Mental health is a dynamic process that changes over the life course. Although childhood mental health influences mental health during adulthood, mental health in adulthood is also influenced by contextual and historical factors. As people move through the life course, changes in economic circumstances, social roles, social integration, social networks, and personal aspirations affect their mental health trajectories. General social trends such as a globalizing economy, changing marriage and divorce rates, and women entering the work force in increasing numbers as well as historical events, including wars, economic depressions, or terrorist attacks, also can affect adult mental health. The impact of these trends and events varies by the age at which people experience them. Historical and generational trends also affect attitudes toward using mental health services, taking psychotropic medications, and the stigma of mental illness. These processes ensure that mental health is a dynamic rather than static object of study across the life course.

## DEFINITIONS OF MENTAL HEALTH AND THEIR RELATION TO THE LIFE COURSE

*Mental health* has a variety of meanings. On its face, it refers to a general feeling of well-being and an absence of mental health difficulties. Researchers and therapists, however, usually use the term in exactly the opposite sense: the presence of mental health *problems* or mental *illness*. Because mental health is now associated with poor mental health, this is the term that will be used in this chapter.

The initial studies of mental health in the community in the 1950s and 1960s used broad measures that had several characteristics (Langner, 1962). First, they did not distinguish types of disorders, even among those that were viewed as distinct. Instead, they contained a variety of symptoms characteristic of general depressive, anxious, and psychosomatic conditions. Scales combined symptoms of anxiety (e.g., restlessness, nervousness, heart beating hard), depression (e.g., low spirits, feeling apart, nothing seems worthwhile) and various psychosomatic symptoms (e.g., pains in the head, cold sweats, acid stomach). Second, they did not make a sharp distinction between healthy and disordered conditions but viewed mental health as a continuum that moved from mild, to moderate, to severe conditions. Third, they asked about general symptoms such as "do you ever have trouble sleeping," "do you have difficulties in concentrating," or "do you ever feel lonely" that were common in nonclinical community samples. Because they emphasized such ordinary problems, researchers found that the vast majority of respondents reported some mental health problem. Indeed, those who reported no symptoms were the exception rather than the rule in these studies.

General and continuous symptom scales, however, have several weaknesses for the study of mental health.

One is that they do not measure serious mental disorders, which are highly stigmatizing and associated with tremendous suffering, limited role performance, and decreased life chances. A second limitation is that these general measures are not congruent with the discrete conditions that have been the focus of mental health professionals since the development of the *American Psychiatric Association's Diagnostic and Statistical Manual* (*DSM*) in 1980. Since that time, the mental health professions have focused on distinct mental disorders such as major depressive disorder, obsessive-compulsive disorder, posttraumatic stress disorder, and phobias, among many others. Finally, mental health policy is most concerned with serious and persistent mental disorders, not the conditions of generalized distress measured by continuous symptom scales. Although general scales of distress are very useful for uncovering the benefits and flaws of social conditions, they have not proven to be very useful for mental health policy making.

This review provides a general overview of depression, anxiety, phobias (a class of anxiety disorders), and anger during adulthood, as well as the treatment of these conditions. It pays special attention to age differences, changes over the life course, and changes over time in each condition. Full knowledge about how mental health varies across the life course requires long-term prospective studies across many different age cohorts. Because such studies are not available, much of our knowledge about mental health over the life course is provisional and subject to error. This review also discusses some of the major problems that studies of mental health over the life course confront and some of the implications of their findings for public policy.

## DEPRESSION

Depression is the single most common diagnosis in psychiatric treatment and one of the most common disorders in the population. It involves states of sad mood, diminished pleasure, sleep and appetite difficulties, fatigue, lack of concentration, feelings of worthlessness, and thoughts of death. Studies in the United States estimate that about 16% of people suffer from major depressive disorder over their lifetime and about 7% have experienced the disorder during the past year (Kessler, Berglund, et al., 2005; Kessler, Chiu, Demler, & Walters, 2005). Major depression disorder is the central disorder in the broader category of mood disorders, which also include bipolar disorder, a serious condition that features mood swings between elation and deep depression, and dysthymia, which features milder but very persistent symptoms of sad mood.

Rates of depression generally decline as people get older. People in their late teens and early twenties consistently report the highest levels of depression. Some studies indicate that middle-age people have the lowest levels of depression whereas other researchers have found that groups including participants 60 years old or older reported the lowest amounts (George, 2007). These patterns seem to be primarily due to the relationship of age and changing economic status: Young people have the lowest and least stable levels of income, and income in turn is a well-documented correlate of depression. In addition to economic well-being, changing patterns of interpersonal relationships, physical health problems, and discrepancies between aspirations and accomplishments also partially account for age differences in depression. The relationship between age and depression also changes across different generations. For example, growing economic security among recent cohorts of the elderly has improved their mental health status relative to other age cohorts.

Experiences in childhood and adolescence have strong effects on mental health at later stages of the life course. Traumatic childhood experiences such as parental abuse or neglect that lead to a lifelong sense of helplessness and other negative cognitive states often make people prone to develop depressive symptoms as adults (Seligman, 1975). Most studies also show adverse effects of parental divorce, especially when it occurs very early in a child's life, on later rates of depression, although the impact of parental divorce on adult mental health might be declining as divorce becomes more common (Cherlin, Chase-Lansdale, & McRae, 1998). Other studies show that socioeconomic conditions during childhood, especially prolonged states of poverty, are associated with depression during adulthood (McLeod & Shanahan, 1996).

Although early experiences do influence later mental health, they do not determine it, because social changes during adulthood alter life trajectories. For example, finding parental substitutes can mitigate the impact of early parental divorce or death (Brown & Harris, 1978). Likewise, the adverse influence of poor economic circumstances on depression during childhood can be overcome through occupational and educational attainment later in life. In addition, childhood is not the only stage of the life course that influences mental health during later periods. Deborah Carr's (1997) research showed that the occupational aspirations women held during their early 30s influenced their levels of depression when these women entered their middle 50s. Those women who did not meet their earlier aspirations had more distress and less purpose in life than women who achieved the goals they set earlier in life. These processes are also tied to historical contexts. Women who are members of birth cohorts that did not value or have opportunities for achievement outside the home were more content with their statuses as homemakers; conversely, younger cohorts of women were more likely to value pursuing careers and so may be more disappointed when they do not realize their expectations.

The importance of generational differences holds more generally. For example, marriage is especially beneficial and marital loss especially harmful for depression during historical periods when beliefs about the permanence, desirability, and importance of marriage are culturally strong and pervasive (R. W. Simon & Marcussen, 1999). Another example is that having a spouse die is more detrimental to levels of depression among recent cohorts of retired men than women (Umberson, Wortman, & Kessler, 1992). This could stem from the high value these men placed on occupational achievement so that widowhood symbolizes loneliness and the inability to manage daily affairs to them. Conversely, widowhood provides new opportunities for self-sufficiency for older women from the same cohorts.

Several other demographic and social factors are consistently associated with the likelihood of depression. Levels of depression among women are significantly higher than among men, usually about twice as much. This could be because women are more likely to be exposed to the kinds of stressful experiences that are associated with depression, including role overload because of conflicting demands from work and family obligations, and social and economic inequality. These stressors are themselves linked to gender role expectations in particular historical contexts and are not invariant. Alternatively, women might express their distress in forms such as depression whereas men react to similar stressors through substance abuse or violence. The expression of distress also varies across generations and historical periods.

Socioeconomic circumstances also have a consistent relationship with depression among adults. Adults with low incomes, who live in physically and socially hazardous environments, who are unemployed, and who are not well educated have higher levels of depression than individuals who have more resources (Eaton & Mutaner, 1999). The lasting impact of socioeconomic circumstances, however, is influenced by historical context. Glen Elder's classic study, *Children of the Great Depression* (1974), indicated that children who experienced childhood and adolescence during the stressful and economically deprived circumstances of the 1930s suffered adverse mental health effects as adults. However, the experience of the Great Depression did not have a lasting negative impact on the mental health of a somewhat older group in their 20s during this period. Elder's work indicates that the developmental impact of historical events depends on the age when they occur in a person's life.

Another consistent finding is that social and emotional attachments to other people are associated with low levels of depression whereas their absence is related to high levels. For example, married people report less depression than unmarried people (Umberson & Williams, 1999). This stems from several factors: Married people receive more social support, have stronger ties to community institutions, and display healthier and less risky behaviors. Conversely, divorced and separated people and, to a lesser extent, unmarried and widowed people report more depression. In contrast, ethnicity is one characteristic that does not seem to be associated with depression. Studies report inconsistent relationships between ethnicity and depression but, overall, do not indicate that any ethnic or racial groups are particularly likely or unlikely to become depressed.

Numerous theories have been proposed for why some people but not others become depressed, although no theory has yet been proven. Many studies associate depression with particular clusters of genes; however, it has not been confirmed that genetic dysfunctions cause depressive disorders. Other studies find that people with depression have smaller hippocampuses, a region of the brain that affects memory processes, although it is just as likely that depression itself or the medications that are used to treat it cause differences in brain size instead of the opposite (Sapolsky, 2001). Another popular biologic explanation of depression is the kindling hypothesis, which posits that social stressors trigger first episodes of depression but that stressful events are decreasingly likely to trigger future episodes, which are more likely to arise because of biologic vulnerabilities (Post, 1992). Although genetic and biologic studies have dominated recent research, consensus is growing that no single type of factor, whether genetic, biologic, psychological, or social, can solely cause depression (Kendler, 2005). Instead, researchers increasingly recognize that biopsychosocial explanations emphasizing the interactions between different levels of explanation offer the most adequate causal explanations for this condition.

Finally, rates of depression vary enormously across cultural contexts. One set of studies shows that rates of depression vary from a low of 3% of women in a Basque-speaking rural area of Spain to a high of over 30% of women in an urban township in Zimbabwe in East Africa (Brown, 2002). These disparate rates are directly related to the different numbers of severe losses suffered by people in these countries. Another summary of community surveys in 10 countries found lifetime prevalence rates that ranged from a low of 1.5% in Taiwan and 2.9% in Korea to a high of 16% in Paris and 19% in Beirut in Lebanon (Weissman et al., 1996). A third study found that rates of depression vary by a factor of 15 among primary medical care patients in 14 different countries (G. E. Simon, Goldberg, Von Korff, & Ustun., 2002). These diverse rates could be due to differences in the rates of social stressors leading to depression across cultures, diverse expressions of depression in different cultures, or methodological difficulties in using instruments that are not sensitive to cultural contexts. To the extent that these huge differences in prevalence across

cultures are real and not the product of methodological artifacts, they suggest that the early 21st century focus on unraveling the genetic correlates of depression might be misplaced and that more attention should be paid to societal impacts on the development of depression.

## ANXIETY

Anxiety disorders involve psychological feelings of worry, nervous tension, foreboding, threat, and alarm; behavioral manifestations such as hyperalertness and excitement; and somatic changes, including increased muscular tension, heart palpitations, difficulties breathing, raised blood pressure, and heavy sweating. Unlike the mood disorders, in which major depressive disorder is clearly the central condition, anxiety disorders are divided into a number of different types (although all generally share the somatic symptoms already mentioned). These include panic disorders that involve sudden and inexplicable episodes in which people lose control of their emotions and often have thoughts of dying (Barlow, 1988); obsessive-compulsive disorders, which feature intrusive, inappropriate, and recurrent thoughts and behaviors; posttraumatic stress disorders, in which the experience of an extreme stressor causes people to experience recurring symptoms of numbing, avoidance, and increased arousal; generalized anxiety disorders with excessive and persistent worries; and phobias, or intense fears of particular objects or situations, which is discussed in the next section.

In contrast to depression, which involves feelings of lethargy, inactivity, and hopelessness, fear and anxiety states are marked by tension, arousal, and alertness. Although depression usually concerns past losses of a love object, important resource, or valued goal, anxiety is directed toward some future threat or danger. Symptoms of anxiety can be normal if they arise in dangerous situations; anxiety disorders exist when people become seriously anxious when they do not face a dangerous situation or their symptoms are disproportionately severe or prolonged relative to their cause.

As a group, anxiety disorders are the most commonly occurring type of mental disorder. Some studies have shown that slightly more than 18% of the American population had experienced an anxiety disorder over the past year and nearly 30% at some point in their lives (Kessler, Berglund, et al., 2005; Kessler, Chiu, et al., 2005). Specific and social phobias are by far the most commonly occurring anxiety disorders, followed by posttraumatic stress disorder, generalized anxiety disorder, separation anxiety disorder, and panic disorder.

As with depression, age and rates of anxiety disorders are inversely related: People over 60 years of age report substantially less anxiety over their lifetimes than those who are younger. The reported age of onset (or first occurrence) for most anxiety disorders is usually during childhood and adolescence, earlier than for depressive disorders. Most people who experience an anxiety disorder at some point in their life report having had their first episode by age 15.

The social correlates of anxiety disorders are comparable with those for depression: being female, unmarried, and of low socioeconomic status, although the relationship of socioeconomic status and anxiety disorders is often not as clear as is the case for depression. Most people who have anxiety disorders also have family members with histories of mental disorder. Most research, however, indicates that little specificity exists in family history: Family members of an affected individual are likely to have some sort of anxiety, mood, or substance use disorder but not necessarily the particular type of disorder that the individual has.

Some researchers have suggested that the social triggers of anxiety and depression are distinct (Finlay-Jones & Brown, 1981). In particular, stressful life events that involve fear generate anxiety whereas events that feature the loss of some valued resource trigger depression. Other scholars, however, suggest that anxiety and depression reflect the same biologic vulnerability to overreactive responses to stressful life events of all kinds (Barlow, 1988). A difficulty in testing these competing explanations is that most major stressful life events involve both fear and loss, so it is difficult to separate these two components. For example, marital dissolution often involves the loss of a valued relationship, but it also may create uncertainties about finances, relationships, children, living conditions, and so on. Few life events solely involve fear or loss, and they typically generate both anxiety and depression.

## PHOBIAS

Phobias are a class of anxiety disorders that involve such strong fears of specific objects or situations that people become extremely uncomfortable and even try to avoid the cause of the fears. The two major subtypes of phobias are simple phobias, which involve specific fears such as snakes (ophidiophobia), spiders (arachnophobia), or heights (acrophobia), and social phobias, which feature extreme anxiety and avoidance of situations in which people are exposed to the scrutiny of others, such as when they must speak in public. The sorts of things that most people are phobic about are not the things that are actually most dangerous in modern life, such as automobiles, guns, or electrical outlets. Instead, people seem to be predisposed to fear the sorts of things that were dangerous many thousands of years ago when the human genome was being formed, such as animals, darkness, strange places, and heights.

Phobias are the most commonly occurring specific mental disorder. At any particular time, about 9% of the U.S. population reports having had symptoms of a specific phobia, about 7% of social phobia, and about 3% of agoraphobia (a debilitating and causeless condition that makes those afflicted afraid to leave the home or, in a more general sense, any wider area that does not provide a sense of comfort and ease) in the past year (Kessler, Berglund, et al., 2005). About 13% reports lifetime experiences of some specific phobia, about 12% of social phobia, and about 7% of agoraphobia. The correlates of phobias (e.g., childhood experiences of physical and sexual abuse, parental history of mental disorders, female gender) are comparable with the predictors of other anxiety disorders.

Social phobia has been the subject of intense debates over whether it represents a true disorder or a variant of the normal personality trait of shyness. Social phobia was not even mentioned in psychiatric diagnostic manuals until 1980. When it appeared for the first time, the manual noted that "The disorder is apparently relatively rare" (American Psychiatric Association, 1980, p. 228). Studies of the disorder before 1980 indicated that only about 1 to 2% of the population reported this condition. Yet, more recent studies find that 12% experience social phobia at some point in their lives and about 40% of people report at least one of six social fears, the most common being fear of public speaking (Kessler, Stein, & Berglund, 1998).

Very small changes in the wording used to measure social phobias account for their huge increase. For example, changing the wording of questions that ask about fears of public speaking from having extreme distress when "speaking in front of a group you know" to "speaking in front of a group" doubled the number of positive responses. Likewise, changing the criteria from have "a compelling desire to avoid" fear-inducing situations to having "marked distress" in these situations resulted in a sharp increase in the reported amount of social phobia. The result was that the percentage of the American population with a lifetime experience of social phobia increased from 2% to 3% to 13.3%, a nearly six-fold increase, and has remained at comparably high levels since.

Critics suggest that the extreme growth in rates of social phobia after survey researchers make only minor changes in wording indicates that surveys might create rather than reflect these conditions (Horwitz, 2001). Others note the influence of pharmaceutical companies in defining the normal personality trait of shyness as a mental disorder to increase sales of their products (Lane, 2007). Many of the *symptoms* of social phobia such as apprehension about speaking in public seem to be normal fears and not mental disorders.

In contrast, advocates of viewing social phobia as a true mental disorder cite the distress, hindered educational and occupational performance, and greater levels of substance abuse among people with social phobia (Kessler et al., 1998). They also note that people with social phobia do not prefer to avoid others but intensely desire to have normal social interactions. They are unable to control their fears and so find certain sorts of social interactions intensely uncomfortable. The controversy over the pathology or normality of the symptoms of social phobia illustrates the difficulty of separating ordinary distress from mental disorder.

## ANGER

Unlike the vast literature regarding depression, anxiety, and phobia, anger is relatively understudied. It refers to feelings ranging from frustration, irritation, and annoyance to fury and rage. It can remain unexpressed, be manifest verbally, or result in behavioral aggression and violence. Anger is intensely social because it is typically directed at other people or social situations. Often, these feelings involve some sort of perceived unfairness between angry people and the target of their anger

Although the *DSM* defines intermittent explosive disorder (IED), this diagnosis has received far less attention than other common mental health conditions. The *DSM* criteria require several discrete episodes involving failure to resist aggressive impulses that lead to serious assaultive acts or property destruction and are disproportionate to a precipitating psychosocial stressor. The first large population survey that measured the prevalence of IED found that more than 5% of respondents qualified for this diagnosis (Kessler et al., 2006). People seem to get less angry as they grow older: Anger is greatest among young adults, declines in midlife, and is lowest among the elderly. Lifetime prevalence of IED was inversely associated with age so that patients ages 18 to 29, 30 to 44, 45 to 59, and over 60 reported declining levels of 7.4%, 5.7%, 4.9%, and 1.9%, respectively. Although the reasons for this are not clear, it is possible that as people age they become more settled and tolerant of situations that produce anger among younger people, or they simply face fewer situations that they regard as unfair.

Because anger is inherently social, it is related to intense interaction with other people (Schieman, 2006). Parents report more anger than the childless, and people who live alone are less angry than those who live with others. Unlike depression and anxiety, which are primarily disorders of girls and women, most people with anger-related disorders are male. It is not yet clear whether the male predominance in anger disorders reflects biologic and psychological predispositions or cultural expression rules that are more tolerant about male than female

displays of anger. Anger is also strongly related to feelings of unfairness: People are angry at those who they believe have received unfair advantages. Workmates who are perceived to have received inequitable economic rewards or promotions, spouses who shirk household and child-care duties, or students who receive unequal treatment are commonly sources of anger. Conversely, situations of social equality are less likely to produce angry emotions.

## INCREASING RATES OF MENTAL ILLNESS?

One of the most puzzling aspects about lifetime rates of all of the conditions considered in this entry is that studies at one point in time consistently show that older people have lower rates of lifetime prevalence of each mental illness. Depression illustrates this pattern. About 25% of people between 18 and 29 years old have had a depressive episode compared with 24% of people 30 to 44 years old, 20% among those 45 to 59 years old, and only 13% for those over 60 (Kessler, 2005). This finding, and similar findings for anxiety, phobia, and anger, is unexpected because, the older people get, the more years they have been at risk for developing a disorder. Older people have passed through each earlier stage of the life cycle so that, other things being equal, their lifetime rates of disorders should generally always be higher than those at younger ages. Yet, epidemiological studies show that lifetime rates of all disorders decrease as people age. What factors account for this phenomenon?

One possibility is that social changes have led to increasing rates of mental illness in each succeeding birth cohort. Many researchers have concluded that actual increases in rates of mental disorders have occurred in successive generations (e.g., Klerman & Weissman, 1989). This explanation, however, is not very plausible for a number of reasons.

Studies that measure mental illness prospectively uncover a striking fact about the reporting of mental illness over time. About half of survey respondents who report a mental illness at one point in time cannot recall the episode after as short an interval as 18 months (G. E. Simon & Von Korff, 1995). This could be because they simply forget the episode or because the symptoms were not sufficiently serious to be recalled. These studies also show a consistent inverse relationship exists between the length of time since an episode of depression occurred and people's ability to recall it. Lifetime age of first onset of mental illness reports are about 5 years before an interview, regardless of a respondent's age. These findings have a number of implications for estimating lifetime prevalence across different generations.

First, because most depressive episodes occur during younger ages, older people are more likely to forget previous episodes because longer periods of time have passed since they experienced the episode. Memories naturally fade when the events they refer to are no longer relevant to the individual. Second, current negative states of mind strongly affect people's recall of past negative states. What people remember depends on their current circumstances and mood when they are asked to remember past episodes of mental illness. Because older people are less likely to have current episodes of depression that can serve as reminders for past episodes they are also less likely to report past episodes. In addition, current older cohorts might be more reluctant than younger ones to acknowledge symptoms of mental illness.

Third, no theory about the cause any mental disorder predicts a consistent increase in prevalence over historical time. Genetic and psychological explanations rely on factors that are invariant or change very slowly over time and so are inconsistent with these trends. Although social theories do predict changing rates of mental disorder over time, they cannot account for why trends have increased so steadily and consistently across all types of disorders. Some social predictors of mental disorders such as rates of parental divorce and living alone have become more common, but others such as poverty and education levels have improved; many other trends, including unemployment and crime victimization, are not consistent over time. Finally, most prospective studies of the same people over several decades do not show rising rates of depression among younger cohorts (e.g., Murphy, Laird, Monson, Sobol, & Leighton, 2000).

The consistent finding that increasing age is associated with lower lifetime prevalence of all the disorders considered here is likely to be due to the difficulty people have in remembering and reporting emotional states that occurred in the distant past. It is much less likely that successive birth cohorts have experienced higher lifetime rates of mental disorder. Retrospective reports of subjective feeling states that occurred a long time ago should be viewed with skepticism.

## MEDICATIONS AND TREATMENTS

People born at different times have had vastly different experiences with the mental health system. Cohorts who entered adulthood during the 1930s, 1940s, and 1950s faced a mental health system that was largely dependent on large, public inpatient institutions. Since that time, most mental health treatment has occurred in outpatient settings or in private or general hospitals. Older people are more likely to associate mental illness with severe and stigmatizing conditions and are less likely to have favorable attitudes toward using mental health services than younger ones. Conversely, cohorts born more recently have been socialized to a therapeutic culture that emphasizes using mental health services and, especially, taking psychotropic

medications. The use of various mental health services, therefore, reflects strong generational effects.

Far more people received treatment for mental health problems in the early 2000s than in the decade preceding. For example, the proportion of people receiving treatment for depression has increased substantially. About 60% of people who report this condition in population surveys now obtain treatment for it, a nearly 40% increase since the early 1980s (Kessler et al., 2003). The percentage of the population in therapy for depression in a given year grew from 2.1% in the early 1980s to 3.7% in the early 2000s, an increase of 76% in just 20 years (Wang et al., 2006). The rate of outpatient treatment for anxiety disorders nearly doubled between 1987 and 1999, from 4.3 of every 1,000 people in 1987 to 8.3 of every 1,000 people in 1999 (Olfson, Marcus, Wan, & Geissler, 2004). Several factors account for rising rates of treatment for depression, anxiety disorders, and phobias, including increased mental health advocacy efforts, the emergence of direct-to-consumer advertisements for psychotropic medications, and growing perceptions of more efficacious and safe medications. People with anger disorders, however, are highly unlikely to seek mental health treatment: not surprisingly, they think that the objects of their anger, not themselves, are the ones at fault for their feelings.

The kinds of treatments people receive for depression and anxiety have also changed dramatically since the 1980s. About 75% of visits to physicians for therapy to resolve mental health problems now involve the use of some medication (Zuvekas, 2005). The most striking change has been the vast increase in the use of antidepressant medications. The use of antidepressants, including fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), venlafaxine (Effexor), and fluvoxamine (Luvox) nearly tripled between 1988 and 2000; in any given month, 10% of women and 4% of men use these drugs. From 1996 to 2001 alone, the number of patients receiving therapy involving selective serotonin reuptake inhibitors, often called SSRIs, increased from 7.9 million to 15.4 million. Therapy involving antidepressants is especially popular among patients currently in their young adult years, although the rate of increase in the use of these drugs is also striking among the elderly (Crystal, Sambamoorthi, Walkup, & Akincigil, 2003).

The rising use of antidepressant medications has been accompanied by a sharp drop in the use of psychotherapy (treating mental, or emotional, or behavioral disorders, generally by means of extensive talk) since 1990 (Wang et al., 2006). For example, patients treated for anxiety disorders in 1999 were approximately half as likely to receive psychotherapy as they were in 1987. The decline in the use of long-term psychotherapy has been especially sharp (Olfson et al., 2002). For example, although cognitive-behavioral therapy (a type of treatment of mental illness that teaches the patient to try to adapt to stress and the environment by thinking about phenomena using precepts taught by the therapist) is often effective for the treatment of anxiety disorders, psychiatrists rarely use it.

A number of reasons account for the rising rates of drug treatment and falling rates of psychotherapy. One concerns the growing importance of managed health care, which relies on strategies that reduce health care expenditures by supporting the least expensive possible treatments (Mechanic, 2007). Most managed care plans provide more generous benefits for drug than for psychotherapeutic treatments and usually place no barriers on antidepressant use. Conversely, these plans often have severe limits on payments for psychotherapy. The result is that patients themselves prefer drug treatments because they involve lower out-of-pocket costs.

In addition, managed care also encourages the use of general practice physicians, who almost always prescribe medication, instead of mental health specialists who are more likely to use psychotherapy. As a result, most of the expansion of mental health treatment occurred in the general medical sector (Wang et al., 2005). Between the early 1990s and early 2000s, rates of mental health service use increased 159% in the general medical sector compared with 117% in specialty psychiatric services and 59% among other mental health personnel (Wang et al., 2006).

Another major trend leading to the growing use of medications has been the massive use of direct-to-consumer drug advertisements in the popular media. Before 1997, drug advertising could only be directed to physicians. Since that date, drug companies can appeal directly to consumers, who have flocked to physicians with requests for these drugs. Other reasons for the changing patterns of mental health treatment include increased mental health advocacy efforts, often funded by pharmaceutical companies, and the more widespread use of screening instruments aimed at detecting mental illness.

The widespread use of antidepressant medications has raised concerns about the harmful consequences of overmedication. These include potential adverse effects from long-term use of antidepressants and other psychotropic drugs, withdrawal difficulties, and their questionable effectiveness for treatment of mild disorders. In addition, the widespread use of medication as a first-line treatment can preclude consideration of other sorts of treatments, including various forms of psychotherapies as well as self-help alternatives such as changes in diet and exercise and the use of natural networks of social support.

## GAPS IN KNOWLEDGE

Many issues about mental health among adults are actively debated. One puzzle regards definitions of mental

disorder. Many mental health professionals and researchers assume that any psychological condition that results in negative outcomes must be a mental disorder. The problem with this assumption is that it defines an enormous amount of human behavior as abnormal. Community surveys of mental illness indicate that almost half the general population has a mental illness at some point in their lives and more than one quarter have experienced a mental illness more than the past year. Yet many of these conditions might actually be temporary and understandable responses to distressing events such as romantic breakups, job losses, or receiving news that an intimate (or oneself) has a life-threatening illness (Horwitz & Wakefield, 2007). Feelings of sadness, fear, shyness, and anger can be impairing but are not necessarily indications of disordered depression, anxiety, social phobia, or IED. Even so, researchers assume that acknowledgement of items on self-reported surveys indicate signs of a mental disorder as opposed to natural responses to distressing social contexts. Much work needs to be done in developing techniques that can distinguish appropriate negative emotions from mental disorders.

The separation of normal from disordered emotions is especially important because it has implications for health care policy. Treating normal emotions as if they were disordered can lead to pharmacotherapy that is neither necessary nor helpful. In addition, this point of view can lead to interventions that are based on pessimistic notions of human resilience. For example, shortly after the September 11, 2001, terrorist attacks, the Commissioner of the New York City Health and Mental Hygiene Department told Congress, "We face the possibility of a sharp increase in chronic and disabling mental health problems" (Satel, 2003, p. 1571). Although studies did show sharp increases in rates of mental health problems in the immediate aftermath of the attack, rates had returned to normal within 6 months of that date (Galea et al., 2002). During the same period, rates of use of mental health facilities did not show any substantial increase. In fact, residents of New York City, Washington D.C., and the United States in general showed great psychological resilience. Mental health policy greatly underestimates the ability of people to manage distressing events through self-help, social support, and informal community institutions.

Another puzzle regards the explanation of the young mean age of onset of most mental disorders, which is between 7 and 15 years for impulse control disorders, 6 to 22 for anxiety disorders, and 18 to 43 for depressive disorders (Kessler, Berglund, et al., 2005). In addition, as has been seen, as people grow older their chances of developing a mental disorder decrease. This pattern is exactly the opposite of that for virtually all chronic physical disorders not present at birth. Why mental disorders uniquely arise during the prime reproductive years and then have declining frequency poses a yet unsolved (and rarely addressed) evolutionary puzzle.

A third issue regards whether the current diagnostic system, which sharply distinguishes many distinct disorders from one another, is optimal or whether broader and more continuous categories better fit the underlying reality of most disorders. The bulk of the evidence indicates that many disorders, especially all the anxiety disorders and forms of depression, could be variable expressions of a similar underlying abnormality (Barlow, 1988). Most of the disorders considered here have very high rates of co-occurrence. Patients with one anxiety disorder usually also have additional anxiety disorders: For example, about 80% of patients with generalized anxiety disorder have some additional disorder. Nearly 90% of patients with agoraphobia and more than 80% with simple and social phobias also report at least one other type of mental disorder (Magee, Eaton, Wittchen, McGonagle, & Kessler, 1996).

In addition, anxious people generally have concurrent symptoms of depression whereas depressed people often present concurrent symptoms of anxiety. The causes, prognoses, and treatments for distinct disorders share more similarities than differences, suggesting that the current emphasis on distinct disorders is as much of a product of the social organization of the mental health professions and their desire to receive economic reimbursement for their services as of scientific knowledge. This has led a number of scholars to suggest that the various anxiety and depressive disorders are variants of the same temperamental type that might better be called *neurotic* or irrationally *harm-avoidant* (e.g., Akiskal, 1998). From this viewpoint, people might inherit predispositions to develop anxiety and mood disorders in general, not a particular type of disorder.

A final gap is the lack of knowledge about how mental health has changed over different birth cohorts and historical time. As already suggested, claims of substantial increases in mental health problems in recent decades seem to have more to do with changes in diagnostic criteria and measurement problems than with actual changes in either mental health or the social conditions that give rise to mental health symptoms. Researchers lack the kinds of prospective studies, particular those undertaken over long periods, that can better estimate changes in mental health over time. Similarly, little is known about how large scale historical trends such as the negative effects of globalization of work, macroeconomic changes, changing gender roles, rising income inequality, and other major social changes affect mental health over the life course.

## POLICY ISSUES

Almost all mental health treatment now takes place in community settings. Most hospitalization that does occur

is usually of brief duration and in general or private hospitals rather than public mental institutions. No indications confirm that the mental health system will return to the widespread use of the large, public inpatient institutions that dominated the system in the 19th and much of the 20th centuries. The challenges for mental health policy lie in delivering the most effective treatment in community-based systems.

One important policy issue regards mental health disorders receiving parity with more clearly physical disorders—that is, the payment for the treatment of mental disorders be seen as on an equivalent basis with physical disorders. At present, long-term treatment, inpatient care, and psychotherapy are reimbursed at lower rates and for shorter periods of time than physical disorders. To date, the many efforts at remedying this situation have not been successful, largely because of fears that parity in payment for mental disorders has the potential to bankrupt the health care system. If the substantial number of people who indicate that they have untreated mental disorders became more likely to seek treatment, it might be impossible for insurance companies or the federal government to cover the costs. Because of these concerns and their implication for mental health parity, it is especially important for the field to develop definitions of mental illness that include conditions that benefit from professional treatment while excluding those that will usually resolve in the absence of professional care. Limiting parity to serious mental disorders may result in a system that is oriented toward treating those conditions that can benefit the most from professional treatment.

The issue of prevention is also critical. Many mental health policies, such as screening for unrecognized mental disorders in primary medical care or in schools or bringing in grief counselors in the immediate aftermath of traumatic events, are based on the assumption that rapid identification and treatment of mental disorders can not only relieve current distress but also prevent more serious disorders from developing in the future. Although prevention has theoretical appeal, it also entails certain costs. Some evidence does suggest that prevention can have positive effects within comprehensive health care settings, but there is no evidence for its efficacy in regular mental health practice. Indeed, evidence is overwhelming that some common forms of prevention, such as single-session debriefings after traumas, are not only ineffective but can be harmful (Rose, Bisson, Churchill, & Wessely, 2002). In addition, given the size of the population with untreated mental disorders, focusing on identifying and treating people with unmet needs for mental health care could overwhelm the health care system. This, in turn, could lead the mental health system away from people with the greatest need for professional services toward those who neither want nor will benefit from treatment.

A final general issue relates to the costs and benefits of subjecting a wide range of human problems to medical care. *Medicalization* refers to defining and treating problems that previously were been outside the medical system as problems to be handled by medical techniques. Normal sadness becomes major depressive disorder, fear is transformed in a variety of anxiety disorders, shyness becomes social phobia, and anger becomes IED. Medicalization promises the benefits of efficient, socially valued, and nonstigmatizing treatment that can often relief the pain of unpleasant emotional experiences. It has the potential costs, however, of neglecting alternative, and sometimes more effective, ways of responding to problems, atrophying self-help solutions, and disregarding the importance of fostering human agency.

# MIDLIFE CRISES AND TRANSITIONS

The boundaries of midlife are not well defined; however, the most common conception is that middle age begins at 40 and ends at 65 (Lachman, 2004). This period is characterized by a remarkable complexity of roles, relationships, and resources. Despite the image of midlife as

a relatively stable life stage, middle-aged adults typically experience multiple life crises and transitions, many of which pose developmental and social challenges. Important crises and transitions include menopause, parental death, marital dissolution, children leaving home, problems in the lives of adult children, and caregiving responsibilities. These events often entail negative consequences, such as economic hardship, social isolation, psychological distress, and threat to self-concept. Yet these adverse repercussions are often short-lived, and over time individuals may even experience positive consequences, such as wisdom, personal growth, improved coping skills, and stronger interpersonal relationships.

## DEFINITIONS OF MIDLIFE CRISES AND TRANSITIONS

Developmental and life span psychologists conceptualize crisis as a normative developmental challenge, a crucial point at which individuals can develop in alternative ways (Lachman & James, 1997). Early work on adult development focused on life stages and orderly transitions. For example, Erik Erikson (1963) placed midlife in the context of eight lifespan stages, whereby each stage encompassed a crisis, or a challenge that needs to be resolved. In midlife, the central challenge is achieving generativity, or moving past a narrow focus on one's self, and instead nurturing and guiding the next generation (Lachman, 2004).

Sociologists, by contrast, conceptualize crises as stressors with potentially adverse consequences for physical and mental health. The meaning of specific stressors is understood from a life course perspective, which places individual development in the context of historical, cultural, and social structures and processes (Bengtson & Allen, 1993). A transition—one of the key concepts in life course research—is a change in status that is discrete and bounded in duration, although it may have long-term consequences (George, 1993). Many transitions are stressors because they threaten well-being and require coping and adjustment (Pearlin, 1999).

Psychological and sociological perspectives on crises and transitions intersect in the notion of a psychological "turning point"—an important life situation or a new insight into one's self that becomes a motive for redirecting and changing one's life (Clausen, 1995). Turning points at midlife can be brought on by both positive and negative experiences.

## COMMON CRISES AND TRANSITIONS IN MIDLIFE

One of the most popular images of midlife is the experience of a "midlife crisis." Research and theory in the 1970s described the midlife crisis as an almost exclusively male phenomenon. It was viewed as a crisis of identity that involved increased introspection, a realization of limited time, and a preoccupation with lost opportunities (Rosenberg, Rosenberg, & Farrell, 1999). However, since then researchers have found little evidence to support the idea that the midlife crisis is a universal developmental phenomenon (Wethington, Kessler, & Pixley, 2004). Instead, other crises and transitions appear to have more profound implications for midlife development.

**Menopause** Menopause has been traditionally viewed as women's midlife crisis because it is a major change in reproductive capacity. Researchers have found no evidence to support the stereotypical view that women hold negative attitudes toward menopause (Avis, 1999). Another notion that persists is that menopause commonly leads to depression. Community-based studies demonstrate that psychological trauma and distress are not typically associated with this normal transition in women's lives (Avis, 1999). The so-called "menopausal syndrome" is more likely explained by personal characteristics and past experiences, such as previous history of depression, than menopause per se (Avis, 1999).

**Parental Death** The death of a parent during middle age is widely recognized as a life-course marker (George, 1993). Parental death may be less stressful than other types of bereavement, partly because it is considered a normal part of middle age. Still, it is a major turning point for most people. It may compel individuals to confront their own mortality, leading to a reevaluation of identities, values, and behaviors (Kranz & Daniluk, 2002). Losing the buffer of the parent generation may force one to finally "become an adult" and may also promote psychological growth, increased maturity, and a greater appreciation of personal relationships (Aldwin & Levenson, 2001).

**Marital Dissolution** Spousal death is most likely to occur to adults in their 70s and older, whereas divorce typically occurs during the first decade of marriage in young adulthood. Thus, both divorce and widowhood are "off-time" transitions at midlife. Off-time events, or events that occur earlier or later than expected, may have particularly stressful consequences (Neugarten, Moore, & Lowe, 1965). Middle-aged widows—those widowed before 60—are more likely than their older counterparts to become poor (Holden & Smock, 1991). Similarly, divorced middle-aged women might experience greater financial problems than their younger peers because the most pronounced declines in per capita income are associated with marriages of longer duration (Holden & Smock, 1991), and middle-aged women have been married, on average, for a longer period than women who divorced in young adulthood. Among men, marital dissolution may be associated with social isolation

and loss of emotional intimacy (Gerstel, Riessman, & Rosenfield, 1985).

A study of men and women who became widowed or divorced between their mid-50s and mid-60s (Pudrovska & Carr, 2005) showed that recently bereaved and divorced persons report higher levels of depression and alcohol use, even after adjustment for selection factors, health, family characteristics, and social and socioeconomic resources. This effect may reflect the fact that persons who lose a spouse or become divorced in their 50s or early 60s have few peers who share their experiences and may lack institutional supports to help them cope with marital loss, given that most recently divorced persons are young adults under 40, whereas most recently bereaved persons are older adults.

**Empty Nest and Problems in the Lives of Adult Children** In the family life cycle approach (Glick, 1977) the empty nest following the launching of the last child is a quintessential midlife stage. The launching process minimally extends from the time the first child leaves home for the first time to the time when the last child leaves home for the last time (White, 1994). The empty nest tends to occur later for parents who are in their intact first marriage, are African or Mexican American, and have more children, more sons, more unmarried children, or a higher income (Aquilino, 1990).

The empty-nest stage has been traditionally viewed as a difficult time for midlife women. This transition symbolized the end of women's most intensive years in the mother role, which was usually considered one of the most fundamental sources of a women's identity (Black & Hill, 1984). Although early clinical studies reported depression following the empty-nest transition, more recent studies of the general population revealed positive psychological outcomes for empty-nest parents (White & Edwards, 1990). The empty nest was shown to be associated with improved marital happiness for all parents and increased overall life satisfaction when there was frequent contact with nonresident children (White & Edwards, 1990).

Because of the increased importance of college education, rising ages at marriage, and soaring housing costs, current generations of young adults remain in the parental home longer than prior generations (Aquilino, 1990). These trends have created a demographic context in which the empty nest is no longer a nearly universal experience at midlife. William Aquilino and Khalil Supple (1991) suggested that most parents who coreside with young adult children report high levels of satisfaction with the presence of children at home, particularly when the quality of parent–child relationships is high. Yet parental satisfaction is adversely affected by adult children's inadequate income and inability to maintain an independent household.

