visiting relationships. In Sweden, for example, 76% of men and 84% of women in their late 40s had ever

married, and in Jamaica, 52% of men and 54% of women had ever married by these ages (United Nations, 2000).

Increasingly, couples form intimate unions by cohabiting, with marriage following at some later point unless the relationship dissolves. In the United States, only 7% of the women born in the late 1940s cohabited before age 25 compared to 55% among those born in the late 1960s (Raley, 2000). The percentage of marriages preceded by cohabitation increased from about 10% for those marrying between 1965 and 1974 to more than 50% of those marrying between 1990 and 1994 (Bumpass & Lu, 2000). Cohabitation is especially common among people whose first marriage dissolved (Brien, Lillard, & Waite, 1999).

Although a number of European countries have experienced similar increases in cohabitation, some have experienced much more and some much less. Cohabitation is strikingly common in the Nordic countries of Denmark, Sweden, and Finland, and France also shows fairly high levels, with about 30% of women ages 25 to 29 being in cohabiting unions. In these countries, cohabitation has many of the legal and social characteristics of marriage. A group of countries including the Netherlands, Belgium, Great Britain, West and East Germany, and Austria show moderate levels of cohabitation—between 8 and 16% of women ages 25 to 29 are in this type of union. And in the southern European countries, as well as in Ireland, cohabitation is rare with less than 3% cohabiting among women ages 25 to 29 (Kiernan, 2000). Societies in which cohabitation is rare also tend to have fairly low rates of unmarried childbearing and tend not to recognize cohabiting unions as alternatives to marriage.

Perhaps the most perplexing issue facing researchers studying marriage in the United States revolves around the rapid and dramatic divergence of family patterns and processes between Whites and Blacks. In about 1950, the proportions of Black and White adults who were married was quite similar. Black men and women show little evidence of the substantial decline in age at marriage that characterized the baby boom of the 1950s and early 1960s for Whites in the United States, and show a much more rapid rise in age at marriage since that time (Fitch & Ruggles, 2000). In the mid-1990s, almost twice as many Black men as White men were not married (Waite, 1995), with a similar differential for women. Joshua Goldstein and Catherine Kenney (2001) have found a dramatic decline in the proportion of Black women predicted to ever marry, especially among those who are not college graduates, whereas marriage remains virtually universal among Whites. The proportion of births to unmarried women is three times as high for Blacks as for Whites (Martin, Hamilton, Ventura, Menacker, & Park, 2002). Although numerous hypotheses for this divergence have been put forward, none explains more than a small portion of the racial gap in family patterns.

## CHANGES IN THE NATURE OF MARRIAGE

Under the family mode of social organization, which has at its core the married couple, kin groups tend to pool resources, including their labor, specialize in particular tasks, coordinate their activities, and connect to the larger community as a unit. In polygamous societies, the married couple may include a spouse with other wives, with pooling of labor among cowives, or other combinations. In patriarchal societies power often resides in the elders in the family, and in men. The family mode of social organization is often associated with agricultural production, but it appears in a wide range of economic environments (Thornton & Fricke, 1989).

The family mode of social organization has been altered as a result of other, far-reaching social changes, including the rise of the market economy, vast increases in productivity with concomitant increases in real income (Fogel, 2000), urbanization, changes in ideology toward greater individualization (Lesthaeghe, 1995), and changes in the structure of education. All of these changes have shifted decision-making and social control away from the family and toward the individual or other social institutions. As families have less control over the time and resources of children, they are less able to influence marriage choices—whether, when, and whom to wed. As more people support themselves through wage-based employment rather than through work on a family farm or small business, families have less stake in the property and family connections that a potential marriage partner brings, and, accordingly, young adults acquire more autonomy in marriage choices (Caldwell, Reddy, & Caldwell, 1983). Urbanization and electronic communication have made one's spouse and family a less important source of companionship and entertainment now than when most people lived on farms or in villages (Burch & Matthews, 1987).

In developed industrial societies such as the United States, the family retains responsibility for reproduction, socialization, coresidence, and the transmission of property across generations. It is the main unit of consumption and often also produces considerable amounts of goods and services. Families provide care and support for both the young and the old. Although older adults receive financial transfers and access to medical care from the government in many societies, they still receive the vast majority of their help and support from family members (Logan & Spitze, 1996), and children are almost entirely dependent on their families for financial, emotional, and instrumental support. However, the more modern family less often consists of a married couple, their children, and other relatives than in the past.

At the same time, the social and economic bases for marriage have changed, especially in postindustrial

societies such as the United States and Britain. Many social thinkers point to a shift toward companionate marriage and intimate relationships, in which the relationship exists primarily to meet the emotional needs of the partners, to be discarded when needs change (Giddens, 1992). Fulfillment of the emotional needs of both partners is a weak reed upon which to build a long-term relationship, making such marriages fragile. The movement of women into advanced education, often at rates equal to men, and into the paid labor force has eroded—but not eliminated—the economic basis for marriage. More women earn enough to support themselves and their children should they be unable or unwilling to marry or stay married (Waite & Nielsen, 2000). Changing attitudes about sex outside of marriage have made some of the services provided by marriage available to those who are not married. And changing gender roles, including rises in women's employment and changing expectations for men's participation in family life, seem to have led to increased conflict in marriage (Amato & Booth, 1995). All these changes have, according to some scholars, weakened the social institution of marriage and made marriages less stable than they were under different conditions.

The married, two-parent family has been the most common family form in the United States and other industrialized countries for some centuries. But even at the height of the married couple family era, many people lived in other types of families, most often due to the death of one member of the couple before all the children were grown (Watkins, Menken, & Bongaarts, 1987). When death ended many marriages relatively early in life, remarriage and stepfamilies were common, as were single-parent families caused by widowhood. High rates of divorce combined with relatively low rates of remarriage, especially for women with children, have been shown to lead to sizable proportions of families with a divorced single mother. The rise of cohabitation and nonmarital childbearing has meant that unmarried-couple families and never-married mother families are now common alternative family forms.

In the United States families consisting of a married couple with children fell from 87% in 1970 to 69% in 2000. The percent of single-mother families rose from 12% to 26%, and that of single-father families rose from 1% to 5%.

One alternative family form consists of two adults of the same sex, sometimes raising children. About 2.4% of men and 1.3% of women in the United States identify themselves as homosexual or bisexual and have same-gender partners (Laumann, Gagnon, Michael, & Michaels, 1994). Although information on the number and characteristics of gay and lesbian couples has not generally been available in the United States, one estimate suggests that in 1990 fewer than 1% of adult men lived with a male partner and about the same percentage of adult women lived with a lesbian partner (Black, Gates, Sanders, & Taylor, 2000). These estimates are based on responses to the unmarried partner question in the U.S. Census and are thus thought to be conservative estimates of the numbers of same-sex cohabitors. This is the case because some of those living in gay and lesbian couples do not identify as such in survey and other data. Legal and social recognition of these unions as marriages is generally not available in the United States. Dan Black and colleagues (2000) have estimated that about 25% of gay men and 40% of lesbian women are currently in or previously were in heterosexual marriages.

## MARITAL QUALITY AND DYNAMICS

The life course of marriage has held endless fascination for scholars of the family and for the lay public since research on the family began. This literature points quite consistently to a pattern in which marital happiness was highest at the onset of marriage, with fairly sharp declines over the next few years, followed by further but somewhat slower declines as children were added to the family, grew up, and left home. At this point, most studies showed that marital happiness tended to rebound, although to levels somewhat lower than during the honeymoon phase (Glenn, 1990), so that marital happiness has a sort of U-shaped relationship over the life course: high at the beginning and at the end and low(er) in the middle.

A number of theoretical explanations have been advanced for changes in marital quality over the course of the marriage. One focuses on transitions in family and other roles and structures. Families tend to add children during the early years of marriage, and the presence of young children has been associated with declines in marital quality, perhaps because of conflicts over childrearing, a shift in attention and resources away from the couple toward their children, and increases in stress. Movements of women into the labor force, changes in family income, retirement, and health all may occur over the life of a marriage, perhaps changing the way in which individuals evaluate their marriages.

A second theoretical perspective points to the social psychological processes that take place in any couple, from the bliss of the falling-in-love stage through adaptation, habituation, and disillusionment. Early expectations of lifelong passion run headlong into the realities of getting dinner on the table and the laundry done. In addition, people may change over time in ways that make them less compatible than they were when they married. This developmental perspective on marriage suggests that changes in happiness are a fundamental part of the course

of any relationship and are not because of changes in social circumstances, social roles, or family structure.

A third perspective argues that the world has changed in ways that have reduced happiness for all marriages. These include changes in gender relations, especially a shift from breadwinner-homemaker families toward dual earner families, in which both spouses provide income and care; increasing individualism and acceptance of divorce, both of which seem to erode relationship quality and stability by reducing investments in marriage; and an increase in economic uncertainty, especially for those with relatively low levels of education, resulting in increasing stress. In a comparison of marriages in two generations of people, those married during the 1970s and those married during the 1980s, when they had been married for the same number of years, Stacy Rogers and Paul Amato (1997) found that those in the younger generation reported less marital interaction, more marital conflict, and more problems in their marriages than the older generation did at the same points in their marriages.