Overall, parents are distressed when their adult children have problems—whether children live in the parental household or independently. Adult children's problems, such as illness, unemployment, financial difficulties, and strains in marital relationships, are associated with parents' greater negative affect (Pillemer & Suitor, 1991), lower levels of positive affect, less self-acceptance, and poorer parent–child relationship quality (Greenfield & Marks, 2006).

**Caregiving Responsibilities** The middle-aged are often viewed as the "sandwich generation" who experience financial, psychological, and physical demands from responsibilities to both younger and older generations while being in the paid labor force, although only a minority of middle-aged adults provide care to their children and parents at the same time (Marks, 1996). Yet more than half of the women with a surviving parent spend at least some time in a caregiving role (Himes, 1994). Women in the middle often face caretaking dilemmas and are more likely than men to sacrifice their careers to take care of spouses and parents (Moen & Wethington, 1999). Caregiving responsibilities often force women to either terminate their employment or reduce work hours, which results in decreased income (Evandrou & Glaser, 2003). As a chronic strain, caregiving may adversely affect caregivers' physical and mental health (Aneshensel, Pearlin, Mullan, Zarit, & Whitlach, 1995). Yet research also reveals psychological benefits from caregiving, such as mastery, self-esteem, and mattering—the sense of being a person of significance to the well-being of loved ones (Moen, Robinson, & Dempster-McClain, 1995).

## COPING WITH CRISES AND TRANSITIONS

The challenges of midlife are typically matched by the extensive material, psychosocial, and coping resources of middle-aged adults; thus, most people in midlife successfully adjust to crises and transition and show resilience to burdening and demanding circumstances (Heckhausen, 2001). One of the most consistent findings to emerge from research on crises is that the negative psychological and interpersonal consequences of stressful events are relatively short-lived, and that psychological well-being of individuals who experience even the most disruptive transitions eventually approaches precrisis levels (Booth & Amato, 1991).

Research has increasingly focused on the positive consequences of crises, such as posttraumatic growth (Tedeschi, Park, & Calhoun, 1998) or the perceived benefits of stress (Aldwin & Sutton, 1998). Crises can lead to ego development, wisdom, stronger interpersonal relationships, more effective coping skills, and higher levels of mastery and self-

esteem (Aldwin & Levenson, 2001). For example, widowhood and divorce in the long term tend to be accompanied by a positive shift into a new life phase, personal growth, and increased sense of control (Feldman, Biles, & Beaumont, 2001; Umberson, Wortman, & Kessler, 1992).

## THE FUTURE OF RESEARCH ON MIDLIFE CRISES AND TRANSITIONS

Although midlife spans 25 to 30 years, little is known about the diversity *within* the middle-aged group with respect to specific periods of midlife, such as early midlife and late midlife (Staudinger & Bluck, 2001). The nature of crises and transitions confronting middle-aged adults is likely to differ by stages of midlife. However, many existing studies that examine such age differences use cross-sectional data and, thus, cannot fully distinguish intrapersonal changes within cohorts from intercohort variation (e.g., Ryff & Keyes, 1995). The use of longitudinal panel data can help to distinguish age-related developmental processes from differences among birth cohorts.

The experiences of members of racial and ethnic minorities at midlife have remained largely unexplored. Yet the nature, antecedents, and consequences of crises confronting middle-aged White persons do not adequately reflect the challenges and circumstances of other racial groups. Detailed racial and ethnic comparisons have not been a prominent theme in the literature.

Finally, demographic trends of recent decades have created a remarkable complexity of family structure and interpersonal relationships. Yet scholars still have limited knowledge about heterogeneity of individual trajectories and the so-called "nonnormative" pathways that become increasingly common, such as having a first child in midlife, choosing to remain single and/or childfree, and being in same-sex relationships and unions. Moreover, despite the trends in men's greater family involvement and women's unprecedented labor force participation (Casper & Bianchi, 2002), the interplay of work and family roles among middle-aged men and women have not been fully explored. Family statuses and transitions matter for midlife men's physical and mental health (Barnett, Brennan, Raudenbush, & Marshall, 1994), whereas career trajectories have profound implications for women's well-being (O'Campo, Eaton, & Muntaner, 2004; Simon, 1995). Given these trends toward increased complexity of family and work arrangements at midlife, public policies should be directed at facilitating work-family balance not only among young adults but also among middle-aged men and women.

# MILITARY SERVICE

Military service entails joining a branch of the armed forces through voluntary enlistment, conscription during a draft, appointment, or in some societies as a mandated duty of citizenship. In the United States, the military services include the Army, Navy, Air Force, Marine Corps, and Coast Guard. Active duty military service refers to full-time engagement in one of these services; it includes members of the Reserve Components when they are serving or in full-time training, but does not include full-time members of the National Guard. Each branch, listed above, has a reserve component. The reserve components of each branch are part-time military personnel who serve a period of active duty after attending basic and job training that usually last several months. Following this active duty training period, reserve personnel return to civilian life; however, for the remainder of their service obligation, they attend trainings and work in their job specialty for their unit one or two days per month. Additionally, they attend a two-week active-duty training each year. After 20 years of reserve service or upon reaching age 60 years, reserve personnel are entitled to a retirement benefit based on reserve pay. Members of the National Guard are under Federal and State jurisdiction, unlike members of the other armed forces, who are under Federal jurisdiction only.

Members of the National Guard can be deployed by the governor of their state or the president. When not

deployed on active duty, members of the National Guard are only required to train one weekend per month and during a two-week period each year. Veteran status is conferred upon those who are on active duty or have served previously on active duty and received an other-than-dishonorable discharge. Exposure to combat is not a prerequisite for active duty, veteran status or benefits eligibility. Active duty service encompasses a range of activities, including training, intelligence gathering, conducting maneuvers to ensure preparedness for combat, and serving domestically and overseas in various capacities deemed important for the defense of the Untied States and its allies.

Although there is variation across historical periods, such as when there is an ongoing war, draft, or mobilization of the Reserve Components, persons who serve in the military generally enter service at relatively young ages and exit after only a few years on active duty. From 1941 to 1973, American men of specific ages and a diverse range of personal characteristics were subject to a draft (Flynn, 1993). However, most men and women who have served in the U.S. military in the 20th and 21st centuries have done so voluntarily. Since 1973, the U.S. military has been in what is commonly known as the era of the All-Volunteer Force (AVF).

Military service is selective, reflecting both individual choices to enlist and the military's authority to reject those deemed incapable of serving effectively. To enter the military, people must meet specified eligibility criteria, pass physical and mental health screenings, undergo standardized training regimens, and be willing and able to adhere to the military code of conduct. Each of the military services is organized hierarchically by rank, with enlisted personnel broadly distinguished from officers. Enlisted personnel begin at the lowest rank in the military and serve as the main workforce within it. Enlisted personnel generally have high school educational attainments; with time, good service, training, and education, advancement can be expected. Officers enter a branch of the military services in a supervisory capacity and must have a 4-year college degree in order to be commissioned as an officer. The chain of command is clearly specified and enforced. While there is opportunity for advancement, especially among those who make military service a long-term career, the enlisted and officer ranks select persons with different characteristics and provide members with access to different types of assignments, risks, and rewards.

Researchers who study military service in relation to the life course recognize that the military is a powerful institution whose potential to transform lives for better or worse varies across individual characteristics, the timing of military service in the life course, service experiences, and historical periods. These insights serve as the foundation for theories about, and empirical life course studies of, the role of military service in men's and, to a lesser extent, women's lives. Taken as a whole, the existing body of life course research on military service succeeds in connecting "the micro- and macro-levels of analysis, thus connecting the soldier's story to that of his [or her] changing society" (Modell and Haggerty, 1991, p. 205).

## MILITARY SERVICE AND LIFE COURSE DISCONTINUITY

Studying the role of military service in the life course provides researchers with a rich opportunity to investigate each of the five major principles of the life course paradigm: human agency; location in time and place; timing; linked lives; and lifelong development. Glen H. Elder Jr. is responsible for some of the most influential theorizing about the role of military service in the life course and the importance of military service for life course studies. By focusing age at entry into the military, his work develops and tests two hypotheses: the military as turning point and as life course disruption. Both hypotheses emphasize the potential of military service to produce discontinuity in the life course.

The military as turning point hypothesis focuses on people who enter the military at younger ages, such as persons who enlist right after high school graduation, because the chances for redirection of the life course are maximized and disruption to an established life course is minimized. Elder (1987) argues that early entry into the military enables a pause in individual development, which both delays the transition to adulthood and allows for the maximal utilization of service benefits. Early entrants are often highly disadvantaged with few other options; they see military service as a route out of difficult life circumstances. These are precisely the persons who may benefit most from the health and educational benefits available to veterans.

According to the life course disruption hypothesis, an individual's relatively late entry into the military has the potential to interfere with established marital, parenting, and occupational trajectories, which may have consequences for the subsequent patterning of the life course and for outcomes later in life. Late entrants often come from more advantaged backgrounds than earlier entrants. Moreover, because late entrants are more likely to have completed their educations and will have less time upon completion of their service to take advantage of veterans' educational benefits, they may not experience the gains that accrue to more disadvantaged, earlier entrants. There are several reasons why people enter the military at older ages. Older entrants include people who enlisted or were drafted during a war; delayed entrance in order to

complete college or a service academy prior to being commissioned as an officer; entered as physicians to complete a "pay back" after the military paid for their medical education; decided after their transition to adulthood that they were prepared to handle the challenges the military entails or that the military offered them opportunities that were not available in the civilian sector; and responded to incentives for enlistment that the military sometimes offers.

Considerable research shows that early entry into the military can produce a positive turning point in the life course trajectories of initially disadvantaged men. For example, focusing mostly on veterans of World War II, Elder (1986) reports that early entrants had more disadvantaged family backgrounds, poorer grades, and lower feelings of self-adequacy. However, because military service delayed their transition to adult roles and responsibilities, they were able to equal the occupational achievements of, and have more stable marriages and experience larger gains in psychological strength than non-veterans. Early entrants were also much more likely than later entrants to report retrospectively that their lives had followed a different and more rewarding course as a result of their military service. Other studies also support the military as positive turning point hypothesis. For example, Sampson and Laub (1996, p. 364) conclude: "Military service in the World War II era provided American men from economically disadvantaged backgrounds with an unprecedented opportunity to better their lives though on-the-job training and further education" (see also Laub and Sampson, 2003).

Elder, Shanahan, and Clipp (1994) provide direct evidence in support of the life course disruption hypothesis. They report that for each year of delay into military service the economic and job benefits associated with

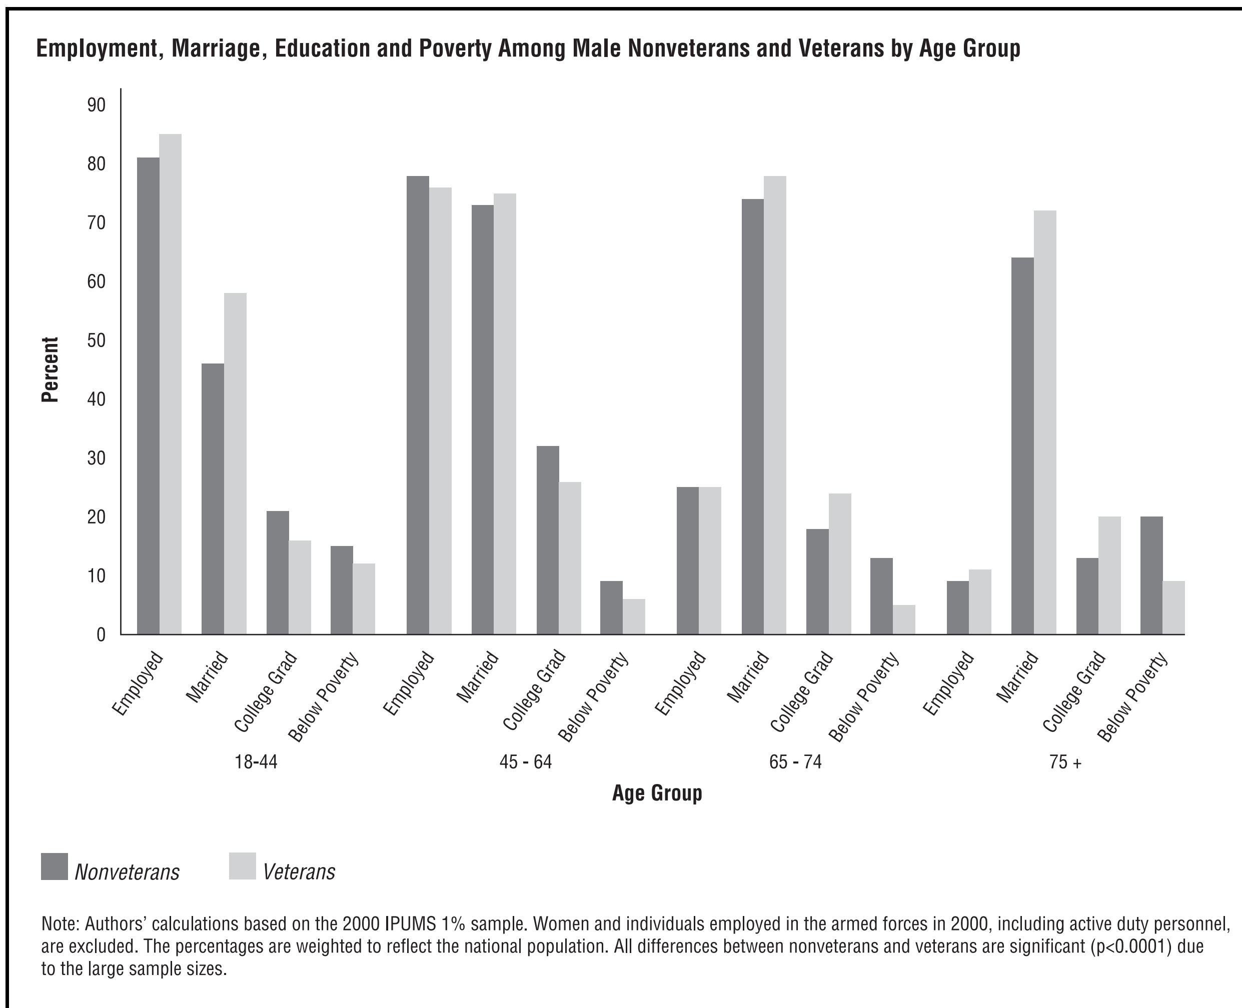

***Figure 1.*** *Differences between veterans and nonveterans across these four age groups, which experienced unique historical circumstances during early adulthood, demonstrate that military service is associated with a variety of social and economic outcomes.* CENGAGE LEARNING, GALE.

## G.I. BILL

The Servicemen's Readjustment Act of 1944 (Public Law 346), more commonly known as the G.I. Bill (of Rights), was signed into law by President Franklin D. Roosevelt on June 22, 1944. The G.I. Bill extended numerous social benefits to any veteran of World War II who had served for 90 days or more, except those who received dishonorable discharges. These benefits included unemployment income support for as long as 1 year; guaranteed, low-interest loans to purchase homes, farms, or businesses; and tuition, fee, and living allowances to support education or vocational training. Although all of these benefits were widely used, the education and training benefits were used most frequently. By 1956, 2.2 million veterans had used G.I. Bill benefits to attend college, whereas 5.6 million had obtained noncollege training. Although the G.I. Bill was inclusive and expanded opportunities for Blacks as well as Whites, some Black veterans, particularly in the Deep South, had difficulty accessing or using benefits for which they were eligible. Overall, the G.I. Bill expanded access to education for veterans of World War II, which transformed their life-course trajectories, the lives of their spouses and children, and the nation as a whole.

military service were reduced and the risk of life disruption and related costs increased. Moreover, partly as a result of the work-life disadvantages they experienced, late-mobilized men were at greatest risk of subsequent downward trajectories in physical health.

### MILITARY SERVICE AND SOCIOECONOMIC, MARRIAGE/ FAMILY, AND HEALTH OUTCOMES

Figure 1 uses data from the 2000 U.S. Census to describe how men who have served in the military are different than men who have not served in terms of employment, marriage, college graduation, and poverty statuses. Four age groups are distinguished to highlight persons with different historical experiences during young adulthood: individuals age 75 years or older in 2000 were born in 1925 or earlier and were young and middle-aged adults during World War II; persons in the 65 to 74 age group were born between 1926 and 1935 and became adults around the time of the Korean War; people in the 45 to 64 age group were born between 1936 to 1955 and were subject to the Vietnam War; and persons in the youngest age group were born from 1956 to 1978 and came of age during the All-Volunteer Force era and experienced the first Gulf War. At all ages, veterans are more likely than nonveterans to be married, and they are less likely to be in poverty. In the youngest and oldest age groups, veterans are more likely than nonveterans to be employed, whereas in the 44–64 age group veterans are less likely than nonveterans to be employed, and in the 65–74 age group the percentage employed is similar among veterans and nonveterans. Differences in marriage and poverty statuses between veterans and nonveterans are larger in the two oldest age categories, suggesting that the social and economic advantages of military service may accumulate over the life course for those who serve in the military as young adults. Differences are also apparent across the age groups in the percentage of veterans and nonveterans who obtained a college degree. Among the two youngest age groups, veterans are less likely to have a college education than nonveterans. But among the two oldest age groups, veterans are more likely than nonveterans to have a college education. These age-based differences likely reflect variation across cohorts in the characteristics of individuals who served, the widespread use of the G.I. Bill among men who served in World War II and Korea, and changes in the terms of the G.I. Bill during the era of the All-Volunteer Force.

Evidence such as this, as well as the foundational work of Elder and his colleagues, point to the importance of military service for socioeconomic, marriage/ family, and health outcomes. Research has addressed a range of questions about how military service in different historical periods has affected outcomes in each of these domains overall and among specific subgroups of veterans.

## SOCIOECONOMIC ATTAINMENT

Considerable evidence shows that large numbers of World War II veterans took advantage of the G.I. Bill benefits available to them and enhanced their educational attainments over what they would have been in the absence of military service (Mettler, 2005). While women and Black male veterans, especially those born in the South, were less likely than White male veterans to use these benefits, the post-World War II G.I. Bill significantly increased training and college attendance among the many veterans who took advantage of its generous benefits.

However, researchers who have examined the effect of military service on educational outcomes in other time periods find that veterans have lower educational attainments than nonveterans. For example, during the Cold War period from 1955 to 1965, G.I. Bill benefits were not available. In her analysis of college attendance among veterans who served during this period, MacLean (2005) finds that those who were drafted were less likely to attend college than those who were not drafted and nonveterans. Additionally, she finds that military service redirected academically ambitious men away from college attendance. Researchers who have focused on Vietnam-era veterans find that veterans have lower educational attainments than nonveterans in the short-term (Teachman and, Call 1996), although they catch up to their non-veteran contemporaries to some extent over time (Teachman, 2005). These differences across and within cohorts may be due in part to variation in enlistment rates between socioeconomic status groups.

Research on the effects of military service during the AVF era on educational attainment also finds negative effects on schooling (Teachman, 2007). This relationship is attributed in part to the reduced availability and value of G.I. Bill benefits in the AVF era. Veterans are now required to contribute some of their earnings in order to access the educational benefit, and many service men and women choose not to do so. However, the effects of military service on educational outcomes are not uniform, as they vary by branch of service and characteristics of veterans. For example, Blacks show increases in schooling reduce the educational deficit they exhibit at the time of discharge.

Other research focuses on occupational attainment and income among veterans and also shows mixed effects

depending upon individual characteristics and historical periods. Dechter and Elder (2004) find that officers in World War II were able to convert their service into post-war occupational advancement, whereas other servicemen actually fared worse than nonveterans. Consistent with this finding, Angrist and Krueger (1994, p. 74) conclude that "World War II veterans earn no more than comparable non-veterans and may well earn less," even though they had access to generous G.I. Bill educational benefits. Studies focusing mostly on Vietnam era veterans suggest that military service in a war zone and combat exposure lead to worse labor market experiences and lower earnings. Angrist (1990) finds that White male Vietnam War veterans earned 15% less than the earnings of comparable nonveterans in the early 1980s. The lower earnings of Vietnam-era veterans may in part be attributable to post-traumatic stress and other psychiatric disorders that are more prevalent among such veterans.

Some studies have demonstrated positive effects on earnings for African-American and other non-White veterans who served in World War II (Teachman and Tedrow, 2004) and during the AVF era (Angrist, 1998), which provides evidence of a positive turning point in the earnings trajectories of initially-disadvantaged men. Recently, Teachman and Tedrow (2007) examined income trajectories among those who served in the AVF era and found that men from disadvantaged backgrounds earned more than their civilian counterparts; however, this premium dissipated after discharge.

## MARRIAGE AND FAMILY OUTCOMES

Reflecting the life course principle of linked lives, researchers have been attentive to the effects of military service on marriage, divorce, and other family-related outcomes. Considerable attention has been paid to the effects of military service on divorce. The accumulated evidence suggests that veterans are considerably more likely to divorce than comparable nonveterans, although one study that focused on active-duty personnel in the AVF era indicates African-American enlistees have lower divorce rates than comparable White enlistees (Lundquist, 2006).

Considerable evidence across different historical periods shows that combat exposure contributes to marital problems and marital instability (Gimbel and Booth, 1994). However, as was the case with socioeconomic outcomes, these patterns vary across persons and periods. Call and Teachman (1991, 1996) focus on the timing of marriage in relation to military service in order to examine the life course disruption hypothesis. Among White male Vietnam-era veterans, they find that both combat and non-combat veterans were as likely as nonveterans to marry, and marital stability was no lower among those who had married prior to entering the military than among those who had married during or after military service. Thus, in contrast to findings for World War II veterans (Pavalko and Elder, 1990), they found no support for the disruption hypothesis among these veterans.

A number of studies have addressed the effect of military service on marriage and fertility in general and Black-White differences in these outcomes in particular (Lundquist, 2004; Teachman, 2007). In this literature, a range of arguments are advanced to support the hypothesis that the American military became a relatively "pro-family," "pro-marriage" institution partly to recruit and retain personnel after the AVF replaced the draft in 1973. For example, policies that link coveted opportunities to live off base with a housing allowance to marriage may promote marriage among active-duty personnel. Beyond these inducements, these authors contend that the enforcement of the military's equal opportunity policies sharply reduces racial discrimination in earnings, job advancement, and promotion, thereby reducing one of the key barriers to marriage for many African Americans. Consistent with these arguments, the Black-White difference in marriage, which is substantial in the civilian population, is not present among active-duty military personnel. This fact likely has important implications for the subsequent life course trajectories of Black veterans, as well as those to whom their lives are linked.

Similarly supporting the "pro-family," "pro-marriage" character of the American military, Lundquist and Smith (2005) found that active-duty military women had higher fertility than comparable civilian women. This fertility difference was explained by the earlier and higher rates of marriage among the active-duty women.

## HEALTH OUTCOMES

A growing body of research links military service to subsequent health and mortality. This work builds on previous life course research that has shown that military service, in particular combat exposure, has a direct impact on health and health-related resources. These studies suggest that military service may directly expose veterans to circumstances, produce injuries, or engender psychological conditions that have negative implications for physical and mental health trajectories and mortality. As noted previously, military service-related health problems may influence socioeconomic and marital/family outcomes, thereby impacting the lives of persons to whom veterans are linked as well as the veterans themselves.

Building on the life course disruption hypothesis, Elder, Shanahan, and Clipp (1994) posit a stress and health relationship. They hypothesized that late age at mobilization produces life course disruptions, which in

turn produce stressful social disruptions, such as separation and divorce, residential changes, emotional distance from children, temporary periods of unemployment and erratic work lives, which have implications for health in later-life. Using data from the Stanford-Terman longitudinal study, which mostly includes World War II veterans, these authors report that late entrants, who are likely to have had the greatest social disruptions, were more likely to experience sporadic health problems, lifetime health declines, and constant poor health after exiting the military. However, social disruption did not fully account for the effect of late entry; rather it was the joint effect of late entry and high levels of social disruption that seemed to adversely affect health. A subsequent investigation by these investigators using the same data (Elder, Shanahan, and Clipp, 1997) found that exposure to combat predicted physical decline or death during the 15-year post-war interval from 1945–1960.

Two studies indicate higher disability and mortality among male veterans decades after the end of their military service. Bedard and Deschênes (2006) found that military service during World War II and the Korean War was associated with higher mortality later in life; 35% to 79% of the excess deaths were due to heart disease and lung cancer. The investigators argue that this excess mortality among veterans is attributable to military-induced smoking resulting from pro-tobacco military policy (i.e., free and reduced-price distribution of cigarettes) in this period. In a sample of men 51 years old and older, London and Wilmoth (2006) found that service in the military led to a greater likelihood of dying compared to those who had not served, even after taking into account early-life circumstances (race and father's education) and mid- to late-life characteristics (marital status, socioeconomic status, health status, and health behaviors). Among the younger cohorts, they found that military service improved the survival of African-American men, which they interpret as evidence of a positive turning point. Such a positive turning point may have occurred because military service afforded these African-American veterans greater access to education, income, family integration, or health care.

## CONCLUSION

While the existing research has revealed us a great deal about the ways in which military service affects the life course (MacLean & Elder 2007; Settersten 2006), there is much that remains to be learned. It is critically important that we continue to follow multiple cohorts as they age so that it will be possible to conduct direct cohort comparisions. There is also a need for further research examining the impact of military service on the lives of women who serve, as well as the lives of those to whom veterans' lives are linked. Finally, as was the case with World War II, the Vietnam War, and the Gulf War, veterans returning from Iraq will face a unique set of challenges. It is important to document how they are faring and how current policies and programs are shaping their life course trajectories in the short- and long-term.

## MILLS, C. WRIGHT
### *1916–1962*

C. Wright Mills was born on August 28 in Waco, Texas, and was raised in Texas. He earned his Ph.D. from the University of Wisconsin and taught at the University of Maryland and Columbia University. Mills was a public intellectual who was known for motorcycle riding and unconventional dress and for a manner that was consonant with his radical sociology. He used social analysis to shed light on the crises of his time, presenting his analyses in both academic and popular venues. A hero to student movements of the 1960s, Mills continues to be a model for academics who see their work as part of political struggles (Gitlin, 2000; Hayden, 2006). He died on March 20 in Nyack, New York.

*C. Wright Mills.* COLUMBIA COLLEGE TODAY.

During the 1950s there was a climate of optimism in American sociology, which was dominated by functionalists who argued that social institutions fulfill specific purposes, all for the general good. Mills's sociology, which was based on conflict theory, challenged that complacency. Although he drew from classic European social theorists such as Karl Marx and Max Weber, Mills had a uniquely American perspective. By orientation and training he rejected disciplinary boundaries (Gerth & Mills, 1953). Mills used case studies of labor leaders, white-collar workers, and the powerful ("elites") to understand the factors that limit people's motivation to work for change. He attempted to understand the conditions that create opportunities and constraints for individuals and institutions and the ways in which power is used.

From his studies of different population segments of the post–World War II United States, Mills developed a theory about the factors that influence the balance of power in a society. He argued that concentrations of power reduce choices for the larger public even as they advance the power of the select few at the top. In *The Power Elite* (1956), he claimed that the United States was controlled by interrelated elite groups in the government, military, and industry, each of which pursued

shared self-interested goals. The average American was duped by an illusion of well-being and minimal economic security. Popular culture, which was controlled by the elite, worked to mold a society of what Mills described in *White Collar* (1951) as "cheerful robots" (p. 233; see also Mills, 2000 [1959], pp. 169–176). Absorbed in the pursuit of personal happiness, cheerful robots were apathetic to the political and economic arrangements that limited their autonomy and circumscribed their choices. This depoliticized public included the American working class, which social theorists might expect to be the source of conflict and change.

Mills contended that the power elite, which relied on unchecked military and industrial growth to sustain itself, inevitably would cause a third world war. He did not predict the social and political upheaval of the 1960s, which contrasted with the complacency that made him despair of social change. He did, however, look to nations such as Cuba and the Soviet Union as models. Some claimed that the inaccuracy of Mills's doomsday predictions discredited his analysis. Mills, however, documented particular historical, economic, and social circumstances to understand mechanisms of power and agency. His complex theories included the idea that, under different circumstances, processes and outcomes would change.

Mills called for social theorists and laypeople to critique social institutions and their own choices, arguing that they must examine what people do rather than uncritically accept their words. Mills believed that most individuals, elites or otherwise, are not conscious of societal power dynamics. In *The Sociological Imagination* (2000 [1959]) he noted the difficulty of identifying connections between societal "issues" such as structural unemployment, and private "troubles" such as the loss of a job. In dynamic modern societies it can be difficult to see the historical and biographical circumstances that shape people. In his letters and autobiographical writings Mills acknowledged that those forces shaped him too (Mills with Mills, 2000).

Although Mills believed that the intersection of biography and history provides constraints and opportunities, neither can determine the future. Social analysts and ordinary people use their sociological imagination to transcend their private worlds and connect their personal experiences to the larger stage of history in the "hope to grasp what is going on in the world, and to understand what is happening in themselves as minute points of the intersections of biography and history within society" (Mills 2000 [1959], p. 7). Mills's perspective differs from social theories that focus on the individual as the locus of change or activity and those which focus primarily on the social milieu or institutions. His work affords neither one primacy and charges social theorists to investigate individual experience and the social environment as well as the reciprocal interplay between them. Mills's ideas were influential in the development of the life course perspective, which emphasizes the links between social forces and individual lives (Elder & Shanahan, 2006).

Mills's social theory has contributed significantly to an understanding of social processes and the interplay among individuals, institutions, and society. He encouraged a critical approach to power, a challenge to complacency, and the expansion of the sociological imagination.

## MOTHERHOOD

Motherhood represents a distinct aspect of a woman's life course. The beginning of motherhood is defined by pregnancy and childbirth, but when it ends is less clear—a woman does not stop being a mother after her children are grown up. Historically in European and North American societies, motherhood was the final step toward adulthood, closely following marriage. Over the past century the place of motherhood in the life course has significantly changed and, at present, it varies widely. Increasing numbers of women are deciding not to become mothers, many women delay motherhood until later in adulthood, and many become mothers regardless of their marital status.

Mothers provide the vast majority of primary care to their children, and, although they mother in various familial and social structural contexts—married or single, within a nuclear or extended family, in relatively privileged or less-privileged social positions based on class, race, and sexuality—being a mother significantly defines and affects their social and economic positions for the rest of their lifetimes.

## SOCIAL ASPECTS OF MOTHERHOOD

Because of women's biological ability to bear children, it is conventionally expected that all women will become mothers. Women's femininity and gender identity are also reinforced by mothering. About 80% of American women become mothers during their reproductive lives. Mothers in the early 21st century, however, spend much less of their life course actively involved in mothering than did women in the past. The average woman spends less than one-seventh of her lifetime doing tasks such as nursing, diapering, or taking care of the everyday needs of a young child (Coltrane & Collins, 2001). The tasks of caring, nurturing, and protecting children are often referred to as *mothering*. They are usually—but not necessarily—performed by mothers; according to some theorists, men or non-mothers also perform mothering tasks when they take care of children (Doucet, 2006; Ruddick, 1995). Even so, motherhood is still seen as the primary purpose of a woman's existence and continues to define and affect women's lives.

Pointing to social, cultural, and historical variations in motherhood roles, norms, and expectations, social scientists argue that motherhood is socially based. The norms of motherhood and defining what a *good* mother is have historically varied and have been applied differentially according to a woman's social status. For example, in the 19th century the belief developed that mothers (rather than wet nurses) were best suited to take care of their babies. American society thus began to expect middle-class mothers to selflessly devote themselves to their children. At the same time, public campaigns, policy measures, and sterilization were used to discourage poor and minority women from becoming mothers at all. Such class differences continue to exist even in the 21st century; middle-class mothers are encouraged to devote as much time as possible to the care of their children, whereas working-class and poor mothers are expected to work outside of the home, leaving their children in the care of others so that they may provide income and even welfare benefits for their families.

The norms and expectations of present-day American motherhood have become more involved and demanding than ever before. The ideology of intensive mothering, as defined by Sharon Hays (1996), is a child-centered child-rearing approach that requires mothers to spend money, energy, and time to raise their children while following expert advice and being fully tuned in to their child's thinking and emotions. This set of social expectations has become the accepted definition of mainstream American motherhood and has spread from the middle class to other layers of society. Hays showed that intensive mothering is not necessary for the healthy development of children, as expert advice and treatment of children in the past often directly contradict intensive mothering methods, providing further evidence for the social foundations of the motherhood role.

Analysis of media images of mothers and motherhood since the 1970s suggests that the media helps to spread and reinforce the myth of perfect, enjoyable, and fulfilling motherhood, performed to the standards of intensive mothering. Described as *new momism*, the media creates "a set of ideals, norms, and practices ... that seem on the surface to celebrate the motherhood but which in reality promulgate standards of perfection that are beyond your reach" (Douglas & Michaels, 2004, p. 4). Both academic research and popular writing indicate that it is neither easy nor enjoyable for women to keep up with these expectations. New mothers quickly discover that they are not well-prepared for the reality of motherhood. They realize that the image of motherhood they had—being "brave, serene and all knowing" (Maushart, 1999, p. 2)—was just a mask covering the chaos and complexity of real life. New mothers thus have to deal not only with the social expectations of intensive mothering but also with the process of sorting out expectations from realities and adjusting to the latter. The stress of these adjustments, along with the demands of taking care of the new baby, may be a contributing factor in postpartum depression. Even during their later years as mothers, women with children tend to experience more distress and depression than non-mothers despite the joys and gratifications associated with parenting (Evenson & Simon, 2005).

## CHANGING PLACE OF MOTHERHOOD IN WOMEN'S LIFE COURSE: DEMOGRAPHIC TRENDS

Twenty-first century women become mothers at a different point in their life course and under different circumstances than was the case for previous generations. Changes in motherhood are closely related to overall changes in the American family structure and to the position of women in the larger society. Women's increasing education levels, and higher career aspirations and opportunities, and higher rates of labor force participation, as well as increasingly available and improving contraception, contribute to the

## MOMMY WARS/IMAGES OF MOTHERHOOD

Should mothers stay at home with their children or pursue careers and contribute to family income? This is the main question behind the *mommy wars*—a cultural debate about whether women who stay at home with their children or women who work outside of the home make better mothers. This debate has been played out in the media since the 1970s, with each camp arguing that their choice is right and that children of the mothers in the opposing camp suffer. However, maternal activists point out that working is a necessity rather than a choice for many mothers and that mothers often move between the worlds of family and work. They are asking the media to stop feeding the mommy wars and to focus instead on issues that unite all mothers, such as the implementation of family-friendly public policies, reliable child care, and affordable health care for all families.

changing significance of motherhood and result in changing demographic behavior.

One of the most obvious demographic changes characteristic of today's motherhood is the postponement or avoidance of motherhood. The proportion of women who remain childless nearly doubled between the 1970s and the 2000s. In the 1970s only 10% of women did not have children during their reproductive lives (defined by demographers as ending at age 44); by 2004, 19.3% of women between the ages of 40 and 44 years remained childless (Dye, 2005). Even though improved reproduction technologies and adoption offer women the possibility to become mothers after this age, this increase suggests that more women are postponing and avoiding motherhood than ever before.

Motherhood also occurs at a later stage of life for women who do become mothers, often in their late 20s and, increasingly, in their 30s. The average age of a first-time mother has increased from 21.4 years of age in 1970 to 24.9 in 2000 (Mathews & Hamilton, 2002). In 2004 about 45% of women between 25 and 29 years of age were childless (Dye, 2005).

Concurrent with the trend toward delayed motherhood, women tend to have fewer children than in the past. The average number of children an American woman bears in her lifetime has dropped from 3.5 children during the 1950s baby boom to about 2.1 in 2006 (Centers for Disease Control and Prevention, National Center for Health Statistics, 2007). Having fewer children allows mothers to devote more attention, energy, and resources to each child they have, as required by the ideology of intensive mothering, but it also allows women more time and opportunities to pursue other interests.

Motherhood has also become increasingly disconnected from another important life course transition: marriage. In the early 21st century, about one-third of children are born to women outside of marriage, and this proportion has been increasing. The proportion of childbearing outside of marriage is even higher for African American women, with almost two thirds of their children born outside of marriage compared to one-quarter of White women (Dye, 2005). This is a considerable change from the not-so-distant past of the 1950s, when having a child out of wedlock was quite rare and considered a scandalous, if not socially punishable, offense.

Having children outside of marriage does not necessarily mean that women raise their children without a father. The increasing prevalence of cohabitation—defined as living in a household with a sexual and romantic partner without marriage—has contributed to the increase in nonmarital childbearing. Women are more likely to become first-time mothers while cohabitating than while married. In 2002, 42% of first births were to cohabitating women, whereas only 29% were to married women (Downs, 2003). The trend toward choosing motherhood without marriage is documented both among middle-class women (Hertz, 2006) and poor women (Edin & Kefalas, 2003).

Statistics show that younger and less educated women are more likely to have children outside of marriage than are older women or women with higher levels of education. The proportion of unmarried mothers is highest among teenage mothers—88% of women under 20 were not married when their child was born (Dye, 2005). This stands in stark contrast to the 1950s, when teenage childbearing was at twice the current rate but the majority of young mothers were married.

The life-course stages of teenage mothers are organized differently than those of women who delay childbearing, mostly in respect to completing education and entering marriage. Despite the threat of possible negative outcomes—including lower rates of high school completion, lower incomes, difficulties obtaining and keeping jobs, and lower stability of later marriages—in communities characterized by low life aspirations, a dearth of access to well-paying, stable jobs, and high divorce rates, motherhood represents an alternative strategy for attaining adulthood and social status.

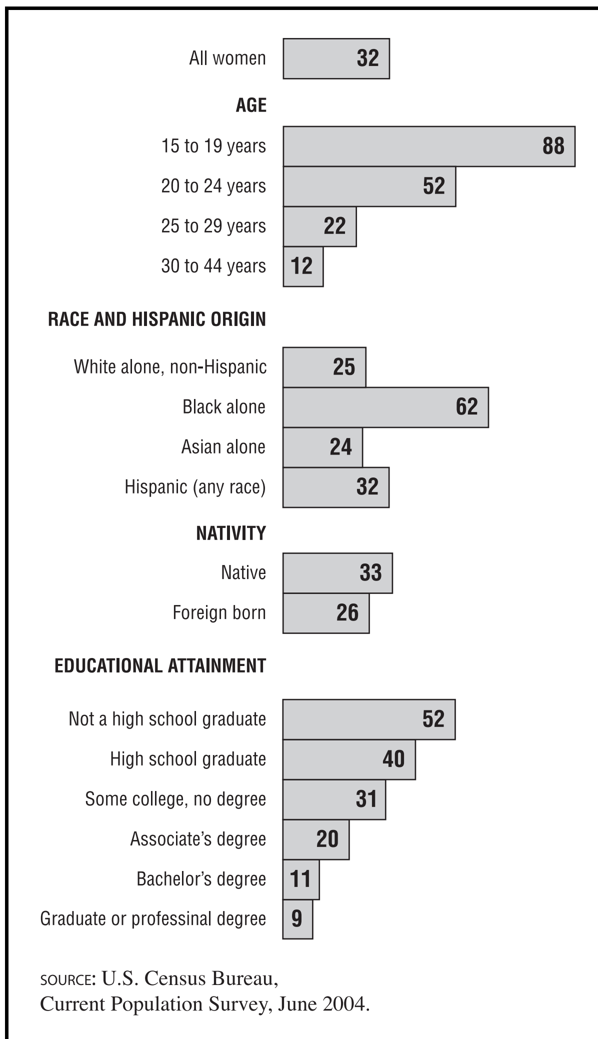

***Figure 1.*** *Nonmarital births by age, race, Hispanic origin, nativity, and education attainment, June 2004. Percent of births born in the preceding 12 months to women who were never married, divorced, or widowed.* CENGAGE LEARNING, GALE.

## ECONOMIC IMPACT OF MOTHERHOOD

Regardless of social background, motherhood has direct and indirect negative economic implications for women that persist through the life course. Although child care and mothering are often referred to as the most important jobs in the world, mothers receive minimal public support and no economic compensation for their work. The benefits of childrearing are diffuse and shared by the whole society, but mothers are more likely than fathers to carry the negative economic costs of having children as they are more likely to limit their work hours, take time out of the labor force to care for the child, or take jobs compatible with childrearing. Ann Crittenden (2001) referred to the overall impact of motherhood on women's socioeconomic status as *the price of motherhood*.

The economic price women pay to be mothers is most visible in the pay they receive for their work in the paid labor market. Full-time working women made about 81% of men's salary in 2006 (U.S. Bureau of Labor Statistics, 2007). Mothers earn less than women without children, earning 73 cents per a dollar earned by men for the same job, taking into account job-related experience and mother-friendly job characteristics. Researchers find that the first child exacts a 2% to 10% wage penalty and two or more children a 5% to 13% penalty, depending on the children's age and the mother's education and race (Anderson, Binder, & Krause, 2003; Budig & England, 2001; Waldfogel, 1997).