Research that has tracked marital happiness over the course of the marriage among the same people married to the same spouse shows no support for the U-shaped relationship so common in the literature. Jody VanLaningham and colleagues (2001) found that marital happiness either declines continuously over the course of the marriage or that happiness declines over a long period and then stabilizes, but does not rebound. The authors suggest that the declines in marital happiness they observe are because of a mixture of developmental processes intrinsic to marriage in which spouses become habituated and thereby less happy, and because of shifts in the larger society and culture that have reduced support for the institution of marriage and increased the demands placed upon it, especially the demand to meet the emotional needs of the partners, introducing new sources of stress and instability.

## THE CONSEQUENCES OF MARRIAGE

As a result of the characteristics of the institution of marriage discussed above, marriage changes the behavior of spouses and thereby their well-being. The specialization, economies of scale, and insurance functions of marriage all increase the economic well-being of family members, and the increase is typically quite substantial. Generally, married people produce more and accumulate more assets than unmarried people (Lupton & Smith, 2003). Married people also tend to have better physical and emotional health than single people, and at least part of this advantage is attributable to being married—rather than to selection effects (or those preexisting traits of persons who marry versus those who remain single) (Mirowsky & Ross, 2003). The social support provided by a spouse, combined with the economic resources produced by the marriage, facilitate both the production and maintenance of health.

Lee Lillard and Linda Waite (1995) find that both men and women show declines in the likelihood of dying when they marry, although these effects appear at marriage for men and cumulate with duration of marriage for women. Men who become unmarried show large increases in the chances of dying, net of other characteristics, regardless of whether their marriage ends with divorce, separation, or widowhood. For women, the end of a marriage through divorce or separation increases the risk of death (Hemström, 1996), but the death of the husband does not. Hilke Brockmann and Thomas Klein (2004) find similar results among West German adults; the health benefits of marriage accumulate over time, whereas the negative health consequences of being single, divorced, or widowed attenuate over time. The beneficial effects of marriage are nonlinear; they are most pronounced in the early years of marriage. Men benefit immediately from marriage, whereas women's mortality risk actually increases at first. Researchers find no evidence that these effects differ by marriage order (that is, whether it is a first or later marriage). Theodore Iwashyna (2001) finds that both men and women show increased risks of dying in the year following the death of their spouse.

A number of recent studies have attempted to assess the mental health consequences of marriage, divorce, and widowhood, and to separate these from the selection of emotionally healthy individuals into marriage and distressed or unhealthy individuals out of marriage. These studies followed individuals over time as some marry, some divorce or become widowed, and some retain their previous marital status. Consistently, transitions into marriage improve mental health, on average, for both men and women, and transitions out of marriage decrease it (Horwitz, White, & Howell-White, 1996; Marks & Lambert, 1998; Simon, 2002). It is important to note that although rates of mental illness are quite similar for men and women in the United States in the early 21st century, women show higher rates of affective and anxiety disorders, with symptoms of nonspecific anxiety, distress, and depression, whereas men have higher rates of antisocial personality and substance abuse dependence disorders, which manifest themselves in antisocial behavior and drug and alcohol problems (Kessler, McGonagle, Zhao, Nelson, Hughes, Eshleman et al., 1994).

Robin Simon (2002) finds that divorce increases symptoms of emotional distress among both women and men, but women show greater increases than men in depressive symptoms following divorce and men who marry show greater reductions in alcohol consumption

than do women who marry. Both men and women who divorce report a significant increase in alcohol abuse. Simon also finds men and women who divorced reported more depressive symptoms and more alcohol problems earlier than those who remained married, which she interprets as both a cause *and* a consequence of disruption.

Studies that control for the selection of the psychologically healthy into marriage, and also include a wider range of measures of mental well-being, find that although there are differences by gender in the types of emotional responses to marital transitions, the psychological benefits associated with marriage apply equally to men and women (Horwitz, White, & Howell-White, 1996; Marks & Lambert, 1998; Simon, 2002).

Of course, the complete picture is more complicated. Research has extended this line of work to examine differences in the consequences of marital transitions for women and men with various characteristics. This research shows considerable heterogeneity in effects and some surprising similarities.

It seems logical that people who enter marriage disadvantaged in some way, such as ill health, a criminal record, a prior divorce, children from a previous relationship, or poor emotional well-being, bring less to the marriage themselves and are likely to get less out of it than those without these problems. And both scholars and advocates have argued that those in marriages marked by violence, especially women, will gain enormously from leaving those relationships. However neither of these observations seems to find consistent empirical support.

One could argue that those with poor mental health prior to marriage would be less likely to marry and would benefit less from marriage than those with good mental health. Depression in one partner might limit the benefits that person could provide to a spouse, increase the demands on the other spouse, and reduce actual and perceived marital quality. But Adrianne Frech and Kristi Williams (2007) find, instead, that those who were depressed before they married show *larger* gains in emotional well-being than others, and that marital quality plays a similar role in moderating the effect of marriage on mental health for those who were depressed prior to marriage and those who were not. The patterns are similar for men and women. In fact, Frech and Williams find that the psychological benefits of getting married are quite modest for those who were not previously depressed and sizable only for those in poor mental health before marriage. These findings stand conventional wisdom on its head.

Another study does the same for marital violence. Matthijs Kalmijn and Christiaan Monden (2006) find, consistent with previous research, that divorce leads to higher levels of depressive symptoms for women but that men show no change. People who divorce from a marriage characterized by verbal aggression, the authors find, show a *stronger* increase in depressive symptoms than others who divorce. Their results also show that women who divorce from a marriage in which there was physical aggression see a *greater* increase in depressive symptoms than other women who divorce. They suggest that the conflict that characterized the marriage often continues or escalates after the divorce, and so continues to reduce emotional well-being.

To the extent that the benefits of marriage flow from the *state* of being married, then marital disruption, either through divorce or widowhood, interrupts the flow of benefits, which may consist of financial well-being, health, or social connections, remarriage reestablishes the flow of benefits. This suggests that the *duration* of marriage matters. Do transitions into a second or higher-order marriage bring benefits equal to those of a first marriage? In theory, later marriages bring all the same advantages—companionship, economies of scale, trust, social connection, and so on—that come with a first marriage. If later marriages bring the same levels and types of advantages, then spouses in these marriages should show outcomes equal to those of the once-married who had been married the same number of years.

Evidence on the benefits of remarriage is mixed, however. Both Anne Barrett (2000) and Nadine Marks and James Lambert (1998) find that higher-order marriages are less enhancing to mental health than first marriages. However, remarriage seems to undo the negative financial consequences of marital disruption, especially for women (Wilmoth & Koso, 2002).

In most societies, marriage circumscribes a large majority of sexual relationships. Data from the United States show that almost all married men and women are sexually active and almost all have only one sex partner—their spouse. Unmarried men and women have much lower levels of sexual activity than the married, in part because a substantial minority have no sex partner at all. (Just under one-quarter of the unmarried men and one-third of the unmarried women who were not cohabiting at the time of the survey had no sex partner in the previous year.) Men and women who are cohabiting are at least as sexually active as those who are married, but are less likely to be sexually exclusive (Laumann, Gagnon, Michael, & Michaels, 1994).

A key function of marriage is the bearing and raising of children. The institution of marriage directs the resources of the spouses and their extended families, especially time, money, attention, information, skills, and social connections, toward the couple's children, increasing child well-being.

## ISSUES REMAINING

Rapid changes in family processes in many postindustrial societies such as the United States mean that researchers

studying cohabitation, marriage, or even the family are aiming at a moving target. Defining each of these is both crucial and difficult. Must families be related by blood or marriage? If so, does a cohabiting couple constitute a family? Clearly not, under the current definition, because they share neither a blood nor legal tie. What if they have a child? Blood ties exist between the mother and the child and between the father and the child, so each of these constitutes a family. It becomes difficult to argue that this triad consists of two separate families, and much easier to argue that they form a single family, although the adults do not share a blood or legal tie.

What about a cohabiting couple with a child belonging only to the woman? The mother and child constitute a family, but does it include the man who lives with them but shares no blood or legal ties to either? It is difficult to say. The man has no legal responsibilities to either the woman or her child, and no legal rights as a husband or father. But the three may share powerful social, financial, and emotional bonds.

A central question becomes, "What *is* cohabitation?" Steven Nock (1995) has argued that cohabitation is incompletely institutionalized, leaving partners, their families, and others unsure about the nature of the relationship. Susan Brown and Alan Booth (1996) have suggested that cohabitation may be *several* institutions, each with distinct characteristics. One consists of couples who are engaged, have no children, and no previous marriages. These couples appear to be similar to married couples in their behavior and relationship outcomes. Another type of cohabitation includes couples with no plans to marry, with children (generally from a previous relationship), and at least one divorced partner. These couples seem to differ in important ways from more committed cohabitors and from married couples. So, scholars must ask, and continue asking, "What kind of a relationship is this? What are the rules under which the partners are operating? How does the relationship affect choices made by the members and by others? How does the existence of the relationship and its form affect the well-being of the individuals involved?"

Family scholars face as many questions about marriage. What are the irreducible characteristics of marriage? In the United States, same-sex couples are forbidden to marry, although in a few places they may register a *domestic partnership*. Opponents of granting same-sex couples access to marriage argue that, by definition, marriage must involve a man and a woman. Supporters argue that if marriage provides a wide variety of important benefits to participants, it is discriminatory to deny these to same-sex couples. Does a registered domestic partnership provide same-sex couples with the same benefits as marriage provides heterosexual couples? What *is* marriage?

## KEY POLICY ISSUES

**Gay and Lesbian Families** Historically and traditionally, a family consisted of people related by blood or marriage in a culturally recognized social network of biological and marital relationships. Marriage is a legal relationship between an adult man and an adult woman to form a new family. Gay and lesbian families, sometimes based on socially recognized or legally recognized relationship, challenge these definitions. Attitudes toward sex between two adults of the same sex have become substantially more accepting in the United States during decades leading up to the 21st century. Extension of the definition of *family* and *marriage* to same-sex couples has been hotly contested and fiercely debated. In the United States, many attempts to extend access to marriage and family rights to same-sex couples have been turned back by legislators or voters, with some notable exceptions. Several European countries have moved furthest on these issues. France now allows same-sex couples to register their partnerships, Denmark has extended child custody rights to same-sex couples, and the state supreme courts in Ontario, Canada, and Vermont have both ruled that same-sex couples are entitled to full and equal family rights. And, perhaps most definitively, the Netherlands has granted same-sex couples full and equal rights to marriage (Stacey & Biblarz, 2001).

Current theoretical issues surrounding marriage focus on the elasticity of the definition. Must marriage, by definition, include only adults of opposite sexes? Is it possible for two men to marry? Two women? An adult and a child? Two children? Clearly, in some societies, a husband may have more than one wife, although the reverse is rarely true (Daly & Wilson, 2000). And, theoretically, in countries such as Norway and Sweden, in which the legal distinction between cohabiting and married couples has shrunken to the point of vanishing, have cohabiting couples become *married*? Is this just a return to the common-law marriages of the past, or is it something different?

The forms and patterns of family life have shifted, quite noticeably in some countries and among some groups. But Homo sapiens developed as a species in conjunction with the development of the family, some would argue in conjunction with the institution of marriage (de Waal & Pollick, 2005). Humans' future and the future of the family are inextricably intertwined and always will be.

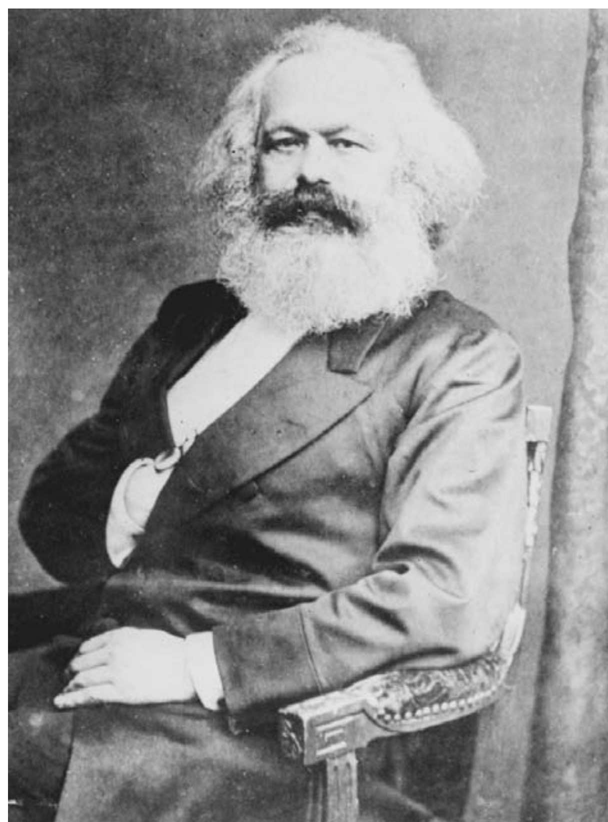
# MARX, KARL

***1818–1883***

Karl Marx, a German philosopher, was a pioneer of the sort of interdisciplinary analyses that would later become integral to the life-course perspective. More famously and infamously, his was the voice that both criticized and drew from existing European socialism to define a movement that he called *Communism*. Marx's work derives from two additional currents: the philosophy of G. W. F. Hegel (1770–1831) and Ludwig Feuerbach (1804–1872) and the political economy of Adam Smith (1723–1790) and David Ricardo (1772–1823). Marx contributed some of the most enduring notions of social class and social conflict.



***Karl Marx.*** AP IMAGES.

Born in Trier, a town near the German border with Luxembourg and France, Marx grew up in an environment heavily influenced by French philosophy and politics. His early life included training in philosophy, history, and law. After receiving his university degree, he founded a series of radical newspapers both at home and abroad that were quickly suppressed. Because of this, Marx returned to his studies of history and political economy.

## MARX'S PHILOSOPHIES

Marx's emphasis on the importance of social class derived from these studies, which allowed him to chart the historical transition of the social classes in Europe during the modern period. He argued that a new class, called the *bourgeoisie*, was displacing the European aristocracy as the dominant political class. This often occurred through violent revolution, most notoriously in France. At the same time that the bourgeoisie was seizing political power, a new lower class was developing. Marx called this class the *proletariat*.

Unlike the bourgeoisie, the proletariat did not own any property apart from the capacities of its members to use their bodies to labor for a wage. As the industrial revolution advanced, members of the proletariat grew more numerous and clustered in industrial centers, especially London. Working conditions for the proletariat were deplorable. Marx pointed out that the working conditions of the proletariat poisoned the relationship that members of the proletariat had to their own activity. This proletariat worked only to live, and live minimally, a situation Marx called *alienation*.

Marx expected the proletariat to rise up in revolution against the bourgeoisie that dominated it, and he documented this expectation in his 1848 *Communist Manifesto*. Penned jointly with Friedrich Engels (1820–1895), who would be Marx's lifelong writing partner, the *Communist Manifesto* is one of the most widely dispersed documents of all time and has been read in many global contexts as an essential call of oppressed peoples to action.

Although Marx's attention to social class is both provocative and significant, his philosophy does far more than simply reveal the importance of social class. Marx gave a name to the mode of production developed in the modern European world: *capitalism*. Marx's unfinished *magnum opus*, the work *Das Kapital* (*Capital*), describes capitalism, particularly as it existed in late 19th-century London. *Capital* also presciently forecasts the ways the capitalist mode of production will extend over the whole world. Although some of Marx's analyses in *Capital* bear the historical marks of the era in which they were produced, the work remains salient. Philosophically, *Capital* may even be said to be a work written for and about the future, as it is much more characteristic of subsequent developments than it was of Marx's own time.

Marx's works are voluminous, although only a tiny portion of them was well known prior to Joseph Stalin's death in 1953. The political power of the movements founded under the name of Communism far overshadowed Marx himself and led to the direct suppression of some of his more philosophical or speculative works. Scholars continue to unpack Marx's legacy in the post–cold war era, an era that may allow people to see him clearly for the first time.

Many of Marx's works in addition to the *Communist Manifesto* and *Capital* are worth close study. The most important of these include *The Economic and Philosophical Manuscripts of 1844*, the *Theses on Feuerbach* (1845), *The German Ideology* (1846), *The Eighteenth Brumaire of Louis Bonaparte* (1851–1852), the *Grundrisse* (1857–1858), and the *Preface to the Contribution to the Critique of Political Economy* (1859).

Marx's work has influenced many social, political, and intellectual currents. Leszek Kolakowski's multivolume work, *Main Currents of Marxism: Its Rise, Growth, and Dissolution*, remains the best encyclopedic text documenting the various strands of Marxism.

After being expelled from the European continent as a part of the suppression that followed the revolutions of 1848, Marx lived his life from 1849 onward in London. Spending most of his days in the British Museum's Reading Room, Marx drew widely from history, economics, theology, political theory, literature, chemistry, and mathematics. In addition he had access to the new kinds of empirical studies on populations that would later be foundational in the discipline Marx himself was instrumental in crafting: sociology.

# MATE SELECTION

Almost all young men and women expect to tie the knot, but not all end up getting married according to Daniel Lichter, Deborah Roempke Graefe, and J. Brian Brown (2003). One reason some people never marry is the difficulty of finding the right person. The conventional pattern of mate selection is for men and women to choose a partner with personal characteristics similar to his or her own. Young women usually marry young men, college-educated women tend to marry college-educated men, Black women most likely marry Black men, Catholics prefer to marry Catholics, and so on. This "like marries like" phenomenon is "partly an unconscious result of a process in which many individuals attempt to achieve the best possible bargain for themselves or their children by weighing marital resources and alternatives" (Elder, 1969, p. 519). It effectively diminishes one way of achieving social mobility. Nevertheless, other factors, including shortages of marriage partners in one group and a prolonged search for marriageable partners in marriage markets, may increase the likelihood that a marriage across group lines would occur. The groups

people marry into are typically those with shorter social distance from the groups to which they belong. As a result, mate selection patterns help explain relative salience of group boundaries in a society.