Mothers are also disadvantaged during the hiring process. According to one study, mothers are 79% less likely to get hired if they present the same experiences and resumes as non-mothers and are also offered significantly lower salaries than non-mothers (Correll et al., 2007). The motherhood penalty and hiring discrimination demonstrate that although the labor force has become more equal in the opportunities and pay available for men and women, policies that accommodate employees' family and caregiving responsibilities are insufficient.

Mothers' careers are often interrupted by the needs of their children, limiting their possibilities for career advancement, promotion, and enhanced income. Phyllis Moen and Shin-Kap Han (2001) described gendered career paths characterized as orderly or high-geared for men and intermittent, with delayed entry or steady part-time, for women. This type of career progression is sometimes referred to as the *mommy track*, characterized by slower career advancement but a better ability to combine work and family. Indeed, although the majority of mothers have paid jobs, most of them work less than full time. In 2002, 24.6% of mothers with children under age 18 stayed at home, 38.8% worked full time all year, and 36.7% worked part-time (Lovell, 2003). Part-time work is preferred by 60% of women with minor children (Pew Research Center, 2007), although it has economic disadvantages, such as lower pay and limited benefits. Part-time workers also often work almost full-time hours to maintain their position in the work organization.

Because of the difficulties in balancing work and family, women sometimes leave the workforce altogether. In a widely discussed article, Lisa Belkin (2003) suggested that professional mothers are increasingly leaving the workforce to take care of their children and choosing family over their careers. This is referred to as the *opt-out revolution*. Further research has demonstrated, however, that most of these mothers do not leave the workforce because they want to reestablish traditional family arrangements or have a desire to be full-time mothers as the media has suggested. Instead, they are pushed out from their jobs by inflexible workplaces

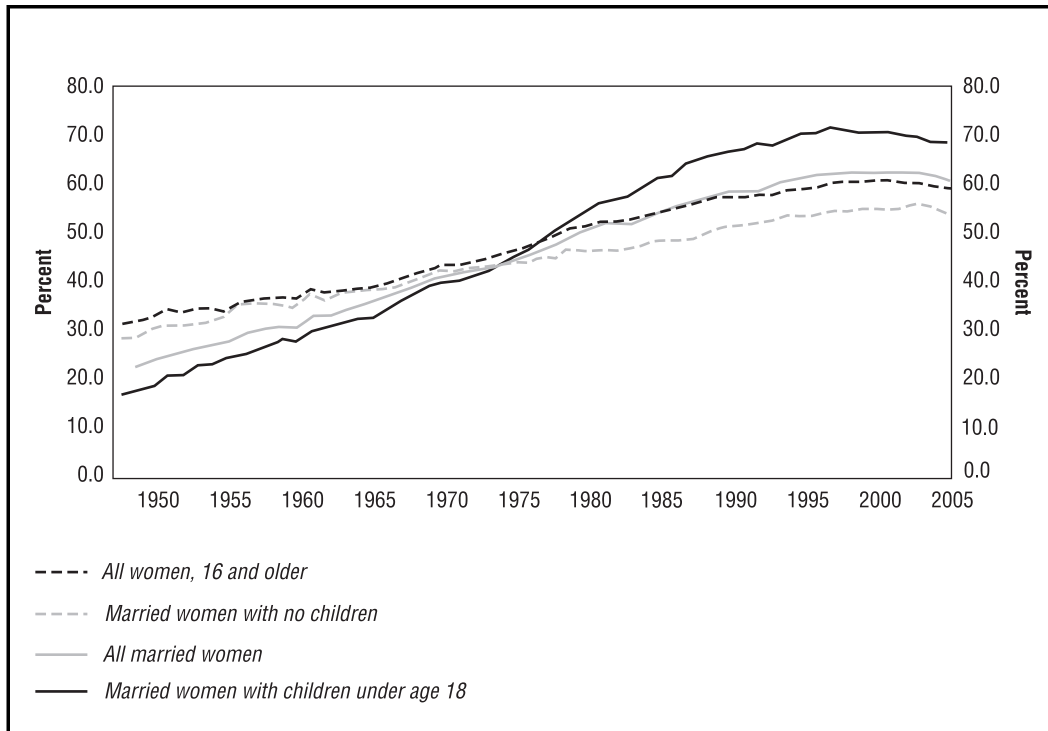

***Chart 1.*** *Labor force participation rates of women by marital status and presence of children, March 1948–2005.* CENGAGE LEARNING, GALE.

that make it difficult or impossible to combine work and motherhood.

Paid labor continues to be structured in a way that disadvantages all caregivers (not only mothers) who cannot perform as ideal workers (i.e., employees fully committed to their jobs and without family impediments to their performance; Williams, 2000). At the same time, cultural expectations for childrearing are still based on the idea that children are better off if cared for and raised by their parents than other caregivers. Therefore, most mothers are socially, culturally, and economically excluded from economically successful roles and forced to opt out or choose mommy track careers. Although women perceive what they do as a choice, it is a choice under the constraints of a social and economic system that is built on the assumption of a division of labor between caregiving and breadwinning. Such a choice is also available only to those who can afford to stay at home, as is clearly shown by the 1996 welfare reform requirements that insist poor mothers work outside of the home to provide for themselves and their families.

The price of motherhood and the economic impact of motherhood on women are not limited to the wage penalty and job discrimination. Indeed, after a divorce, women often slip into poverty because of their limited workforce participation while married, a division of gender roles in the family that is not reflected in the majority of divorce settlements, and their predominant post-divorce care of the children, whereas fathers usually improve their standard of living.

## MOTHERHOOD AND PUBLIC POLICY ISSUES

In the contemporary United States, raising children is still primarily considered the mother's responsibility. Comprehensive family-oriented public policies, common in most of the world, such as paid family leave after the birth of a baby and subsidized preschool education, are thus lacking. In fact, the United States is the only industrialized country without a policy that allows mothers to stay home with an infant and maintain an income for the family (some countries even provide paid leave for fathers). The current U.S. policy, the 1993 Family and Medical Leave Act (FMLA), provides unpaid leave to take care of a new baby or sick family member for up to 12 weeks to employees in companies with more than 50 employees. However, even eligible employees often cannot afford to take the unpaid leave. Individual states are therefore passing their own legislation to improve this federal policy.

Similarly, working parents are responsible for providing child care for their children before they achieve

school age, as there is no comprehensive, publicly funded preschool system in the United States. Finding good quality and affordable preschool and child care is often very stressful for mothers.

Social movement organizations have been advocating improvement of mothers' and caregivers' social and economic positions, attempting to bring these policy issues to the national consciousness and political debate. Among these are MomsRising.com, Mothers Ought to Have Equal Rights (MOTHERS), the National Association of Motherhood Centers, Mothers & More, Mothers Acting Up, the National Organization of Women (NOW), and many others. They argue that although mothering is a life-changing experience, it should not be a difficult one, much less one that leads to discrimination and poverty.

## DIRECTIONS FOR FUTURE RESEARCH

Motherhood and its economic and social value remain highly contested topics in American society. Although much more is known about motherhood and mothers than a few decades ago, changing social, political, economic, and cultural contexts create new challenges for women as they enter motherhood and combine it with other identities and roles. Future research will likely emphasize the diversity of maternal experiences, as women mother under different social, cultural, and economic conditions that are not always reflected in current research. The identities, ideologies, and meanings that women of various backgrounds give to their mothering experiences and the place of motherhood in their life courses are still to be examined in more detail. At the same time, similarities in women's experiences, the issues mothers face, and the prevalence of mainstream motherhood norms across social classes also need to be addressed.

Analyses of the economic implications of motherhood for women and their families are likely to be carried out in the light of new social policies and increased maternal and caregiving activism. Will the new social movements change the way mothers act and organize their family lives and impact the public and corporate family policies? Will this affect the way mothers position themselves in the work-family space? Research into combining work and family obligations will also gain a new dimension as new generations of women enter motherhood. How will these young women, who saw their own mothers juggle work and family obligations, incorporate their experiences into their lives? Will they continue the trend of delaying motherhood into later stages of their life course in order to establish their careers and devote themselves to motherhood afterward, or will they find a way to do both at the same time? Will they continue to follow the expectations and pressures of intensive mothering or will the social expectations on mothers be gradually replaced? There is also a lot to be learned about the long-term life-course implications of the choices previous generations of mothers made on their identities, health, family relations, and overall well-being.

## NEIGHBORHOOD CONTEXT, ADULTHOOD

The concept of *neighborhood* refers to an individual's immediate residential community. Research linking characteristics of neighborhoods to adult outcomes reflects a long tradition of sociological research on the role social context has in shaping lives. Results of this research suggest that neighborhoods are more than simply places of residence; they also provide proximate access to opportunities for residents, including employment opportunities, social opportunities, and access to beneficial resources. Just as neighborhoods provide access to positive factors, however, neighborhoods can also negatively affect residents through exposure to crime, social and physical disorder, and environmental and health risks.

### THEORETICAL FOUNDATIONS OF NEIGHBORHOOD RESEARCH

The idea of neighborhoods as important social contexts has its origins in the human ecology perspective of the Chicago School of sociology (Park, Burgess, & McKenzie, 1925), which emphasized the interaction between humans and their environments. A key insight of this perspective was that characteristics of residential communities can affect residents' behaviors and beliefs above and beyond their own personal characteristics. In particular, Shaw and McKay (1942) found that neighborhoods with certain characteristics showed higher rates of juvenile delinquency and infant mortality, regardless of the race or ethnic background of the groups living there. Shaw and McKay's *social disorganization* approach focused on three neighborhood characteristics: economic disadvantage, racial and ethnic heterogeneity, and residential instability. These elements were thought to erode a community's capacity for social organization, leading to the cultural transmission of crime and risky behavior with eventual effects on neighborhood crime rates and residents' health.

This insight spurred an interest in the neighborhood as a meaningful locus of intervention: If the problems experienced in disadvantaged neighborhoods were not attributable to the types of people who lived in these neighborhoods, efforts directed at the neighborhood should lift the fortunes of those living there. However, ambitious efforts such as Robert Park's Chicago Area Study, in which he divided the city into a set of community areas and targeted troubled areas for intervention, yielded mixed results (Kobrin, 1959). As a result, by the middle of the 20th century sociological interest in neighborhood research waned.

However, several factors led to a resurgence of interest in neighborhoods in the latter part of the 20th century. First, Kornhauser (1978) critically evaluated and reformulated Shaw and McKay's social disorganization theory, deemphasizing the cultural transmission process, and instead emphasizing the key role of neighborhood social organization. Second, researchers became interested in the causes of observed increases in the spatial concentration of poverty in the United States. By linking the neighborhood to the structure of U.S. society, these researchers addressed a weakness in Shaw and McKay's (1942) work—its inattention to the larger, social structural forces that produced differences in neighborhoods. For example, Massey and Denton (1993) found that the spatial (i.e., geographic) concentration of poverty was intertwined with persistent patterns of residential segregation by race that remained

long after the practices that produced them were outlawed (such as *red-lining* primarily minority neighborhoods to indicate their undesirability for mortgage loans). Wilson (1987, 1996) argued that the impact of segregation was compounded by economic changes that eroded job opportunities for low-skilled workers in urban settings, leading to neighborhood decline and the concentration of economic disadvantage in particular urban neighborhoods (Wilson, 1987, 1996). Residents of these neighborhoods were described by Wilson (1996) as *socially isolated*—rooted in their neighborhood contexts, but isolated from mainstream social and employment opportunities.

More recent research on the importance of neighborhood contexts builds on Wilson's (1987, 1996) work, and considers the mechanisms that *link* neighborhood economic, social, and demographic characteristics to neighborhood levels of crime, health problems, and other social ills, as well as the well-being of individual residents (Jargowsky, 1997; Sampson, Morenoff, & Gannon-Rowley, 2002). Consistent with Kornhauser's (1978) reformulation of social disorganization theory, researchers separately examine processes of neighborhood social organization and neighborhood cultural transmission.

## LINKS BETWEEN NEIGHBORHOOD CHARACTERISTICS AND OUTCOMES

**Social Organization** Research on the links between neighborhood social organization and neighborhood and individual outcomes considers how characteristics of neighborhoods can attenuate or promote a community's capacity to regulate the behavior of its residents (Kornhauser, 1978). This research draws on the concept of social capital, the capacity for action on behalf of an individual or group that inheres through networks of social relationships (Bourdieu, 1986; Coleman, 1990). Although social capital is thought of as a good that may be employed for positive goals, it can also have a downside—it may be used, for example, to reinforce social advantage among some groups, to the exclusion of others (Portes, 1988).

Much research on the role of social capital has examined its importance for health and well-being; that is, the way social ties can provide social supports and opportunities to engage in healthy (and health risk) behaviors, as well as the capacity for action that can be employed to lure health-promoting institutions (Lochner, Kawachi, Brennan, & Buka, 2003; Carpiano, 2007). For example, Lochner, Kawachi, Brennan, and Buka (2003) found positive relationships between low levels of social capital and neighborhood total mortality rates, as well as rates of death from cardiovascular disease. Carpiano (2007), however, found that social support was, surprisingly, positively associated with health risk behaviors such as smoking and binge drinking, although informal social control was negatively associated with such behaviors. This research highlights the importance of goal-oriented aspects of social capital—or the ability of a community to employ its social ties for the collective good—and the ways in which social ties supply opportunities for both healthy and health risk behaviors.

**Collective Efficacy** One important application of social capital theory to the neighborhood context is the concept of *collective efficacy* (Sampson, Raudenbush, & Earls, 1997) that is defined as "the linkage of mutual trust and the willingness to intervene for the common good" (p. 919). Collective efficacy is thus a social good that helps maintain neighborhood order through informal social control. Collective efficacy is goal oriented, and incorporates a neighborhood's capacity for prosocial action.

The structural and demographic characteristics of disadvantaged neighborhoods identified by Shaw and McKay (1942) and by Wilson (1996) serve to limit a community's capacity to achieve collective efficacy, with effects on neighborhood social conditions (e.g., community rates of crime or health risk behaviors) as well as individual outcomes (e.g., victimization or participation in health risk behaviors). Residents of neighborhoods that are residentially unstable, for example, will have difficulty recognizing shared values and may hesitate to intervene in the event of trouble because they cannot be assured that their views are shared by others in the community. Similarly, in some racially and ethnically heterogeneous neighborhoods, hostility among groups may hinder their ability to band together in support of neighborhood goals; moreover, they may not agree on goals for the neighborhood.

Aspects of disadvantage also potentially inhibit neighborhood collective efficacy. In economically disadvantaged neighborhoods, the individual challenges faced by poor residents may not permit residents to engage meaningfully in forms of neighborhood social control. Further, competing allegiances to law-abiding residents and those who are engaged in illegal enterprises, such as the sale of drugs, may restrict residents' willingness to get involved when they recognize illicit activity (Pattillo-McCoy, 1999). Finally, neighborhoods with a high proportion of single-parent families have fewer adult residents available for shared collective supervision of the neighborhood environment.

The emphasis on social control in the concept of collective efficacy has led to a research focus on its effects on child and adolescent outcomes. However, researchers have also found evidence for the importance of collective efficacy for a variety of neighborhood and adult outcomes. Sampson, Raudenbush, and Earls (1997) found that neighborhoods with higher levels of collective efficacy had lower rates of violent crime. Collective efficacy also has been found to be negatively associated with intimate homicide rates and nonlethal partner violence (Browning, 2002).

***Neighborhood at War.*** *North Las Vegas police officers handcuff a suspected gang member during a patrol of a North Las Vegas neighborhood.* AP IMAGES.

Finally, collective efficacy has been found to be positively associated with self-rated physical health (Browning & Cagney, 2002), and negatively associated with obesity (Cohen, Finch, Bower, & Sastry, 2006).

**Institutional Resources and Environmental Hazards** Researchers have also identified the importance of social capital as a means to attract and retain institutional resources that are beneficial for neighborhood residents (Elliott, Wilson, Huizinga, & Sampson, 1996). Neighborhoods that are socially organized and able to exploit social ties to decision makers outside the neighborhood may be able to influence the placement of desirable institutions (e.g., health care facilities, community centers, police and fire substations) within the neighborhood. As a result of the proximity of these desirable institutions, the residents' sense of well-being may increase (Leventhal & Brooks-Gunn, 2001). In addition, residents of socially organized neighborhoods may be better able to work together to reduce hazards and risks (Leventhal & Brooks-Gunn, 2001), which include physical disorder (e.g., broken glass, litter, biohazards), social disorder (e.g., public intoxication, prostitution), or the placement and regulation of harmful institutions in or near the neighborhood (industries that pollute).

Skogan (1990) found a positive relationship between aspects of physical disorder and neighborhood levels of crime. Sampson and Raudenbush (1999) found that, even though physical disorder and neighborhood crime are correlated, the relationship is not causal; rather, both stem from the same set of predictors related to a given neighborhood's high levels of concentrated poverty and low levels of collective efficacy. However, the effects of physical disorder may be perceived through its impact on residents' fear and the effects of that fear on residents' health and well-being (Ross & Mirowsky, 2001). Finally, Altschuler, Somkin, and Adler (2004) examined the effect of neighborhood amenities and liabilities (e.g., pollution, available food stores, effective municipal services) on resident self-rated health. Their findings indicated the importance of goal-oriented social capital for the attraction of neighborhood amenities and the elimination of liabilities.

**Routine Activities and Opportunities for Crime** Neighborhood social organization may also affect individual opportunities for participation in crime and problem behavior. Cohen and Felson (1979) argued that most societally deviant (i.e., transgressive) behavior, including crime, is a function of an individual's routine, everyday activities. This approach emphasized the unplanned nature of much criminal activity. Using this perspective, neighborhoods may experience increased crime and problem behavior if they have few *guardians*, that is, people who keep watch over the activities of other people and over public and

private property; and many vulnerable *targets*, or people who are susceptible to victimization and property that is unsecured or isolated. Although the routine activities framework focuses on deficits in social organization, it shares an emphasis on opportunity with theories of cultural transmission.

**Cultural Transmission** Differential social organization approaches emphasize the *absence* of social organization and forms of informal social control as key determinants of crime and risk behavior. In contrast, cultural transmission perspectives emphasize the *presence* of problematic behaviors and attitudes in some neighborhoods, and consider how these features also structure residents' opportunities for participation in crime and health risk behavior. These approaches are also called *subcultural* or *epidemic* approaches (Anderson 1990; Crane 1991), and are rooted in early theories of crime and gang delinquency (Short & Strodtbeck, 1965; Cloward & Ohlin, 1960; Smith & Jarjoura, 1988). These perspectives argue that the proliferation of problem behaviors and crime in a neighborhood provides an illegitimate opportunity structure in opposition to mainstream society. In disadvantaged neighborhoods, these illegitimate opportunity structures may present an alternative path for residents who are blocked from mainstream opportunities for success. Ethnographic researchers who studied the lives of adults in disadvantaged settings found evidence to support the cultural transmission of acquired styles that may promote risk or criminal behavior (Liebow, 1967; Duneier, 1992; Anderson, 1978, 1990).

## ISSUES OF DEFINITION, MEASUREMENT, AND ANALYSIS

Several methodological considerations arise when examining neighborhood effects. First is the definition of *neighborhood* itself. Researchers have employed different definitions of this term, such as administrative boundaries (census tracts or blocks) (Sastry, Ghosh-Dastidar, Adams, & Pebley, 2006; Hipp, 2007); areas set off by streets, railroad tracks, and other ecological boundaries (Sampson, Raudenbush, & Earls, 1997; Grannis, 1998); social networks (Wellman & Leighton, 1979); and residents' subjective definitions of their sociospatial neighborhood (Lee & Campbell, 1997).

A second consideration is selection bias. The same characteristics that lead individuals to select certain neighborhoods in which to live may also influence their own outcomes. For example, individuals who have a propensity or desire to participate in crime or illicit behavior may seek out contexts that facilitate (or do not inhibit) such criminal or illicit behavior (Stark, 1987). As a result, observed neighborhood effects may be attributable instead to the aggregation of these unmeasured resident characteristics (Duncan, Connell, & Klebanov, 1997). Researchers attempt to address this issue by employing sophisticated statistical models to adjust for individual characteristics associated with neighborhood selection. An alternative way of dealing with selection is to use data from a quasiexperiment in which people are assigned at random to neighborhoods. Such data usually come from social programs, for example, the "Moving to Opportunity" (MTO) project, sponsored by the U.S. Department of Housing and Urban Development, in which some residents of disadvantaged neighborhoods were given housing vouchers to live in more affluent neighborhoods (Kling, Liebman, Katz, & Sanbonmatsu, 2004).

## THE FUTURE OF RESEARCH ON NEIGHBORHOOD EFFECTS ON ADULT OUTCOMES

To date, research on neighborhoods has largely focused on neighborhood level outcomes or children, adolescents, and the elderly, who may have the greatest exposure to the residential neighborhood. In contrast, adults with jobs visit a variety of settings in a given day. They may work outside their neighborhoods, shop outside their neighborhoods, and visit with friends in distant communities. A new direction in research takes into consideration these less geographically rooted existences of adults, and the potential impact of multiple contexts on individual and neighborhood outcomes. For example, Morenoff, Sampson, and Raudenbush (2001) examined spatial interdependencies as determinants of neighborhood variation in homicide rates. Mears and Bhati (2006) examined the social influence of neighborhoods to which residents shared social ties. Using ethnographic data, Pattillo-McCoy (1999) considered the social influence of adjacent neighborhoods on resident outcomes.

More recently, researchers have melded perspectives from geography, sociology, and statistics to consider the importance of individual residents' *activity spaces*, or the potential impact of the characteristics of places residents visit regularly, as well as the aggregate activity space of a neighborhood—the collective span of its residents' activity spaces (Kwan, Peterson, Browning, Burrington, Calder, & Krivo, 2008). These new approaches envision the relationships between adult residents and spatial contexts as dynamic, and move the direction of neighborhood research beyond a narrow, residence-based conception of the neighborhood.

A second new area of research examines neighborhood effects in settings outside the United States. Zhang, Messner, & Liu (2007), for example, who are conducting research in China, are applying collective efficacy theory to residential burglary and theft outcomes there. Wacquant (2007) conducted a study using both qualitative and quantitative data to consider urban social marginality in both the United States and France. Efforts such as these will yield important information about the applicability of theories based on data from the United States in an international context.

Future research on neighborhood effects will be facilitated by recent improvements in both statistical software and survey design. First, researchers are able to account for the clustering of residents within neighborhoods through the use of multilevel statistical models (Raudenbush & Bryk, 2002). Second, surveys of large metropolitan areas, such as the Project on Human Development in Chicago Neighborhoods (PHDCN) and the Los Angeles Family and Neighborhood Survey (LA FANS), have been specifically designed to examine the effects of sociospatial contexts on individual residents (Earls, Raudenbush, Reiss, & Sampson, 2002; Sastry, Ghosh-Dastidar, Adams, & Pebley, 2006). Third, researchers have employed methods of systematic social observation (SSO) to capture both objective and subjective aspects of neighborhood contexts. PHDCN researchers videotaped activities in Chicago neighborhoods in the course of their study and reviewed the tapes to code the extent of physical and social disorder in the neighborhoods (Sampson & Raudenbush, 1999).

In sum, neighborhood effects research helps policymakers understand how neighborhoods can have "good" or "bad" influences on the life chances and outcomes of their adult residents. Detrimental aspects of neighborhood environments are of great concern because they can compound the effects of family poverty on resident outcomes. Programs aimed at reducing the geographic concentration of disadvantage, and community-based efforts to build social cohesion and trust among neighborhood residents, may increase health and well-being, particularly among those residing in urban contexts. For example, the MTO study allows policymakers to assess the potential of voucher programs for reducing the geographic concentration of inequality and increasing access to institutional resources. Other potential interventions include increasing institutional resources within disadvantaged neighborhoods, and reducing the extent to which residents of these neighborhoods are exposed to environmental hazards, and physical and social disorder. An increased understanding of the mechanisms that lead to the spatial concentration of economic disadvantage, crime, poor health, and other social ills, is an important step toward addressing these problems.

## NONCUSTODIAL PARENTS

A noncustodial parent is a parent who is legally responsible for the support of a dependent minor child and who does not live in the same household as the child. The terms *nonresident parent* and *noncustodial parent* are often used interchangeably. Noncustodial parents may have joint legal custody of their children, but the children's primary residence is with the other parent. The two primary paths to noncustodial parenthood include (a) births that occur outside of a union to parents who are not married or living together, and where one parent, almost always the father, does not live with the child; and (b) noncustodial parenthood resulting from divorce or separation, after which the children live primarily with one parent. The latter may result from the break up of cohabiting unions as well as marriages.

Becoming a noncustodial parent has profound consequences for the adult life course. The transition to parenthood is a vastly different experience when it occurs in the context of not living with the child and the other parent, as when births occur outside of a union. Unmarried, noncustodial parents (most often fathers in this circumstance) will face severe challenges in forming and maintaining close relationships with their children. For example, relationship difficulties with the other parent are likely to constrict noncustodial parents' access to their children.

Noncustodial parenthood following divorce engenders experiences of separation and loss, the possibility of damaging legal battles, and increased ambiguity in the parental role when not residing with children. Often divorce is only the beginning of a series of life-altering transitions for the noncustodial parent, including changes of residence, reduced socioeconomic status, possible new romantic relationships and union formation, and additional childbearing with a new partner. Each of these transitions has implications for relationships with nonresident children. Thus, becoming a noncustodial parent may have a lifelong influence on the quality of a parent's ties to children and on intergenerational relationships in later life.

## TRENDS IN NONCUSTODIAL PARENTHOOD

Divorce remains the primary cause of noncustodial parenthood. Estimates by demographers show that about half of all marriages will end in divorce, although the divorce rate has leveled off in the early 21st century. (Raley & Bumpass, 2003). An estimated 47% of White women's and 70% of Black women's marriages will end in divorce. Although mothers typically have physical custody of children following divorce, a growing proportion of fathers have full custody (10%) or shared custody (15% to 20%; Coley, 2001). Thus, there has been a substantial increase in the number of noncustodial mothers in the United States. Marjorie Gunnoe and Eileen Hetherington (2004) estimated that there were 1.2 million noncustodial mothers in the United States in the 1980s, with the numbers increasing during the 1990s. Data from the 2005 and 2006 Current Population Surveys show that about 9.3% of U.S. children under the age of 18 were not living with their biological mother (about 6.8 million children). Only about half of these children were living with their father, whereas the remaining half lived with neither biological parent.

Nonmarital childbearing is a rising cause of noncustodial parenthood in the United States. Since the late 1970s, nonmarital births more than tripled for White women ages 20 to 39 and increased by one-third for Black women (Gray, Stockard, & Stone, 2006). Currently about one-third of all births (and two-thirds of Black births) in the United States occur outside of marriage. In assessing nonmarital childbearing and its consequences, it is critical to distinguish between births to parents not in a union and births to (unmarried) cohabiting couples. About 40% of nonmarital births are to women who are cohabiting with the baby's father (Woo & Raley, 2005). Thus, in addition to divorce, the break up of cohabiting unions may also lead to noncustodial parenthood.

National survey data from 2002 show that about 40% of American men ages 15 to 44 had fathered a child outside of marriage, with rates higher for Hispanic (50%) and African American (74%) men (Nock, 2007); this included men who were cohabiting with the mother and were therefore resident parents, at least initially. However, national surveys may miss millions of unmarried, nonresident fathers who are not in the household population and difficult to recruit into research studies. Compared to resident fathers, nonresident fathers tend to be younger; have lower levels of schooling, employment, income, and assets; and are more likely to have substance abuse problems (Nelson, 2004). Nearly one-quarter of nonresident fathers are below the poverty line.

## RESEARCH ON NONCUSTODIAL PARENTHOOD

The vast majority of empirical studies in this area focus on noncustodial fathers. (The few studies on noncustodial mothers are discussed separately.) Research has shown consistently that noncustodial fathers are less involved with their children than resident, custodial fathers. Fathers after divorce may act more like visitors than parents, emphasizing leisure time with children rather than parenting. Living apart from children because of divorce or nonmarital birth makes it more difficult for men to provide financial and social capital to their offspring. Men in separate households have less income to share with children and have more difficulty in being active parents or active participants in their children's lives. National survey data in the United States show that from 25% to 50% of minor children almost never see their noncustodial fathers, whereas about one-fourth to one-third are in frequent contact with them (Nelson, 2004). Children's contact with noncustodial fathers tends to fade over time. Contact rates may vary across countries. An Israeli study found high levels of father involvement with adolescent children 6 years after divorce (Mandel & Sharlin, 2006). In measuring noncustodial father involvement, the informant matters. Mothers consistently report lower levels of involvement than do the fathers themselves. Interparental conflict leads to greater discrepancies between mothers' and fathers' reports.

To what extent is noncustodial father involvement related to a child's long-term well-being? Research on this linkage has produced mixed results. The clearest findings are

that father involvement enhances a child's cognitive development and educational attainment (Coley, 2001), whereas the evidence that fathers affect children's socioemotional development is weak. Analysis of national survey data with children ages 5 to 11 show that positive father–child relationships (e.g., warm, supportive, and responsive fathering behaviors) had modest, negative associations with adolescent internalizing and externalizing problems (King & Sobolewski, 2006). However, a child's relationship with the custodial mother had stronger linkages to well-being. Other research by Valarie King (2006) supported the *primacy of residence* hypothesis, which assumes that the most influential people on an adolescent's well-being are the people with whom he or she lives. Adolescents whose custodial mother remarried benefited from having close relationships with stepfathers and nonresident biological fathers, but relationships with stepfathers appeared to be more influential than relationships with biological fathers. More adolescents reported feeling close to stepfathers (61%) than to biological fathers (41%).

Contact frequency alone is not strongly or consistently associated with a child's adjustment or development. What matters most is what noncustodial fathers do with their children when they spend time together. When noncustodial parents engage in authoritative parenting with their offspring, and when they provide emotional and material support, they likely will contribute to a child's well-being. Contact is a necessary but not sufficient condition for strong relationships between noncustodial fathers and children. More contact leads to more support from fathers to children and more actual parenting as opposed to shared leisure time.

## PREDICTORS OF NONCUSTODIAL FATHER INVOLVEMENT

**Divorce Versus Nonmarital Birth** Children born outside of marriage have less frequent contact with and are less close to noncustodial fathers than children who experienced their parents' divorce. About half of unmarried noncustodial fathers have regular contact in the first years of their child's life, but this drops to about one-third when children are adolescents (Coley, 2001). Laura Argys and Helen Peters (2001) estimated that about 28% of adolescents ages 12 to 16 had weekly contact with nonresident fathers when parents were divorced, but less than 20% had weekly contact if parents had never married. More than 80% of the children of divorced parents had at least one contact with their noncustodial father over the past year, compared to only 57% of the children with unmarried fathers.

**Custody Agreement and Payment of Child Support** Having joint legal custody has been linked to a noncustodial fathers involvement with and feelings of closeness to his children, compared to fathers without legal custody. Fathers who are more involved with their children prior to divorce are more likely to share custody afterward. Joint legal custody gives fathers an equal say with mothers in decisions regarding the child. Having joint physical custody, whereby children split time between the two parental households, promotes involvement. It is difficult for men to establish and maintain an active father role based on visitation only and without daily involvement with the children. Men may feel they have lost their children because of unfair treatment by the legal system.

Rates of child-support payment by noncustodial fathers are low. About 60% of eligible families have a legal child-support award; among those with a legal award, about 20% of children receive all the financial support they are entitled to (Coley, 2001). Only 13% of unmarried fathers pay formal child support, although some offer informal support by providing goods and services for the child (McLanahan & Carlson, 2004). The longer a father is absent from the home, the less likely he is to pay child support. Nonpayment of mandated child support may weaken a father's connection to his children, resulting in lower levels of visiting the children and less influence over childrearing decisions. Mothers who do not receive mandated child support may impede men's access to their children.

**The Coparental Relationship** One of the most important barriers to noncustodial father involvement is a poor coparental relationship with the mother. The coparental relationship refers to the ability of the custodial and noncustodial parent to cooperate in childrearing. The coparental relationship tends to deteriorate over time (after the divorce or nonmarital birth), leading to disengagement and a decreased role for fathers in childrearing and decision making about the children. Cooperative coparenting is not common. In a nationally representative sample, about two-thirds of the custodial mothers reported that the noncustodial father had no influence on childrearing decisions (Sobolewski & King, 2005). A cooperative coparental relationship facilitates contact between the noncustodial parent and children, leading to stronger father–child relationships and more responsive fathering and has been linked to a higher probability of joint custody. Conflict between the parents deters men's involvement with their children and makes it harder for them to parent effectively. The most common pattern of nonresident fathering combines nonauthoritative parenting with low levels of interparental cooperation.

**Family Composition and Transitions** Research has shown that the noncustodial father's remarriage complicates the paternal role and leads to a reduction in contact with his nonresident children. A father's additional childbearing also

leads to a drop in visits with nonresident children, as the father may appear to embrace a new set of biological children and concern himself less with his children from previous marriages. The custodial parent's remarriage also may impact the noncustodial parent. When children acquire a stepparent, contact with the noncustodial parent declines.

**Fathers' Education and Socioeconomic Status** Noncustodial father–child contact is lower in poorer families. Based on research with unmarried fathers, Sara McLanahan and Marcia Carlson (2004) concluded that the male breadwinner role continues to be central to father–child relations. When men are not able to fulfill the breadwinner role for their children, they are more likely to withdraw. Data from a nationally representative sample of adolescents show clear linkages between a noncustodial father's education and their involvement with children (King, Harris, & Heard, 2004). Education was the most influential factor in explaining racial or ethnic differences in father involvement. Lower involvement among Black and Hispanic fathers (compared to White fathers) was explained by lower education levels and a higher probability of having nonmarital births. Education also differentiated the involvement of White fathers. The more educated White fathers (those who attained more than a high school degree) had the highest involvement levels of any ethnic or socioeconomic group, whereas less educated White fathers had the lowest involvement. The work migration of fathers in Hispanic families reduced father involvement in Mexican, Central, and South American families.

**Child Gender** Father involvement does not appear to vary greatly by the child's gender, although boys have reported somewhat higher involvement with noncustodial fathers than girls (King et al., 2004).

## NONCUSTODIAL MOTHERS

The proportion of noncustodial parents who are women has grown in the decades leading up to the 21st century. Nonetheless, research has focused almost exclusively on noncustodial fathers, and relatively little is known about women who occupy this role. This is the largest gap in research concerning noncustodial parenthood. Evidence suggests that sole father custody after divorce is more likely when mothers struggle to fulfill the maternal role because of personal problems (the maternal deficit model) and when mothers enter a new romantic relationship immediately upon separation while fathers remain unattached.

Mothers relinquishing custody of minor children is often viewed as deviant or abnormal. This custody arrangement violates cultural expectations of fathers as breadwinners and mothers as nurturers. Catalina Herrerías (1995) administered a life history questionnaire and clinical assessments to 130 noncustodial mothers. About 75% of these noncustodial mothers voluntarily gave up custody. Their reasons centered on financial considerations, emotional problems, the threat of a legal custody fight, and having a destructive relationship with the father. Although nearly all the mothers in this sample maintained connections to their children, the societal disapproval they experienced led the women to have negative self-perceptions as mothers. Research in the United States suggests that a noncustodial mother's parenting is more intense and of higher quality than that of noncustodial fathers. Susan Stewart (1999) reported in a national survey that noncustodial mothers were as likely as noncustodial fathers to have face-to-face contact with their children. The noncustodial mothers, however, had significantly higher levels of telephone and letter contact with their children. In contrast to noncustodial fathers, whether or not the noncustodial mothers paid child support did not affect their social contact with children. Noncustodial mothers are more likely than noncustodial fathers to perceive a child support order as fair.

Gunnoe and Hetherington (2004) noted that traditional sex roles encourage mothers more so than fathers to be loving toward and responsible for children. In their research with adolescents, they found that a significantly higher percentage of offspring with noncustodial fathers (52%) had no contact with their noncustodial parent than offspring with noncustodial mothers (31%). Noncustodial mothers exerted a more positive influence on adolescent adjustment than did noncustodial fathers, providing greater social support, engaging in more communication, and knowing more about the children than did noncustodial fathers.

## POLICY AND SOCIAL ISSUES

One of the central policy issues of noncustodial parenthood is how child-support awards and their enforcement impact the involvement of noncustodial parents with their children. The majority of noncustodial fathers, especially poor, unmarried fathers, pay no child support at all. Has the stepped-up enforcement of child support orders, including garnishing the wages of parents delinquent in their payments, created a disincentive or barrier to parents in maintaining connections to nonresident children? Men often perceive the child-support order as unfair and are less likely to make the payments when they think the legal system has not been just. One study (Lin & McLanahan, 2007) showed that custodial mothers see paternal obligations and rights as linked and feel that a father's visitation and decision-making rights should be conditional on payment of child support. Men who cannot or will not pay may feel cut off from their paternal role. One family legal scholar has proposed legally requiring nonresident parents to have contact with their

children regardless of their ability to pay child support. The aim is to create a norm of involvement for noncustodial parents that is not tied to the economic support of their children. It is not clear whether this controversial proposal will garner support among policy makers.

Rebekah Coley (2001) described the lack of societal norms about the role and responsibilities of noncustodial parents, especially fathers. How do the role expectations for noncustodial parents change as children grow older, when the custodial or noncustodial parent remarries, or when either parent has children with a new partner? Similar to Andrew Cherlin's (1978) description of remarriage, noncustodial parenthood can be viewed as an incomplete institution that lacks clear social and legal guidelines for role performance. The lack of societal expectations for continued involvement with children may make it easier for noncustodial parents to grow less responsible and responsive to their offspring.

A study conducted by William Marsiglio and Ramon Hinojosa (2007) raised the intriguing possibility that the remarriage of the custodial parent could serve to help rather than hinder a noncustodial father's involvement with their children. Based on qualitative research with a broad-based sample of stepfathers, Marsiglio and Hinojosa found that, although many stepfathers have strained relations with the nonresident biological fathers, there are also many cases in which stepfathers seek to facilitate and support the biological father's relationships with his nonresident children. These stepfathers acted as allies to the noncustodial father and developed a cooperative style of interaction. This study offers the possibility that interventions with remarried families could be developed to help stepparents become facilitators of strong connections between children and noncustodial parents.

## OBESITY, ADULT

The world's population is becoming increasingly overweight. Currently more than 1 billion adults are overweight, and at least 300 million of them are clinically obese (WHO 2008). Obesity is usually measured by the Body Mass Index (BMI), calculated as weight (in kilograms) divided by height (in meters squared). This measure is considered an indicator of body fat. The use of a standard measure is useful for screening patients, for public health interests, and for comparison across time and countries. The National Heart, Lung, and Blood Institute (NHLBI) issued the first federal U.S. guidelines on the evaluation and treatment of obesity in which they adopted the definitions of *overweight,* defined by a BMI of 25 to 29.9 kg/m$^2$, and *obesity*, defined by a BMI of 30 kg/m$^2$ or greater. Within the category of obesity further distinctions are made between *class I obesity*, BMI between 30 and 35; *class II obesity*, BMI between 35 and 40; and *class III obesity*, BMI exceeding 40. These guidelines are consistent with those adopted by the World Health Organization (2000) and used in international studies.

### TRENDS AND DIFFERENTIALS IN OBESITY

In nearly every nation the proportion of the population considered overweight has increased over the past two decades. This increase in body size is particularly evident in the United States. The proportion of the American population that is overweight and obese has risen dramatically for all age groups, although there is evidence that this trend may be slowing. Between 1960 and 2004, the proportion of adult men who were overweight rose from 50% to 71%, while the proportion of women who were overweight rose from 40% to more than 62%. The percentage of men who were obese rose from 10% to 31%, and the proportion of women who were obese rose from 15% to about 33% in the same 44-year period (Ogden, Carroll, Curtin, McDowell et al., 2006). However, between 2004 and 2006 there was no significant change in obesity prevalence for either men or women in the United States (Ogden, Carroll, McDowell, & Flegal, 2007). Rates of overweight and obesity generally increase with age until age 75, when there is a small drop (Flegal, Carroll, Kuczmarski, & Johnson, 1998). Men are more likely than women to be overweight, but women are more likely to be obese, especially with BMIs greater than 35 (Hedley, Ogden, Johnson, Carroll et al., 2004). During the peak years, ages 55 to 74, more than 70% of men and women are overweight and more than 35% are obese. After age 75, the rates drop slightly; just over 60% being overweight and just over 20% classified as obese. Differences in overweight and obesity rates for women vary starkly by race and ethnicity but are not as apparent for men. Across racial and ethnic groups, men have similar prevalences of overweight and obesity (Flegal et al., 1998; Hedley et al., 2004). Black and Hispanic women, by contrast, are much more likely to be overweight and obese than White women. According to the NCHS analysis of National Health and Nutrition Examination Survey (NHANES) data (Hedley et al., 2004), 77.5% of Black women are overweight, compared to 71.4% of Mexican women and 57% of White women. The prevalence of obesity is similarly skewed with the rates for Black, Mexican, and White women at 49.6%, 38.9%, and 31.3%, respectively. Fully 10% of middle-

aged Black women are morbidly obese, with BMIs greater than 40 (Flegal et al., 1998).