## THE MARRIAGE MARKET

Social scientists view the mate selection process as analogous to the matching of employers and employees in labor markets. In labor markets, job searchers seek the best job possible, subject both to opportunities (e.g., jobs available) and constraints (e.g., their skills and credentials). Among all potential job offers, some will be acceptable to the job searcher, but others will be unacceptable, failing to meet his or her aspirations regarding work type, pay level, or work condition. Finding the best job among all possible potential job offers is both costly and time-consuming; search activities therefore do not continue indefinitely. Instead, job seekers decide on a minimally acceptable match, the so-called "reservation wage." Searchers reject job offers below the reservation wage and accept the first offer at or above the reservation wage. All else being equal, the lower the reservation wage, the more likely searchers will find a job quickly.

By analogy, in marriage markets, men and women seek the best partner possible given their own opportunities (available partners) and constraints (their own characteristics and preferences). According to Paula England and George Farkas (1986), marriage-seekers have in mind a "reservation quality partner"—analogous to the job seeker's reservation wage. Their minimally acceptable marital partners would be somebody similar to themselves. So when men and women look for the best match in marriage markets, they often end up marrying someone with similar characteristics. Those who set too high a standard for the reservation quality partner prolong the search process. Eventually, they will never marry or will have to "cast a wider net" to lower their reservation quality partner and form mismatched marriages.

## HOMOGAMY AND ENDOGAMY

Mate selection processes in marriage markets clarify why people around the world are likely to form homogamous (similar in achieved statuses, such as educational attainment) or endogamous marriages (similar in ascribed statuses, such as race/ethnicity). In traditional societies parents typically play a large role in arranging their children's marriages. The outcome is that their sons and daughters are well matched in socioeconomic status (Goode, 1982). In the United States, young men and women have free choice and prefer to marry someone they fall in love with; however, the mates that young men and women choose based on love are usually much to the liking of their parents. In American society parents no longer arrange marriages for their children—a practice still common in many less developed countries. However, thanks to socialization, American sons and daughters choose mates in the same way their parents would do on their behalf—by finding someone with common interests and backgrounds.

Individuals who are similar in age, belong to the same racial or ethnic group, have the same levels of educational attainment, come from similar family backgrounds, and/or have the same religious beliefs appear to be more "lovable" to each other because of their common interests and backgrounds. Yet an exact match on all those traits is not easy. Certain traits (religion or race) are often more important than others (educational attainment) but, over time, the relative importance of these traits can shift. In the United States, Matthijs Kalmijn (1991) noted that religious boundaries are breaking down, and interfaith marriages have become more common in recent generations. Racially endogamous marriages still are the norm, as Zhenchao Qian and Daniel Lichter (2007) pointed out, but interracial marriages are on the rise, especially among U.S.-born Americans. Meanwhile, educational boundaries have become more rigid, according to Christine Schwartz and Robert Mare (2005). In other words, compared to the past in the United States, marriages involving men and women with similar levels of education have increased whereas those involving men and women who belong to the same racial/ethnic group have declined.

Changes in racial endogamy and educational homogamy reflect changes in social structure and in the openness of American society. Social scientists such as Peter Blau and Otis Dudley Duncan (1967) have argued that, in modern, developed societies, ascriptive traits, such as family and racial background, have become less important than achieved qualities, such as education, in determining economic positions. It makes sense then that in early 21st century marriage markets men and women place more emphasis on educational attainment and less emphasis on race in choosing marriageable partners.

## INCREASES IN EDUCATIONAL HOMOGAMY

In the early decades of the 20th century, educational homogamy was high. As shown in Figure 1, in 1940, 59.3% of the husbands and wives had the same level of education. Such a high level of homogamy is not surprising; half of the married men and women had fewer than 10 years of schooling, and there was little variation in educational attainment in the population at that time. Improvements in educational attainment since then initially reduced educational homogamy—the percentage of married couples with the same level of educational

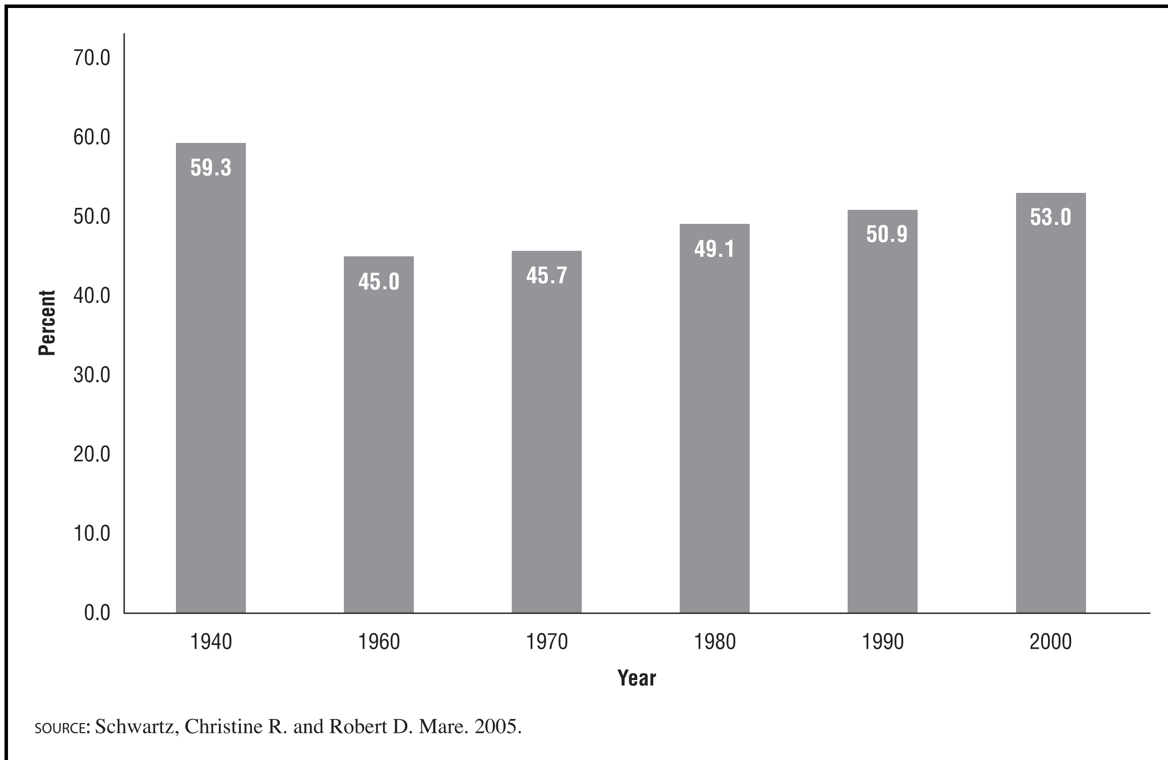

***Figure 1.*** *Percent of married couples with same levels of education, 1940–2000.* CENGAGE LEARNING, GALE.

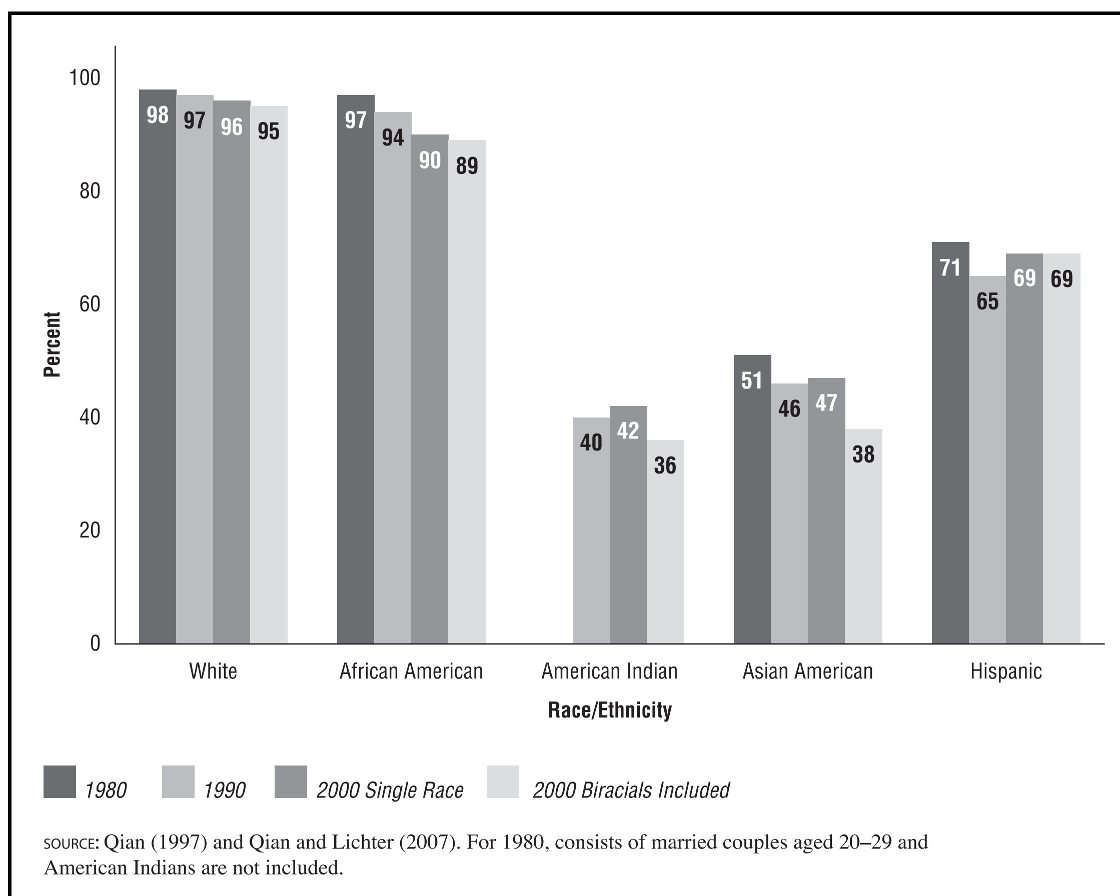
attainment declined to 45% in 1960. At the same time, Richard Rockwell (1976) pointed out that husbands had more education than their wives in an increasing share of marriages. Gary Becker (1981) noted that marriage at that time emphasized spousal complementarity—husbands concentrated their efforts in the labor market, whereas wives specialized in domestic labor. Under these conditions, husbands' earning potentials as measured by educational attainment were more important in the marriage market than wives' educations.

The reversal in educational homogamy started in the 1970s. The percentage of couples with the same educational level increased from 45.7% in 1970 to 53% in 2000. Most of the increase in homogamy is attributable to an increase in marriages in which both the husband and wife have a college education. In large part this is because, according to Claudia Buchmann and Thomas DiPrete (2006), on average, women's educational attainment increased more than men's during this time. This increase closed the gender gap in educational attainment. More women with college educations and more women in the labor force since have moved women's socioeconomic positions upward. Responding to this change, men increasingly find women's socioeconomic resources important in marriage markets. Indeed, Megan Sweeney and Maria Cancian (2004) indicated that women's position in the labor market has become more attractive over time as a determinant of their position in the marriage market. Consequently, achieved statuses such as educational attainment have become equally important for men and women in marriage markets.

## DECLINES IN RACIAL ENDOGAMY

Levels of racial endogamy depend in part on the size of each racial group. The larger the group, the more likely group members will find marriageable partners of their own race. Thus, Whites, the largest racial group in the United States, have the highest percentage of endogamy. Endogamous marriages accounted for 98% of the White marriages in 1980 and 96% of White marriages in 2000. Endogamy, on the other hand, was much lower for American Indians and Asian Americans, which have much smaller population sizes. Statistical differences in racial/ethnic endogamy are also partly attributable to differences in the size of each group. For example, one Asian-White marriage affects the percentage of endogamous marriages much more for Asians than for Whites because the Asian population is much smaller than the White population. For the same reason, although just 4% of Whites were involved in interracial marriages in 2000, 92% of all interracial marriages include a White partner.



SOURCE: Qian (1997) and Qian and Lichter (2007). For 1980, consists of married couples aged 20–29 and American Indians are not included.

***Figure 2.*** *Percent of racially endogamous marriages among U.S. born couples aged 20–30.* CENGAGE LEARNING, GALE.

Figure 2 shows an overall decline in racial endogamy for all racial/ethnic groups, from 97% to 90% for African Americans and from 51% to 47% for Asian Americans between 1980 and 2000. The trend reversed for U.S.-born Hispanics due to a large influx of immigrants from Latin America; the increase in group size enables greater racial endogamy. Given population size differences, comparing rates of intermarriage among groups can be difficult. Statistical models can account for group size, identify the extent to which any group is marrying another more or less than one would expect given their population group size, and then reveal other factors affecting intermarriage (Qian & Lichter 2007). Results using these models show that racial endogamy among the U.S.-born has indeed declined in the past decades for each racial group.

Racial endogamy has declined for several reasons. First, increases in educational attainment among racial minorities are associated with declines in racial endogamy. College-educated men and women are more likely to marry interracially than those with less education. The fact that Asian Americans attend college at relatively high rates helps explain their low level of racial endogamy. Highly educated minority members often attend colleges, work in places, and live in neighborhoods that are integrated. They find substantial opportunities for interracial contact, friendship, romance, and marriage.

Second, the growth of the multiracial population has blurred racial boundaries and reduced racial endogamy. The U.S. Census Bureau classifies people into four major race categories: Whites, African Americans, Asian Americans, and American Indians. Hispanics can belong to any of the four racial groups but are considered as one separate minority group. In the 2000 census, Americans could choose more than one racial group for the first time. Most multiracial Americans are part White and part Black, American Indian, or Asian. When biracial Americans are included, Qian and Daniel Lichter (2007) reported, racial endogamy declines even further, especially for American Indians and Asian Americans, who have greater shares of multiracial individuals compared to African Americans.

## COHABITATION

In recent decades in the United States, educational homogamy has increased steadily whereas racial endogamy has declined. Clearly, achieved social status and

economic positions have become an important mate selection criterion whereas racial barriers have broken down to some extent. These changes also result from the fact that marriage has become more selective, as cohabitation has arisen as a viable alternative to marriage. Cohabitation can serve as a stepping stone to marriage. Debra. Blackwell and Daniel Lichter (2000) call this type of cohabitation a *winnowing process*. Educational homogamy and racial endogamy are relatively low among cohabitating couples but are much greater among those who make transitions to marriage. In other words, those who make transitions to marriage are more likely to share similar racial and educational backgrounds than those who do not.

The connection between cohabitation and marriage, however, is weakening (Cherlin 2004). Fewer cohabiting unions end in marriage. Kathryn Edin (2000) found that lack of economic resources and uncertain labor markets dampened marriage prospects for cohabiting couples. Also in 2000 Larry Bumpass and Hsien-Hen Lu indicated that a large fraction of unmarried births were to cohabiting women. This reduces the likelihood of marriage among unmarried women with children because prospective spouses may be unwilling to assume the economic and parental responsibilities associated with marriage to an unmarried mother. Thus a prior cohabitation may signal a poor "position" in the marriage market. (Qian, Lichter, & Mellott, 2005). However, cohabitation is a short-lived living arrangement. The cohabitating couples that do not make transitions to marriage often end up going their separate ways quickly.

Patterns of mate selections by race and education reflect changes in relative importance of these traits over time. Yet, they also result from increasing selectivity of marital unions—fewer people ever marry and more men and women move from one cohabitating relationship to another. Existing literature on mate selection focuses more on marriages. Future research needs to take into account men and women who are in marriage markets but have not yet formed marital unions.

## MATERNAL MORTALITY

Maternal mortality refers to death during pregnancy, childbirth, or the postpartum period (defined as 42 days following the termination of pregnancy) from causes directly or indirectly related to the pregnant state. The leading direct cause of maternal mortality globally is hemorrhage (bleeding), with the majority of these deaths occurring in the immediate postpartum period. Other leading direct causes include sepsis (severe blood infection), high blood pressure due to pregnancy, obstructed labor, and induced abortion (with most abortion-related deaths caused from hemorrhage or sepsis). Common indirect causes, which are preexisting conditions made worse by pregnancy, include HIV, malaria, and anemia. The time around delivery is by far the period of greatest

risk. Estimates suggest that two-thirds of maternal deaths occur between late pregnancy and within 48 hours after delivery (AbouZahr, 1998).

The estimated number of maternal deaths globally was 536,000 in 2005, with 99% occurring in developing countries. Nearly half of maternal deaths occur in five countries: India, Nigeria, Democratic Republic of the Congo, Afghanistan, and Ethiopia (Hill et al., 2007). The difference in the risk of maternal death between developing and developed countries is greater than that for other common health indicators. For example, the maternal mortality ratio across developed countries is 9 maternal deaths per 100,000 live births, compared to 905 per 100,000 live births in sub-Saharan Africa. Estimates of the maternal mortality ratio for individual countries range as high as 2,100 deaths per 100,000 live births (Hill et al., 2007). Viewed from a life-course perspective, maternal death represents the leading or second leading cause of death among women 15 to 49 years of age in many developing countries. The proportion of deaths due to maternal causes among females ages 15 to 49 ranges from less than 1% in developed countries to 15 to 45% in developed countries (World Health Organization, United Nations Children's Fund, & United Nations Population Fund, 2004).

Measuring maternal mortality is difficult and leads to imprecise estimates. The challenges vary by setting. Even in developed countries with well-established systems for registering births and deaths, maternal mortality has been shown to be underestimated by one-third of the actual maternal mortality ratio on average (Hill et al., 2007). This is primarily due to death certificates that do not specify the pregnant state of the woman at death. Thus, causes of death such as sepsis, embolism (blood clot), or indirect causes of death are not categorized as maternal (AbouZahr, 1998). However, only 26% of the world's population live in countries with complete death reporting via vital registration, and this drops as low as 7% and 1% in Africa and Southeast Asia, respectively (Mahapatra et al., 2007). In these countries, survey or census-based methods are used to estimate maternal deaths in the household or among siblings. Countries with no empirical data must rely on estimates from statistical models. The 2005 series of maternal mortality ratios included 61 developing countries, representing 25% of global births, for which model-based estimates were required (Hill et al., 2007).