## HEALTH-RELATED CONSEQUENCES OF OBESITY

Overweight and obesity are significant risk factors for several chronic conditions and may impede proper medical care. Those who are overweight, and particularly those who are obese, are significantly more likely to have diabetes, high blood pressure, high cholesterol, coronary heart disease, and certain types of cancer (WHO, 2008). Because the likelihood of developing diabetes increases significantly as body fat increases, many have attributed the increased prevalence of Type 2 diabetes to the increased obesity of the world's population. According to the *World Health Report 2002*, approximately 58% of diabetes globally is attributable to excess weight (WHO, 2002), while in the United States the prevalence of diabetes rose 120% between 1980 and 2005 (CDC, 2008). Most of the increased risk for chronic diseases is a direct physical result of overweight and obesity, but several authors suggest that the stigma of being overweight is so pronounced in the medical field that many people avoid going to the doctor, complicating the diagnosis of medical conditions and their care (Puhl and Brownell, 2003).

Despite the clear effect of obesity on the development of chronic conditions, the effect of weight on mortality risk is ambiguous. Several studies have shown that being overweight or mildly obese does not increase, and for some may decrease, the risk of dying (Flegal, Graubard, Williamson, & Gail, 2005; Krueger, Rogers, Hummer, & Boardman, 2004; Reynolds, Saito, & Crimmins, 2005). Others find that obesity increases mortality risks, but the overall magnitude and age gradient is less clear (Fontaine, Redden, Wang, Westfall et al., 2003). The risk seems to be highest for those who have been overweight for longer periods of time and decreases if one does not become overweight or obese until after age 50 (Flegal et al. 2005). In longitudinal analyses, obesity in middle adulthood (ages 30 to 49) has been shown to be associated with an approximately six-year lower life expectancy when compared to normal weight individuals (Peeters, Barendregt, Willekens, Mackenback et al., 2003).

Excess weight creates functional limitations, diminishes mobility, and impairs the ability to exercise at all ages. Those older adults who develop chronic illness due to their obesity still experience functional limitations beyond those created by the illnesses themselves as a result of being overweight (Himes, 2000). The relationship between obesity and disability has important implications for the projection of future disability rates. The rise in obesity may result in higher rates of disability at older ages or increased years of disability in later life (Reynolds, Saito, & Crimmins, 2005). Given the rising rates of obesity at middle ages, it is important to understand how the aging of the obese population may affect disability rates and health care needs in the future.

## SOCIAL CONSEQUENCES OF OBESITY

Several studies report economic discrimination against the overweight at all stages of employment. Societal attitudes about being overweight shape employers' attitudes about the abilities of overweight employees. For example, employers often think that overweight employees are slow-moving, have poor attendance, are unattractive, and are not good role models because of negative personality traits (Roehling, 1999). Overweight persons are less likely to be hired than applicants of normal weight. Additionally, overweight and obese people are hired for less prestigious jobs than their normal weight counterparts and have lower occupational attainment (Pagan & Davila, 1997). Overweight and obese employees are paid less than employees of average weight, but the wage penalty varies by gender, race, and age. Women face a greater wage penalty for being overweight than men (Baum & Ford, 2004). Wages of White women are affected by weight more than wages of Black and Hispanic women (Cawley, 2004). Older overweight employees are penalized more than younger workers, and those who gained weight early in life face greater wage penalties than those who gained weight later in life (Baum & Ford, 2004).

Studies suggest that social discrimination continues to occur on the basis of body size. Common stereotypes about overweight persons include laziness, self-indulgence, impulsivity, and incompetence (Rothblum, 1992). People hold overweight individuals responsible for their own condition and often think that if the overweight simply had more willpower, they would reduce their food intake and, thus, lose weight (Puhl & Brownell, 2003; Rothblum, 1992). These stereotypes persist despite evidence that overweight people generally do not have higher caloric intakes than those of average weight (Rothblum, 1992).

In addition to the personal and emotional costs of disability, chronic diseases translate into increased health care and disability costs. Lakdawalla and colleagues (2005) used simulations to calculate that obese 70-year-olds spend an excess $39,000 of health care compared to non-obese 70-year-olds. Society-wide, the direct economic cost associated with obesity has been estimated at 4% to 7% of all health care costs, or about $51.6 billion in 1995. A slightly lower amount, $47.6 billion in 1995, represents the indirect costs of lost economic output caused by morbidity and mortality due to obesity (Allison, Zannolli, & Narayan, 1999).

## CAUSES OF OBESITY

Social and environmental factors have been implicated in the global spread of obesity. Body fat is a normal and necessary part of the human body. Fat serves an important function as a store of energy that can be used by the body in response to metabolic demands. At the most basic level, obesity results from an imbalance between energy intake and energy expenditure. However, this imbalance may be the result, individually or in combination, of excess caloric intake, decreased physical activity, or metabolic disorders.

Globally, the obesity epidemic has been attributed to a broader "nutritional transition" in which, with increasing modernization and urbanization, diets have tended to shift from ones consisting of complex carbohydrates to diets with a higher proportion of saturated fats and sugars (Popkin, 2001). The introduction of sweetened beverages and processed foods in low-income countries is one factor contributing to the rapid weight gain. Other dietary changes include the inclusion of more animal-source foods and energy-dense foods. These changes in dietary patterns, combined with a decrease in physically demanding jobs, have created overall weight gain worldwide.

In developed countries, the increase in childhood obesity, in particular, has been linked to declines in physical activity. These declines take the form of reduced time spent in physical education classes and recess time in elementary schools, the increased prevalence of video and computer games as entertainment, and the reduction of family physical recreational activities. Research has pointed to the spread of obesity through social networks.

***Obesity Crisis.*** *Obesity raises the risk of a multitude of conditions, especially Type 2 diabetes. Statistics show that 90% of people with the disorder, which causes the body to become resistant to insulin, have a Body Mass Index of more than 23.* AP IMAGES.

Christakis and Fowler (2007) find that, over and above the effects of shared environment, there is evidence that individual weight is affected by the weight of those with whom individuals have close interpersonal relationships. Therefore, as obesity becomes more common it is spread among social networks.

The fight against the spread of obesity is taking place on many fronts. In 2004 the World Health Organization (WHO) issued its statement, *Global Strategy on Diet, Physical Activity, and Health*. Their recommendations cover a broad spectrum of individual and societal initiatives. These include an emphasis on improved school lunch programs and nutrition education for children, and campaigns to increase physical activity among both adults and children. The WHO notes that public policies that influence the pricing of food, either through taxation, subsidy, or direct pricing, need to be considered in ways that will encourage healthy eating. Agricultural policies and food programs are other avenues through which healthy eating and better

nutrition can be encouraged. In the United States there has been increased interest in the role of government in nutrition policy. Legislation at the local, state, and national levels has aimed at taxing foods high in calories, fat, and sugar. One proposal would use the revenue generated by these taxes to fund nutrition and physical activity programs (Jacobsen & Brownell, 2000).

The future health and economic impacts of the increased prevalence of obesity in young and middle adulthood are likely to be large. Many diseases associated with obesity, diabetes in particular, have long-lasting impacts on health, health care needs, and the ability to work. The implementation of policies designed to improve nutrition and increase physical activity may be able to reduce these future impacts. Because the longer an individual is obese, the greater the health risk, targeting individuals early in the life course may have life-long effects.

# OCCUPATIONAL PRESTIGE AND STATUS

**SEE** Volume 2: *Social Class.*

# OCCUPATIONS

*Occupation* refers to the kind of work usually done by someone to earn a living. The type of work a person does provides one of the best simple summaries of life circumstances available to social scientists, because current occupation reflects past and future opportunities to acquire assets and gain benefits in competition with others. Occupation is a window into social stratification—that is, to the persisting unequal distribution of rank, power, and resources in a society. Although the connection between occupation and inequality is strong, it is also highly nonuniform. Thus, one's occupation is one of the most complex indicators of life circumstances in widespread use.

## MEASURING AND CONCEPTUALIZING OCCUPATION

One first issue is what counts as an occupation. Many researchers and most government statistical agencies restrict occupation to work performed for pay outside the home. Unpaid domestic or household labor is thus commonly excluded. Agricultural labor by kin for kin, including work done by children, is also not counted. These activities are excluded because they do not match the idea of *usual occupation* as work involving relatively specialized tasks that are regulated by contract and require formal training, licensing, or previous experience. This model emerged as rural agricultural economies were displaced by urban and industrial alternatives. Relatively unspecialized work gave way to specialized, potentially life-long, vocations that became key determinants of mode and level of living. Eventually the concept of work became equated with labor performed in the formal sector of an industrialized, market economy.

Government concern about ensuring that vocations had adequate supplies of labor is almost as old as urbanism—the Roman emperor Diocletian (245 C.E.–ca. 312 C.E.) decreed that all sons would follow the trade of their fathers, although practical means of enforcement hardly existed. Modern occupational tabulations date from the early industrial era when statistics retained its older meaning of measures created for purposes of state (Desrosiéres, 1998).

Although many terms are used to describe vocations, government tabulations such as the U.S. Census require classifications based on standardized uniform coding rules. From the outset, designers of codes at the U.S. Census Bureau took occupation as a potential master status, "the best single criterion of a man's social and economic status" encompassing "the kind of associates he will have," "the kind of food he will eat," and "the cultural level of his family" (Alba Edwards, in charge of occupational statistics for the U.S. Census Bureau 1920 to 1940 and quoted in Conk, 1980, p 26).

Code creation was an uneven exercise. The scale was daunting. Only government agencies could afford the massive expense of addressing the full range of occupations that individuals report. For the U.S. Census, the raw material was the answers written out in the manuscript census, in which census-takers recorded responses to questions about work usually performed. In the early 20th century, efforts were made to impose a coherent yet detailed classification scheme on such answers. Where possible, code designers relied on folk distinctions among popular trades, such as masonry, which were thought to require special skills. From 1920 on, further job titles were added to accommodate emerging educational specialties in business, engineering, and science. Solid reasons, hunches, and guesswork all played a part. Code designers often rued the lack of reliable information on which decisions could be based. This uncertainty is reflected in the residual categories, such as *Precision Machine Operatives, Not Elsewhere Classified* that are provided as catch-all categories for positions that lack a clear fit.

The result resists easy summary. Many coding schemes implement treelike patterns, in which large coarse classes may be subdivided into finer constituents. The more elaborate catalogues—dictionaries of occupational titles—list upwards of 10,000 distinct categories, whereas survey researchers distinguish at most several hundred down to as few as three. Compromise thus becomes unavoidable.

Categories, although useful, are not intrinsically ranked and thus are ill suited for addressing researchers' questions about occupational change or development. The widely shared intuition that occupation was a master status, however, implied that occupations could be viewed as locations in a social hierarchy.

## RANKING OCCUPATIONS

Various techniques for ranking and assessing occupations have been proposed (Nam & Boyd, 2004). Prominent options include ranking by sample surveys of perceptions of desirability (sometimes termed *occupational prestige*; Treiman, 1977), by distance reflected in relative infrequency of social relations such as marriage and inheritance, (Bottero & Prandy, 2003), and by weighted sums of education and earnings' levels typical of incumbents (Nam & Powers, 1983). The most influential has been the *socioeconomic index*, commonly abbreviated SEI, originally developed by sociologist Otis Dudley Duncan (1961). Every occupation is ranked by a weighted sum reflecting incumbents' earnings and level of education (adjusted for age and measuring level as a percentage of incumbents' above-the-population median for education and earnings, respectively, adjusted to some baseline decennial census). An initial motivation was the happy result that the composite based on nearly equal weights for education and earnings correlates well with prestige rankings. However, the details give rise to variants

among which researchers must choose, more or less arbitrarily (Hauser & Warren, 1997). Although empirical differences among scales are generally modest, the alternatives draw on conceptions that overlap but have not been reconciled, so that no unified interpretation exists for the difference in values across different scales.

Occupational scales (e.g., the SEI) transform occupations from discrete categories (e.g., professionals, laborers) into a continuum or hierarchy. This provides the key step for addressing occupation as some sequence of levels or ranks that occur over the life course. Blau and Duncan (1967) pioneered such studies of status attainment. They examined statistical models for social mobility based on viewing adult occupation as the culmination of a causal sequence of earlier ranks that occurred as stages over the life cycle.

The initial stage in Blau and Duncan's (1967) life-cycle model was family of origin, represented by the male parent's occupational rank (which required adopting some options for scaling occupation). Possible extensions included fathers' education and attributes of the mother.

The next cluster was schooling, which spawned an entire subfield of educational attainment research, devoted to attempts to assign relative weights to such factors as race, gender, parental background, cognitive ability, school quality, and assorted measures of motivation and encouragement.

The category *completed education* was simplified to *years completed.* This was followed by the rank of the individual's first job. From that point, typically in young adulthood, an occupational trajectory followed, culminating in the current job.

The sequence of origin, schooling, labor market entry, and current job provides a framework that allows abstraction from the detailed statistical results. At each stage, the immediately preceding stage has substantial impact. Thus, social origin influences years of schooling, whereas labor market entry level influences current job. As any further stage is reached, echoes of the past diminish, so that current job reflects origin less than first job or schooling. At every stage, variation that is residual—independent of all earlier factors—is substantial. Hence, the two themes are cumulation, in which every outcome depends on relative success or failure at earlier stages, and decoupling, in which later statuses diverge from earlier ones.

The initial scheme was an open-ended framework. Inserting more measurements between any two stages allows for statistical estimates of the relative contribution of the new factors to the transition. One of the most prominent additions, often called the Wisconsin model after the university and state where the research occurred, emphasized the importance of aspirations in persisting at school and in ending up in a high-ranking job (Sewell, Hauser, Springer, & Hauser, 2003).

Status attainment implies an overall pattern for occupational trajectories. A rough sketch is straightforward. As age-mates advance through young adulthood, a shrinking proportion continues on to the next year of school. The fraction that leaves school then enters the labor market. At each step, those who lasted one more year obtain better jobs than those who left earlier. In the United States, a curvilinear pattern exists in which the bump-up for an added year in school rises sharply with each succeeding year (Hauser & Featherman, 1977, Fig. 5.4).The result is a fan, exposing ever-wider gaps between average rank of first jobs with each increment to education. These initial gaps then widen further because increases in job rank, up to peaks at around 40 years of age, are greater the higher the initial labor market entry point.

An analogy helps shed light on how this unfolds. At issue are differences due to how time is spent during the critical years. A good year is one spent earning top grades at a top school. A bad year is one spent working in a menial position in a fast-food restaurant. One might liken this to drawing cards in a card game. The good year is the equivalent of drawing a top card, such as an ace. Flipping burgers is like losing a turn. These lost turns do not come back, however, and results are cumulative. Only those who collect enough *good cards* in a timely manner are allowed to keep playing when the higher stakes finally come up for grabs.

So who ends up with good cards? Many are already dealt at birth. However, with rare exceptions, birth portions do not directly translate into occupational advantage. High cards, such as birth advantage, only grant access to higher stakes tables, such as better schools, but completing school, and gaining adequate marks, remains an individual accomplishment. These particular achievements (e.g., admission to medical school) are the same in name only, however, because those with better birth portions will require less effort or ability to complete particular achievements. The result is shading—step by step, when higher (versus lower) ranks are examined, the predominance of higher (versus lower) origins is more marked, whereas exceptions are more unusual, but they do occur. In a parallel manner, greater success at school, or labor market entry, favors higher adult occupational rank, but only as increased odds of success and almost never strict certainty.

## RACE AND GENDER DIFFERENCES IN OCCUPATIONS

Another source of divergence in occupations and careers are ascribed (or inborn) characteristics, including gender and race. Occupations are strongly influenced by gender. Coarse, medium, or even extremely fine occupational distinctions show strong occupational sex segregation—female workers are heavily concentrated in a relatively

small proportion of occupational titles or categories (Jacobs, 1989). This has diminished over time but has hardly disappeared (Queneau, 2006), and it has survived despite the disappearance of any male advantage in overall education (Bae, 2000).

Women are much more likely to work part-time and to leave and rejoin the labor force sporadically, a pattern thought to indicate weak labor force attachment on the part of such employees. This undermines the accumulation of experience and employer willingness to invest in training. Lower wages result (Jacobsen & Levin, 1995). Another consequence is that occupations are more tightly tied to level of education, that is, less open to subsequent career developments (Treiman & Terrell, 1975).

Why this occurs remains open to debate. Reskin and Roos (1990) described the pattern wherein changes in female proportions were restricted to relatively few occupations as due to *queuing*, whereby the less-desired gender is allowed in only after the more desired gender is elsewhere accommodated. Evidence also exists, however, that returns, such as wages, decline *after* feminization and do not precede it, as queuing would require (England, Allison, Wu, & Ross, 2007).

Family pressures, both perceived and real, play a role. Gender is a proxy, an imperfect but inexpensive indicator, of liability to child-bearing and child-care obligations that could compete with work. Trade-offs between job flexibility and lack of career advances might be at work (Bender, Donohue, & Heywood, 2005). However, although women do more unpaid housework than men do and absorb more of the burden of child care when children are young, these differences diminished quite sharply from 1965 to 1995 (Bianchi, Milkie, Sayer, & Robinson, 2000). Meanwhile, evidence remains strong of glass ceilings in which differences in career outcomes are greater toward the top and tend to grow over the length of careers (Cotter, Hermsen, Ovadia, & Vanneman, 2001).

Research on racial differences in careers also focuses primarily on wage levels and only indirectly on the contributions of occupation. Racial differences in careers are marked. Divergence increases over time, and some evidence of glass ceilings has been provided (Maume, 2004). A key debate continues whether differences between races trace back to premarket differences of less effective education and lower cognitive skills (Neal & Johnson, 1996). Much of the racial contrast, however, can be shown to emerge as careers mature and with greater impact among the better educated, showing that the accumulation of assets valued by employers is impeded by apparent discrimination (Tomaskovic-Devey, Thomas, & Johnson, 2005).

## LIFE COURSE IMPLICATIONS OF OCCUPATIONS AND CAREERS

The very concept of a career, of a sequence of jobs that progress upward over the life cycle, is likely becoming more restricted to a narrowing slice of better jobs. This corresponds to the concept of dual labor markets, in which low pay, low skill, and absence of advancement contrast with conditions in jobs that offer higher pay, chances to use and accumulate skills, and good chances for promotion. The most recent variant emphasizes computerization as a cause of polarization. Some tasks, such as bookkeeping, are highly routine and subject to direct replacement by information technology. Nonroutine tasks, however, such as writing persuasive legal briefs, cannot be done by computers, even though computers aid in some related tasks, such as legal research. Thus, adding computers has a polarizing effect, undermining the market value of much routine work while enhancing returns to some, but not all, nonroutine jobs. Impacts are apparent within detailed occupations and between major occupational groups—increases in computer use undermine the value of less-skilled occupations but raise both average rewards and internal differences within higher skilled occupations (Autour, Levy, & Murname, 2001) Another factor undermining the relative returns of workers with lower skills is increased international competition (e.g., globalization; Acemoglu, 2003).

The overall pattern is that inequality in earnings began to rise rapidly after 1970. Differences rose between individuals within occupations, as did differences between occupations, and the size of gaps attributable to additional years of schooling (Levy & Murnane, 1992). This is complemented by evidence that more recent cohorts entering the labor force experience polarization in career outcomes that are more dramatic and rapid than in the past (Bernhardt, Morris, Handcock, & Scott, 2001).

This overshadows the longer term tendency in which rising average educational levels translate into occupational upgrading. Ever since continuing economic development began with the emergence of industrialism, the mix of jobs has improved over any decade or longer duration. First, agriculture gave way to industrial jobs, which initially became more common in the latter half of the 19th century. By the 1920s, slightly more than half of all jobs outside agriculture were nonmanual, and the proportion of such nonmanual labor rose to more than 80% by the turn of the 21st century (U.S. Census Bureau, 2008). Although coarse classifications such as manual versus nonmanual only roughly capture the concept of worse-versus-better jobs, as illustrated by contrasting tool-and-die maker (i.e., manual) with food-service worker (i.e., nonmanual), an overall trend to work requiring more training and offering better working conditions and rewards becomes apparent.

Contrasts in rewards due to differences in occupation are not limited to earnings. Morbidity, liability to various causes of ill health, and increased early mortality vary sharply with social rank. Such health gradients are not only apparent within a given country but in comparisons among countries as well (Marmot & Wilkinson, 2006). Whether this is uniform or whether distinct patterns link components of rank, such as education or earnings, to different facets of health is likely to remain a lively source of controversy for the foreseeable future.

## PARENT–CHILD RELATIONSHIPS, ADULTHOOD

The relationship between parent and child is one of the most durable bonds in the family, usually lasting far beyond the offspring's childhood and ending only with the death of parent or child. Once a child reaches adulthood, relationships with his or her parents are no longer driven by the child's dependence and development. Scholars of the family are interested in the characteristics of adult parent–child relationships both because of their implications for individual well-being and because of what they suggest about the institution of the family.

With life expectancy almost doubling in length since the turn of the 20th century, children now commonly reach midlife, and not unusually old age, with at least one parent still alive. Although co-survival of generations may have expanded opportunities to exchange resources across generational lines, other trends, such as geographic mobility, weakening norms of responsibility, and the rise in divorce and remarriage rates, have possibly rendered these relationships less dependable than before.

### THEORETICAL AND CONCEPTUAL MODELS

Several different models exist that deal with adult parent–child relationships, including the functionalist, intergenerational solidarity, intergenerational conflict and ambivalence, and intergenerational transfers perspectives.

**Functionalist Perspective** Early theories of adult parent–child relationships evolved from functionalist perspectives in the social sciences that viewed the unmooring of adults from their families of origin as necessary to societal modernization (Goode, 1963; Ogburn, 1932). In this line of reasoning, extended familism was considered incompatible with an increasingly technocratic and meritocratic society that required a trained, specialized, and geographically mobile labor force. Nuclear families needed to be free from the constraints of older generations to maximize their educational and occupational success and, by extension, the economic vitality of the nation (Parsons & Bales, 1955).

The next generation of theories proposed a more nuanced model. Research revealed that even as opportunities for frequent face-to-face interaction between generations were reduced, relatively rapid transportation and communication technologies allowed the maintenance of strong affective ties, in what came to be described as "intimacy at a distance" (Rosenmayer, 1968). This *modified-extended family* was considered to fit well with the demands of modern economies and served as a corrective to the isolated extended family as a normative family form (Shanas & Sussman, 1977).

During this period, several perspectives emerged to explain the behavior of parents and adult children toward each other. *Task-specific theory* (Litwak, 1985) proposed that adult children were better at performing some tasks than other relatives or friends. For instance, the theory predicted that older adults would receive long-term chronic care from nearby adult children but not from friends and neighbors. Children, unlike friends and neighbors, tend to have the level of commitment necessary to

provide intensive care giving but also need to live close to the care recipient. The notion that adult children could relocate on an as-needed basis to meet the challenges of care giving highlighted the flexible nature of family arrangements. A competing theory, the *hierarchical compensatory model*, proposed that older adults turn to others for assistance in a hierarchy based on preferences. Spouses are at the top of the hierarchy, and adult children follow the spouse as preferred providers, but, if children are not available, then other relatives, friends, and finally formal services follow in rank order (Cantor, 1979). Both theories supported the notion that adult children were committed to ensuring the well-being of their older parents and that older parents preferred to rely on their children for help.

**Intergenerational Solidarity Perspectives** In the 1970s researchers turned toward codifying and classifying the nature of intergenerational relations. Borrowing in part from Emile Durkheim's (1858–1917) concept of social solidarity and Fritz Heider's (1958) and George Homans's (1950) theories of small-group cohesion, David Mangen, Vern Bengtson, and Pierre Landry Jr. (1988) developed the *intergenerational solidarity paradigm*. Both a conceptual scheme and a measurement model, the solidarity paradigm itemized the sentiments, behaviors, attitudes, values, and structural arrangements that bind generations together. Intergenerational solidarity was operationalized along seven dimensions: affectual solidarity (emotional closeness), associational solidarity (social interaction), structural solidarity (opportunity for interaction based mostly on geographic proximity), normative solidarity (filial obligation), consensual solidarity (perceived and actual agreement on values and opinions), and functional solidarity (provisions of material, instrumental, and social support).

Since its development, the solidarity paradigm has been the de facto gold standard for assessing the strength of intergenerational relationships both in the United States (e.g., Lawrence, Bennett, & Markides, 1992) and internationally (e.g., Lowenstein, Katz, & Daatland, 2005). However, research demonstrated that the separate dimensions of solidarity could not justifiably be added together to form a single measure of intergenerational solidarity (Roberts & Bengtson, 1990). More promising were approaches that were relationship centered rather than variable centered, which could group intergenerational relationships based on seemingly antithetical dimensions, such as being geographically distant but emotionally close (Silverstein, Bengtson, & Lawton, 1997).

**Intergenerational Conflict and Ambivalence Perspectives** Responding to criticism that the solidarity paradigm did not allow for negative emotions and behaviors, researchers subsequently added the dimension of conflict to the model (Clarke, Preston, Raksin, & Bengtson, 1999). Indeed, challenges to the solidarity model came into high relief by scholars advancing *intergenerational ambivalence theory*, a perspective that focused on mixed feelings—the simultaneous occurrence of affection and hostility—that come from the tension between autonomy and dependence in intergenerational relationships. Although ambivalent feelings are obvious early in the family lifecycle (e.g., adolescents striving for independence), they are evident in older families as well (e.g., aging parents becoming dependent, adult children not living up to parental expectations; e.g., Pillemer & Suitor, 2002). Research has moved toward integrating the solidarity and ambivalence perspectives.

**Intergenerational Transfers Perspective** A different perspective on adult parent–child relationships is provided by research on intergenerational transfers, which is concerned with identifying motives for providing time and money resources to family members across generational lines. In this line of research, parents and their adult children are considered interdependent actors who provide for each other over the life course.

Findings that transfers tend to be targeted at children with the greatest need offer some evidence that older parents distribute resources altruistically. Research showed that adult children in the lowest income category were more than 50% more likely than those in the highest income category to receive a money transfer from their parents (McGarry & Schoeni, 1997). Similarly, older adults in European nations with relatively generous pension programs are more likely to provide economic transfers to needy children (e.g., Fritzell & Lennartsson, 2005).

Reciprocity has been a consistent theme in the study of adult parent–child relationships. This perspective maintains that the obligation to pay a debt is found in intergenerational family relations as well as market relations. In developed nations, the most commonly tested question is whether adult children who receive more money from their parents provide more instrumental support to them. Several investigations have shown such a pattern (e.g., Caputo, 2002), but others have not or have found substantively small effects (McGarry & Schoeni, 1997).

Several studies found that parents who in middle age provided financial assistance to their young-adult children were more likely to receive social support from them in old age (Silverstein, Conroy, Wang, Giarrusso, & Bengtson, 2002). The obligation to reciprocate is reinforced through norms and emotions; one study found that adult children who felt they owed their aging parents a debt of gratitude were more prolific providers of support to them (Ikkink, Van Tillburg, & Knipscheer, 1999).

It has long been known that the strength of emotional bonds between parents and children is positively

correlated with the volume of intergenerational transfers between them (Rossi & Rossi, 1990; Silverstein, Parrott, & Bengtson, 1995). However, motives for transfers are often mixed and not easily distinguished. Transfers of money that stimulate time transfers from children (visiting, social support) may strengthen intergenerational attachment and prompt additional transfers (Attias-Donfut, 2000).

## VARIATION IN ADULT PARENT–CHILD RELATIONSHIPS

Several factors have an influence on the nature of parent–child relationships, including family structure, ethnicity, and national contexts.

**Family Structure** As a result of historical increases in divorce and remarriage, the family has fragmented into myriad family forms that include complex configurations of step- and biological kin (Casper & Bianchi, 2002). Numerous studies have found that parental divorce suppresses transfers of money and time between parents and their adult biological children and that remarriage does the same between stepparents and their adult stepchildren (e.g., Furstenberg, Hoffman, & Shesthra, 1995; Pezzin & Schone, 1999; Silverstein et al., 1997). Divorce has been shown to disrupt transfers by weakening normative beliefs about intergenerational responsibility and by reducing opportunities for interaction and the development of emotional cohesion between generations. Incomplete bonding with a stepparent, competition with stepsiblings, conflict between custodial and noncustodial parents, and the absence of clear institutional rules for establishing normative expectations within stepfamilies conspire to put children at risk of having strained or distant relations with both step- and divorced biological parents (Furstenberg & Cherlin, 1991).

The impact of divorce on intergenerational transfers is greater for fathers, who are less likely than mothers to receive primary custody of their children and more likely to remarry and live with stepchildren. Research by Frank Furstenberg, Saul Hoffman, and Laura Shesthra (1995) suggested that lower levels of intergenerational support received by divorced fathers is not a function of the amount of child support they provided but of the diminished investments of time and emotion they made in their natural children when the children were growing up. Liliana Pezzin and Barbara Steinberg Schone (1999) found that fathers were less sensitive in responding to the needs of their stepchildren than they were to the needs of their biological children, concluding from this that altruism is less a potent social force toward children that fathers did not sire.

An alternative to the support deficit perspective is that marital disruption and remarriage, and the various family recombinations that result, have expanded the kin supply and increased the potential support portfolio of older adults by adding step-relatives to the family network. Taking these social changes into consideration has resulted in the need to develop new models of complex family forms. For instance, the *latent kin matrix* (Riley & Riley, 1993) brings to light how close intergenerational relations are culled from the pool of kin and nonkin associates but also emphasizes greater uncertainty in the stability of these more voluntary family ties.

**Ethnic Variation** Some scholars posit that elders from minority and traditional cultures have greater opportunities to exchange family support across generations (Angel & Angel, 2006). For example, African Americans are more likely than Whites to reside in extended family households, live close to relatives, and report having "fictive kin" (Chatters & Jayakody, 1995). Latinos also are more likely than Whites to reside in multigenerational households (Himes, Hogan, & Eggebeen, 1996). However, other evidence suggests that economic insufficiency in minority families may suppress their ability to deliver care despite stronger intentions to do so (Silverstein & Waite, 1993).

Older immigrants are more likely to live with kin than their native-born counterparts. This pattern is characteristic of immigrants worldwide. Judith Treas and Shampa Mazumdar (2004) pointed out several unique intergenerational challenges facing older immigrants. First, older immigrants are at elevated risk of social isolation as a result of their limited English proficiency and tendency to subordinate their own needs to those of their families. Second, older immigrants are expected to care for their grandchildren at an age when they are also likely to experience the need for care themselves. Third, they are often called on to sustain the cultural integrity of their native land while their adult children are acculturating into the host society. The popular image of immigrant elders contentedly embedded in family-based support networks is likely an oversimplification.

**National Context** Formal support mechanisms—government, voluntary organizations, and private enterprises—have become more important in serving the needs of older adults in developed countries. Research finds that the salience of intergenerational relations—as measured by proximity, frequency of contact, and provisions of support—tends to be weaker in nations with more generous public services and benefits to the elderly and less coercive family cultures.

A key question with respect to public policy is whether more liberal social benefits (a) "crowd out" intergenerational

family transfers, (b) "crowd-in" intergenerational family transfers, or (c) complement intergenerational family transfers. Evidence shows some support for all three mechanisms (Künemund & Rein, 1999). One study, for instance, found that formal support reduced informal support among older Whites but not among older Blacks (Miner, 1995). However, another found no evidence that more extensive use of formal services was associated with less extensive informal care (Penning, 2002). Similarly, cross-societal research finds that welfare state services tend to be complementary with respect to family care (Attias-Donfut & Wolff, 2000). However, Gerdt Sundstrom, Lennarth Johansson, and Linda Hassing (2002) in an historical analysis found that newly instituted policies restricting eligibility of older adults for home help services in Sweden was followed by increases in family care, providing some evidence that the state had crowded-in adult children.

Complementarity appears to be less true for income transfers. Universal income maintenance programs effectively substitute for financial transfers from adult children, as there are relatively few older adults in need of transfers from children in modern welfare states (Lee, 2000). Net intergenerational financial transfers are decidedly downward—from older parent to adult children—as enabled by generous pension provisions (Fritzell & Lennartsson, 2005; Lowenstein et al., 2005).

In most developing nations, older adults rely almost exclusively on their families for needed support. Time-for-money exchanges between generations describe a common type of mutual aid in the less developed world, where older parents provide household labor and/or childcare services to the families of their adult children in exchange for money or food (Frankenberg, Lillard, & Willis, 2002). However, the primacy of intergenerational relations has declined in rapidly developing nations. In many East Asian nations, filial piety is said to have weakened, altering traditional expectations and social understandings between generations. In the least developed nations of sub-Saharan Africa, adult children have few resources to exchange with their parents and instead devote them mostly to their children, creating a crisis in the support systems of older adults (Aboderin, 2004).

## FUTURE DIRECTIONS

Five themes emerge as fruitful directions for future research on adult intergenerational relationships. First, the gerontological implications of family change will soon come to fruition, as those in more complex, less traditional, and smaller families enter old age. How much older parents can rely on their children for support in these "new" family forms remains an open question. Second, increased longevity has verticalized multigenerational families, creating the possibility that middle-aged individuals may need to support frail older parents, young adult children, and/or grandchildren at the same time. Those in the sandwich generation clearly face difficult challenges if they are simultaneously caring for older and younger generations. Third, the free flow of labor across national borders has made most European and North American nations more culturally heterogeneous. Understanding how immigrants and their descendants negotiate the normative constraints of their native cultures and the forces of assimilation will inform policy makers about the shifting terrain of family life for older and younger generations.

Fourth, public policies, particularly those related to pensions and other benefits will loom large for the well-being of the elderly and their descendants. Postponing age of eligibility for Social Security benefits and reducing the value of European pensions will lower standards of living for older generations and impede transfers received by younger generations. Studies of the impact of public policies on older persons and their family members must account for interdependence between generations. Finally, the concept of ambivalence has taken hold as one of several dominant paradigms guiding research on adult intergenerational relationships. Questions that remain to be answered include how ambivalence is psychologically and socially managed or resolved, how it changes over the life course and varies across social groupings, how emotional and structural ambivalence are connected, and whether ambivalence can be incorporated into the other conceptual models, such as solidarity, or whether it is a unique and independent aspect of intergenerational relations.

# PERSONALITY

Personality refers to relatively enduring individual differences in patterns of thoughts, feelings, and behavior. A classic definition of personality is provided by author Gordon Allport (1897–1967): "Personality is the dynamic organization within the individual of those psychophysical systems that determine [her or his] characteristic behavior and thought" (1961, p. 28). Embedded in Allport's definition are the ideas that (a) personality attributes are individual difference characteristics; (b) personality attributes partially reflect biological processes (i.e., psychophysical systems); and (c) personality attributes influence patterns of adjustment to the environment.

## IDENTIFYING BASIC PERSONALITY TRAITS: THE BIG FIVE

A major task for personality scholars is to identify and classify the many possible personality attributes or traits. One starting point for this task is language itself. According to the *lexical hypothesis*, the most important personality attributes are reflected in the terms used to describe individuals. Using the logic of the lexical hypothesis, many personality psychologists believe that an analysis of how personality-related adjectives (e.g., calm, talkative, dominant, kind) cluster together might provide some insight into the number and nature of the basic units of personality.

In 1936 Allport and psychologist Henry Odbert (1909–1995) attempted to classify the personality trait names in the English language. Since that time, several researchers have engaged in this process, and there is now considerable agreement that five broad domains—the *Big Five*—capture many of the personality adjectives found in the English language. Each factor consists of a cluster of related characteristics: extraversion (traits such as being talkative and energetic); agreeableness (traits such as being cooperative and kind); conscientiousness (traits such as being responsible and dependable); neuroticism (traits such as being tense and nervous); and intellectual or openness to experience (traits such as being curious and artistic). Studies using languages other than English usually find similar dimensions. The exceptions are that an openness dimension sometimes does not appear distinctly in different languages, and that additional dimensions particular to a certain culture will sometimes appear. Nonetheless, the first four dimensions of the Big Five appear to be more or less robust across languages and thus cultures.

There is emerging (but not complete) consensus that the Big Five can serve as a reasonable working model of the basic dimensions of adult personality. Moreover, most of the Big Five traits are evident in adolescents and in children as young as age 5. (Openness, however, may not become clearly evident until late adolescence.) The Big Five also can organize the ways that psychologists have classified the individual differences that are evident in very young children (often called dimensions of temperament). This extension of the Big Five to the very youngest ages helps to focus attention on a core set of personality dimensions that are broadly relevant for functioning and adaptation across the life span.

## THE ORIGINS OF PERSONALITY: GENETIC AND ENVIRONMENTAL FACTORS

Consistent with Allport's convictions about the biological basis of traits, researchers are interested in genetic influences on personality. Much of the evidence in support of this idea comes from studies examining personality similarity in twins. One approach is to compare the degree of similarity of identical twin pairs reared in the same household, with the degree of similarity of fraternal twin pairs reared in the same household. If identical twins are much more alike than fraternal twins, then researchers infer that genetic factors must account for some part of personality. This reasoning draws on the fact that identical twins share all of their genes, whereas fraternal twins share, on average, 50% of the same genes. Thus, because both types of twins are living in the same environment, the major explanation for any increased similarity in identical twins is their increased genetic similarity.

A few broad conclusions can be drawn from twin studies. In general, identical twins are more similar in terms of the Big Five than are fraternal twins. Likewise, the few studies that have been able to examine identical twins reared apart indicate that these twins are fairly similar in terms of their personality attributes in adulthood, despite growing up in different circumstances. Thus, genetic factors do account for personality differences between people. However, identical twins are not perfectly alike in terms of their personalities (regardless of where they were reared), indicating that non-genetic factors (called environmental factors in this context) also play an important role in shaping personality. Some examples of environmental factors may include early school experiences and experiences with peers; researchers are currently working to develop a precise understanding of the particular environmental factors that shape personality. In sum, twin studies underscore a point raised by Allport many years ago: "No feature of personality is devoid of both hereditary and environmental influence" (1961, p. 68).

## THE DEVELOPMENT OF THE BIG FIVE IN ADULTHOOD

Research that suggests a genetic basis for the Big Five does not exclude the possibility that personality traits

change with age or that personality traits can be affected by life experiences. The study of personality development attempts to answer these questions. Researchers examining questions about personality development ideally use longitudinal designs, in which the same group of individuals is followed over a long period of time and assessed repeatedly with the same personality measures. Most of this research is descriptive in that it attempts to quantify the degree of personality stability and change across the life span. A complication in such research is that there are several ways to conceptualize and measure stability. The two most commonly investigated questions have to do with *differential stability* and *absolute stability*.

Studies of differential stability evaluate whether the relative ordering of individuals on a Big Five attribute are consistent over time. A researcher who wants to evaluate the differential stability of extraversion, for example, might investigate whether individuals who are relatively extraverted compared to their peers in their 20s are also relatively extraverted compared to their peers in their 40s. Studies about absolute stability, by contrast, examine the *degree* of stability in the exact amount or level of a personality attribute over time. A researcher who wants to evaluate the absolute stability of extraversion might examine whether, on average, individuals are more extraverted in their 20s compared to their 40s. Alternatively, this researcher might want to know how many members of a sample increased in extraversion from their 20s to their 40s, compared to how many members decreased during that time. Although questions about differential and absolute stability are distinct, both are important questions about personality development.

**Research on Differential Stability in Adulthood** Differential stability is usually examined by calculating the correlation (a statistic that assesses the degree to which two variables are associated) between the same measures administered on different occasions to a sample followed across substantial intervals of time (e.g., 1 or more years). Because a sizable number of studies have evaluated differential stability, researchers have used a statistical technique called *meta-analysis* to summarize these results. Meta-analytic techniques allow researchers to essentially average results from all available information and then draw quantitative conclusions from an entire research literature.

One prominent meta-analysis summarized correlations from 152 longitudinal studies. The general result was that the Big Five traits showed increasing differential stability with age. Specifically, there was a fairly modest amount of differential stability when individuals were followed during their early childhood years, whereas there was a very strong amount of differential stability when individuals were followed in their 50s and older. This pattern of differential stability was basically the same for all Big Five traits, and there was little evidence of gender differences in differential stability.

These meta-analytic findings are noteworthy because they confirm that the Big Five traits are relatively enduring characteristics by the time a person reaches adulthood. The current explanation for increasing differential stability with age is that adulthood is a time in the life span when maturational changes are reduced, social roles stabilize, environmental changes are increasingly subject to individual control, and individuals have a more stable sense of self. These conditions tend to promote stability. Even so, the meta-analytic findings also indicate that there is never a time in the life span when personality is set in stone. This seems to contradict a suggestion by the American psychologist William James (1842–1910), who said that personality is "set like plaster" by the age of 30. The Big Five traits do become increasingly stable after age 30; however, there does not appear to be a point when personality is fixed for all people.

**Research on Absolute Stability in Adulthood** Research on this topic has generally focused on comparing mean levels of traits measured at different ages. In others words, much of this research is useful for answering questions about whether there are differences in average scores on measures of the Big Five for 20-year-olds compared to 40-year-olds. Across studies and meta-analytic results, it appears that average levels of agreeableness and conscientiousness increase with age, whereas average levels of extraversion, neuroticism, and openness decline. Many of the absolute changes in the Big Five tend to be small and gradual when viewed as year-to-year comparisons.

The absolute changes in the Big Five tend to reflect increases in personal qualities that help individuals meet the demands of the adult roles of worker, committed romantic partner, and parent. This trend has been labeled the maturity principle of personality development (i.e., there is increased personality maturity with age). Young adulthood (i.e., the years between the late teens and late 20s) is a time when many absolute changes in personality occur. This is also a time in the life span when individuals gradually start to assume the roles of worker, partner, and parent. Thus, the average absolute changes in the Big Five seem to match the demands of the life course. This finding raises important, but mostly unanswered, questions about the causal connections between adult roles and personality change. For example, it might be the case that assuming the role of a worker or a committed romantic partner creates increases in conscientiousness.

## PERSONALITY AND LIFE OUTCOMES

Allport noted that, "personality *is* something and *does* something" (1961, p. 29). Literally hundreds of studies link personality to life outcomes. Fortunately, a number of meta-analyses on these topics provide some of the best evidence that personality differences are associated with important life outcomes, including longevity and health behaviors; crime and aggression; relationship satisfaction and stability; achievement-related outcomes; and overall life satisfaction.

**Longevity and Health** A life outcome of great importance to individuals and society is longevity. A striking example linking personality with mortality comes from an analysis that followed a group of more than 1,200 individuals from the 1920s through the mid-1980s who were mostly middle class. Study participants who were rated by their parents and teachers as more prudent and conscientious when they were children tended to live longer than participants who were rated as less conscientious. Indeed, conscientiousness appears to be the strongest Big Five personality predictor of longevity based on one meta-analysis and review (Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007). This report also summarized evidence indicating that people with personality characteristics such as high levels of agreeableness, high levels of extraversion, and low levels of neuroticism lived longer lives.

One potential explanation for the association between conscientiousness and longevity is that conscientiousness statistically predicts many of the behaviors that either promote or hinder physical health. One meta-analysis summarized the results of more than 190 studies on this topic (Bogg & Roberts, 2004). Conscientiousness was negatively associated (i.e., as scores on this trait increased, these behaviors decreased) with drug, alcohol, and tobacco use; risky sexual activity; unsafe driving practices; suicidal ideation; and involvement in violence. As conscientiousness increased, involvement in these sorts of behaviors decreased.

**Crime, Delinquency, and Antisocial Behavior** Crime and antisocial behavior have enormous consequences for society. One meta-analysis examined the association between personality and crime (Miller & Lynam, 2001). Agreeableness and conscientiousness were negatively associated with antisocial behavior (i.e., as scores on these traits increased, antisocial behavior decreased), and similar results were obtained when researchers examined links between antisocial behavior and comparable traits from other personality models. In short, individuals who engage in criminal behavior tend to be antagonistic to others and to lack the ability to control impulses or otherwise delay gratification.

**Relationship Outcomes** Close relationships are valued by most adults, and consistent evidence links personality with relationship satisfaction and stability. One meta-analysis found that neuroticism was negatively associated with marital satisfaction (Heller, Watson, & Ilies, 2004). Agreeableness was positively associated with marital satisfaction, although that relation was examined in 19 studies compared to the 40 studies that examined neuroticism. In fact, there were detectable associations between personality and marital satisfaction for the other Big Five traits, with perhaps the exception of openness. In terms of predictors of divorce, one meta-analysis reported that high levels of neuroticism combined with low levels of agreeableness and conscientiousness were associated with an increased risk for divorce (Roberts, Kuncel, Shiner, Caspi, & Goldberg, 2007). These three individual personality effects were each stronger than the association between socioeconomic status and risk for divorce.

**Achievement and Work Outcomes** Applied psychologists and organizational scholars have had long-standing interest in the connection between personality and job performance. Meta-analytic findings suggest that conscientiousness is the best overall predictor of job performance out of the Big Five dimensions. Consistent with the effects of conscientiousness on job performance, a series of studies were conducted finding that conscientiousness predicted college grade point average (GPA) even when accounting for achievement test scores such as the Scholastic Aptitude Test (SAT) (Noftle & Robins, 2007). Thus, conscientiousness appears to be a robust predictor of achievement-related outcomes. Personality traits also are associated with ratings of job satisfaction. In particular, low levels of neuroticism and high levels of extraversion are related to job satisfaction, according to a meta-analytic review; however, there are also indications that conscientiousness is also positively associated with job satisfaction.

**Life Satisfaction** Some people are happier and more satisfied with their lives than others, and these life satisfaction judgments are related to personality dimensions. One meta-analysis from 19 studies involving more than 12,000 participants concluded that all Big Five traits except for openness were related to life satisfaction (Heller, Watson, & Iles, 2004). The strongest predictor was a low level of neuroticism, whereas extraversion, agreeableness, and conscientiousness were all positively related to life satisfaction at about the same degree. In short,

personality traits may partially explain why some people are happier with their lives than others.

## FUTURE DIRECTIONS FOR RESEARCH

Personality research is an active area that intersects with many disciplines. A considerable amount is known about the structure, development, and correlates of personality traits in adulthood. However, personality is also a contentious research area that can ignite vigorous debates and disagreements. For example, some researchers favor models of personality structure other than the Big Five. In response, other researchers note that the Big Five enjoys a level of support currently unmatched by any other competing model. Some of the debates in personality simply have to do with the topic itself. Personality covers human individuality, and there are always exceptions to every generalization. Thus, there is a wellspring of material for contrary arguments by critics. At the same time, some of the debates in personality psychology occur because the subject raises so many questions that have yet to be fully answered.

Three issues stand out as important directions for future research. First, there will be continued interest in the neurological systems, brain structures, and specific genes that underlie the Big Five. For instance, theoretical and empirical work traces extraversion and its childhood analogues to a biological system that govern one's sensitivity to rewards or incentives. There is also considerable interest in identifying specific genes associated with personality characteristics, and in studying precisely how genes interact with life events to shape life outcomes. All told, future work will continue to evaluate how biological processes and life events work together to shape personality. Research that ignores either of these two major factors will become increasingly less informative.

Second, there will be continued efforts to understand adult personality development. For instance, there is a debate between proponents of the *intrinsic maturational* perspective and proponents of the *social investment* perspective. The intrinsic maturational perspective argues that changes in personality are driven by biological processes, such as changes in the prefrontal lobes of the brain that might lead to increases in conscientiousness in young adulthood. The social investment perspective, by contrast, posits that changes in adult personality are related to involvement in or anticipation of particular roles such as committed romantic partner, worker, and parent. According to the social investment perspective, personality changes are generated by life experiences such as the birth of a child and involvement in steady and satisfying employment, which, for example, may create demands for increased conscientiousness. Future research will determine the level of support for the intrinsic maturation and social investment perspectives, and it is likely that aspects of both perspectives have some merit.

Third, future investigators will strive to identify the processes that link personality to life outcomes. It seems likely that multiple mechanisms will be involved for each broad association. For instance, several potential processes may explain why personality is correlated with job performance. Some mechanisms may involve direct effects, whereby certain people simply perform tasks better than others or have fewer conflicts with coworkers because of their personalities. However, additional and more subtle processes may play out over the life course. For instance, more conscientious individuals might select certain educational or career paths, and conversely, gatekeepers such as employers or college admissions boards might select people based on their personality attributes or motivational tendencies as evidenced in application materials. Nonetheless, involvement in these particular settings may further accentuate conscientiousness and thus promote job performance. Thus, ongoing transactions between social selection and social influence may ultimately help explain the links between personality and life outcomes.

All in all, personality is an active and contentious specialty area in the social and behavioral sciences. Personality is a fertile meeting place of insights from biology, psychology, and sociology, which makes it a vibrant and exciting topic. Despite many unanswered questions, it is clear that personality "is something that does something" when it comes to understanding adaptation across the life span.

## POLICY, EMPLOYMENT

Employment policy shapes people's work lives and thus a diverse range of life course outcomes. Along with economic factors such as unemployment rates or industrial trends, policies set the context in which people's work lives unfold by regulating certain aspects of employment and attempting to fix perceived injustices. Employment policies may also involve direct interventions in one's labor market experiences, such as opening career doors to a member of a subgroup who had once been denied entry to a job. It can also refer to macroeconomic policies designed to foster desired conditions for all individuals in a society. Traditionally, employment policies focused on unemployment, often involving financial programs to support individuals during times of job loss.

Although smoothing the transition between employment and nonemployment remains a central goal of some employment policies, policy makers have come to recognize and address other forms of transition that have both short- and long-term consequences for individual well-being. Among the wide range of transitions encompassed by employment policies are (a) ensuring that schools and postschool forms of education prepare younger people adequately for the world of work; (b) enabling workers to manage the simultaneous demands of employment with domestic responsibilities, such as child care or elder care; and (c) easing the transition for older people from employment into retirement through pension policies.

Governments enact employment policies to ensure that the law enforces employment practices that mesh with societal-level values such as equality of opportunity. Specific polices encompass gender equality in terms of income and access to specific occupations, equal access to employment for groups traditionally excluded from particular paid forms of employment, and the protection of workers' health and well-being. An important goal of most employment policies is to eliminate discrimination from the workplace. (To discriminate against someone means to treat that person differently, or less favorably.) Individual employees can be discriminated against by coworkers, managers, or business owners.

The employment policies enforced by different governments (including the United States in particular) are put in place to protect individuals against employment discrimination when it involves (a) unfair treatment because of race, religion, sex (including pregnancy), national origin, disability, or age; (b) harassment by managers, coworkers, or others in the workplace because of one's race, religion, sex (including pregnancy), national origin, disability, or age; (c) denial of a reasonable workplace because of religious beliefs or disability; and (d) retaliation from employers because of worker complaints about job discrimination.

When looking at specific policies, one can see what potentially sweeping impacts they have on both the immediate and future life experiences of workers. The following two examples of the Equal Pay Act (EPA) and affirmative action are indicative of employment policies that seek to minimize disadvantages experienced on the basis of race, class, gender, or religion that historically have impeded one's occupational trajectories over the life course.

## THE AMERICAN EQUAL PAY ACT

In 1963 the U.S. Congress (under President John F. Kennedy [1917–1963]) passed the EPA to prohibit discrimination on account of gender in the payment of wages by employers. Within the text of the EPA, Congress included a clear and concise policy statement that briefly described the problems it intended to remedy. The clear statement of congressional intent and policy guiding the EPA's enactment was indicative of the congressional desire to fashion a broad remedial framework to protect employees from wage discrimination on the basis of gender. The Supreme Court has expressly recognized the view that the EPA must be broadly construed to achieve the congressional goal of remedying gender discrimination. Congress passed the EPA out of "concern for the weaker bargaining position of women," as a way to provide a remedy to discriminatory wage structures that reflect "an ancient but outmoded belief that a man, because of his role in society, should be paid more than a woman." The EPA protects both men and women. It also protects administrative, professional, and executive employees who are exempt under the Fair Labor Standards Act.

The EPA is the first law to suggest that the pay of women should be equal to men when their positions are equal. The purpose of the EPA is to secure equal pay for women who have jobs similar to men and to seek to eliminate discrimination and the depressing effects on living standards caused by reduced wages for female workers. Although sources indicate that women's pay is still approximately 25% less than men's pay even in 2008, the EPA is still considered one of the best attempts to help close the gap. At the same time, the EPA has one major practical limitation: It requires that men and women be given equal pay for equal work, yet in practice men and women are rarely employed in the same occupations.

The EPA states that employers may not pay unequal wages to men and women who perform jobs that require equal skill, effort, and responsibility and that are performed under similar working conditions within the same establishment. Among the criteria used to gauge equality are skills required for the job, amount of physical and mental exertion required on the job, degree of accountability required of workers, and physical work conditions such as workplace health hazards.

Despite the establishment of such equal pay policies, gender gaps in earnings persist in the United States and have important implications of gender equality over the life course. For example, there is a 17% gap between men's and women's pay for full-time work in the United States with a woman earning, on average, $80 for every $100 a man earns (Powell, 2006). When accumulated over the life course, these earnings gaps contribute to vast economic disparities in later life. In the United States, women comprise 59% of those age 65 and over; they account for 72% of the older poor (Powell, 2006). Older women's average income is roughly 50% lower than that of their male peers. These disadvantages are particularly pronounced for African American women; in 1990, a stunning 82% of older Black women were classified as poor or "near poor" (Powell, 2006). The case of race and gender disparities clearly illustrates how employment policies targeted toward young or working-age populations have implications for one's well-being over the life course.

## AFFIRMATIVE ACTION

A second key theme of employment policy relates to affirmative action. This can be defined as positive steps taken to increase the representation of women and ethnic minorities in areas of employment, education, and business from which they have been historically excluded.

In the United States, the effort to improve the employment and educational opportunities of women and members of minority groups has taken the form of preferential treatment in job hiring, college admissions, the awarding of government contracts, and the allocation of other social benefits. First undertaken at the federal level following the passage of the landmark Civil Rights Act of 1964, affirmative action was designed to counteract the lingering effects of discrimination that had taken place throughout history. The main criteria for inclusion in affirmative action programs are race, sex, ethnic origin, religion, disability, and age. The policy was implemented by federal agencies enforcing the Civil Rights Act of 1964 and two executive orders, which provided that government contractors and educational institutions receiving federal funds develop such programs. The Equal Employment Opportunities Act (1972) set up a commission to enforce such plans.

The establishment of racial quotas in the name of affirmative action brought charges of so-called reverse discrimination in the late 1970s. The U.S. Supreme Court placed important limitations on affirmative action programs in a 1978 ruling (*Regents of the University of*

*California v. Bakke*). Although the Court accepted such an argument in *Regents of the University of California v. Bakke*, it let existing programs stand and approved the use of quotas in 1979 in a case involving voluntary affirmative action programs in unions and private businesses.

In the 1980s the federal government's role in affirmative action was considerably diluted. In three cases in 1989, the Supreme Court undercut court-approved affirmative action plans by giving greater standing to claims of reverse discrimination, voiding the use of minority set-asides where past discrimination against minority contractors was unproven, and restricting the use of statistics to prove discrimination, because statistics did not prove intent.

The Civil Rights Act of 1991 reaffirmed the federal government's commitment to affirmative action. In the late 1990s, however, in a public backlash against perceived reverse discrimination, California and other states banned the use of race- and sex-based preferences in state and local programs. Several subsequent Supreme Court decisions (e.g., *Adarand Constructors v. Pena* in 1995 and *Hopwood v. Texas* in 1996) imposed further restrictions. A 1995 Supreme Court decision placed limits on the use of race in awarding government contracts; the affected government programs were revamped in the late 1990s to encompass any person who was "socially disadvantaged." In 1996 California voters passed Proposition 209, which prohibited government agencies and institutions from discriminating against or giving preferential treatment to individuals or groups on the basis of race, sex, color, ethnicity, or national origin. Similar measures were subsequently passed in other states. In 2003, in two landmark Supreme Court rulings involving admission to the University of Michigan and its law school, the U.S. Supreme Court reaffirmed the constitutionality of affirmative action but ruled that race could not be the preeminent factor in such decisions.

The effectiveness of affirmative action programs has been widely debated. Conservative scholar and writer Thomas Sowell (2004) asserted that affirmative action policies have not worked. Sowell argued that such programs encourage "nonpreferred" groups to designate themselves as members of "preferred" groups (i.e., primary beneficiaries of affirmative action) in order to take advantage of group preference policies. Further, he argued that such policies tend to benefit primarily the most fortunate among the preferred group (e.g., wealthy Blacks), often to the detriment of the least fortunate among the nonpreferred groups (e.g., poor Whites).

Sowell (2004) further suggested that affirmative action programs reduce the incentives of both the preferred and nonpreferred to perform their best—the former because doing so is unnecessary and the latter because it can prove futile—thereby resulting in net losses for society as a whole. Controversially, Sowell suggested these programs engender animosity toward preferred groups as well as on the part of preferred groups themselves, whose main problem in some cases has been their own inadequacy combined with their resentment of nonpreferred groups who—without preferences—consistently outperform them.

However, the majority of social scientists conducting research point to evidence showing that affirmative action opens professional and educational doors to persons who have historically lacked access to such opportunities. In doing so, these programs allow individuals to explore their untapped talents. Yet society also benefits, by fostering and ultimately utilizing the talents of all persons—regardless of their gender or racial and ethnic background.

The extent to which affirmative action has expanded minority employment in skilled positions is clear (Estes, Biggs, & Phillipson, 2003). The female-to-male ratio of earnings of full-time, year-round workers was roughly stable at around 60% from the early 1900s until the mid 1970s. In 1993 earnings of women who worked full-time, year-round had risen to 72% as much as men. After adjusting for differences in education, experience, and other factors, the wage gap is reduced by about half (i.e., the adjusted ratio is approximately 85; Powell, 2005). An increase in women's work experience and a shift into higher-wage occupations are the major causes of their improved economic position relative to men. The decline in higher-paying manufacturing jobs, which is partly responsible for the decline in the earnings of less-skilled men, has also contributed to the narrowing of the male-female wage gap. Nevertheless, a substantial part of the improved earnings of women cannot be explained by these factors and probably reflects positively how well affirmative action is working (Estes et al., 2003).

Scholars also argue that affirmative action is still needed, yet they also recognize the difficulty in proving beyond a doubt that a worker is the target of unfair or discriminatory practices. Psychological research documents that almost all people have trouble detecting a pattern of discrimination unless they are faced with a blatant example or have access to aggregated data documenting discrimination (Dixon & Rosenbaum, 2004). Affirmative action programs call for the collection of clear data on racial and gendered patterns of hiring and promotion, among other information. These aggregated data, in turn, can help decision makers to avoid or correct imbalances before they become widespread or harmful.

These data are particularly important because it is difficult to document that discrimination is occurring

simply by looking at statistics showing that women or ethnic minorities have a poorer quality job or lower earnings than their male and White peers, respectively. For example, Joseph LeFevre (2003) argued that a large proportion of minorities and women are locked into low-wage and low-prestige jobs, yet he attributed this over-representation to a factor other than discrimination: LeFevre reasoned that these two groups have been disproportionately affected by current trends in workforce downsizing. Service-oriented industries disproportionately employ women and minorities, and these industries are particularly susceptible to downsizings and undesirable working and pay conditions. However, many employment policies—taken together—do aim to ensure equality of opportunity and, ultimately, equality of outcome for all workers.

### FUTURE IMPLICATIONS OF EMPLOYMENT POLICY

Achieving a balance between economic efficiency and social equity is the ultimate goal of employment policy. Policies are intended to meet the needs of the employers by maintaining economic efficiency yet at the same time must also contribute to social equity by providing workers with fair and equitable benefits so that they can fund and enjoy healthy living. Employment policies also affect adults even after they have exited the workforce and enter retirement. Chris Phillipson (1998) observed that the retirement experience is linked to the timing of economic reduction of wages and that enforced withdrawal from work has made many older people in the United States financially insecure.

It could be argued that the biggest issue affecting employment policy may not come from the nation-state or their policy makers but from global forces. Globalization has created economic conditions that both hinder and facilitate the implementation of employment policies, thus transcending the power of the nation-state (Estes et al., 2003). Phillipson (1998) has noted four ways that globalization shapes both the need for and content of nation-states' employment policy. First, international competition, typically from newly industrialized countries, will cause unemployment growth and increased wage disparity for unskilled workers in industrialized countries. Low-cost imports from low-wage countries exert pressure on the manufacturing sector in industrialized countries, and foreign direct investment is attracted away from the industrialized nations toward low-waged countries. Second, economic liberalization may result in increased unemployment and wage inequality in developing countries. This happens as job losses in uncompetitive industries outstrip job opportunities in new industries. Third, workers may be forced to accept worsening wages and work conditions, as a global labor market results in a "race to the bottom" (Phillipson, 1998). Finally, globalization reduces the level of autonomy exercised by the nation-state. The reach of globalization is expansive, and virtually no worker is untouched. For example, in industrialized countries, an estimated 70% of workers are employed in the service sector. Ultimately this is a result of changes and trends of employment, an evolving workforce, and globalization that is represented by a more skilled and increasingly more diverse labor force, which is growing in nonstandard forms of employment policy and practice (Phillipson, 1998).

## POLICY, FAMILY

The goal of family policy is to promote the well-being of families (Zimmerman, 2001). At a minimum, family policy is targeted explicitly at the formation and structure of families (e.g., laws concerning adoption or divorce), family rights, and the functioning and well-being of families. However, because many policies not designed to overtly target families ultimately have implications for families, family policy may be conceptualized in broader terms (Zimmerman, 2001). For this reason, family policy

is sometimes considered a policy perspective instead of a specific type of policy (Bogenschneider, 2002). Family policy is pertinent to family members of all stages of the life course (e.g., children, parents, aging and elderly parents) and, as discussed later in this entry, may have important ramifications for a person's progression through his or her life course.

Because of changes in the economy and both family structure and process since the late 1960s, policies aimed at supporting working families and facilitating parents' employment are particularly important in the United States. These work–family policies include federal, state, and local government policies and employers' "family-friendly" policies. The focus here is on the former, specifically federal work–family policies. This review of federal work–family policies emphasizes policies attentive to parents and children, but many of the policies also pertain to elderly parents, sick relatives, and dependents in general.

## TYPES OF WORK–FAMILY POLICIES IN THE UNITED STATES

Government work–family policies include family leaves providing employees time off from work for caregiving, publicly supported childcare programs, other forms of support for child and dependent care (e.g., tax breaks), and regulation of work time and work arrangements (Kelly, 2006; Smolensky & Gootman, 2003). Scholars have documented how few policies the United States has in place, particularly in contrast to European countries (e.g., Gornick & Meyers, 2003). Nonetheless, although U.S. policy is relatively limited in this regard, several features of its current work–family policy landscape are important and noteworthy.

## FAMILY AND MEDICAL LEAVE

In 1993 the Family and Medical Leave Act (FMLA) was signed into law by President William J. Clinton, following years of Congressional debate and two vetoes by President George H. W. Bush (Elving, 1995). The law requires employers to allow employees (both men and women) to take up to 12 weeks of unpaid leave to recover from their own serious illness or to care for a baby, a newly adopted child, or a seriously ill relative. The law applies to work establishments with at least 50 workers at one site (or within a 75-mile radius), and only employees working at least 1,250 hours over the past year are eligible for FMLA leaves.

Prior to the FMLA, temporary disability insurance policies in some states afforded some mothers partially paid leaves when they were physically recovering from pregnancy and birth; feminists disagreed on whether to pursue maternity leave through sex discrimination claims, which relied on an analogy between pregnancy and other disabilities, or to advocate for maternity leave on the basis of a mother's need to care for her infant (Williams, 2000). This came to be known as a debate between equal or special treatment strategies. These temporary disability insurance policies remain an option for mothers who are covered by such a plan (Kelly & Dobbin, 1999; Smolensky & Gootman, 2003). Advocates considered the FMLA groundbreaking, however, because it improved job security for employees facing demanding health and caregiving situations and recognized both women's and men's caregiving. Nonetheless, the FMLA has significant limitations.

First, the FMLA does not cover all work establishments and employees. Only 11% of U.S. work establishments are estimated to fall under the FMLA; these establishments, however, employ just over half of the total workforce (Cantor et al., 2001). To help address this shortcoming, legislation in a subset of states extends FMLA's coverage to establishments with fewer than 50 employees (Institute for Women's Policy Research, 2007).

Another concern is that FMLA leaves are unpaid, which reduces the usefulness and value of the law for some workers. Research has shown that the majority of employees in need of a leave cannot afford to go without the pay, and among those who take a leave, a portion have to truncate their leave because of financial constraints (Cantor et al., 2001). Scholars also have raised concerns about the implications of unpaid leave for gender equity because men in general are less likely to take unpaid leave (Kelly, 2006). One state, California, offers its residents a paid family leave program, providing partial paid leave (up to 55% of wages) to an employee for up to 6 weeks to care for a newborn, a newly adopted child, or an ill family member. The benefit is funded through a payroll tax paid by employees contributing to the state's disability program (California Employment Development Department, 2005).

A final limitation to the FMLA concerns employer compliance with the federal law (Albiston, 2005; Kelly, 2004). Employers may violate FMLA's requirements by not allowing an employee to take the full 12 weeks of leave or by not fully or clearly disclosing employees' rights under the law. An employer also may fail to maintain an employee's health insurance coverage during a leave or may somehow penalize workers following a leave. Kelly's 1997 survey of employers found that about a third of workplaces covered by the FMLA violated the law in terms of the length of leave permitted for paternity or maternity reasons (Kelly, 2004). In a survey conducted 3 years later and using a different questionnaire, 13% of covered employers reported that they did not permit up to 12 weeks of leave for any FMLA reason (Cantor et al., 2001). Such violations likely speak to gaps in employers'

## FAMILY AND MEDICAL LEAVE ACT

The Family and Medical Leave Act (FMLA) was signed into law by President William J. Clinton in 1993 after years of congressional debates and two vetoes by President George H. W. Bush (Elving, 1995). The law requires employers to allow both male and female employees to take up to 12 weeks of unpaid leave to recover from a serious illness or care for a baby or newly adopted child or a seriously ill relative. The FMLA applies to work establishments with at least 50 workers at one site or within a 75-mile radius, and only employees who worked at least 1,250 hours in the past year are eligible for FMLA leaves. Only 11% of U.S. work establishments fall under FMLA; however, those establishments employ an estimated 58% of the total workforce (Cantor et al., 2001). The passage of the FMLA was considered a victory by its advocates because it improved job security for employees with demanding health and caregiving circumstances and recognized both women's and men's caregiving. Nonetheless, the FMLA has significant limitations, including the number of uncovered work establishments and employees, the unpaid nature of FMLA leaves, and employer noncompliance (Kelly, 2004).

understanding of the law as well as their concern that leaves will make it difficult to meet business goals or create burdens for other workers.

Enforcement of the FMLA is limited in that it is largely reactive, focused on responding to reports of potential violations (e.g., employee complaints to the U.S. Department of Labor). Although the FMLA mandates that covered employers maintain records to comply with the law, federal monitoring is minimal because the law does not require employers to submit records to the Labor Department regularly. In fact, employers are not required to submit records unless requested by the department, and without reasonable cause, the department may not ask employers to submit such records more than once during a year (U.S. Department of Labor, 2008).

### CHILD/DEPENDENT CARE

Working parents must find care for their children for the hours the parents are at work. Many American parents rely on family members, such as grandparents or older children, for childcare, or spouses work complementary hours so that a parent is usually with the children (Casper, Hawkins, & O'Connell, 1994; Presser, 1988). Beginning in the 1980s, more parents sought nonfamilial sources of childcare, such as private childcare providers or employer-based centers (Casper & Bianchi, 2002).

With the exception of national emergencies such as the Great Depression and World War II, when the U.S. federal government subsidized childcare centers (Auerbach, 1988; Michel, 1999), the federal government historically has not directly funded childcare for the general public. Instead, the United States provides different types of support for families at different income levels (Kamerman & Kahn, 1987, 1997; Michel, 1999), ranging from family tax abatements, tax reductions for employers who provide childcare benefits to their employees, and subsidies for some low-income families. Given their wide coverage, family and business tax breaks represent the broadest childcare policy in the country. In fact, tax expenditures were the most expensive childcare policy for much of the 1980s and 1990s (Kelly, 2003). Prior to an increase in subsidies for low-income families (discussed more below), the federal government depleted more funds through childcare-related tax reductions than it spent directly funding or subsidizing childcare programs.

**Childcare-Related Tax Deductions for Families** Federal income tax regulations offer at least two childcare-related reductions to qualifying families. The first is a nonrefundable tax credit, the Child and Dependent Care Credit, aimed at offsetting child/dependent care expenses incurred by working families. A tax credit reduces the amount of tax owed by an individual or family; a nonrefundable tax credit cannot lower the tax below zero and therefore may not result in a refund. Since 1954, federal tax credits have been available for a portion of employment-related child and dependent care expenses. Although income level is not a factor in qualifying for the credit, the amount of the tax credit varies inversely with income to provide more support to low-income households.

Several factors, however, limit low-income families' ability to benefit from the tax credit, and, in fact, the credit is most often used by middle- and upper-income families (Forry & Anderson, 2006). For example, if a family's earnings are so low that it does not have to pay taxes, the tax credit is by definition not available to the family. Further, the nonrefundable nature of the credit prevents low-income families from receiving the benefit if their tax credit exceeds the amount they owe in federal income taxes.

The second childcare-related tax reduction is a Dependent Care Expense Account (DCEA), also known as Section 125 or ''cafeteria'' plans, dependent-care assistance plans, flexible spending accounts, or tax-free or pretax spending accounts. Such an account is available to individuals whose employers have established a DCEA as an employee benefit and allows employees to set aside a share of their income each year to pay for qualified child- or dependent-care expenses. The funds placed in the account (up to $5,000 per year) are not considered taxable income, which therefore reduces a person's taxable income, resulting in a lower tax burden for participants. Employers also save on their Social Security and Federal Insurance Contributions Act (FICA) contributions, which are calculated based on an employee's taxable earnings (Beam & McFadden, 1996). Access to this tax reduction is contingent on an employer offering the program. An estimated 30% of larger companies (with 50 or more employees) offer these accounts (Kelly, 2006). Although the tax code requires that benefits such as this one be available to all employees (Employee Benefit Research Institute, 2005), higher-income individuals are more likely to benefit from a DCEA, primarily because they are more likely to work for larger employers with more generous benefit packages (Kelly, 2006).

**Government Encouragement of Employer-Based Childcare** The federal Economic Recovery Tax Act of 1981 was intended to encourage the establishment of employer-based childcare centers by offering tax reductions to employers who provide workplace-based child- and dependent-care benefits. Under this law, employers are allowed to deduct childcare benefit-related expenses from their income tax (Employee Benefit Research Institute, 2005). More recently, the Economic Growth and Tax Relief Reconciliation Act of 2001 granted another tax reduction to employers for providing childcare services or referrals. Employers may earn a tax credit (up to $150,000) for a portion of the expenses incurred in setting up and operating a workplace childcare center for employees (up to 25% of expenses) and providing childcare resources and referrals to employees (up to 10% of expenses). Still, workplace childcare centers continue to be rare in the United States. In a 2005 national survey of employers, only 7% reported a childcare facility at or near the work site (Bond, Galinsky, Kim, & Brownfield, 2005).

**Head Start Program** The federal government's longest-running involvement with childcare has been via the Head Start program, which during fiscal year 2007 enrolled more than 900,000 children up to age 5 in the United States (Administration for Children and Families [ACF], 2007b). Initiated during President Lyndon B. Johnson's War on Poverty in the 1960s and most recently reauthorized by President George W. Bush in December 2007 for 5 years, Head Start is intended to better prepare low-income and disadvantaged preschool children for school by providing childcare and other services. Head Start's mission is to promote ''school readiness by enhancing the social and cognitive development of children through the provision of educational, health, nutritional, social and other services to enrolled children and families'' (ACF, 2007a). Historically, Head Start targeted children ages 3 to 5 years. As part of the reauthorization of Head Start in 1994, Early Head Start, a companion component for children younger than 3 years of age was added. Most children in Head Start are enrolled in a full-day or half-day program at a local center or facility (ACF, 2005).

Although Head Start has served a vast number of children—24 million since its inception in 1965 (ACF, 2007b)—the program has its shortcomings. First, not all children who are eligible are served by the program. In 2001 it was estimated that only 50% of eligible children ages 3 and 4 years were being served under Head Start (Currie, 2001). Eligible children may not be enrolled for a number of reasons, including inadequate program funding or program outreach efforts, language/cultural obstacles, or parents' preferences for other early education and childcare providers. Moreover, if the program is a part-year and/or part-day program, it may be only minimally helpful to a working family (Gornick & Meyers, 2003; Smolensky & Gootman, 2003).

**Temporary Assistance to Needy Families Program and Other Key Federal Childcare Funding Sources** Introduced as part of the 1996 welfare reform legislation, Temporary Assistance to Needy Families (TANF) replaced Aid to Families with Dependent Children and other earlier welfare programs. As part of the reform, the federal government terminated federal entitlement to welfare assistance yet continued to fund welfare assistance to families in need through the new TANF program. Established as a federal grant program for states, TANF is a combined federal and state effort designed to provide temporary income assistance to families. TANF was reauthorized for 5 years by Congress and President George W. Bush in 2006.

The goals of TANF are to (a) assist needy families so that children can be cared for in their homes; (b) reduce the dependency of needy parents by promoting job preparation, work, and marriage; (c) prevent out-of-wedlock pregnancies; and (d) encourage the formation and maintenance of two-parent families (ACF, 2006a). The program provides up to 5 years of income assistance, work opportunities, and other services (including childcare) to qualified families as long as they meet specific employment requirements. TANF has

evolved into a significant source of public childcare funding (Smolensky & Gootman, 2003). The program supports childcare in the form of direct expenditures on childcare for families receiving TANF payments and in the form of transfers to the Childcare and Development Fund (CCDF) and Social Services Block Grant, which are additional federal block grants to states that provide childcare services to eligible families.

Although the federal government has increased its childcare funding to low-income families (ACF, 2006b) since 1996, and the reauthorization legislation signed in 2006 further increased this funding, there are several limitations to federal funding of childcare. First, not all eligible low-income children are served. It has been estimated that as few as 10% to 15% of families eligible for CCDF receive benefits (Smolensky & Gootman, 2003), and waiting lists for benefits exist. Second, the payments/vouchers provided to families to pay for care are not necessarily adequate given actual childcare costs. Finally, quality of care is a critical issue. For example, under the CCDF, although providers must meet state health and safety requirements, only a small percentage of CCDF funds must be used toward improvements in the quality of care. The CCDF "does not specify or control the quality of care that children receive" (Smolensky & Gootman, 2003, p. 251).

## REGULATION OF WORK TIME AND WORK ARRANGEMENTS

Among work–family policies, work-hour regulation may have the broadest reach because manageable and flexible work hours are important for all families regardless of their specific work and family demands. "[W]orking-time regulations can help allay work–life conflicts that occur across the life course, among parents whose children are young and older, among those caring for ill or disabled relatives, and even among those workers who do not have many family demands" (Kelly, 2006, p. 109).

In the United States, the main law regulating work time is the Fair Labor Standards Act (FLSA) of 1938. Although the law does not overtly define "full-time" and "part-time" work, it implicitly does so by defining overtime as hours worked beyond 40 hours per week. The Fair Labor Standards Act guarantees a higher wage for overtime hours (1.5 times the normal wage) for employees who are covered by the law and work overtime during a given week. The percentage of workers who are exempt from the law, however, has grown (Gornick & Meyers, 2003) due to changes in the law catergorizing more workers as exempt and increases in labor market participation in exempt jobs. Furthermore, the law does not protect workers from mandatory overtime. In contrast, policies elsewhere in the world (e.g., the European Union) cap working hours, including overtime, and require employers to consider flexible work arrangements for any employee who requests such an arrangement (Kelly & Kalev, 2006).

## RESEARCH ON THE IMPACT OF WORK–FAMILY POLICIES ON FAMILIES, PARENTS, AND CHILDREN

As discussed above, work–family policies are intended to facilitate parents' employment and to support members of working families. A growing body of research has examined the effects or consequences of the types of policies described here for families, adults, and children. Research has centered on the impact of work–family policies in several areas: women's employment, wages and equality, and child development.

Research suggests that there is no straightforward relationship between work–family policies and labor force participation among women. Family leaves increase women's employment rates, but, not surprisingly, these findings vary by leave duration (e.g., Gornick & Meyers, 2003). Overall, in the United States, where FMLA leaves are unpaid and short (compared to leaves required in other countries), family leaves have had little impact on overall women's labor force participation (Waldfogel, 1998a). Other U.S. research on maternity leaves has shown that access to such leaves is associated with several employment outcomes among women: the continuation of their involvement in the labor force following childbirth, their retention of the same job following childbirth, and a faster return to work (Estes & Glass, 1996; Glass & Riley, 1998; Hofferth, 1996).

Childcare costs also affect parents' employment decisions. Higher childcare costs are associated with a reduction in women's labor force participation (Gornick & Meyers, 2003). For this reason, the presence of public programs subsidizing childcare costs would be expected to increase women's employment rate, and cross-national research has shown this to be the case (Pettit & Hook, 2005; Stryker, Eliason, & Tranby, 2004).

With regard to women's pay, research has shown that mothers who use work–family policies and stay in the workforce following childbirth have higher wages than mothers who leave the labor force and later return (e.g., Waldfogel, 1998b). Wage consequences from a break in employment are not just short term but continue over time, resulting in a cumulative disadvantage in lifetime income (Jacobsen & Levin, 1995; Noonan, 2001).

Finally, in terms of the impact of work–family policies on children, scholars have examined the effects of policies supporting mother's employment, family leaves, and childcare. Overall, work–family policies have a

positive impact on children (Gornick & Meyers, 2003). One study (Kamerman, Neuman, Waldfogel, & Brooks-Gunn, 2003), for example, found that policies supporting mothers' employment had an indirect but significant effect on children's well-being by increasing overall family income. As documented for decades, poverty is associated with a variety of negative child outcomes such as poor health, slower cognitive development, and lower school achievement (e.g., Duncan & Brooks-Gunn, 1997).

Sufficient family leaves following a birth of a child can facilitate breastfeeding and child–parent bonding as well as enhance maternal health (Galtry, 1997; McGovern et al., 1997). Longer family leaves that allow parents to be home with their children or to work part-time during the first year of life also are important because research has shown that children who spend more time with their mothers during the first year score better on cognitive tests (Gornick & Meyers, 2003). For this reason, longer family leaves may be beneficial to children's development and school achievement. Unpaid leaves, however, could be associated with poor outcomes for children if such leaves cause significant financial strain on the family. Finally, for preschool children, studies have highlighted the positive relationship between high-quality childcare and children's development, school readiness, and academic performance (e.g., Kamerman et al., 2003).

## FUTURE DIRECTIONS

Research has yielded useful information on the implications of public work–family policies for working families, but important policy and research questions remain. More attention needs to be paid to the linkages between work–family policies and other areas of family policy, including supports for low-income families. How can public policies better support low-wage working parents, who have particular challenges but less access to family leaves, childcare benefits, and flexible work arrangements?

Other questions pertain to the consequences of work–family policies for broader outcomes, such as career advancement, health status and well-being, and community involvement. Beyond wages, are there negative career consequences (e.g., regarding job security and promotion) for using family leaves (e.g., Glass, 2004)? Can public policies be constructed so that workers use the available options without fear of career reprisals? Finally, what is the connection between work–family policies (or the absence thereof) and the health and well-being of parents, caregivers, and their dependents? Research provides some evidence that work–family policies may have benefits beyond the immediate family and work organization because employees with fewer work–family conflicts have better health, are better able to attend to the health and development of their families, and are more likely to be involved in their communities (Bianchi, Casper, & King, 2005; Bookman, 2004).

# POLICY, HEALTH

Health policy is a type of social welfare intervention deliberately designed to improve and preserve the health of individuals and populations. Sociologists who study health status and the life courses of individuals and

families have documented how experiences that seem far removed from the domain of health policy nonetheless have a profound influence on health-related outcomes. Although health policies formally structure the relationships between individuals and health systems, other institutional realms, such as education, housing, the workplace, and the community, form the context within which good (or ill) health develops and is experienced.