Analysis of a time series of global maternal mortality ratios suggests only a 5.4% decrease between 1990 and 2005, with negligible change in sub-Saharan Africa (Hill et al., 2007). This stagnation is in sharp contrast to the historical experience in developed countries. In the early 20th century, maternal mortality ratios in developed countries were similar to those seen in developing countries in the early 21st century, with ratios ranging from 200 to 600 maternal deaths per 100,000 live births. Beginning around 1931, maternal mortality ratios decreased by at least 50% every 10 years over the following 50 years, stabilizing with ratios of 10 maternal deaths or less per 100,000 live births (Loudon, 1992). These declines have been attributed to the discovery of antibiotics, improved procedures for cesarean sections and blood transfusion, as well as the professionalization of midwifery care, which some authors believe explains differences in the pace and timing of the declines (De Brouwere & Van Lerberghe, 2001).

Social and economic factors related to maternal mortality have varied over time, vary currently by setting, and vary when considered at the individual versus population level. Historically, maternal mortality, unlike infant mortality, was not related to the woman's socioeconomic status. During the 19th and early 20th century in Europe and North America, for example, women delivering in a health facility were at substantially greater risk of death from sepsis than women delivering at home because of unsanitary provider practices before recognition and acceptance of germ theory.

At a global level today, although all pregnancies are at risk of obstetric complications, maternal mortality is highly concentrated among the poor. Data from developing countries show risks of maternal death up to 6 times higher for women in the poorest quintile of households relative to the wealthiest (Ronsmans, Graham, & Lancet Maternal Survival Series Steering Group, 2006). By contrast, in the United States, the risk of maternal death varies dramatically by racial and ethnic group, with African American and Hispanic women not born in the United States showing risks 4 times and 1.6 times higher than White women, respectively (Berg, Chang, Callaghan, & Whitehead, 2003). Economic status of the woman does not fully explain these differentials, however. Likewise, wealth at the national level does not fully explain differences in risks of maternal mortality, as there are 40 countries with lower maternal mortality ratios than the United States (World Health Organization et al., 2004); in addition, there are very large differences in maternal mortality at similar levels of per capita income among developing nations (Ronsmans et al., 2006).

Key areas of research regarding maternal mortality encompass clinical research and research into effective service delivery approaches. There is a substantial body of randomized clinical trials assessing the effectiveness of drugs and specific procedures (some but not all of which use risk of maternal death as an outcome), the majority of which were undertaken in developed countries (Ronsmans, Graham, & Lancet Maternal Survival Series steering group, 2006). Examples of such procedures include the use of magnesium sulfate for preeclampsia and eclampsia (a condition in pregnancy characterized by very high blood pressure), the use of

active management of the third stage of labor to prevent postpartum hemorrhage, and the use of the partograph for monitoring labor. Only one randomized population-based trial was identified in which maternal death was designed as a primary outcome; in this trial, which assessed the effectiveness of traditional birth attendants for home-based delivery in Pakistan, no significant effect on maternal death was reported (Jokhio, Winter, & Cheng, 2005).

The paucity of population-based trials for maternal death is related to the need for very large sample sizes and the difficulties associated with designing a trial that must assess multiple interventions to address the various causes of maternal death while controlling for confounding factors associated with the social determinants of maternal death, such as women's education, transport, and local infrastructure. Researchers and policy makers continue to debate the acceptability of results from quasi-experimental and other nontrial-based evaluations.

Many questions remain unanswered regarding how to reduce maternal mortality in the countries where 99% of these deaths occur, despite 20 years of advocacy, research, and program implementation by the Safe Motherhood Initiative, the international initiative dedicated to addressing maternal death. As stated above, trend data suggest little improvement in high mortality countries. It is not clear why some countries have succeeded in reducing maternal mortality, where others have not. A key question to answer is this: Where and with whom should women give birth? A systematic review suggests that the use of traditional birth attendants for home-based births has not been effective in decreasing maternal mortality (Sibley et al., 2007). However, the relationship between national rates of use of a medically skilled attendant at birth (which equates to births taking place in a health facility in the vast majority of countries) and national maternal mortality ratios is negative, although weak (Graham, Bell, & Bullough, 2001). Furthermore, although approximately 50% of developing world births report having a medically skilled attendant at birth, there are large areas of South Asia, in particular, where the percentage of births attended by a medical professional is less than 20% (United Nations Children's Fund, 2007).

The inadequate number of skilled health care workers is among the most pressing challenges facing developing countries. It has been estimated that the training of approximately 330,000 new skilled birth attendants would be required for 72% of global births to be assisted by a medical professional (World Health Organization, 2005). Thus, assuring that all births take place with a medically skilled attendant must be viewed as a long-term goal and begs the question of what the most cost-effective, context-specific interventions should be for the immediate future.

# MEDIA AND TECHNOLOGY USE, ADULTHOOD

Classic mass media (television, radio, newspapers, magazines, movies, and books) and information and communication technologies (ICT) (telephones, mobile phones, and the Internet) play a central role in everyday life. Media and technology use is one of the most important leisure activities and thus accounts for a great deal of time use over the life course. In addition, media and ICT are important in shaping the life course. The technological environment is a critical part of the historical and structural contexts in which people live their lives. For example, people coming of age at the beginning of the 21st century are doing so in the so-called information society, in which mass media and ICT are much more important for individuals, organizations and companies, nations, and global society than they were in the middle of the 20th century.

This fundamental social change has altered many aspects of life; for example, ideas about the speed and frequency of interpersonal communication have been transformed by the availability of cell phones and the Internet. These technologies also are important for the messages they convey about everything from the appropriate timing of life events to the kinds of consumer goods one needs to mark those events (e.g., what new parents need to purchase). Thus, whether or not they represent reality accurately, media and ICT are a means of conveying cultural ideas about the life course and society. ICT in particular have changed the nature of social relationships over the life course in that contemporary people are embedded not only in real social networks but in virtual social networks on the Internet that may span the globe.

## THE DIGITAL DIVIDE

There are differences in access to and use of mass media and information and communication technologies (ICT) among global regions (e.g., northern hemisphere versus southern hemisphere), countries with different political systems (e.g., democracy versus autocracy), regions within countries (e.g., urban versus rural), social traits (e.g., age, income, education, and ethnicity), and individual characteristics (e.g., literacy, psychological traits). In the case of most media and technologies the ability to afford the cost of the device (television, radio, computer) or the service fee (newspapers, pay television, cinema, Internet) is a precondition for use. The term *digital divide* refers to unequal access to and use of the Internet (Norris, 2002). Therefore, the main digital divide parallels the financial divide. In addition, women in most countries are less likely to have access to the Internet and, if they have access, use it less intensely. However, in 2007 a higher percentage of U.S. women than U.S. men used the Internet (Center for the Digital Future, 2007). Access to the Internet exposes individuals to new information and enables the development of skills. Thus, unequal access to these resources may contribute to further inequalities over the life course.

## ACCESS TO MASS MEDIA AND ICT

Access to mass media and ICT is an indispensable precondition for their use. Research shows that some subgroups of individuals are less likely to have access to these technologies. However, history shows that these access gaps usually diminish or disappear over time as a technology is diffused throughout society. For example, in European and North American societies there are few gaps in access to classic mass media; the U.S. Census estimates that more than 95% of poor households own a color television. When specific types of media are examined, gaps are apparent. Thus, even though television and radio sets are found in well over 90% of households, access gaps arise because not all content is freely available, such as cable and satellite programming. Similar differences can be observed in comparing access to free versus paid newspapers and magazines. This contrast is important because of the quality differences between free and paid media.

## MOTIVES FOR USE OF MASS MEDIA AND ICT

Research on mass media before the 1970s tended to examine the impact of media on users, viewing them as passive actors causally influenced by powerful media organizations. Beginning in the 1970s, the focus shifted to the motives underlying the use of mass media. The central research question was no longer "What do media do with their users?" but "What do users do with media?" (Rosengren, Wenner, & Palmgreen, 1985). This so-called uses and gratifications approach is still prominent in mass media research.

Researchers categorize the gratifications of using media in various ways, depending on the theoretical approach and research question. One of the most general and widely used categorization distinguishes four gratifications: cognition, affection, social interaction, and integration/habitus. Cognitive gratification refers to the need for information and learning, whereas affective gratification includes aspects such as entertainment, diversion, escapism, and excitement. Social interaction combines two kinds of interaction that are fostered by mass media. On the one hand, mass media provide topics for everyday conversations and therefore for social integration. On the other hand, electronic media such as television and radio can provide parasocial interaction. For example, people may feel personally addressed by news anchors saying "good evening" or "see you tomorrow at the same time" and feel that they are engaging in a social interaction.

The habitus gratification is based on the human need for rituals, stability, and structure. Mass media offer a reliable structure for the rhythm of days, weeks, and years. People often adjust their lives to enable or accommodate their use of media. They may take a different route to work to pick up a free newspaper or buy a magazine, align their dinnertime with the evening news, and not go out when their favorite television shows are screened; major sport events are important landmarks in the yearly calendar. Research has compared the relative importance of these motivations for types of mass media (e.g., television versus newspapers) and examined how the motivations for media use differ from those for other everyday activities (e.g., watching talk shows versus meeting friends). One of the core findings of this line of research is that television outreaches most other mass media on nearly all dimensions. Only newspapers obtain higher ranks on the cognitive function.