There are two major endeavors governed by health policy. The first is population-level interventions that promote public health. The need for publicly financed health policies is taken for granted, even in the most market-oriented societies. The second health policy endeavor structures national health care systems, shaping the cost, quality, and access to individual health care. Individual entitlement to basic health care is a widely accepted right in both developed and developing nations. Still, national perspectives on what services basic health care covers and how a right to basic care is enacted and paid for create wide variations in the details of national health policies around the world.

## DEFINING HEALTH AND HEALTH POLICY

To grasp what constitutes health policy and what does not, it is first important to understand the parameters used to define health. This is because health and health policy, considered broadly, cover such an extensive range of potential actions and interventions that they can be surprisingly difficult to define precisely. In the mid-20th century, physical health and illness were generally viewed as shaped by biological processes and health care. Current definitions are much more complex. For example, one authoritative international source defines health as the state of physical, mental, and social well-being, not just as an absence of disease (World Health Organization [WHO], 1994). In a similar vein, *Healthy People 2010*, a program established by the U.S. Department of Health and Human Services (2000) to minimize or eliminate health disparities in the United States by 2010, notes that the complex factors shaping health disparities demand interventions on multiple fronts, including improved housing, education, employment, and health policies.

Health policy, in the most general sense, is the set of rules, regulations, and procedures that countries use to explicitly coordinate national practices, investments, and systems that are directly health related. Policy makers and stakeholders in the health care system negotiate health policy legislation and the regulations that determine national levels of health expenditure, decide how public and private spending and medical care provision are balanced, and prioritize actions to change health care system arrangements. At the individual level, national health policies determine the cost, quality, and access to health care and medical services faced by individuals and their families. At the population level, health policies govern public health initiatives, workplace and environmental safety regulations, and the specifics of national health care system arrangements and financing. The overarching purpose of health policies is to improve individual well-being and population welfare by enacting programs and practices to preserve health and prevent disease.

Only governments can efficiently undertake collective public health measures on the scale needed to preserve population health. These activities range from ensuring clean food and water supplies, to regulating the safety and efficacy of pharmaceutical products, to implementing population immunization programs and responding to epidemics. Although some countries (especially developing countries) devote more attention and the largest proportion of national expenditures to public health, most citizens in developed countries experience national health policies as individual health care consumers interacting with health care professionals. Most are less aware of public health activities such as safe water supplies and universal vaccination programs, which are collective, behind the scenes, and indirectly experienced.

Despite current definitions of health, which emphasize the importance of policies from other social policy domains in shaping health (such as in *Healthy People 2010*), and despite the emphasis on social inclusion and well-being by the WHO, only policies that directly impact individual, physical, and mental health are conventionally considered within the rubric of health policy. Thus, education, housing, and the workplace factors are not conventionally considered health policies, although such policies would obviously influence individual health status over the life course. Perhaps because the value of most public health measures is taken for granted, or because policy making is most active on the second front, most people who study health policy focus on the relationships between the health care system and individuals accessing medical care.

## VALUES AND HEALTH POLICY

Although the purpose of health policy as a way to preserve health and prevent disease seems universal, the specifics of national health policies vary substantially. Each country's health policies reflect its distinctive values and cultural traditions, its unique array of economic, demographic, and political circumstances, and the particular financing and organizational arrangements of health care systems. Nationally, health policies encompass the political decisions that generate health-related laws and regulations, reflecting "more general perceptions about what is fair or important or doable (or all three) in a

particular culture, at a particular time, in a particular place" (Stevens, 2006, p. 2). When considering the capacity for health policy to address particular health needs, feasibility depends not only on the concrete resources and infrastructure available for implementation, but on the cultural norms and dominant value systems of the society.

As prominent medical sociologist David Mechanic (who has studied health policy and its outcomes for his entire career), Lynn Rogut, David Colby, and James Knickman (2005) have observed, debates about health policy, regardless of where they occur, are often driven by moral and ideological positions, rather than by evidence about which particular policies could be most effective for the most people. Instead, contests over health policy are often fueled by disagreements over "personal versus collective responsibility, government versus self-help, individual fault versus social causation" and the merits of designing health policies for populations that are regarded as "worthy versus unworthy" (Mechanic et al., 2005, p. 2).

Both the WHO (1994) and the U.S. Department of Health and Human Services (2000) define health and the policies that can influence it based on values of justice, equity, and social inclusion. Yet one of the values reflected in the U.S. health care system is the primacy of individual risk over government responsibility (O'Rand, 2003) and an emphasis on individual fault rather than social causation in explaining illness. Nonetheless, values that presume collective responsibility for public health and individual entitlement to health care are elsewhere widely accepted across the political spectrum and in both the developed and developing world. Broad-based political support for redistributive health policy—whereby resources are redistributed toward the most vulnerable, from the lucky healthy to the unlucky sick—is typically greater than for redistribution in other social policy domains. Regardless of political preferences, most stakeholders and policy makers acknowledge that publicly financed public health measures are essential and that routine access to individual health care should be guaranteed. Still, particular national perspectives on what is appropriate and feasible (given cultural realities and resource constraints) in the realm of public health and what constitutes adequate access to basic individual care is expressed in the myriad variations of health policies observed throughout the world.

One fundamental question that distinguishes how values are expressed differently among national health care systems is, "Who is responsible for paying for and providing health care?" The answer varies cross-nationally, but most developed countries provide universal entitlement to health care for all citizens, from cradle to grave. Some countries, such as the United Kingdom and Spain, have comprehensive national health services that are supported by general taxation; most medical care is delivered by health professionals employed in the public sector. Canada and the Scandinavian countries depend on universal, publicly financed national health insurance, with most health care providers working in the private sector. Other countries, such as France and Germany, complement public programs with mandated employment-based insurance to guarantee universal access.

Alone among developed countries, the United States has no guarantee of universal access to care (see sidebar). Instead, a patchwork of public programs and private insurance structure individuals' access to medical care. Without a national guarantee of health insurance for infants, children, or working-age adults, many nonelderly working individuals and their families depend on private employment-based health insurance; others go without any health insurance at all. Very poor mothers (but not very poor fathers), their infant and preschool-age children, and some segments of the permanently disabled population are covered by Medicaid. Medicaid is a state-federal health insurance program for the poor that applies strict income and asset tests to determine eligibility for coverage. Since the mid-1990s some states have relaxed income eligibility rules and expanded Medicaid insurance coverage to many more low-income children. However, this expansion of public health insurance for children has not occurred evenly across the country, and states encountering fiscal difficulties often withdraw the expanded coverage. Individuals who are over age 65 are eligible for Medicare, a federal program of nearly universal health insurance for the elderly. Medicare covers many of the acute medical care needs for elderly Americans but does not provide long-term care. Thus the United States is unique in the role that life course circumstances—especially the interaction of age with other individual and family characteristics—play in how or whether individuals are likely to gain routine entrance into the health care system and who will pay the bill when they do.

In countries where universal access is guaranteed, the life course basis of health policies may not always be as obvious as in the United States, yet they certainly exist. Countries may enact specialized initiatives to target particular health problems or risks most prevalent at particular life course stages or for particularly vulnerable subpopulations. For example, public health policies may discourage smoking initiation, educate about sexually transmitted diseases, or provide special prenatal care programs for vulnerable pregnant women—policies geared mostly toward the health concerns of teenagers and young adults. Alternatively,

## NATIONAL HEALTH INSURANCE

National health insurance (HI) guarantees universal access to basic health care for entire populations. Countries with multi-payer national HI systems, such as Germany, combine compulsory, private insurance (usually employment-based) with public programs for individuals not privately insured. Canada's single-payer HI system provides government-administered coverage for all citizens. Among industrialized democracies, only the United States lacks guaranteed access to health care for all and is distinctive in its heavy reliance on voluntary private HI. Working-age Americans and their families typically are covered by employment-based group HI. Population groups deemed by private insurers as too risky to insure usually rely on public programs for HI coverage: Medicare (HI for the elderly), Medicaid (HI for the poor), and myriad smaller public programs (e.g., coverage under the Veteran's Administration, Indian Health Service, prison health care) account for nearly half of U.S. health care spending. Nearly 47 million Americans lack health insurance coverage. Advocates of national HI note three advantages: (a) everyone has access to basic health care, (b) administrative costs are low, and (c) health costs can be controlled by managing supply. Critics argue that national HI compromises the benefits of private sector HI, including (a) investment in medical innovation, (b) consumer choice, and (c) cost-consciousness that moderates wasteful health care consumption.

policy attention may focus on implementing widespread monitoring of midlife adults to catch the onset of chronic conditions or to preserve mobility or address the risks of polypharmacy among the elderly. In countries where routine access to health care is an entitlement, access to health care in the first place is not shaped by life course influences to the extent that it is in the United States, but the focus of health investments and health policy outcomes certainly are.

### THE EFFECTS OF HEALTH POLICY ON LIFE TRAJECTORIES

Historically, the most dramatic improvements to overall population health and to improving and prolonging the lives of individuals were due to advances in public health. Although modern medicine has made stunning advancements that improve health—ranging from the discovery of antibiotics and antivirals, to increasingly effective disease interventions, to organ transplants—the health gains of the most broadly applied medical intervention pale in comparison to the continuing contributions of public health. It is for this reason that, in developing countries, individuals' life chances are often enhanced more by population-level public health policies than by policies relating to individual health care. In developed countries, where public health policies are well-developed and their impact is taken for granted, most health policy attention is usually paid to decisions affecting individual-level interventions and outcomes (such as reforms to spending or arrangements of national health care systems) rather than to population-level initiatives.

Yet precisely how individual-level health policy is implicated in shaping life course trajectories is not entirely clear. It does structure the capacity for individuals to access and benefit from medical advances. Where universal health insurance is provided, there are no financial barriers to accessing medical care, minimizing access and care differences between advantaged and disadvantaged groups. In the United States the fragmented public–private health insurance system multiplies the advantages of some by easing access to health care and reduces the advantages of others by restricting access. Still, in the United States, acute illness and accidents are treated even among the uninsured; it is routine checkups and preventive care that are missed when access to medical care is restricted due to lack of insurance. Yet even elsewhere, where health policies remove financial barriers that impede access to medical care, health disparities begin early in the life course and persist (with rare exceptions) over its span. This emphasizes the complexities of health outcomes, which involve much more than straightforward interactions between individuals and medical care.

Despite significant medical advances throughout the 20th century, low socioeconomic status (SES) is everywhere associated with more adverse health outcomes across all major health conditions. The association between SES and health occurs in both directions. First, an individual's health status impacts his or her ability to work, income level, and wealth built over the life course. Second, increases in income and education are strongly correlated with increases in measured health (Braveman et al., 2005). Research indicates that, in most instances, the impact of SES on health outcomes strengthens across the life course, so that current socioeconomic advantage or disadvantage impacts an individual's immediate and longer-term health. Scholars use this concept of cumulative (dis)advantage to understand how the effects of risk factors for disease accumulate over an individual's life course (Ferraro & Kelley-Moore, 2003).

Many researchers have attempted to determine what specific aspects of SES lead to differential health outcomes. One vehicle through which SES impacts health is individuals' exposure to stress. Individuals with low SES experience, on average, more stressful and negative major life events throughout their lives, and the exposure to such events is associated with higher risks of ill health and death. Bruce Link and Jo Phelan (1995) argue that SES is a fundamental cause of health disparities, because an individual's SES is linked in so many different ways to his or her capacity to gain access to and mobilize resources when needed. Access to important resources, whether knowledge, money, social support networks, or other advantages linked to SES, may explain why the association between SES and health is so persistent across so many different disease outcomes, and why the association between low SES and poor health outcomes persist even when disease risk factors change. The *fundamental cause* perspective explains how an individual's social and economic positions structure access to resources that can either prevent exposure to risks for disease or can be used to shield the effects of disease when it does occur.

Alternatively, lack of resources is implicated in exposure, risk, and shortage of resources to effectively deal with health conditions and setbacks (Link & Phelan, 1995). SES as a fundamental cause of health represents not only a cross-sectional risk but a life course one as well. Most research indicates that low SES (specifically education and income) contributes to cumulative disadvantage over the life course—diverging gaps in physical health among individuals of varying SES at older ages. However, some research indicates that for a handful of conditions, age may be a "leveler" in that some conditions (such as depression) appear to converge across SES groups with increasing age (Kim & Durden, 2007). A tentative explanation for this emphasizes the role of pensions (e.g., Social Security in retirement) in closing some of the gap between incomes and health policy.

According to the *life course health development* model, SES in childhood and early adulthood sets individuals on differing health trajectories (Halfon & Hochstein, 2002). These differing health trajectories differentially expose individuals to experiences that may either buffer or amplify the risks for disease, resulting in greater health disparities as individuals grow older. Children from poor families experience different sets of risks from children in more affluent ones, starting them on a trajectory of life course outcomes that magnify disadvantage over time (Wagmiller, Lennon, & Kuang, 2008). Childhood and family social relationships are associated with later physical and mental health outcomes (Institute of Medicine, 2002), emphasizing the importance of childhood experiences even in mid- and later life health outcomes.

In none of these instances could conventional public health or individual health policies intervene to do much to minimize or ameliorate the life course health risks posed by such early exposures to adverse environments. Rather, Linda George (2005) called for a "simple" health policy approach to "redistribute income and educate children to their maximum potential" (p. S138) and to devote more attention to fixing social institutions than people. Research shows that economic hardship over the life course has cumulative effects on health over time (Hayward, Crimmins, Miles, & Yang, 2000), indicating that alleviating hardship through education (which mitigates health risks and contributes to resilience) and minimizing income inequality may have the most potential to be effective health policies—considered from a life course perspective.

## GAPS IN KNOWLEDGE AND ISSUES TO BE RESOLVED

Even when health policies are specifically designed to do so, they do not necessarily benefit the most vulnerable. To the extent that health policies target individuals rather than groups or populations, the initial outcome of a policy intended to improve conditions for the least advantaged may, paradoxically, widen health disparities in the short term. This is because advantaged individuals within any society are nearly always in the best position to take the earliest and greatest advantage of medical innovations that bestow predominantly individual (rather than group) benefits.

Most sociologists of the life course agree that health status is closely related to social status, regardless of the unique risks associated with a particular time period in the life course. Although the risks of particular health statuses and outcomes may change from period to period, an individual's social status is the most fundamental condition in any period. Some health policies, such as effective public health measures, have collective benefits that are quite independent of social status. Adequate sanitation, clean and safe drinking water and food supplies, and immunization programs benefit entire populations and all the groups within them. However, because it is social status that influences whether individuals can access the other kinds of resources they need to maintain health and prevent illness, individuals with more money and social resources have additional capacity to marshal whatever range of resources they need to prevent disease and maintain health, compared to less advantaged individuals.

The *life course health development* framework developed by Neal Halfon and Miles Hochstein (2002) suggests a set of research and health policy goals to improve

life course health trajectories and minimize health disparities for vulnerable groups. The authors proposed research that identifies critical and sensitive periods of early health risk and protective factors. By pursuing a developmental approach, they argued that health policy could shift from later interventions focused on ill health to earlier and more effective interventions that could prevent illness and optimize developmental health. Because of the complexity of health development over the life course, Halfon and Hochstein maintained that health disparities can be addressed only within a framework that recognizes the social nature of disparities and cannot be addressed by additional health care access or resources alone. They also argued that successful interventions will depend on reducing inequalities in income and employment benefits and family and social relationships. In this sense, their health policy prescriptions come full circle from the conventional, but restricted, definition of health policy that is most often considered to the more expansive WHO and U.S. Department of Health and Human Services definitions.

Link and Phelan (1995), pioneers of the fundamental cause framework, recommended that health policy initiatives identify strategies that could help individuals who are SES-disadvantaged to compensate by equalizing the coping strategies that now link SES advantages to improved health outcomes. New health advances targeted to individuals, even when targeted especially to disadvantaged individuals, will not necessarily improve health outcomes. In fact, individually targeted health policies may widen disparities, at least initially, because the wealthy are always positioned to take more advantage of innovation. Additional research on life course health trajectories may suggest ways to equalize coping strategies at critical junctures or sensitive turning points in life course trajectories that could inform health policy innovations. The Link and Phelan framework reinforces the importance of broadening the way policy makers think about health policy to address persistent health disparities currently experienced by vulnerable groups.

It seems obvious that health policies that are universal and that minimize dependence on individual resources hold the most promise to smooth health trajectories, address health risks, and minimize health disparities over the life course. Enacting and implementing universalist policies intended to operate at the group or population level—policies resembling public health interventions rather than the dominantly individual medical care preoccupation of current health policy debates—could potentially reduce disparities among the most vulnerable who are unlikely to have their health improved by contemporary health policies that target individuals.

# POLITICAL BEHAVIOR AND ORIENTATIONS, ADULTHOOD

Citizen engagement, or the constellation of behaviors that people engage in order to change the political and social world around them, is a multidimensional phenomenon. Despite an early preoccupation with analyzing people's involvement in elections (e.g., political behavior), scholars have come to recognize that citizen engagement extends far beyond the ballot box and encompasses activities such as protesting, volunteering, and even using their power as consumers through engaging in boycotts (not buying certain products, goods, or services) and buycotts (buying only certain products, goods, or services) in order to reward or punish the company that produces them. However, in this entry the focus is on adult political participation, namely voting and a few other behaviors that are centered around elections. In addition to what people *do*, this entry will consider what people *think* about politics. Although studying people's thoughts about politics raises a variety of issues, attention here largely focuses on two indicators related to political orientations—party affiliation and political ideology. (e.g., where one locates oneself along the liberal/conservative continuum).

## STABILITY AND CHANGE IN POLITICAL BEHAVIOR AND ATTITUDES ACROSS THE LIFE COURSE

Researchers have long observed increases in political engagement with age (Verba Nie, 1972). For example, one study (Zukin, Keeter, Andolina, Jenkins, & Delli Carpini, 2006) found that political engagement increases with age, reaching a peak at or around age 65 and then falling sharply among individuals near and beyond age 70. The researchers used five indicators to measure political engagement: regularly voting in local and national elections; attempting to persuade others politically around the time of an election; displaying campaign buttons, signs, or sticker;, making a campaign contribution; and volunteering for a candidate or political organization. In the 2004 presidential election, voting turnout followed a similar pattern. Self-reported turnout was the lowest among those between the ages of 18 and 24 (47%) and highest among those older than 55 (73%; Faler, 2005). Turnout increased steadily with age in the intervening years.

It is important to also point out that although youth remain disproportionately absent from participation in electoral politics, the 2008 presidential primaries and caucuses witnessed sizable increases in the number of youth who turned out in predominantly Democratic contests. Inspired by the two historic firsts (Barack Obama as the first viable African American candidate and Hillary Clinton as the first viable female candidate for a major party nomination), and the use of the Internet as a tool for political organizing, young people increased their participation markedly from the 2000 nominating contests (Center for Information and Research on Civic Learning and Engagement, 2008).

Why would voting or volunteering for a campaign be related to age? First, in the words of Sidney Verba and Norman Nie (1972), there is "gradual learning," which refers to the acquisition of political knowledge over the course of one's life that makes navigating the political system easier. Similarly, Steven Rosenstone and John Mark Hansen (1993) suggested a life experience hypothesis, which holds that "people acquire resources that promote participation as they grow older" (p. 137). These resources include political knowledge (regarding parties, candidates, and public affairs more generally), political skills, and denser social networks that increase the likelihood of being asked to take part in public life.

Additionally, the acquisition of new roles and life experiences may account for increases in political participation in adulthood. Once an individual moves beyond young adulthood, responsibilities emerge that can pull him or her toward becoming an engaged citizen. The nomadic existence of youth is now a thing of the past, as adults begin to plant roots upon becoming spouses and parents. Doing so, in turn, helps to foster more political engagement as people come to recognize the importance of politics for concerns such as taxes, public safety, and the quality of schools. One's profession can also play a role in fostering more participation because the workplace is often a site for political discussions and mobilization among peers. Finally, the onset of retirement and widowhood often foreshadows one's declining health and cognitive capacity, which makes active engagement in the polity more difficult than in previous years.

Turning to political orientations, two indicators stand out for their predictable life course patterns: party affiliation and ideology. Party affiliation, or one's willingness to identify with one of the two major parties in the United States (Democrat and Republican), is shaped largely by the nature of the times during which one was

being socialized early in life. This means that despite changes in the political environment over the life course, an individual will likely cling to the party that was dominant during the impressionable years of one's youth (Alwin, Cohen, & Newcomb, 1991; Jennings & Markus, 1994; Sears & Funk, 1999). This is not to suggest that the transition to adulthood brings with it virtually no chance of changing one's party affiliation over the life cycle; what it does suggest is that, for example, differences in the party affiliation of those socialized in the 1960s (Baby Boomers) versus the 1980s (Generation Xers) are best explained by generational versus life course effects. (Generational effects refer to the sum of common experiences, opportunities, and situations that help shape an age cohort's behavior and attitudes across the life cycle.) Simply put, Boomers came of age when the Democrats were the dominant party in government, whereas Xers did so during a Republican resurgence led by former U.S. President Ronald Reagan (1911–2004). In short, although change is possible, partisanship tends to remain a stable part of one's identity over the life cycle.

An aspect of party affiliation that does follow a predictable pattern across the life cycle is the strength of partisanship. That is, in addition to asking about a person's party affiliation, pollsters also ask how strongly a person identifies with his or her chosen party. Strong partisanship tends to increase with age, with 41% of those age 55 and older in 2004 identifying themselves as "strong" partisans compared with only 23% of those under 30 (Eriksen & Tedin, 2007). Similar differences have been observed across the life course in previous years. Having had a lifetime to consider whether one is a Democrat or Republican, individuals tend to harden their commitment the closer they get to the end of the life course.

Strength of partisanship is not the only aspect of political orientation that is susceptible to life course effects. Political ideology, or the extent to which a person locates him or herself on a continuum ranging from conservative to liberal, changes in accordance with where he or she is in the life course. The trend in adulthood is to become more conservative with age, and this is true regardless of the time period in which data is collected. Moreover, as Robert Eriksen and Kent Tedin (2007) pointed out, "Each generation starts out with the same level of liberalism and drifts rightward about the same rate" (p. 156).

Underlying the life course effect in political ideology are a variety of factors thought to push one in a conservative direction. The first centers on personal finances. Age brings greater accumulation of wealth, which, in turn, makes conservative economic policies more favorable. Even if the political rhetoric of lower taxes translates into reality for only a small subset of voters, the idea of having more money in one's bank account on payday of course resonates positively with voters.

***Canvassing.*** *Anne Walpole talks to Frank Hill about the gay marriage amendment while canvassing in Richmond, VA.* AP IMAGES.

Additionally, age brings with it a propensity to cling to social norms that were a defining part of one's youth. As is so often the case, social norms are often challenged the most forcefully by young people. Unhappy with the status quo, youth often behave in ways that unsettle older adults who prefer to adhere to established norms of behavior. For example, surveys today reveal a marked age difference in attitudes toward gay rights. Young people are significantly more in favor of allowing gay marriage than are older adults. In one report, 53% of those between the ages of 18 and 29 were in favor of gay marriage, compared with 38% of those age 30 through 49, 30% of those 50 through 64, and only 16% of those 65 and older (Pew Research Center, 2006). Because opposition to the liberalization of marriage laws is most closely associated with conservatism, it is no surprise to see older citizens more closely identified with this end of the ideological continuum than younger adults.

## THE CONSEQUENCES OF LIFE COURSE PATTERNS IN POLITICAL BEHAVIOR AND ORIENTATIONS

The disproportionate political activism of older voters compared to younger voters can pose challenges to the crafting of equitable public policies. Naturally, policy makers tend to respond more to those who are politically engaged. At any point in time, policies are likely to be more reflective of the interests of those closer to the end of the life course than the beginning.

For example, the U.S. social welfare policy known as Social Security is facing long-term financial difficulties. Social Security provides retirement income for those age

62 and over. A recent attempt to reform the system by allowing some investment of Social Security contributions in the stock market was met with varying support across the life course. Young people generally favored the plan. A 2002 poll conducted by the *Washington Post*, the Kaiser Family Foundation, and Harvard University estimated support among youth (ages 18 to 24) at 61%. Support dropped off significantly among older adults, and only 24% of those age 65 and older supported such a plan (Zukin et al., 2006). Despite a concerted effort by the White House to rally public opinion behind President George W. Bush's (b. 1946) plan, it was soundly defeated in Congress. Legislators, instead, listened to those who reliably vote—and those who opposed the plan. To *not* have listened would have risked alienating the support of those whom a legislator needs on Election Day.

This example highlights a problem posed by disproportionate activism across the life course. Kay Schlozman, Sidney Verba, and Henry Brady (1999) referred to the "equal protection of interests" rationale for robust citizen engagement, by which they mean the willingness of citizens with conflicting interests to take part in public life. Clearly, different levels of political participation over the life course challenge the ideal of equal protection of interests on any issue in which interests vary by age.

## CHALLENGES TO THE MEASUREMENT OF LIFE COURSE EFFECTS ON POLITICAL BEHAVIOR AND ORIENTATIONS

Two issues arise when considering life course effects on political orientations and behavior. The first concerns the use of cross-sectional surveys to measure changes over the life course. Typically, researchers interview different groups of people at different points in time and, by comparing the responses of people born in the same years (a birth cohort) at these different interviews, assess the extent to which individuals alter their behavior or orientations as they age (this design is called a pooled cross-section). Because the same person is not being asked the same question at different times in his or her life, it is difficult to say for certain whether changes in a birth cohort's orientations and behavior are the result of individual maturation. It is likely that these studies reveal a little bit of both—that is, changes that arise over the life course but also stability in some individual behavior, an artifact of cross-sectional data that makes it difficult to measure precisely changes over the life course. A related complication is period effects. These occur when a political or social event, such as the attacks of 9/11, cause an abrupt but temporary change in the behavior of a cohort or cohorts. News interest and political attentiveness were markedly higher among all cohorts in the days after the attacks but returned to their pre-9/11 levels within a year after the event.

Estimating life course effects using cross-sectional data can thus be a limited enterprise. What is needed are more longitudinal data sets from which to gauge changes in adult behavior and orientations with age. This type of survey (a panel or longitudinal survey) tracks the same individuals over the life course and provides more telling insights into how age affects one's orientation to the political world. Unfortunately, longitudinal surveys are few and far between, largely because of cost and an unwillingness or inability of respondents to maintain their participation over many years.

The second issue to complicate the estimation of life course effects on adult political orientations and behavior is the need for more cross-national studies. To say with any certainty how age influences one's political identity requires analyses that extend beyond the United States. However, as Roberta Sigel (1989) pointed out, "We still do not have enough cross-national studies, especially those conducted in the non-Western world.... The importance of obtaining such information is so self-evident as not to require further elaboration here" (p. 469).

Many of the points raised in the preceding analyses are ripe for further elaboration. Scholars in fields such as political science and sociology have developed a rich tradition of inquiry in this area, but there is still much to understand.

# POVERTY, ADULTHOOD

Poverty generally refers to individuals residing in households that lack the income to purchase a minimally adequate daily basic "basket" of goods and services. The actual measurement of poverty, however, varies widely across countries. In the United States poverty is officially measured in terms of whether various-sized households fall below specific annual income levels. Considerable debate exists regarding the adequacy of this measure (Blank, 2008; Iceland, 2005). In Europe, poverty is frequently defined as residing in a household that falls below one-half of the national median income. In developing countries the standard often used is living in a family earning less than a dollar per day. The concept behind all of these approaches is that there is a basic minimum amount of income necessary in order for individuals to adequately carry out their day-to-day activities. Households that fail to acquire such income are considered poor. Other measures of poverty (such as those developed by the United Nations) have begun to incorporate aspects of social deprivation into their measurement of poverty, such as shortened life expectancy, illiteracy, and long-term unemployment (United Nations Development Programme, 2007). This entry examines poverty within the context of the life course, and explores the likelihood, consequences, and solutions to poverty from a life course perspective.

## THE RISK OF POVERTY ACROSS ADULTHOOD

The social scientific study of poverty across the life course began with Rowntree's (1901) study of 11,560 working-class families in the English city of York. Rowntree estimated the likelihood of falling into poverty at various stages of the life course. His work was seminal in developing the concept of the life cycle, and it demonstrated that working-class families were more likely to experience poverty at certain economically vulnerable stages during their adulthood (e.g., starting a family and during retirement). Since Rowntree's initial work, much has been learned regarding the patterns and dynamics of poverty across adulthood.

Cross-sectional surveys (such as those conducted annually by the U.S. Bureau of the Census) have shown that within the United States, children and young adults are at the greatest risk of experiencing poverty. The risk declines during the prime earning years of the 40s to mid-50s, and then slowly increases as adults reach their retirement years (DeNavas-Walt, Proctor, & Smith, 2007). In addition, cross-sectional analyses indicate that certain characteristics can place individuals at a greater risk of experiencing poverty. These include having low education and few job skills, living in single-parent families, being non-White, residing in economically depressed inner cities or rural areas, and having a disability (DeNavas-Walt et al., 2007). All of these characteristics tend to put individuals at a disadvantage when competing in the labor market.

Comparative analysis using the Luxembourg Income Study (a data source containing income and demographic information on households in approximately 30 industrialized nations) has shown that U.S. poverty rates are among the highest in the developed world. This is true whether one looks at poverty among children, working-age adults, or elderly persons (Smeeding, 2005). Two reasons stand out as to why Americans at the lower end of the income distribution do so badly compared to their counterparts in other countries. First, the social safety net in the United States is considerably weaker than in other industrialized countries, resulting in more households falling into poverty (Alesina & Glaeser, 2004). Second, the United States has been plagued since the early 1980s by relatively low wages at the bottom of the income distribution scale compared to other developed countries (Blank, Danziger, & Schoeni, 2006; Fligstein & Shin, 2004). These factors contribute to both the relative and

absolute depths of U.S. poverty in comparison with other industrialized nations.

Beginning in the 1970s, researchers in the United States have increasingly sought to uncover the dynamics of poverty over time. The emphasis has been on understanding the extent of turnover in the poverty population from year to year and determining the length of poverty spells. These studies have relied on several nationally representative panel data sets, including the Panel Study of Income Dynamics, the National Longitudinal Survey of Youth, and the Survey of Income and Program Participation. This work has shown that most spells of poverty are fairly short term (1 to 3 years in length), but that households that experience poverty will often encounter poverty again at some later point in the life course (Duncan, 1984; Stevens, 1994, 1999). In addition, this work has demonstrated that particular events, such as job loss, family breakup, or ill health, are important factors leading households into poverty. This body of work has also shown that a relatively small number of households will experience chronic poverty for years at a time. Such households typically have characteristics that put them at a severe disadvantage vis-à-vis the labor market (e.g., individuals with serious work disabilities, single-headed families with a large number of children, racial minorities living in economically depressed inner-city areas).

An alternative approach for understanding the scope of poverty has been to analyze impoverishment as a life course event. For example, what are the chances that at some point during their adulthood an American will experience poverty? The work of Rank and Hirschl (1999, 2001b) has addressed this question. Their results indicate that between the ages of 20 and 75, nearly 60% of Americans will have spent at least 1 year below the official poverty line, while three-quarters of Americans will encounter poverty or near poverty (below 150% of the poverty line). Consistent with the earlier mentioned studies of poverty dynamics, individuals experiencing poverty throughout the life course often do so for only 1 or 2 consecutive years. Once an individual experiences poverty, however, it is quite likely that the person will encounter poverty again at some later point in his or her life course. This work has indicated that falling into poverty is a common life course event for the majority of Americans.

Rank and Hirschl have also found that the periods of early and later adulthood are characterized by a heightened risk of poverty (as indicated in cross-sectional studies). For example, between the ages of 20 and 40, 36% of Americans experienced poverty; between the ages of 40 and 60, 23%; and between the ages of 60 and 80, 29% (Rank & Hirschl, 2001a). This body of work has also

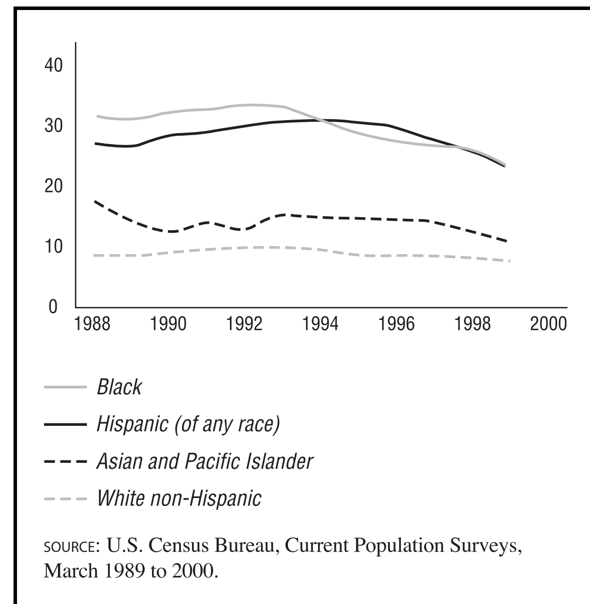

***Figure 1.*** *Poverty rates for individuals by race and Hispanic origin, 1988–1999.* CENGAGE LEARNING, GALE.

shown that the odds of using a social safety net program during adulthood are exceedingly high (Rank & Hirschl, 2002, 2005). Consequently, 65% of all Americans between the ages of 20 and 65 will at some point reside in a household that receives an income-based welfare program (such as food stamps or Medicaid).

## THE LIFE COURSE IMPACT OF POVERTY

A second major area of life course research on poverty has been to analyze the impact of poverty on various life outcomes. Two specific areas have received a considerable amount of research attention—intergenerational poverty transmission and the long-term health effects of living in poverty.

Analyses of the American system of stratification show that while some amount of social mobility does occur, social class as a whole tends to reproduce itself (Beeghley, 2008; Fischer et al., 1996). Those with working-class or lower-class parents are likely to remain working or lower class themselves. Similarly, those whose parents are affluent are likely to remain affluent. The reason for this is that parents' economic differences result in significant differences in the resources and opportunities available to their children. These differences, in turn, affect children's future life chances and outcomes (such as the accumulation of skills and education), which in turn affect their economic status (DiPrete & Eirich, 2006; Rank, 2004).

Consequently, growing up in poverty can have a significant impact upon one's later economic well-being (Bowles, Gintis, & Osborne Groves, 2005; Duncan & Brooks-Gunn, 1997). For example, Rodgers (1995) found that of those who experienced poverty as an adult, 50% had experienced poverty as a child, while an additional 38% had grown up in homes that were defined as "near poor" (below 200% of the U.S. poverty line). Research has also shown strong associations between parents' and children's income, wealth, occupational status, and neighborhood status (Beller & Hout, 2006; Shapiro, 2004; Sharkey, 2008). This research illustrates that prior economic advantages or disadvantages can have a profound effect on future life outcomes.

Researchers have also examined the impact that poverty exerts on future health outcomes. One of the most consistent findings in epidemiology is that the quality of an individual's health across the life course is negatively affected by lower socioeconomic status, particularly impoverishment (Mullahy, Robert, & Wolfe, 2004). Poverty is associated with a host of health risks for one's self and one's children, including elevated rates of heart disease, diabetes, hypertension, cancer, infant mortality, mental illness, undernutrition, lead poisoning, asthma, and dental problems. The result is a death rate for the poverty-stricken between the ages of 25 and 64 that is approximately three times higher than that for the affluent within the same age range (Pappas, Queen, Hadden, & Fisher, 1993), and a life expectancy that is considerably shorter (Geronimus, Bound, Waidmann, Colen, & Steffick, 2001). For example, Americans in the top 5% of the income distribution can expect to live approximately 9 years longer than those in the bottom 10% (Jencks, 2002).

## LIFE COURSE POLICY APPROACHES FOR ALLEVIATING POVERTY

Although there are a variety of key policy approaches toward poverty alleviation (e.g., macroeconomic policies to stimulate job creation, tax policies such as the Earned Income Tax Credit), a life course approach emphasizes the importance of timing and development across the life span. With this in mind, three such strategies appear critical. First, policies that invest in the well-being and growth of individuals, particularly children, are vitally important. These include increasing access to quality child care, health care, and education. Each of these areas is essential in allowing individuals to fully develop their human and economic potential and thereby reducing their risk of poverty in the future. In addition, such policies have been shown to be quite cost effective in that an investment of resources early in life can produce sizable economic and societal benefits as individuals age across the life course (Holzer, Schanzenbach, Duncan, & Ludwig, 2007).

A second life course approach to poverty alleviation focuses on asset-building strategies for lower income households and communities (Rank, 2007). Individual asset accumulation provides an effective strategy for coping with economic pitfalls that occur across the life course. A savings account or other source of liquid wealth can allow families to tap into financial reserves during times of economic hardship. Economists refer to this as the ability of assets to protect consumption against unexpected shocks. In addition, wealth and assets can allow individuals to accomplish more of their long-term economic and social goals. For example, financial assets can be instrumental in furthering an education, purchasing a home, or planning for retirement (Schreiner & Sherraden, 2007). Examples of asset-building policies benefiting lower income households include Individual Development Accounts in the United States, Child Trust Funds in the United Kingdom, and the Central Provident Fund in Singapore.

Just as the acquisition and development of assets are important for individuals, they are equally important for the communities in which individuals reside. Poor neighborhoods are often characterized by a lack of strong community assets, such as quality schools, decent housing, adequate infrastructure, economic opportunities, and available jobs. These, in turn, affect the life chances of residents living in such communities. Strengthening the major institutions found within lower income communities is vital because such institutions have the power to improve the quality of life, foster the accumulation of human capital, and increase the overall life course opportunities for community residents (Grogan & Proscio, 2000).

A third life course approach toward poverty alleviation is the strengthening of the social safety net. As noted earlier, a majority of individuals will encounter poverty at some point during their lifetime. Having a strong and effective safety net in place is critical in providing support so that individuals and families are able to get through such difficult economic times. Programs that provide economic relief during times of unemployment, ill health, and family disruption are fundamental to the life course well-being of individuals and families (Esping-Andersen, 2002).

All of these policy approaches recognize the importance of understanding poverty within the context of the life course. Poverty is a life course event that will affect the majority of the population. Effective poverty alleviation policies are those that recognize and confront the life course patterns, dynamics, and effects of poverty for individuals and households.

## RACISM/RACE DISCRIMINATION

Racism is an organized system that categorizes, ranks, and differentially allocates societal resources to human population groups (Williams & Rucker, 2000). According to James Jones (1997), racism builds on the negative attitudes arising from prejudice and rests on three broad assumptions: (a) that group characteristics are based on presumed biology; (b) the superiority of one group over others; and (c) the rationalization of institutional and cultural practices that formalize hierarchical domination of one racial group over another.

Racism is thus a complex construct. It is not synonymous with related terms such as prejudice, discrimination, bigotry, or bias that do not necessarily incorporate hierarchical domination in the form of social stratification or power. For example, *prejudice* is "a positive or negative attitude, judgment, or feeling about a person that is generalized from attitudes or beliefs held about the group to which the person belongs" (Jones 1997, p. 10). *Discrimination* involves behavior aimed at denying members of particular groups equal access to societal rewards and, as such, goes beyond merely thinking unfavorably about particular groups.

Racism should not be confused with other forms of oppression such as sexism, heterosexism, or homophobia. Whereas these forms of oppression share a similar root in that one group is viewed as superior to another, racism is distinct because it is founded on cultural conceptions of race. There are important implications of racism for the life course, including negative psychological effects, socioeconomic disadvantage, and racial health disparities.

### RACISM AND THE CONCEPT OF RACE

Understanding racism requires an examination of the concept of race and its function in U.S. history and culture. While many have sought a genetic foundation for categorizing population groups, there is no scientific consensus that racialized groups are genetically distinct. Population groups are transformed into races for political purposes on the basis of arbitrary but distinctive phenotypic (i.e., physical appearance) and cultural criteria. The belief that groups of people identified on the basis of these criteria are *also* inherently different and genetically distinct is the unfortunate remnant of an outdated pseudo-scientific idea (Smedley & Smedley, 2005). The ideology of racism is built upon this pseudo-scientific racialization of targeted population groups.

Racism in the United States began during the colonial period, although the exact nature of the historical development of racism has been heavily debated. From one perspective, the ideology of racism is said to be a deliberate invention of early colonists to justify the enslavement of Blacks for economic purposes (Handlin & Handlin, 1947). Others argue that racism developed from preconceived prejudices against African Americans, rooted in early 19th century European biological determinism that classified humans into four hierarchical, mutually exclusive groups—mongoloid, caucasoid, negroid, and australoid—with Blacks at the bottom of the ranking. This categorization was not neutral but characterized physical differences as innate and immutable characteristics. These notions were used to justify slavery and the pseudoscience underlying this classification evolved simultaneously with the development of slavery and legal segregation (Jordan,

***Hurricane Katrina.*** *Tangeyon Wall stands by a broken window in her home, which was flooded by Hurricane Katrina in New Orleans. Wall is angry that utility services are returning to her neighborhood of predominantly Black residents much slower than they are to other areas of the city.* AP IMAGES.

1974). Regardless of chronology, racism grew as a system of beliefs and practices that propagated ideas about the inferiority of persons not classified as *White*. While any ethnic group can be the target of racism, in the United States racism is particularly relevant to non-White ethnic minority groups. The lasting effects of the country's racist policies are observable in persistent racial inequities in criminal justice, education, employment, health, health care, housing, income, and other areas. While the emphasis in this entry is the United States, racism occurs in every country throughout the world.

## LEVELS OF RACISM

Racism is a process that operates on multiple levels of experience, from the psychological to the social. Racism can be *internalized* when persons accept the ideology of their racial inferiority; *personally-mediated* as when persons are dehumanized or treated differentially by others because of their race; or *institutionalized* due to restricted access to material resources and opportunities for empowerment throughout society (Jones, 2000). The various levels at which racism is experienced affect personal stress and life chances, which in turn affect the well-being of individuals, families, and communities.

*Institutional racism* is a systematic set of procedures, practices, and policies that penalize, disadvantage, and exploit individuals on the basis of race. In addition, institutional racism is the extension of individual beliefs by using and manipulating institutions to restrict the choices, rights, mobility, and access of certain individuals. Such effects are distributed throughout society through institutional structures, ideological beliefs, and the everyday actions of people (Jones, 1997). Three examples of institutional racism in the United States are chattel slavery, the *Plessy v. Ferguson* decision of the U.S. Supreme Court, which legalized racially separate facilities, and racial residential segregation. These actions were not only associated with an ideology of racism, but they led to policies and practices that unequally distributed resources and opportunities so that people experienced unequal physical environments, educational systems, and economic opportunities.

*Structural racism* refers to how social structures, historical legacies, individuals, organizations, and institutions interact to disadvantage some racial groups and advantage others. Structural analysis and critical race theory suggest that racism is not an aberrant belief or behavior, but is consistent with U.S. cultural values that tangibly advantage some population groups (Ladson-Billings & Tate, 1995). A structural analysis of racism highlights the important interplay between educational, criminal justice, housing, health, and economic institutions. It is this interinstitutional interaction that distinguishes structural racism from other forms of racism or discrimination.

## MEASURING RACISM AND RACIAL DISCRIMINATION

The main challenge of conducting research on racism and racial discrimination lies in the area of measurement. Currently there is little consistency or agreement on how racism or racial discrimination should be measured, much less is there available data on the psychometric properties of current measures. One construct used in research on racism and racial discrimination is perceived discrimination. The construct is based on the process of perception and emphasizes the attributions made by those trying to understand the underlying cause of interpersonal interactions. Perceived discrimination deemphasizes the intention and ideology of the actor and places the subjective interpretation of the observer at the center. In this respect, perceived discrimination is conceptually related to Ellis Cose's (1993) list of race-based daily hassles that take up time and mental energy. Much of this research is based on descriptive survey self-reports. Less empirical information is available on the cognitive processes by which people understand and decide whether or not a particular act is indeed discriminatory. This is an area in need of additional research.

Another approach is to measure experiences of discriminatory behavior. Rebecca Blank and colleagues (2004) provide four types of individual and organizational discriminatory behaviors that can guide measurement and analysis. *Intentional discrimination* is consistent with traditional

notions of discrimination whereby people deliberately treat persons of different racial or ethnic groups differently. *Subtle or automatic discrimination* occurs when people unconsciously categorize people based on their race or ethnicity. Similarly, *statistical discrimination* (or profiling) occurs when an individual uses overall beliefs or generalizations about a group to make decisions about an individual in that group. Finally, in addition to the types of discrimination that can be perpetrated by individuals, organizations can reflect the same biases as people who operate within them. This type of discriminatory behavior can be referred to as *organizational discrimination*.

Racism and discrimination have led to residential segregation, exclusionary housing patterns, differential hiring and promotion practices, and other such organizational and institutional practices. Practices and laws that appear to be neutral may, in fact, lead to differential outcomes, regardless of intended impact, and therefore may be considered discriminatory. This also means that the definition of *racism* is unlikely to be universally agreed upon, because different groups will disagree on the inferences made about the causes of observed racial inequalities in income, employment, education, and health. The idea that the consequences of racism need not be intentional suggests that racism is the product of the perception of different observers. Often, terms describing such an idea are used as reactions to institutional and structural conceptualizations of racism that do not require intentionality but illustrate disparate outcomes.

## EFFECTS OF RACISM AND DISCRIMINATION OVER THE LIFE COURSE

Numerous personal accounts as well as social scientific research demonstrate the pervasive negative effects of racism on outcomes spanning the entire life course (Collins, David, Handler, Wall, & Andes, 2004). Moreover, while most studies examine racism as though it occurs at a specific point in time, researchers are beginning to argue that racism is a dynamic process (Blank et al., 2004). The consequences of racism range from negative psychological effects, to socioeconomic disadvantages, to health disparities. For example, exposure to racism and racial discrimination has been associated with elevated blood pressure and unhealthy coping behaviors such as smoking or overeating (Krieger & Sidney, 1996), and socioeconomic disadvantage and poor health outcomes during gestation and childhood have been shown to predict chronic diseases in later life (Barker, 1998).

Racism also exerts its toll through suppressed anger and rage and the cognitive burden of dealing with racism on a frequent basis (Feagin & McKinney, 2003). The chronic wear and tear of racism-related stress can alter the body's ability to adapt in a healthy manner over time, thus producing adverse mental, behavioral, and physical health consequences (McEwen, 1998). The impact of racism over the life course is not always linear or continuous. There might be some critical periods, such as early childhood or in old age, where the harmful effects of racism are most intense, or disadvantage at different life stages can have a cumulative dose-response effect (Graham, 2002). Moreover, human agency can moderate the effect of racism exposures at any point during the life course.

## SELECTED ISSUES OF DEBATE AND CONTROVERSY

Many provocative issues and questions are the subject of current debates regarding racism. Although there remains disagreement about what race and racism are, what is clear is that these constructs have not been treated with the same care and precision as other key social and scientific variables (LaVeist, 1996). It is common to read studies that carefully define and operationalize each variable in the analysis except race and that conflate racism with discrimination, prejudice, bias, and other related terms.

Many definitions of racism imply that a person or an act is either racist or it is not, but do not distinguish between racism and related terms such as *discrimination* and *prejudice*. Some scholars argue that this duality is a simplistic way to think of racism, which has sparked a variety of new conceptualizations of racism, including *color-blind racism*, *silent racism*, and *liberal racism* (Bonilla-Silva, 2003; Sleeper, 1997; Trepagnier, 2006). Each of these terms suggests that the oppositional categories of *racist* or *not racist* are outdated and should be replaced with a continuum that portrays 21st century racial reality in the United States. However, defining racism as a continuum suggests that just about any statement or behavior can be designated as racist. In addition, reducing racism to a question of individual-level behavior, beliefs, and attitudes clouds the distinction between racism, bias, prejudice, and discrimination.

Prejudice, bias, and discrimination are commonly used to describe the attitudes and behaviors of individuals that are hypothesized to lead to negative interpersonal interactions. Such behaviors are also used to infer the presence of systemic organizational and interrelated social, economic, and political contexts that affect differentially people by race in the absence of identifying individuals who may be biased, ethnocentric, or prejudiced. Hypothesizing racism as the fundamental cause of persistent racial differences in outcomes also can be useful for explaining the differential impact of policies and practices. Inferring the existence of racism neither requires nor precludes individuals who are biased or prejudiced against people of other races.

Sloppiness in use and measurement of the concept of racism raises concerns about how the term can potentially lead to erroneous or misleading conclusions and problems. For example, terminology such as "playing the race card" refers to efforts to infuse social stratification, institutional racism, and structural racism into the discussion of disparate outcomes. The notion that racism is nothing more than an excuse to rationalize personal incompetence or that ethnic minorities cause their own problems is often a result of efforts to discount how cultural and historical institutions advantage some and disadvantage others. Racism is not a proxy for discrimination and prejudice, but a framework for understanding how social stratification advantages some and disadvantages others. The subjective nature of the process employed to identify racism guarantees continuous debate and disagreement about what acts constitute racism and subsequently who is or is not racist. This view accentuates racism as a *process* of understanding how someone is accused of being racist as well as whether that person (or persons) accepts this conceptualization of their behaviors or statements.

The fact that a broad array of behaviors and statements can be, and often are, viewed as racist contributes to a certain degree of cynicism when objectionable discriminatory behavior and bigoted remarks are protested. Some go as far as to argue that racism is no longer a significant problem for people of color (D'Souza, 1995). Like so many contentious political disagreements, what is or is not racist is difficult to prove, except in the legal realm, because labeling something as racist often presumes or requires intention. The objectionable nature of statements, behaviors, or differences in outcomes will continue to be interpreted by many within a framework that views racism as the underlying cause. Certainly not all objectionable statements are worthy of being designated as racist, but it is important for people to understand the complexity of racism that transcends basic notions of prejudice, bias, or discrimination. Racism is an *ideology* that ranks population groups according to a hierarchy of inferiority and superiority and leads to devastating effects on people of color.

Research on racism has had important policy and practice implications. Racism has provided an important perspective for understanding persistent racial differences in such important outcomes as socioeconomic standing, housing patterns, and health. Examining the health of African Americans through the lens of racism highlights how housing policy can lead to racial residential segregation and the unequal distribution of educational and financial resources that affect opportunities for leading long and healthy lives.

# RELATIVE COHORT SIZE HYPOTHESIS

The relative cohort size hypothesis aims to explain changes in birth rates, family formation, and well-being observed in the United States since the mid-20th century. It does so by positing that the economic and social fortunes of birth cohorts stem from their size relative to the size of their parental cohorts. It is also known as the Easterlin hypothesis, named after the economist Richard Easterlin who developed it, and the relative income or relative economic status hypothesis, named after the central concept linking relative cohort size to social and economic outcomes.

Easterlin (1961) first developed the relative cohort size hypothesis to account for fertility rates during the baby-boom years of the mid-20th century and the baby-bust years that followed (Easterlin, 1973). He later applied the argument to trends in marriage, divorce, education, female labor force participation, suicide, homicide, and alienation (Easterlin, 1978, 1987). The originality, insight, and broad scope of the hypothesis have generated a large collection of empirical studies.

## THEORY

Relative cohort size has two components: the size of a birth cohort and the size of the parental cohort that produced it. First, like cohort or generational influences more generally, the size of a birth cohort has important implications for the life experiences of its members. The number of persons born during the same year or historical period affects all stages of the life course, including high school graduation, employment, starting salaries, job promotions, salary increases, marriage, childbearing, divorce, retirement, and death. The key mechanism behind these influences of cohort size is income or earnings potential. Members of smaller cohorts face less crowding in the family and receive more attention from parents, less crowding in schools and more opportunities for educational attainment, and less crowding in the labor market and better job and earnings prospects. Larger cohorts face greater crowding and worse economic prospects.

Second, the size of the parental cohort—those born 20 to 40 years earlier—influences the expected standard of living or material aspirations of a birth cohort. Smaller parental cohorts provide a better standard of living for children, who become accustomed to that standard and develop high aspirations for their own standard of living as adults. Large parental cohorts, in contrast, create a lower expected standard of living among children.

These two components, the income potential or resources of a cohort and their expected standard of living or aspirations, define relative income. Demographic behavior, economic decision making, and social well-being follow directly from this comparison of resources to aspirations. Relative income in turn follows directly from the size of a younger cohort relative to an older cohort. In response to low relative income, members of a large cohort respond to the prospect of a deterioration of their living level relative to that of their parents by making a number of adaptations. They tend to marry late, postpone childbearing, rely on wages of working wives, and experience marital problems. Members of smaller cohorts with higher relative income require fewer such adaptations, more often following traditional norms for early marriage, two or more children, and homemaking roles for women.

The theory nicely fits the fertility swings of the post–World War II baby boom and bust. Cohorts entering young adulthood in the 1950s had been raised by a large parental generation during the poor economic times of the 1930s. Their small size, due to dropping fertility in the 1930s, created economic opportunities during the postwar prosperity. The combination of low aspirations and skyrocketing income led to early marriage, an unexpected burst of childbearing, and adoption of traditional family roles. By the 1970s the course of both relative cohort size and fertility reversed, however. The large baby boom cohorts born after World War II reached childbearing age when the high aspirations generated by the prosperity of their childhood conflicted with an overcrowded labor market and low income prospects. Couples closed the gap between their income and aspirations by avoiding the financial pressures associated with family responsibilities. They delayed marriage, had fewer children, and increased the hours worked by wives.

The logic of the theory also fits other social behaviors. According to Easterlin (1987), the sacrifice of family life and the effort to maintain economic status induce stress among members of large cohorts. This psychological and

economic stress may lead to high rates of out-of-wedlock births, suicide, crime, and, homicide—behaviors particularly common among baby-boom cohorts. In contrast, cohorts with smaller relative size and less stress, such as those born during the baby-bust years, experience fewer of these social problems.

Following the implications of his argument, Easterlin (1978) boldly predicted continued changes or reversals in fertility and other social behavior in decades to come. Although many theories predicted the continuation of past trends, the relative cohort size hypothesis posited counter-cyclical change. A small cohort with high relative income has many children, who belong to a large cohort. The large cohort, raised under good economic conditions and developing high expectations, faces crowding in families, school, and work. They then adjust their family behavior to have fewer children. The next smaller generation is positioned for higher relative income and fertility, and so on. Cycles of two decades of good times thus alternate with two decades of bad times. During the 1970s, a period of social and economic malaise, Easterlin predicted a turnaround in the 1980s and 1990s as smaller cohorts entered adulthood.

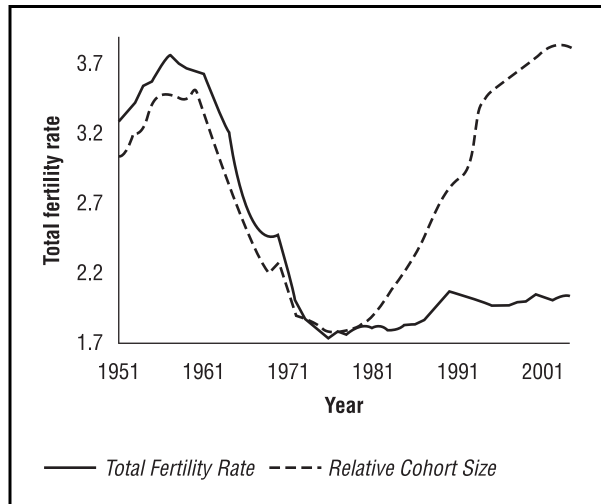

***Figure 1.*** *Trends in the total fertility rate and relative cohort size, 1951–2004.* CENGAGE LEARNING, GALE.

## EVIDENCE

The initial application of the theory to the baby boom and baby bust gave striking evidence of support. Easterlin proposed testing his hypothesis with two measures: the income of younger persons relative to older persons and the number of younger persons relative to the number of older persons. Graphing the total fertility rate by the latter measure—more precisely, the number of persons ages 30 to 64 as a ratio to persons ages 15 to 29—shows a remarkable match from 1951 to 1980 (see Figure 1). The theory does better than others in accounting for the puzzling and unexpected rise in fertility during the 1950s and the sudden and steep drop in the 1960s and 1970s.

However, the vast empirical literature stimulated in more recent decades by this provocative and testable hypothesis has been less clearly supportive. Perhaps most conspicuously, fertility failed to rebound to higher levels in the 1980s and 1990s as relative cohort size increased (see Figure 1). Otherwise, studies have shown much support but also a fair amount of disconfirmation. Interpretations of the diverse evidence have taken three forms.

First, some discount the validity of the theory. In a meta-analysis of 19 studies, Waldorf and Byun (2005) found that only 49 percent of 334 estimated effects of age structure on fertility support the relative cohort size hypothesis. They concluded that "several factors undermine the empirical support of the age structure/fertility link as hypothesized by Easterlin" (p. 36). Others favor competing theories of fertility change. For example, Lesthaeghe and Meekers (1986) and others saw a shift in norms and values as responsible for the drop and continued low levels of fertility in the United States and Europe. The feminist movement, youth protest, and concern with self-realization during the 1960s and 1970s represented the start of a long-term cultural trend toward individualism and post-materialism that fostered lower fertility and changing family forms. Instead of a component of counter-cyclical fluctuations caused by relative cohort size, such changes may be seen as part of a permanent second demographic transition (van de Kaa, 1987).

Second, defenders of the hypothesis argue that relative cohort size has effects that are clear and consistent, although other factors prove important as well. Macunovich (1998) found that 15 of 22 micro-level fertility studies and 15 of 22 macro-level fertility studies provided significant support for the Easterlin hypothesis. In addition, Macunovich (2002) presented wide-ranging evidence of the influence of relative cohort size on jobs, wages, relative income, female employment, college enrollment, marriage, divorce, fertility, economic demand, goods, and inflation.

Third, an integrative view argues that the influence of relative cohort size proves strong under certain conditions but not others. Easterlin (1987) hinted at this viewpoint by stating, "One would expect cohort size effects to dominate a cohort's experience only when other factors are relatively constant" (p. 3). Waldorf and Byun (2005) and Macunovich (1998, 2002) also recognized the contingent nature of the relative cohort size effects, but Pampel and Peters (1995) and Pampel (2001) presented the most extensive version of the argument. They argued that conditions during the American baby boom and bust such as low immigration, a sexual division of labor in work and family roles, and limited welfare programs intensified the importance of relative cohort size. Since then, rising immigration and movement

toward gender equality has weakened the importance of relative cohort size. In a similar way, strong welfare states have limited the importance of relative cohort size for fertility and other outcomes in European nations.

After decades of intense activity, research on relative cohort size has declined to a trickle (the work of Macunovich, 2002, and Waldorf and Byun, 2005, being notable exceptions). The trend no doubt results from the more limited success of relative cohort size in explaining contemporary behavior in contrast to behavior from the 1950s to the 1970s. Yet the potential value of studying the influence of cohort numbers remains. Researchers need to improve on previous work by controlling for factors that attenuate the influence of relative cohort size, improving measures of relative income, and recognizing the contingent nature of relative cohort size effects. With such improvements, the relative cohort size hypothesis may still offer insights into demographic and social behavior.

# RELIGION AND SPIRITUALITY, ADULTHOOD

Religion is an important part of adult identity. Almost two-thirds of American adults believe in God without having doubts, and 61% claim membership in a religious organization (Sherkat & Ellison, 1999). In fact, some scholars assert that belief, along with relationships and work, is one of the three pillars of developing an identity as one becomes an adult (Arnett, 2004). Although it is a central component of identity, religiosity is not stable over the course of adulthood. Instead, ebbs and flows in religiosity coincide with major life course transitions. Moreover, historical trends suggest changes in religiosity at the societal level, and there are ongoing scholarly debates about the nature and extent of those changes.

## DEFINITIONS AND MEASUREMENT

*Religion* is an ambiguous term that has been used to describe both personal beliefs and formal organizations. The coming of age of the baby boom generation forced a better articulation of what is meant by religion in the scholarly literature. In their rejection of many formal institutions, baby boomers challenged institutionalized religion. They were among the first to draw a distinction between being religious and being spiritual (Roof, 1999). Being religious meant being associated with formal religious institutions and adhering to doctrinal decrees, whereas being spiritual meant interacting with higher or nonphysical powers that helped in one's search for meaning in life. Spirituality, then, can exist via formal religious institutions but also can exist outside them (Zinnbauer, Pargament, Cole, Rye, Butter, Belavich, et al., 1997). Many baby boomers claimed that they were spiritual, but not religious (Roof, 1999).

This distinction between religiosity and spirituality continues to exist, but because spirituality is more difficult to measure than religiosity, it is less often the focus of study. Religiosity is measured in various ways, including denominational affiliation, service attendance, belief in a deity, and conviction or strength of beliefs. Those measures are relatively common in surveys such as the General Social Survey (GSS), one of the primary sources for tracking aggregate changes in religiosity over time (Sherkat & Ellison, 1991, Firebaugh & Harley, 1991, Chaves, 1991, Hout & Fischer, 2002).

Because of its highly personal nature, spirituality is more difficult to define with simple survey questions. The relatively smaller set of studies that consider spirituality tend to use small sample surveys with open-ended questions (Zinnbauer et al., 1997) or ethnographic methods (Sargeant, 2000) to understand how individuals view the place

of spirituality in their lives. Large surveys that take individual spiritual activity into account such as the GSS often use measures such as prayer and meditation, which originate from organized religions. Those measures may overlook new or unique ways of practicing spirituality. A number of religious institutions are incorporating new practices meant to enhance the individual's interaction with a higher power, adding to the difficulty in separating the two concepts. In an age when the boundaries between spirituality and religiosity are being highlighted by some and blurred by others, continued research on individuals' and researchers' definitions of these concepts is important (Roof, 1999).

## TRENDS IN RELIGIOSITY OVER TIME

Two main trends in religion dominated the scholarly landscape at the start of the 21st century: the redistribution of individuals among denominations, or switching, and the process of secularization, that is, the process by which U.S. society was becoming less religious and thus more secular. In general the denominational affiliation of a person's parents is highly predictive of that person's affiliation in adulthood. However, a substantial minority of Americans—about one-third—switch affiliations during their lifetimes. Membership in conservative Protestant, Jehovah's Witness, Mormon, and nonreligious categories is growing, whereas mainline Protestant denominations are declining in membership. The denominations that are gaining members are also the ones most likely to retain members, and so their ranks are likely to remain stable or continue to grow (Sherkat & Ellison, 1999). The percentage of Americans who reported no religious preference doubled from 7% to 14% from 1991 to 1998 at the same time that those claiming a conservative Protestant affiliation grew (Hout & Fischer, 2002). This may represent an increasing polarization of belief in the United States, with more people subscribing to no formalized beliefs or strict fundamentalist beliefs.

Whether the United States is secularizing and why are perhaps the most debated questions in the contemporary scholarly study of religion. Whereas some point to the stability of attendance rates at religious services as evidence against secularization, others argue that a process of secularization is taking place nonetheless. This belief stems mostly from changes in common correlates of religious participation, as was shown by Robert Wuthnow in his 2007 book *After the Baby Boom: How Twenty and Thirty Somethings Are Shaping the Future of American Religion*. First, getting married and having children traditionally have been the primary triggers for initiating or reinitiating religious involvement. However, in more recent cohorts of young adults marriage is delayed substantially, and people are starting families later and having fewer children. Moreover, whereas religious involvement increases with education, women who earn graduate degrees are less likely to attend services than are those who have only a bachelor's degree. As more women earn advanced degrees, religious involvement among women probably will drop. Thus, although overall service attendance rates have remained stable, rates for young adults have declined and may continue to decline. In fact, the greatest declines have been among those who are not married and those without children, two groups that are increasing in size as a result of the trends in family formation mentioned above.

Although attendance may be declining for recent generations, Wuthnow's (2007) assessment indicates that religious beliefs seem to have remained robust since the 1970s. However, Wuthnow argues that although religious beliefs still are held by many young adults, the content of those beliefs has taken a different form. Instead of doctrinal beliefs, young adults are "tinkering" with a variety of faith traditions, experiences, and resources to build their belief systems. Moreover, belief systems are developed around individual needs as people seek meaning in their lives. Thus, overall attendance rates have not changed in recent decades, but contemporary young adults are less involved in formal religion than were their counterparts in the 1970s; their faith-seeking quests highlight a renewed interest in spirituality.

In a series of studies sociologists have debated the question of why religious attendance rates have been so resilient across decades of major social change (Chaves, 1991, Firebaugh & Harley, 1991, Hout & Fischer, 2002). On the one hand, if marriage and childbearing spur religious involvement, the coming of age and family formation of the baby boomers should have led to increases in church attendance. On the other hand, the previously mentioned rejection of institutions, including formal religion, by the baby boomers should have led to declines in church attendance. Researchers have suggested a number of reasons for this stability. First, a religious revival in the 1980s that increased all cohorts' attendance rates might have masked declining attendance rates across generations. Second, although younger cohorts have lower attendance rates than the older cohorts they are replacing, the large number of baby boomers may be hiding the potential decrease in attendance. Still others feel that life cycle effects remain constant across cohorts and that changes in family structure and cohort size are the key influences on attendance rates.

Regardless of its causes, most researchers agree that the stable attendance and belief rates indicate that secularization has not occurred in the United States, particularly compared with Western Europe, where attendance rates have declined in recent decades. However, the changes in family structure, education requirements, and comparatively low attendance rates among young Americans mentioned above have led some to wonder about the future of organized religion in the United

***Buddhist Meditation.*** *Residents from the Manhattan borough of New York participate in a group meditation session during the sixth annual Change Your Mind Day in Central Park. The free event included meditation teachings from various Buddhist traditions, contemplative exercises, poetry, and music.* AP IMAGES.

States. The ability of organized religion to adapt to these changes may determine its staying power in the United States. As Penny Edgell discusses in *Religion and Family in a Changing Society* (2006), the many church programs that were built around the family structure of the 1950s are often ill equipped for the hectic schedules of modern dual-earner and single-parent families. However, she found that innovative congregations are exploring new programs (day care programs, singles groups, intergenerational activities) that are inclusive of all family forms while continuing to provide a moral vision of the "good family" and that those congregations are flourishing. This study illustrates the ability of religion to adjust to a variety of structural changes.

## RELIGION ACROSS THE LIFE COURSE

Religiosity is very responsive to life changes triggered by common transitions in the life course. As young people transition from adolescence to adulthood, religiosity diminishes. There are several reasons for this. First, as Jeffrey Arnett (2004) noted, developing one's own beliefs and values is a core aspect of becoming an adult. Young people want to decide for themselves what their religious beliefs will be, and as they do so, they may relinquish their parents' beliefs at least temporarily. In addition, many young people pursue education beyond high school, and service attendance is noticeably low among college students. This may be due to the freedom college students have to explore their beliefs when separated from their parents and an increased exposure to people from other faith traditions. Another explanation is that college promotes scientific thinking that is at odds with the supernatural beliefs of many religions (Johnson, 1997). Yet others argue that many college students simply "stow" their religion while they are in college because it is not part of mainstream college culture; they maintain their beliefs but do not voice them or outwardly practice their religion (Clydesdale, 2007).

Family formation is generally the first life course event in adulthood that triggers or renews religious participation (Wilson & Sherkat, 1994). Religious involvement increases with both marriage and childbearing (Mueller & Cooper, 1986, DeVaus, 1982, Chaves, 1991). There are several reasons why religious involvement increases with family formation. Parents may be prompted to become involved to socialize their children into a faith tradition. Families may increase their involvement to take advantage of the social support available to them in many religious institutions. However, it appears that these family formation events do not prompt an increase in religiosity among everyone. Rather, increases in religious involvement occur when people make these transitions at normative ages, not early or late (Stolzenberg, Blair-Loy, & Waite, 1995).

Perhaps the social connections available through religion are more accessible if one is of the same age as other adherents who are experiencing these life transitions. It also could be the case that religious involvement is part of a normative script that those making family transitions at the "right" time are more concerned about following. Also, adults who view religion as intimately connected to family life are more likely to return to their religion (Edgell, 2006). Moreover, it is "traditional" family formation, not just any kind of family formation, that induces an increase in religiosity. For example, those who cohabit or who have children outside marriage do not experience the same increase in religious involvement as those who have a child within marriage (Chaves, 1991).

Two less desirable life course events—divorce and death—usually occur after marriage and childbearing. Although less prevalent than marriage or childbearing, divorce is an increasingly common event that triggers

changes in religiosity, although in different directions for men and for women. Men who divorce are more likely to drop out of religion, whereas women who divorce are more likely to take up religion. Again, these effects apply to those who divorce at normative ages for divorce: the early thirties (Stolzenberg et al., 1995). Morbidity or impending mortality may prompt increases in religiosity as individuals cope with health problems and contemplate their place in an afterlife (Ellison, 1991).

## INFLUENCES OF RELIGION

Religious institutions are family-friendly institutions (Edgell, 2006). D. A. Abbott, M. Berry, and W. H. Meredith (1990) discuss the ways in which marriages and parenting benefit from religious involvement. Religious communities offer families a variety of social supports. Families build friendships with other members that facilitate the exchange of favors such as child care, meal assistance when a loved one is sick, and occasional transportation assistance, all of which are helpful in managing family duties. Some religious institutions provide formal family services such as food pantries, shelters, counseling, and activities for parents, children, and families. Many religions also have teachings about how to treat family members, including directives on respect, selflessness, and forgiveness, all of which should be beneficial for spousal and parent-child relationships. In fact, couples who are more religious report happier and more stable marriages (Call & Heaton, 1997, Scanzoni & Arnett, 1987, Wuthnow, 2007), although it is difficult to know whether religion makes these couples less likely to divorce or if they would be less inclined to divorce even without adult exposure to religion. Finally, religious families may rely on divine intervention to cope with family issues or stress. Believing that there is a higher being guiding family life can relieve pressure in times of strain and help families cope with adversity (Ellison, 1991).

Some researchers argue that various religious traditions may influence family formation in different ways (Wilcox, 2004). For example, conservative Protestant denominations are more likely to promote a male-breadwinner family model that emphasizes the dependence of each spouse on the other, whereas liberal Protestant denominations more commonly emphasize egalitarian relationships. Considerable time is devoted to teachings on parenting in conservative Protestant denominations, which emphasize strict discipline paired with affection and emotional investment (Wilcox, 2004). Although there is debate about which family form and parenting style is most beneficial for families, different religious family directives probably produce different outcomes or different ways of interpreting one's family.

In addition to offering benefits for families, religion can serve other positive purposes for individuals. Specifically, religion and its teachings often make behavioral proscriptions to encourage healthy and lawful behavior. For example, religions promote health by discouraging smoking and alcohol and drug use (Sherkat & Ellison, 1999). In addition, many religions discourage nonmarital sex, a practice that often increases pregnancy and disease risks if the partners are casual or nonexclusive (Barkan, 2006). Religious involvement and belief have been shown to promote positive psychological well-being as well (Bjorck & Thurman, 2007, Willits & Crider, 1988). As was noted above, religious individuals are better able to cope with stress and strain, in part because they believe life circumstances are out of their control and in the hands of a divine being (Ellison, 1991).

## RELIGION AND POLICY ISSUES

Since the year 2000 religion has been granted a greater role in policy debates and federal programs. During his presidency George W. Bush created the White House Office of Faith-Based and Community Initiatives (FBCI), which oversees similarly named centers in eleven federal agencies. The purpose of that action was to "lead a determined attack on need by strengthening and expanding the role of faith-based and community organizations in providing services" (White House, 2007). Particularly relevant to life course transitions, one FBCI center in the Department of Health and Human Services operates the Healthy Marriage Initiative, a program whose goal is to encourage healthy marriages and promote involved, committed, and responsible fatherhood (U.S. Department of Health and Human Services, 2007). Many of the grantees under this federal initiative are faith-based organizations such as Catholic Charities, Lutheran Immigration Refugee Services, Aish HaTorah, and the United Methodist Church. Thus, religious institutions increasingly are playing a role in federal efforts to shape life course events such as marriage.

Immigration is another issue that has generated renewed political interest in part as a result of the faith traditions of recent and future immigrants. The United States has long been a Christian-majority country, with more than 80% of its citizens claiming membership in Christian denominations (Sherkat & Ellison, 1999). However, recent immigrant groups are increasingly non-Christian. Of the top five birth countries of the U.S. foreign-born population in 2000, three were non-Christian nations: China, India, and Vietnam (U.S. Census Bureau, 2003). Moreover, the refugee population in the United States increasingly is coming from predominantly non-Christian nations (U.S. Department of Homeland Security, 2006). The ways in which religion operates in the life course of adults probably will become more variable as the content of Americans' religious beliefs and practices becomes more variable. In addition, the way the new immigrants are incorporated into a very different constituent faith fabric will be a new and stronger test of the American ideal of religious pluralism.

## EMERGING QUESTIONS

The destandardization of the life course, particularly delays in marriage and childbearing and increases in cohabitation and nonmarital childbearing, will challenge religious institutions that long have catered to "traditional" families. Research should continue to monitor the relevance of religion to individual and family lives as those lives unfold in less traditional forms. Will religious institutions continue to adapt to bring nontraditional family forms into the fold? If so, how will they do that?

A related topic that merits more attention is the degree to which the faith-seeking quest of individuals will continue to grow. Wuthnow (2007) and others have noted that current generations of young adults are tinkering with many religious and spiritual beliefs and practices in a quest for a more individualized faith that suits their lives. The emergent church movement is an example of how that quest has become formalized. The emergent church gives individuals a space in which to encounter a number of beliefs and views and, through interaction with one another, build their own belief systems. It will be interesting to follow this and other similar movements to discover the ways in which they are addressing particular needs of contemporary adults. Will the individualized faith-seeking quest continue as this new generation of young adults reaches middle age, or is it specific to this particular life stage? Is it simply a form of religious revival or part of a long-term trend toward the deinstitutionalization of religion? Future research should investigate the changing nature of individual beliefs.

Historically, religion and spirituality have occupied a central place in individual identity. They have many documented benefits, including family and social support and physical and psychological health. The importance and usefulness of religion ebb and flow with life course events and across time as the structure and purpose of religious institutions fit more or less with contemporary individual and family life. As the life course undergoes substantial change, religion will have to adapt to remain relevant to future generations of adults.

# REMARRIAGE

Given that roughly one in two marriages is not expected to last a lifetime, it is no surprise that remarriage is an important event in the life course of many Americans. Just under half of all marriages in the mid-1990s involved at least one previously married partner (Clarke, 1995), making remarriage unusually common in the United States relative to other countries. The context in which remarriage occurs differs from that of first marriage in a number of important respects. For example, remarriage tends to occur later in the life course than first marriage. In the mid-1990s women's average age at remarriage after divorce was 39.7 (42.5 years for men), compared to an average age of 26.6 years for first marriage (28.6 years for men; Schoen & Standish, 2001). Remarried individuals bring with them experiences and obligations from at least one prior marriage, which may include changed attitudes about relationships, children, or ongoing interactions with a former spouse. Remarriage often creates complex kinship networks involving parents, children, and siblings with varying relationships to one another. It is also important to keep in mind that remarriage can offer an important route to postdivorce economic recovery for women and children, who tend to experience a substantial drop in standard of living when a marriage ends. Because this entry focuses on remarriage in adulthood rather than later life, the discussion emphasizes remarriage following divorce rather than widowhood. The experience of children living in remarried families is the focus of a separate entry.

## REMARRIAGE TRENDS AND PATTERNS

Remarriage is historically common in the United States, although pathways into remarriage have changed substantially over time. Most notably, in the early 21st century remarriage is much more likely to follow divorce than the death of a spouse. Remarriage was more than three times as likely to involve a widowed partner as a divorced partner in 1900 (Jacobson, 1959). By 1990 this pattern had turned on its head, with remarriage more than nine times as likely to involve a divorced partner as a widowed partner (Clarke, 1995). This shift has important implications for the nature of remarried family experiences. For example, in the case of families with children, rather than "substituting" for a parent who has died, a stepparent is often added to an existing set of parental figures in the lives of children (Ganong & Coleman, 2004).

Although remarriage continues to be common in the United States, rates of remarriage declined sharply during the latter half of the 20th century. Between 1970 and 1990, the annual rate of remarriage declined from 123 to 76 marriages per 1,000 divorced women and from 205 to 106 marriages per 1,000 divorced men (Clarke, 1995). Although previously married people are remarrying less, they are no less likely to live with a romantic partner. In fact, the proportion of individuals living with a partner after marital separation increased somewhat between 1970 and the early 1980s (Bumpass, Sweet, & Cherlin, 1991). Cohabitation is more common among separated and divorced people than among the never married, with cohabitation a step along the path to remarriage for the majority of Americans. Indeed, 54% of individuals entering a remarriage during the early to mid-1980s lived with their partner before marriage, compared to only 39% of those marrying for the first time (Bumpass & Sweet, 1989). Cohabiting relationships also tend to be of longer duration among the previously married than among the never married and are more likely to involve children (Bumpass et al., 1991). Thus, nonmarital cohabitation is an important setting for postdivorce family life.

The experience of formal remarriage differs between men and women and across racial and ethnic groups. Estimates for the mid-1990s suggest that just over two-thirds of women but more than three-quarters of men eventually remarry after divorce (Schoen & Standish, 2001). The male advantage in remarriage is even larger after the death of a spouse than after divorce, although this largely reflects gender differences in the likelihood of remarriage at older ages (discussed below). Considerable variation in the likelihood of remarriage also exists across

racial and ethnic groups in the United States. Whereas 58% of non-Hispanic White women remarry within 5 years of divorce, the same is true for only 44% of Hispanic women and 32% of non-Hispanic Black women (Bramlett & Mosher, 2001). Reasons for racial and ethnic differences in the likelihood of remarriage are not well understood.

Those who remarry tend to do so relatively quickly, with roughly half remarrying within 3 years of the time a first marriage ends in divorce (Kreider & Fields, 2002). However, because some people never remarry, it takes about 7 years for half of all people experiencing divorce to remarry (Bumpass, Sweet, & Castro Martin, 1990). It is also important to keep in mind that some separated couples may not obtain a legal divorce until at least one partner wishes to remarry, which means that this figure may somewhat underestimate the average total time to remarriage after partners no longer live together (Sweet & Bumpass, 1987). This fact is particularly important when evaluating racial and ethnic differences in patterns of remarriage. Fully 91% of non-Hispanic White women legally divorce 3 years after separating from a first spouse, compared to only 57% of non-Hispanic Black women (Bramlett & Mosher, 2001). For these reasons, family scholars frequently consider the period "at risk" of remarriage to begin when spouses stop living together rather than at the time of legal divorce.

## DETERMINANTS OF REMARRIAGE

Although considerably less is known about the process of remarriage than first marriage, a number of studies examine which types of people are more or less likely to remarry after divorce. For example, individuals who are older at the time of separation are less likely to remarry than are individuals who are younger when their marriages end. The relationship between age at separation and remarriage is more pronounced among women than men (Sweet & Bumpass, 1987), perhaps because the pool of available marriage partners declines more rapidly with age for women than for men. This occurs for a number of reasons, including sex differences in life expectancy (women live longer than men) and because men tend to marry women somewhat younger than themselves whereas women tend to marry men somewhat older than themselves (Goldman, Westoff, & Hammerslough, 1984). Individuals who married for the first time at a relatively young age also are more likely than others to remarry after divorce, perhaps because they have an unusually strong desire to be married or because they have less experience with life outside of marriage (Bumpass et al., 1990; Waite, Goldscheider, & Witsberger, 1986).

A number of studies consider how children influence the likelihood that their parents will remarry. Children may constrain their parents' resources and time, affect the desire to remarry, or influence a parent's attractiveness to others as a potential marriage partner. Many studies suggest that having a relatively large number of children or having young children reduces a woman's likelihood of remarriage after divorce (e.g., Bumpass et al., 1990; Koo, Suchindran, & Griffith, 1984). Children place less of a constraint on men's chances of remarriage, perhaps because men are less likely than women to live with their children after divorce. Some research suggests, however, that men who are highly involved with their nonresident children are more likely than other nonresident fathers to enter new unions (Stewart, Manning, & Smock, 2003). One possible explanation for this finding is that the kinds of men who are highly involved fathers may also tend to be more committed to their romantic relationships than other men or tend to have better "relationship skills." Living in an area with relatively stricter enforcement of child support laws is also associated with lower rates of remarriage among low-income fathers (Bloom, Conrad, & Miller, 1998), perhaps because such laws increase the perceived financial obligations of previously married men.

Social scientists have also considered how socioeconomic characteristics such as education and earnings influence the likelihood of remarriage. Relatively higher earnings are generally found to increase remarriage among men, but the nature of this association among women is less well understood (e.g., Glick & Lin, 1987; Morrison & Ritualo, 2000; Wolf & MacDonald, 1979). No association between education and remarriage is found for White women, but among Black women remarriage probabilities are lowest for those with the least education (Smock, 1990). After adjusting for group differences in characteristics such as age at separation and number of children, Black women who are high school dropouts have a 60% lower rate of remarriage than otherwise similar Black women with more education. Although most research reports no overall relationship between men's remarriage and education, little work has investigated racial differences in this association among men.