## PATTERNS OF MASS MEDIA AND ICT USE

In many cases the mass media are financed substantially or solely by advertisements, and the purpose of every advertisement is to reach as many people in a target group as possible. Therefore, media producers want to know in as much detail as possible how many and which people use their products. Thus, a great deal of quantitative research on patterns of media use is conducted by private companies or industry associations. An international comparative analysis showed that nearly every household in the industrialized world has a television set: Central and Eastern Europe 94.1%, Western Europe 95.3%, Japan 99.4%, United States 98.2% (IP/RTL Group, 2007). Even though access to television is widespread, viewing patterns differ significantly between countries and differ within individual countries on the basis of age, gender, race, social class, and other demographic characteristics.

| | Minutes per Day | | | | | |
|---|---|---|---|---|---|---|
| | Television[1] | | Other Media[2] | | | |
| Country | Age Group | (2006) | Newspapers | Radio | Internet | Year |
| United States | 18+ | 295 | 28 | 191 | 32 | 2001 |
| United Kingdom | 16+ | 232 | 30 | | | 2005 |
| Spain | 16+ | 228 | 13 | 110 | 27 | 2005 |
| Germany | 14+ | 227 | 28 | 221 | 73 | 2005 |
| Japan | 20+ | 213 | 27 | 94 | 71 | 2003 |
| Switzerland (Italian speakers) | 15–74 | 182 | | | | |
| Switzerland (French speakers) | 15–74 | 175 | | | | - |
| Denmark | 12+ | 160 | 19 | 188 | 18 | 2004 |
| Norway | 12+ | 156 | 46 | 133 | 30 | 2005 |
| Switzerland (German speakers) | 15–74 | 147 | 37 | 94 | 43 | 2005 |

***Table 1.*** *TV, newspaper, radio and internet use in selected countries.* CENGAGE LEARNING, GALE.

Table 1 shows the average number of minutes per individual per working day spent viewing TV in selected industrialized nations. People in the United States spend the most time watching television; Americans spend twice as many minutes per day as do people in the German-speaking part of Switzerland, who spend the least amount of time. Especially in Europe, television use and newspaper reading are inversely related (both on the individual and national level). Whereas newspapers are read widely in middle and Northern Europe (e.g., Switzerland, Germany, Norway), television is the major mass medium in Southern Europe (e.g., Spain).

It is difficult for researchers to make direct comparisons of time spent using specific media because inconsistent measures and operationalizations are used across media types and across contexts. Whereas television use is measured with devices attached to the television set and is therefore reliable, reading time usually is measured by self-reports, which are less reliable. Cultural influences on media use are apparent in Table 1, which shows that the three different language regions of Switzerland have different levels of television viewing. Viewing patterns also vary by cultural and national context. For example, Figure 1 shows the percentage of the audience that watches television throughout the day in Denmark, Japan, and Spain. In Denmark viewing levels are low during the day; the 30% point is reached only with the evening news at

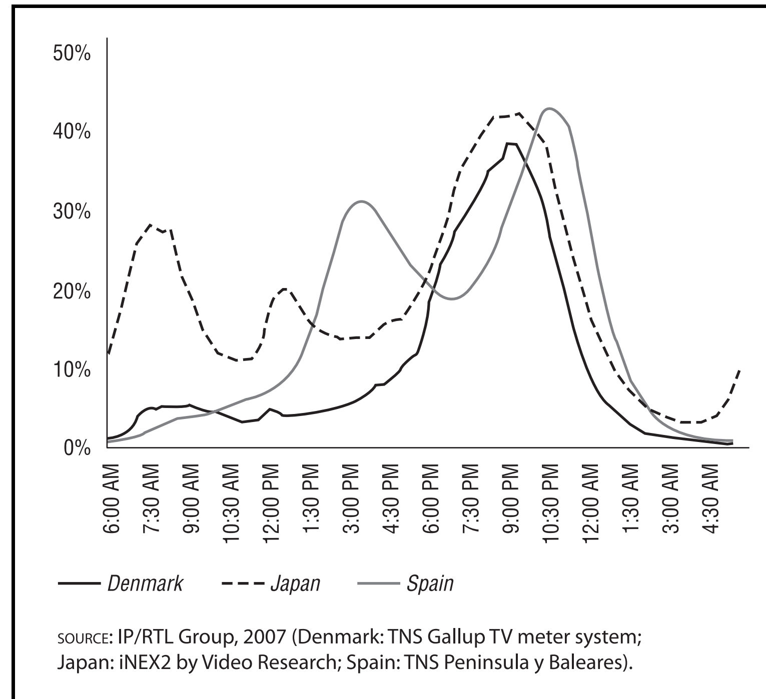

***Figure 1.*** *Daytime TV viewing pattern of selected countries. Percent of population watching television at a particular time on a week day.* CENGAGE LEARNING, GALE.

7:30 P.M. Japan reaches a first peak of 29% audience viewing in the early morning. In Spain there is a clear siesta peak in the late afternoon and a much later prime-time peak, and at midnight 30% of the audience still has the televison on; in contrast, that share is only 10% in Denmark.

Researchers have noted that use of media during recreational time has reached a saturation level; that is, usage rates have reached a ceiling and cannot increase much more. Thus, use of new media devices such as the Internet leads to a reduction in time spent using other media or to a pattern of parallel use: The radio and television are on while people surf the Internet, read a magazine, or do non-media-related activities.

## EFFECTS OF MASS MEDIA AND ICT USE

Researchers have long been interested in the effects of mass media use on individuals, social groups, and societies; that interest has extended to ICT. Contemporary research questions cover issues related to entertainment (e.g., "Does violent and pornographic content in movies affect real-life behavior?") as well as news (e.g., "Does the press influence political opinions?") and interpersonal communication devices (e.g., "Are social networks affected by the Internet?").

The most influential theoretical approaches in this field are agenda setting, framing, and cultivation. The agenda setting perspective assumes that mass media do not have a strong influence on what people think but are effective in influencing what people think about. Thus, whether an issue is perceived as important by the public is not just a result of its true importance. Instead, people's perceptions are biased by the mass media, and issues are perceived as more important when they are covered extensively by the media. The framing approach is related to this perspective and can be treated as second-level agenda setting. The media are assumed to influence people by telling them how to think about a certain topic. The same topic can, for example, be framed as an economic, moral/ethical, technical, or conflict issue. Empirical research shows that there are often situations in which these agenda setting and framing effects of mass media can be observed. However the influence of mass media is far away from deterministic and reverse effects in which the public sets the media agenda are observed as well.

Whereas agenda setting and framing refer more to the short-term and medium-term effects of media on users, the cultivation approach studies longer-term effects. In the 1970s George Gerbner and associates coined the term *cultivation approach* to refer to the finding that mass media use evokes a biased perception of the real world by establishing distorted stereotypes (Gerbner, Gross, Morgan, Signorielli, & Shanahan, 2002). Research in this area focused initially on violence but later was applied to

gender, minority, age roles, family, and other topics. Findings show that heavy users of television have a more biased perception of the real world. For example, those viewers have a disproportionately high estimate of the number of criminals, police officers, medical doctors, and lawyers in the population because of the overrepresentation of those occupations on television (Gerbner et al., 2002).

In addition to these three approaches there is a more sociologically oriented approach that focuses on the effects of mass media and ICT on social relationships. This perspective emerged in the 1980s and 1990s from concern that heavy use of television and computers would lead to social isolation. As a result of the widespread use of the Internet and its possible interactive use (e.g., instant messaging enables communication between people), the question was reformulated as whether ICT use leads to a shift from offline to online relationships or whether increases in the size of a person's social network facilitate the creation of new relationships and the maintenance of distant relationships. Online communities are often related to hobbies or professions but are used only by a minority (15%) of U.S. Internet users (Center for the Digital Future, 2008). However, among U.S. users who are members of an online community, 43% say that "they feel as strongly about their virtual communities as they do about their real world communities" (Center for the Digital Future, 2007, p. 1). A survey in the United Kingdom showed that students are most likely to make online friends (42%) but that the employed and the retired are more likely to meet those new friends offline (Dutton & Helsper, 2007).

### FUTURE RESEARCH

Research linking media, ICT, and the life course is relatively limited because the concept of the life course is not widely known in communication science, and life course research incorporating media and technology use is extremely limited. In light of the increasing importance of ICT and the enduring importance of mass media, an integration of these fields seems overdue. The shortcomings of existing research on media and technology use with regard to the life course lie primarily in their regional focus and their segregation in different scientific disciplines. Cross-national comparative research is very limited because of different research traditions, settings, and methods. Furthermore, research on media and ICT use is biased by the interests of applied research and the focus on target groups of economic relevance.

## MENOPAUSE

Menopause can be defined as an event, a transition, and a set of stages. As an event menopause is marked by the last menstrual period in a woman's lifetime. Unlike other events, such as a birthday, menopause as a definitive event can be defined only retrospectively. Menopause also represents a transition from menstruating episodically (having periods) to the permanent absence of menstrual cycling. As a transition or passage from one stage of life to another, menopause can be quick, straightforward, easy, and uncomplicated or protracted and disruptive. Although physiologically most women enter a postreproductive, postmenstrual phase of life, societies and cultures assign additional and variable meanings to that phase.

Menopause has been scientifically, though equivocally, demarcated as a set of stages through which women progress. Premenopause is the stage in which most adult women experience regular menstrual cycles. Perimenopause, during which a woman experiences significant changes in menstruation, is characterized by changes in cycle length and the intensity of menstrual bleeding. Postmenopause is the postmenstrual and postreproductive stage. The perimenopausal stage also is referred to as the climacteric and is associated most closely with "the menopause" or, more euphemistically, "the change." Along with unpredictable menstrual bleeding, underlying changes in a perimenopausal woman's

endocrine system contribute to hot flashes, a sudden, intense sensation in the face, neck, or upper body of overheating and sweating. Those symptoms can be a potential source of personal discomfort and social embarrassment. A similar vasomotor symptom (a symptom related to the constriction or dilation of blood vessels) that is attributable to perimenopause, night sweating, is essentially a hot flash that occurs while a person is asleep, often disturbing that person's sleep.

Although menopause can be thought of as a strictly biological phenomenon, it has been culturally imbued with meanings related to associated roles and statuses in women's lives. For example, menopause often is viewed as a marker of aging: Old (i.e., older) women are menopausal. Without social or technological interventions, menopause represents the end of reproduction and the role of a new mother. Although "no more periods" can represent freedom from a periodic persona problem, it also can represent a loss of youthful sexual and reproductive desirability. Both popular and scientific descriptions of menopause are notable for their reliance on analogies to loss, wear, and trouble. These negative connotations coupled with endocrine changes, unpredictable and disruptive bodily sensations (irregular bleeding, hot flashes, and night sweats), and interrupted sleep patterns may contribute to an altered self-concept and depressed psychological well-being among some perimenopausal women.

The solidification of a so-called menopause industry (Coney, 1994) during the 1990s can be regarded as a life course case study of the intersection of age, cohort, and historical time within particular sociocultural contexts. Women born in the post–World War II baby boom entered their mid-forties and early fifties during that period, which coincided with the growth of research on the health of women in midlife. For example, the Office of Research on Women of the U.S. National Institutes of Health, which funded the Women's Health Initiative, was founded in 1990. Public discourse on menopause expanded during the 1990s as well. Particularly focused on the self-help arena, book publication on the change proliferated during that period. Influential books such as Germaine Greer's (1991) *The Change* and Gail Sheehy's (1992) *The Silent Passage* heralded a new area of publishing, including positive approaches; menopause diets; exercise plans; advice books from women physicians and feminist activists; source books and guides for women, for men/husbands, and "for dummies" or "complete idiots"; and a pop-up book. By 2001 *menopause* had become the title of a musical.

## EVOLUTIONARY, CLINICAL, AND BIOMEDICAL PERSPECTIVES

A broad bioevolutionary perspective considers whether menopause serves an adaptive purpose. The grandmother hypothesis attempts to explain why, relative to most other mammals, the human female reproductive period ends early in the life span. Prehistoric grandmothers provided assistance to their daughters and their progeny once the grandmothers completed bearing and raising their own children. Thus, grandmothers could invest in the survival of their offspring.

From a clinical vantage point, menopause is inherently pathological and women experiencing menstrual changes are in a diseased or prediseased state. Menopause is defined as functionless or dysfunctional. For example, in the International Classification of Diseases of the World Health Organization, menopause is coded and discussed medically as ovarian failure. In medical textbooks the menopausal stages are portrayed with reference to chronic degenerative diseases such as cardiovascular diseases. A typical analogy is made between menopause and diabetes as hormone deficiency diseases of estrogen and insulin, respectively. Thus, the problem of menopause necessitates medical treatment with estrogen therapies. Hormone therapy—previously termed hormone replacement therapy—includes estrogen medication taken on a continual or daily basis, often combined with progestin. These therapies are prescribed to treat short-term menopausal symptoms such as hot flashes and, more controversially, long-term chronic diseases such as osteoporosis and heart disease. However, estrogen-based hormone therapy is not the only clinically available therapeutic option. Irregular and heavy bleeding associated with the climacteric is addressed medically through hysterectomy. Sexual difficulties among menopausal patients sometimes are treated with estrogen or testosterone. Some depressed and sleep-disturbed patients receive hormone therapy or a variety of psychiatric medications.

Biomedical perspectives are supported in part by empirical findings that the timing of menopause is related to overall health (early menopause may be influenced by poor health practices and can be a marker for subsequent ill health) and longevity (later ages of menopause are positively correlated with longevity). Biomedical research on menopause tends to be conducted on patient populations rather than random samples drawn from the community, and so these perspectives emphasize therapeutic intervention to alleviate the troubles of discomfited patients. However, menopausal patients are not representative generally of menopausal women. Population-based studies of midlife women, by contrast, generally show lower levels of menopause-related sickness and find little evidence for a menopausal syndrome that includes symptoms beyond hot flashes and night sweats (Avis et al., 2001; Rossi, 2004).

## FEMINIST AND SOCIAL SCIENTIFIC PERSPECTIVES

Feminist perspectives tend to categorize the medicalization of menopause as a way for the institute of medicine

to regulate (Martin, 1987; Zita, 1993). Social scientific perspectives on menopause focus on attitudes and laypersons' understandings of what menopause is and how different women (and men) experience it. Research insights from these perspectives emphasize the diversity of menopause across different sociocultural contexts. For example, anthropological studies document the divergent cultural definitions and consequences of menopause in different countries and geographic regions (Seviert, 2006). Margaret Lock (1993) contrasted the aches, pains, and poor eyesight that tend to characterize the change of life (*konenki*) in Japan to the hot flashes and night sweats considered typical of menopause in North America. Within societies, attitudes toward menstruation influence women's experiences of menopause (Bowles, 1992; Papini, Intrieri, & Goodwin, 2002). Extensive life history data from women enrolled in the Tremin Research Program on Women's Health have helped document many aspects of women's menstrual and menopausal lives, including women's concerns about maintaining self-control and limiting social disclosure during potentially disruptive symptoms and behaviors (Kittell, Mansfield, & Voda, 1998). Applying a biopsychosocial framework to a national study, Alice Rossi (2004) found that somatic amplification—awareness of and sensitivity to one's private bodily functions—influences women's and men's reports of symptoms that often are labeled as menopausal.

## RESEARCH DEBATES ON HORMONE THERAPIES

Estrogen, which can help prevent hot flashes, is the most widely used treatment for menopause and, arguably, feminine aging (MacPherson, 1993; McCrea, 1983; Voda & Ashton, 2006). In the 1960s the gynecologist Robert Wilson (1966) advocated estrogen supplementation to help aging women look young and be *Feminine Forever*. By the early 1980s solo estrogen therapy was known to cause uterine cancer. Since that time menopausal hormone therapies for women with intact uteri have combined estrogen with progestin, and during the 1990s those noncontraceptive hormones were prescribed widely for midlife American women. Pharmaceutical companies developed an array of hormone delivery methods, including patches, topical creams, vaginal rings, and low-dose pills. Although those regimes were approved for short-term relief of menopausal symptoms, there was no evidence of long-term benefits. Observational epidemiologic studies found that women who used hormone therapy were healthier and lived longer than other women, but was this because hormones caused better health or because healthier women chose to use hormones (Matthews, Kuller, Wing, Meilahn, & Plantinga, 1996)?

In 1993 the Women's Health Initiative (WHI) was funded to help provide definitive evidence on the relationship between hormone therapies and cardiovascular diseases by enrolling thousands of perimenopausal and postmenopausal women in randomized clinical trials. In 2002, three years before the planned conclusion, the combination hormone therapy component of the WHI was halted when unexpected adverse outcomes were detected. Hormonal treatments increased women's risk of heart attack, stroke, blood clots to the lung, and invasive breast cancer (Rossouw et al., 2002; Voda & Aston, 2006). As a consequence of the WHI, many women stopped taking hormones, contributing to a lower incidence of breast cancer caused by estrogen-sensitive tumors (Ravdin et al., 2007). Some skeptics of the WHI results (Grodstein, Manson, & Stampfer, 2006) advanced a new hypothesis based on the timing of prevention: Hormones benefit only women who start therapy early, and the WHI trials enrolled women who were too old and began hormone therapy too late.

## IMPORTANCE TO LIFE COURSE RESEARCH

Research on menopause fits well within life course perspectives. The timing of menopause and cross-cultural menopausal attitudes, beliefs, and practices are important areas of life course studies. In light of the personal and social dimensions of menopause, life course trajectories related to gender, family, and employment may be confounded with menopausal dynamics. The dominant life course model of menopause frames it primarily as an age-related process. Although the sociocultural contexts of menopause have been studied widely, other time dimensions, such as cohort and history, also should be considered within an explicit life course framework.