Finally, prior research also considers whether "initiator status" in divorce has implications for subsequent patterns of remarriage. The nature of the divorce experience may differ considerably depending on whether individuals initiate divorce themselves or end their marriages based on a decision made by a dissatisfied spouse. Diane Vaughan (1986) argued that the initiating partner has a critical advantage over the noninitiating partner with respect to time, such that the initiator has a head start on emotional adjustment to divorce and more time to identify potential alternative marriage partners. Evidence suggests that the availability of new marriage partners is sometimes itself a factor in the decision to divorce (South & Lloyd, 1995). It is thus perhaps not surprising that remarriage tends to occur more quickly for initiating

than noninitiating partners (Sweeney, 2002). This difference is most pronounced within the first few years of a marital separation and for women who are relatively older at the time their first marriages end.

## THE NATURE OF REMARRIED RELATIONSHIPS

A number of studies explore the nature of remarried relationships, generally defined as marriages involving at least one previously married partner. Outcomes examined include childbearing, marital power and autonomy, and relationship quality and stability. For example, studies suggest that roughly one-half of remarried women bear children within their new unions (Wineberg, 1990), although the presence of stepchildren from a previous relationship reduces the likelihood of childbearing with a new spouse (Stewart, 2002). The association between stepchildren and childbearing intentions is weaker, however, when children are the biological offspring of the husband rather than the wife in a remarried relationship. This again may stem from the increased likelihood of children living with their mothers after divorce rather than their fathers, as the husband's children are relatively less likely to live in the remarried couple's household.

Research suggests that remarriages tend to be more egalitarian than first marriages and are more likely to involve shared decision making, although findings vary across studies (Ganong & Coleman, 2004). Wives tend to do more housework than husbands in all marriages, yet chores tend to be shared more equally in remarriages than first marriages and tasks are less likely to be segregated based on gender in remarriages (Ganong & Coleman, 2004). Some evidence also suggests that remarried families may tend to organize their finances differently than first-married families, with husbands and wives in remarriages being more likely to keep at least some of their money in individual rather than pooled family accounts (Treas, 1993). This may because of a relatively greater desire for financial independence or because of remarried husbands' and wives' greater likelihood of having financial obligations to family members from a previous marriage. Wives in remarried families also tend to perceive themselves as having greater influence over family financial matters than do wives in first-married families (Ganong & Coleman, 2004).

Although most studies report only small differences between remarried families and first-married families with respect to levels of marital quality, remarriages do tend to be less stable than first marriages. Roughly 36% of women entering a second marriage in the early 1980s ended these unions through separation or divorce within 10 years, compared with only 27% of women entering first marriages during the same period (Kreider & Fields, 2002). The higher instability of remarriages is particularly pronounced within the first few years of a marital relationship (Sweet & Bumpass, 1987). Andrew Cherlin (1978) argued that the lower stability of remarried families may exist because remarriage after divorce is "incompletely institutionalized," meaning that remarriage is not supported by the same laws or shared expectations about social roles and obligations as first marriage. Remarried families have fewer social norms to guide them in making decisions such as which kinship terms to use in reference to individual family members (e.g., should a stepfather be called "Dad" by his wife's children?) or what kind of relationship a stepparent should have with a stepchild (e.g., should a stepparent have the authority to discipline a stepchild?). Remarried families involving stepchildren are also governed by different legal rules than first-married families with only shared biological children. For example, stepparents do not generally have the same legal obligation to provide financial support to a stepchild as a biological child and do not generally have the same presumptive right to visitation with stepchildren after a marriage to the child's biological parent has ended (Mason, Fine, & Carnochan, 2004).

The relatively lower stability of remarriages than first marriages may also result from preexisting differences in the characteristics of people who marry multiple times versus those who marry only once. For example, remarried individuals tend to differ from first-married individuals with respect to divorce risk factors such as level of educational attainment and the perceived ability to cope with divorce (Booth & Edwards, 1992; Castro Martin & Bumpass, 1989). Furthermore, remarried individuals are more likely than first-married individuals to have entered their first marriages as teenagers, which some argue may reflect personality characteristics (e.g., impulsiveness, conscientiousness) or other background factors that make it difficult to choose appropriate romantic partners or maintain relationships throughout the life course (e.g., Castro Martin & Bumpass, 1989).

## DISCUSSION

Although almost half of recent marriages in the United States involve a previously married partner, scholars still know considerably less about remarriage than about first marriage. It is important to study remarriage in its own right because of key differences in the context in which remarriage tends to occur. Much of what scholars do know about trends and differentials in patterns of remarriage comes from data collected by the mid-1990s. In the 1970s Cherlin argued that remarriage was "incompletely institutionalized." As increasing numbers of individuals and families have experienced

remarriage after divorce, has remarriage become more fully institutionalized? Have the norms, expectations, and determinants associated with the formation and stability of remarriage changed over time? In short, despite a large body of research investigating remarriage, much remains to be learned.

# RESIDENTIAL MOBILITY, ADULTHOOD

The United States has long been known, for better or worse, as a nation of movers. According to popular belief, the high geographic mobility rate in American society provides access to opportunity but fosters personal and community disorganization. Social scientific evidence,

however, suggests that the truth about the consequences of mobility lies somewhere between these stereotypic extremes. Social scientists also have learned much about why certain segments of the population are disproportionately likely to move. For the type of movement examined here—residential mobility—life course transitions prove crucial. Local changes of address tend to be triggered by a range of events, including school completion, household formation, marriage, parenthood, divorce, widowhood, and ups and downs in financial status. The development of mobility decision-making models represents an attempt to understand how people adjust their housing situations in response to these events.

## CONCEPT AND MEASUREMENT

Geographic mobility research focuses on movement involving a permanent or semipermanent change of residence. This definitional criterion excludes a variety of temporary phenomena (e.g., commuting, out-of-town work assignments, extended vacations) from consideration. Among permanent moves, residential mobility is distinguished by its local character. Unlike international or interstate migration, residential mobility begins and ends inside the same community, which might range from a single municipality to a metropolitan-wide housing or labor market. In general, the community should be small enough that moves within it do not require the movers to find new jobs (Clark, 1986).

The U.S. Census Bureau operationally defines residential mobility as *intracounty* mobility. Because counties are recognizable government units with stable boundaries, they provide reasonable approximations of community. The fact that they vary greatly in size and shape, however, leaves room for inconsistencies. Some counties in the Southwest cover thousands of square miles, so that "local" moves within these jurisdictions can be quite long. At the other extreme, the multicounty makeup of a metropolis such as Atlanta means that even short moves may cross one or two county lines—and therefore not count as mobility—despite taking place in the same housing market.

Data on residential mobility are available from censuses, large-scale surveys (e.g., the Current Population Survey conducted by the U.S. Census Bureau), and community case studies. A few nations maintain population registers that contain complete residence histories for all persons. Mobility is typically measured with questions asking whether respondents occupied their current dwelling unit one year or five years earlier and, if not, where the previous unit was located (Long, 1988). As the length of the reference interval increases, so do the risks of recall error (because of faulty memory) and underestimation (because of the comparison of addresses at only two dates, which will miss any moves between those dates). Occasional investigations have measured respondents' mobility desires or expectations rather than actual changes of residence. The preferred approach, though, is to use a *prospective design* in which information gathered about people's residential circumstances, including their thoughts about moving, is supplemented with data from a later time point that indicates whether a move has transpired. In a longitudinal survey such as the Panel Study of Income Dynamics, the same respondents are interviewed repeatedly over many years, facilitating analysis of residential mobility within a larger life course framework.

## AGGREGATE PATTERNS

From an international perspective, the footloose reputation of American society appears well deserved. Only a handful of Western countries with large private housing stocks and little tradition of public housing (e.g., Australia, Canada, New Zealand) rival or exceed the United States in overall geographic mobility (Long, 1992). The more modest mobility rates in developing nations can be traced to limited supplies of adequate housing, restricted financing options, and state curtailment of the freedom to move (Huang & Deng, 2006). Few such obstacles exist in the United States, where roughly 40 million people, or 14 to 15% of the total population, have changed addresses annually since 2000, and 120 million (46%) moved at least once between 1995 and 2000. These aggregate mobility levels translate into an average of nearly a dozen moves per person over a lifetime, based on age-specific rates of movement.

About three-fifths of all moves occur within counties, satisfying the definition of residential mobility. Mobility rates vary by region (the West highest, the Northeast lowest) and by state: The percentage of persons moving locally in California, for example, is one-and-a-half times greater than in New Jersey (Berkner & Faber, 2003). An urbanism gradient can also be detected: Central city dwellers are the most likely to make intracounty moves, nonmetropolitan residents are the least likely, and suburbanites rank in between. To some extent these mobility patterns reflect geographic differences in housing market conditions, but they also reflect population composition. Thus, the high percentage of young adults and renters in cities—two especially mobile groups—helps account for higher urban than rural mobility rates.

Although residential mobility is by definition local, its degree of localism remains striking. Intracounty moves cover very short distances on average, with most ending in the neighborhood of origin or no more than a few miles away. This destination proximity makes sense given the limited scope of home seekers' *awareness space*, that portion of the larger community context with which they are

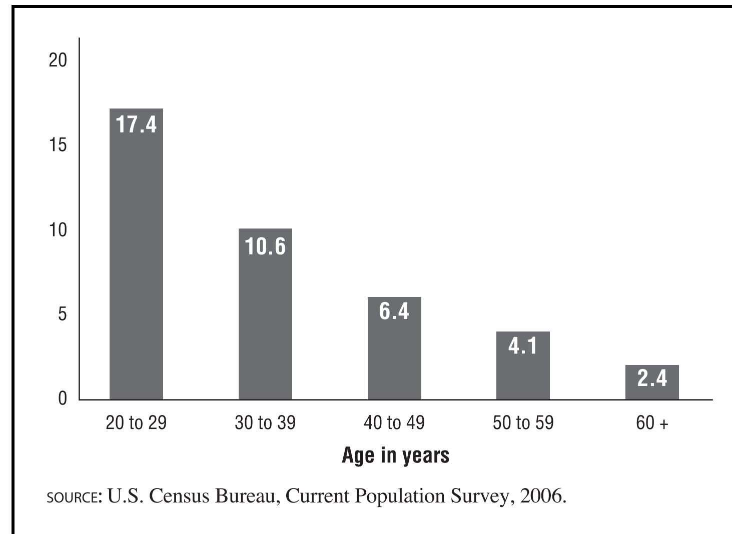

***Figure 1.*** *Adult residential mobility rates, 2005–2006.* CENGAGE LEARNING, GALE.

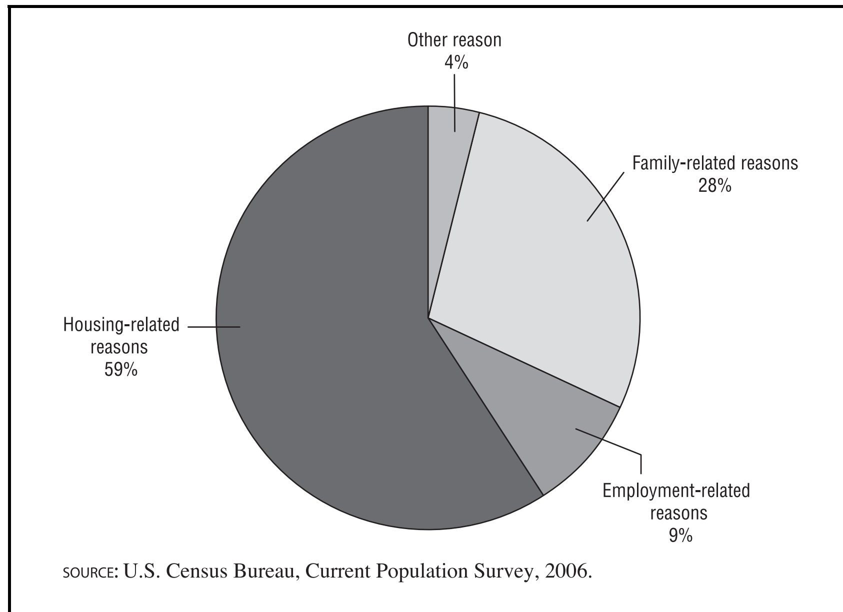
most familiar and which shapes their search. The spatially compressed nature of residential mobility is matched by its temporal compression, or seasonality. Local moves occur more often in the summer, even among households without school-age children, and are least common during the winter months, when weather, work and academic schedules, and the holiday season are deterrents.

Despite its still-impressive level in the early 21st century, mobility was much more common in the past (Fischer, 2002). Historical analyses spanning the 1800s through the early 1900s suggest annual rates of residential turnover in excess of 50% for some American cities. The rates were driven in part by large, transient rooming-house populations and a variety of disruptive events (e.g., high mortality among primary-wage earners, economic downturns, natural disasters) that led to moving. As these forces diminished, and as home ownership became accessible to the masses, the annual total (all movement) and local mobility rates dropped to 20% and 14% of all persons, respectively, soon after World War II. Since then, local mobility has fallen further, whereas inter-county movement has remained stable. One plausible explanation for this trend, in addition to the continued rise in ownership, is the outward expansion of commuting ranges. Moves within metropolitan areas now cover greater distances, crossing into neighboring suburban counties and beyond the U.S. Census Bureau's definition of residential mobility.

## WHO MOVES?

The intertwining of mobility with other aspects of the life course implies that persons at key transition points should be the most likely to move. Because these transitions are concentrated in young adulthood, age is a powerful correlate of mobility (see Figure 1). Steps taken by people in their 20s—achieving independence from their parents, pursuing an education, marrying, having a child—frequently trigger a change of address, not only in the United States but also abroad (Long, 1992). By their mid-30s, many have settled down, perhaps after an additional move to accommodate an expanding family or in response to increased earnings. Subsequent transitions, particularly in marital status, increase the odds of moving again. Divorced or separated persons exhibit markedly higher local mobility rates than their married counterparts, as do never-married individuals.

The fact that these single-person and single-parent households are often economically vulnerable suggests another characteristic underlying their high mobility: income. According to 2003 Current Population Survey data, members of households with incomes under $25,000 have mobility rates double those in the $100,000+ category; a similar differential is observed for persons below and above the poverty line (Schachter, 2004). Needless to say, financial hardship makes it difficult to stabilize one's residential situation. The transition in housing tenure (i.e., whether one owns or rents) from renting to owning is a crucial stabilizing force. Renters are four times more likely than owners to move over the course of a year. Owners stay put because, on average, their dwelling units are of better quality, can be altered more easily, and represent a substantial asset. The transaction costs associated with moving from an owned unit are also higher than moving from a



SOURCE: U.S. Census Bureau, Current Population Survey, 2006.

***Figure 2.*** *Main reason for making local moves, 2005–2006.* CENGAGE LEARNING, GALE.

rented unit. Finally, the longer owners remain stable, the stronger their bonds to home and neighborhood become.

Several potential antecedents of residential mobility prove relatively unimportant. Career-based transitions such as transfers or new jobs, for instance, appear more influential in prompting long-distance than short-distance movement. With respect to race, Blacks and Hispanics move locally more often than Whites. The differences are small, however, and they shrink to insignificant once other characteristics that vary by racial group are taken into account. Those characteristics—age, marital status, family size, income, and tenure—tap, at least indirectly, some of the main motivations and resources shaping a household's probability of moving.

Another way to assess the dominant influences on mobility is to ask people why they have moved. In general, the reasons given align well with the demographic correlates already identified (see Figure 2). Three-fifths of respondents to the Current Population Survey, which contains geographic mobility questions in its annual social and economic supplement, cite housing-related factors as their main reason for making a local move. Such factors include preferences for a new or improved unit, home ownership, affordability, and a better neighborhood. A second cluster of reasons, mentioned by more than a quarter of respondents, focus on family or life course transitions, most notably the establishment of a separate household, changes in marital status, and increases or decreases in family size. Work-related reasons, which figure prominently in intercounty and interstate migration, are rarely offered as explanations for residential mobility (Schachter, 2001).

## DECISION-MAKING MODELS

Attempts to theorize mobility assume that it represents voluntary behavior designed to avoid confusion with mobility "intention" (see later discussion) to maximize well-being. As a consequence, mobility models emphasize decision making. In his pioneering Philadelphia study, Peter Rossi (1955) argued that life course transitions, especially shifts in family composition, create new housing needs that reduce satisfaction with the current dwelling, setting the decision process in motion. Elaborations of Rossi's approach by sociologists and geographers (e.g., Moore, 1972; Speare, Goldstein, & Frey, 1975) have supplemented the life course variables with other factors hypothesized to influence satisfaction, including housing and neighborhood characteristics, local social attachments, and a person's values and standards of assessment. Only if these factors combine to markedly lower satisfaction does a household develop a desire or intention to move. It then initiates a search for possible destinations, the costs and benefits of which are presumably weighed against those of the origin. The ultimate decision to change addresses depends on whether the anticipated satisfaction associated with the chosen housing unit (discounted by the time, effort, and expense of moving) exceeds what is presently being experienced.

Although generic models of this sort continue to guide research, they are subject to numerous caveats and qualifications. One issue concerns just how pivotal a role residential satisfaction plays in decision making. Satisfaction fails to explain the relationship of housing, demographic, and

other variables to mobility, and it rarely has a dominant direct effect itself (Landale & Guest, 1985). More telling is that moves occur despite high levels of satisfaction. People content with their current home might happen onto a "windfall" opportunity that allows them to fulfill long-term housing aspirations. Alternatively, satisfied individuals are sometimes displaced by cost increases, eviction, fire, and the like or feel compelled to leave by events unrelated to housing quality (e.g., divorce or the death of a spouse). Some studies estimate that as many as one-fourth of all local moves are forced or imposed (Sell, 1983). Models that assume the voluntary nature of mobility decisions are less relevant in these cases.

Even when fully voluntary, decision making has been difficult to capture because of its complexity (Michelson, 1977). With the exception of people who live alone, the decision process is collective rather than solitary, involving negotiations among household members at every step. Because members bring their own unique perceptions and standards to the task, they often evaluate the same objective housing circumstances differently. They might also respond differently to stress while contemplating a move. The brief length of many searches, for example, has been attributed to uncertainty about the number of opportunities and competitors, which can pressure home seekers to settle quickly on an acceptable unit (or to stay put) rather than holding out for the ideal destination. Suffice it to say that households vary in how complicated their decision process is.

Households vary in *mobility capital* as well, especially in the United States and other societies with high immigration and growing racial and ethnic diversity. Both ethnographic and quantitative work indicates that English-language ability, time since arrival, citizenship status, and the strength of own-group ties complement more conventional forms of human capital in determining the degree of difficulty newcomers face when navigating the housing market. Their options are further constrained by institutional actors. Despite signs of progress, the 2000 Housing Discrimination Study showed that minority group members (whether foreign- or native-born) still tend to get less favorable treatment from real estate agents and landlords than do comparable Whites (Turner & Ross, 2005). They receive information about fewer units, visit a smaller number, are given less assistance with financing arrangements, and are steered more frequently toward vacancies in minority neighborhoods. Similar discriminatory practices have been documented among lenders and insurers. Thus, the finding that Black and Hispanic households struggle to avoid and escape poor neighborhoods is unsurprising (South, Crowder, & Chavez, 2005).

Such evidence casts doubt on the implicit assumption that households considering a move have complete information about and access to all opportunities. Likewise, moving should not be regarded as the sole strategy available for reducing residential dissatisfaction. After a fruitless search, some individuals revise their standards of evaluation, bringing aspirations in closer agreement with objective reality. Others elect to voice rather than exit, mobilizing politically in response to neighborhood problems. Finally, because homeowners have a more flexible situation than renters, they may physically modify their units (via repairs, remodeling, or adding on) to alleviate dissatisfaction (Deane, 1990).

What the foregoing critique suggests is that a nontrivial thread of unpredictability runs throughout the mobility decision process. This can be observed in the weak correlations among dissatisfaction, the intention to move, destination selection, and actual mobility, not to mention the variable sequence and time frame in which these decision stages are implemented. The ultimate result is that longitudinal studies identify a large proportion of unexpected movers and even more unexpected stayers, people whose decision making turns out to be somewhat convoluted (Duncan & Newman, 1976). In short, models of residential mobility may overestimate the human capacity for rational, effective planning.

## CONSEQUENCES OF MOBILITY

Interest in mobility is motivated in part by the belief that moving is disruptive and therefore harmful to the parties involved. Yet available evidence paints a positive picture with respect to residential consequences. According to 2005 American Housing Survey data, recent movers are far more likely to consider their current dwelling and neighborhood better rather than worse than their previous ones. A parallel finding emerges from research on the concept of the *housing career*, which refers to the succession of units that a person occupies after reaching adulthood and entering the housing market. Most Americans exhibit an upward trajectory over time—toward ownership and higher-quality units and locations—despite occasional setbacks associated with divorce, the loss of a job, or other life events (Clark, Deurloo, & Dieleman, 2003). As already noted, characteristics such as race and nativity can condition how fast and far one's housing career proceeds. Nevertheless, a general pattern of progress holds across all segments of the population.

Nonresidential consequences of mobility have been examined in substantial detail for children, but they remain understudied among adults. Several forms of political participation, including voting, appear depressed in the short run by both local and extralocal moves. This suggests that a practical cost of mobility, the requirement to reregister to vote, rivals social disconnectedness, information deficits, and other explanations of lower civic engagement among movers (Highton, 2000). There are also hints that frequent movement as a child may have long-term (adult)

implications for educational attainment, health, and the "inheritance" of a propensity for mobility (Myers, 1999).

These scattered results should be regarded as tentative, however, until their causal basis is more firmly established. *Spuriousness* represents a particularly serious threat to methodological integrity. As an illustration, premove factors (e.g., poverty, domestic violence) might increase the odds of an address change *and* of civic withdrawal or health problems. Moreover, the mechanisms through which mobility influences a given outcome are unclear in most instances, as is the generality of the effect, which could depend on characteristics of both the mover and the move itself (e.g., voluntary vs. involuntary, type of destination). In light of such complications, one should avoid concluding that residential mobility always has harmful consequences or that it affects all individuals in the same manner.

A different way to think about the impact of mobility is at the community level. Criminologists, for example, regularly identify high residential turnover as a significant determinant of neighborhood crime rates, arguing that it undermines social networks, normative consensus, and collective efficacy. Moves also cumulate in urban structural change. The most obvious scenario of this sort entails racial or ethnic transition, when the strength of own-group preferences produces a combination of entries and exits that alters the population composition of a neighborhood. Less visible but more typical is the pairing of high mobility with neighborhood stability. Often the price, size, and style of housing in an area appeals to a narrow market segment, ensuring that arriving households resemble those departing on many social and demographic attributes (Moore, 1972).

Even in the absence of turnover, changes in neighborhood population mix may occur. This counterintuitive notion—that residential *immobility* leads to change—reflects the joint maturation of households and neighborhoods. Imagine that a number of couples move into a new subdivision at roughly the same time and then stay put. Over the life course, they will experience family expansion (and contraction), income growth, and aging, each of which will be manifested in neighborhood-level shifts. Realistically, events such as financial hardship or marital dissolution will necessitate some mobility and thus influence neighborhood change in more conventional fashion. These events, along with immigration and other macro trends, primarily impact neighborhoods via increased demand, but the supply side of the equation also matters. Housing construction, usually concentrated in peripheral locations, can prompt chains of moves that have ripple effects on neighborhoods throughout the metropolis.

## THE POLICY DOMAIN

Two basic relationships exist between residential mobility and public policy. The first treats mobility as an outcome and consists of federal, state, and local policies that target discriminatory practices in the real estate market. In the United States, civil rights and fair housing legislation has sought to enhance the residential opportunities available to a range of disadvantaged groups. Current laws prohibit housing and lending discrimination based on race, color, national origin, gender, religion, family status, and physical or mental disability. In terms of race, declines in Black–White residential segregation since 1970 suggest that these laws have had some effect in reducing barriers to mobility. The Housing Discrimination Study results cited above, however, caution against an overly optimistic interpretation.

In the second type of mobility–policy linkage, intervention programs use residential mobility as a means to an end, such as fostering desegregation or reducing concentrated poverty and its consequences. The programs typically provide poor families in distressed neighborhoods with vouchers for relocating to subsidized housing in more advantaged neighborhoods. Whereas certain programs (e.g., Section 8) give participants freedom to choose their new setting, others (such as the Gautreaux and Moving to Opportunity experiments) have stipulated which types of neighborhoods are eligible destinations. Fair-share programs in many American cities pursue similar objectives by redistributing public housing across low- and middle-income residential areas.

Evaluations of these mobility-as-means programs have been mixed, and hence their worth is hotly contested. Generally speaking, comparisons of postmove with premove measures reveal that adult participants report better physical and mental health, improved job opportunities, and lower rates of welfare receipt (Goering & Feins, 2003). Some critics, however, emphasize the limited evidence of actual employment and wage gains, maintaining that policies designed to move poor families into home ownership rather than better neighborhoods would be more effective. Although mobility-as-means programs have so far been tried in only a handful of U.S. metropolises, they are candidates for wider application. Indeed, as housing stocks in European nations and elsewhere increasingly shift from the public to the private sector, such programs have become more germane as a way to alleviate poverty and ethnic concentration.

## RISK

*Risk* can be defined as "the probability or relative uncertainty of an anticipated opportunity or outcome" (O'Rand, 2000, p. 228). The concept of risk generally has a negative connotation, implying the chance of harm, but risk can also be viewed positively as an opportunity for gain (Giddens, 1999). The study of life course risk is a relatively new area, initially stemming from a dialogue between sociologists and members of other disciplines such as economists, psychologists, anthropologists, and environmentalists, who have historically studied the concept of risk.

One area of research focuses on individual estimations of risk and subsequent decision making in situations involving uncertain outcomes. Research suggests that people are not good at estimating risk and have difficulty understanding information about the probabilities associated with a broad range of activities (such as gambling and financial investment) and behaviors (such as health-related behaviors associated with disease risk; Tversky & Kahneman, 1974, 1981). People's interpretations of risk information are distorted by a number of factors, such as the way risk information is framed by others—leading to individual perceptions of risk that differ from the estimates offered by experts. Building on this work, researchers have begun to examine the effect of social locations (e.g., social class) on perceptions of risk and decision-making processes, focusing on topics such as purchasing health insurance or investing in the stock market (Hardy, 2000; Heimer, 1988).

A second area of study focuses on the social processes involved in the development and identification of risks. Researchers using a social constructionist perspective question an objective model of risk that treats the probability of particular events as knowable and quantifiable. In general, this body of research examines the social and cultural factors that influence perceptions of risk. Researchers seek to understand how social actors (such as government agencies, social movements, and professions) identify and define hazards and risks (e.g., lifestyle risks such as smoking or technological hazards such as chemical pollution) and the role that power plays in framing debates about risks (Adam & van Loon, 2000; Clarke & Short, 1993).

Another body of research strives to understand risk as a function of broader changes within social structures and social institutions. Anthony Giddens's (1991) discussion of the modern self relies heavily on the idea of modernity as a *risk culture* that results from the combination of sophisticated knowledge, a great degree of uncertainty, vulnerability to unrecognizable and uncontrollable risks, and an emphasis on individual choice. Giddens describes modernity as involving the decline in the proportion of risks that are *external risks* (risks that are relatively predictable, easily calculated, and insurable,

such as disablement and unemployment) and the growth of *manufactured risks* (new risks that are produced by the progression of science and technology, that are ambiguous in nature, and with which society has little previous experience, such as nuclear power, chemical pollution, global warming, and genetic engineering). Manufactured risk is associated with what Ulrich Beck (1992) described as a *risk society*—a society affected by forces of globalization and techno-science and characterized by an increasing preoccupation with controlling the future and eliminating risk (see Elliott, 2002, for a review).

Angela O'Rand's (2000, 2003) development of the concept of *life course risks* recognizes that the transitions that constitute the life course present individuals with socially constrained opportunities and risks, such as unemployment, poor health or disability, and family disruption. She argues that, in addition to increases in risk stemming from globalization and information technology, demographic trends such as increases in life expectancy influence social policy and lead to individualized risk, as governments devise new solutions to address the challenges of supporting the health and financial security of an aging population.

A central theme within research on risk is that a defining aspect of modern society is the privatization and individualization of risk in all aspects of life. One example is the privatization of economic risk—a process that can be thought of as the *devolution of risk* from the state to the individual. An example of the devolution of risk is change in U.S. pension and health policy, in which collective risk sharing declined and individual responsibility for bearing life course risks related to work and health increased (see O'Rand & Shuey, 2007; Shuey & O'Rand, 2004). Historically, insurance institutions developed as a response to societal perceptions of individual risks of income loss, illness, and death, and these institutions were designed to spread risks across populations, such as those defined by citizenship, employment organization, or profession (see Heimer, 1985; Jacoby, 2001).

The idea of *risk spreading* or *risk sharing* is being replaced, however, by an ideology of *risk embracing* that seeks individualized, market-based solutions for economic risks and shifts the perception of risk from one individual vulnerability to loss to one of opportunity for accumulation (Baker & Simon, 2002). For example, new pension instruments (such as defined contribution plans) and diverse health management arrangements that minimize employer responsibility and liability (such as HMOs and other forms of managed care) arrived at workplaces in the United States and other Western countries beginning in the early 1980s. Old, occupation-based welfare systems that insured many workers with lifetime pensions and retiree health insurance have declined in prevalence.

The result has been the increasing devolution of labor market risks to households, which then have greater responsibility for planning for and managing expected and unexpected circumstances associated with income loss (such as job loss or stock market volatility) and health problems (O'Rand, 2000, 2003). Shifting corporate and state risks to individuals has the effect of protecting large institutions while exposing individuals to potentially catastrophic results—although, ironically, the discourse surrounding these changes suggests that they represent autonomy, choice, and opportunity for individuals to excel, rather than risks (Dannefer, 2000).

The research discussed above raises many public policy questions and unresolved issues. First, given the rise of new types of risk in modern society, what does the future hold for welfare state policies originally developed as a form of collective risk management to protect individuals from external risks (Giddens, 1999)? What is the effect of increasingly market-based solutions for managing life course risks on levels of inequality? Finally, at the micro level, more research is needed to better understand how individuals and households make decisions across the life course in light of the prevalence of manufactured risks in modern societies.

# ROLES

A *role* is usually defined as a set of expectations for how individuals should behave in certain social situations. It can be thought of as a way of organizing and categorizing social actors. Roles link social behavior, which is easily observed, to social structure and can thus be seen as a link between the individual and society (Goode, 1960). Roles can be used to describe the behaviors and identities of individuals, the social organization of a small group or institution, or the structure of an entire society.

Perhaps because the concept of role has a long history and is used widely across a number of disciplines, the usage of the term varies. *Role* sometimes refers to expectations for behavior, the behaviors themselves, or the social position itself (Biddle, 2000). Although people enact roles but occupy social positions, the term *role* is often used synonymously with *social position*. For example, the social position of "mother" has specific legal definitions in the United States, referring to documents such as birth certificates and adoption papers. This is no guarantee, however, that a person will engage in behaviors that meet society's expectations for "mothering"—the mother may be estranged from her child, or the person doing the mothering may be a sibling or grandparent.

In some situations, the socially constructed demands of a role, an individual's own definition of the role, and the actions of that individual may be highly congruent (Levinson, 1959). In these situations, recognizing the various meanings of role may not be as important. However, in many situations, one or all three of these aspects of roles are in conflict. For example, a member of a particular religious organization may be expected to behave a certain way, but an individual member may not accept all the tenets of the religion and therefore sometimes act in ways that violate the religious expectations.

## ROLE THEORY

Role theory developed in two distinct sociological traditions. In functionalist theory, based on the work of sociologist Talcott Parsons (1902–1979), the focus is on how roles help solve problems of social coordination by assigning behavioral expectations to people in particular situations. In functionalist theory, individuals conform to role expectations created by social consensus. The focus is on formal organizations and status networks. Roles, in this view, help define groups and establish hierarchies. Job titles in a large organization are a good example of functional role. People's assigned roles in an organization tells them who they have control over, who has control over them, who they work with on a daily basis, and what tasks they are allowed to do.

In contrast, interactionist theory focuses on how roles are negotiated between individuals engaged in interaction (Mead, 1934). Rather than seeing roles as templates provided through socialization, the emphasis is on how individuals create role expectations through interaction with role partners. An original focus of interactionist theory was on *role taking*, or the ability to take another person's perspective and to use that perspective in making decisions about one's own behavior. This role-taking perspective was also influenced by sociological theorists Everett Hughes (1897–1983) and Erving Goffman (1922–1982) and is a foundation of symbolic interactionism, a major theoretical paradigm in the social sciences (Biddle, 2000). There may be broad agreement, for example, about the expectations for individuals who enact a student role, but the specifics of the expectations and behavior of students in a particular class will depend on their interaction with the teacher. The teacher may also revise his or her behavior and expectations in interaction with the students.

## AGE AND ROLES

Traditional role theories have little to say about timing, yet timing is an important aspect of roles. Most roles are

associated with age norms, which specify the age range of people expected to fill the role. The *college student* role, for example, carries certain expectations about age, such that the modifiers *traditional* and *nontraditional* clearly express expectations about the normal age range of people who attend college.

If certain roles are appropriate for certain ages, a potential series of role entrances and exits as individuals age is implied. The individual life course is often defined by these role transitions; thus the concept of roles is fundamental to the life course perspective. The transition to adulthood, for example, is marked by maturing into the normal roles of adulthood. Adolescents often look forward to being of legal age to drive, vote, and drink alcohol. Work and family roles both have role entrances that form part of the transition to adulthood—leaving school, entering the full-time workforce, getting married, and becoming a parent.

In contrast, the transition from adulthood to old age is more often marked by role losses and exits rather than the accumulation of new roles (Morgan, 1988). Although older adults may look forward to gaining the role of grandparent, many also exit the work role and experience the death of a spouse. Because the roles that older adults most often enact (grandparent, volunteer) tend to be seen as less demanding than roles characteristic of the middle years (worker, parent), old age has been called a "roleless role" (Burgess, 1960).

Indeed, gerontological theories make explicit claims about the roles that are thought to be best for older adults. Disengagement theory suggests that it would be beneficial, both for individuals and for society, if older adults disengage from the roles associated with the middle years (Cumming & Henry, 1961). By giving up a work role, for example, older adults can focus their efforts on their health and on existential issues and at the same time free up a work position for younger persons just entering the labor force. Activity theory, however, claims that greater well-being in old age is associated with having a greater number and variety of roles (Havighurst, Neugarten, & Tobin, 1968). As a counterpoint, continuity theory argues that it is the continuity of meaningful roles that promote well-being, not the number of roles (Atchley, 1989).

Much of this picture of role accumulation early in the life course and role loss later in life is predicated on what Matilda and John Riley (1994) described as the "three boxes" of the life course. This describes the normative expectations that people will focus on education in their early years, work in their middle years, and leave leisure as the main concern for their later years. This structures age norms for many roles and thus what roles are available to people in different life stages. In contrast to this age-differentiated social structure, an age-integrated social structure would mean that "role opportunities in work, education, and other structures are more and more open to people of every age" (Riley & Riley 2000, p. 267).

## MULTIPLE ROLES

In formal organizations, individuals may be described as having only one role, but most individuals see themselves as occupying multiple social roles, such as worker, parent, spouse, and citizen. The interplay between different roles is a very important stream of roles research. Functionalist role theory suggests that role obligations imposed by society are demanding and that roles are inflexible and difficult to combine (Lynch, 2007). This perspective, then, would tend to view multiple roles in a negative light.

William Goode (1960) defined role strain as the felt difficulty in fulfilling role obligations. In Goode's formulation, individuals are constantly facing choices about which role behaviors to choose, which then necessitates *role bargains*. Role strain might result from individual roles that are difficult to perform or have overwhelming demands; strain might also be a result of role conflict, where the expectations from two or more roles are in opposition to each other. An area of role conflict of interest to many researchers in the early 21st century is that of working parents, who seek to combine roles with very different expectations.

For both men and women, enacting roles many people view as belonging to the opposite gender can create a situation of role conflict. This might be true for women participating in a traditionally male sport or men participating in a traditionally female occupation.

Not all researchers, however, see multiple roles as a problem. In the *role enhancement* perspective, occupying multiple roles improves individual well-being through the accumulation of benefits associated with a variety of roles (Marks, 1977). Paid employment, for example, brings with it the possibility of monetary rewards, feelings of competence, and social rewards. Indeed, satisfaction in one role (perhaps running a successful club) may compensate for problems in another role (such as having an unsatisfying job).

A key resource that may be associated with social roles is social integration. Social integration has been a major theme in sociology since the work of Emile Durkheim (1858–1917) and can be defined broadly to include "both participation in meaningful roles and the network of social contacts" (Pillemer, Moen, Wethington, & Glasgow, 2000, p. 8). Social integration can also be understood in relation to its opposite: social isolation. In the role context, if roles are the link between the

## TIME BIND

The "time bind" generally refers to conflict between individuals' work and family roles, especially their competing time demands. Attention to work–family conflict grew in the 1980s as women entered the labor force in large numbers and workers felt pressured by a tougher economic climate. Concerns about the effect of work demands on individuals and families were brought to the public in books such as Hochschild's (1989) *Second Shift* and Schor's (1991) *Overworked American*.

Hochschild's (1997) later book, *The Time Bind*, centers on the paradox that employees generally want more time with their families, but very few take advantage of "family-friendly" options for part-time work, job sharing, and flex time. Barriers to utilizing these policies include a work culture that values work hours as a sign of commitment (Hays, 1998). Although Hochschild suggested that the time bind may be leading to less satisfaction with family life, other research shows that relative satisfaction with work and family has been fairly stable over time (Kiecolt, 2003).

individual and society, multiple roles are a measure of social integration.

In general, research generally supports the view of multiple roles as beneficial for individuals. Research links multiple roles to positive physical health outcomes (Verbrugge, 1983) and to reductions in psychological distress for both men and women (Thoits, 1986). Research into multiple roles and care giving suggests that productive roles may have a positive effect on older caregivers (Moen, Robison, & Dempster-McClain, 1995).

### ROLES AND THE LIFE COURSE

Roles are central to the life course perspective, and the life course perspective has added much to the study of roles. First, the life course emphasis on process suggests that looking at roles cross-sectionally (at one point in time) gives a misleading picture. The impact of being laid off from a job, for example, would be quite different for a seasonal worker compared to an individual who had worked continuously for many years. Viewing roles as part of an ongoing trajectory also broadens the concept of a career beyond the realm of paid employment. The parental career, for example, would connect a variety of family-related role transitions into a meaningful trajectory in the same way that the work career potentially connects and gives context to a large number of individual jobs and transitions into and out of work.

Attention to role trajectories is evident in several areas of current research. Research on care giving is increasingly using the concept of the care-giving career (Lawton, Moss, Hoffman, & Perkinson, 2000). Research in the area of substance abuse is using the concept of the role trajectory to study the development of the drug abuse career (Boeri, Sterk, & Elifson, 2006).

Although research attention is being given to various kinds of role transitions (parenthood and retirement, for example), the impact of timing on these role changes also is being examined. Role transitions that occur during a period in one's life that are not in step with normative cultural expectations may be more stressful than transitions that are. Examples of the importance of timing is evident in research on the transition to adulthood. Early, as opposed to on-time, entry into adult roles is associated with aggressive behavior (Roche, Ensminger, Ialongo, Poduska, & Kellam, 2006) and substance abuse (Krohn, Lizotte, & Perez, 1997), but these negative outcomes are likely both a cause and a consequence of these "off-time" transitions.

Related to the issue of timing is the issue of the sequencing of roles. Again, during the transition to adulthood, the normative sequence of roles is entering the labor force, getting married, and then having children. Pamela Braboy Jackson (2004), however, showed that the role sequences that are associated with positive mental health vary by race, gender, and cohort. Whereas the normative sequence of work, marriage, and children was associated with better outcomes for Whites, African Americans who began work, had children, and then married had better outcomes.

The importance of context is a key component of the life course perspective. One application of the role concept would be to examine the interplay and quality of

particular roles, rather than assuming that all roles contribute equally to either role strain or role enhancement. Research on care giving illustrates the importance of this insight (Edwards, Zarit, Stephens, & Townsend, 2002). Both the work role and the care-giving role can lead to costs and rewards for the individual in these roles. For example, it is not necessarily the case that work is beneficial and care giving is stressful for every individual. Research shows that role occupancy alone is not effective in explaining differences in depressive symptoms, but role quality is (Baruch & Barnett, 1986). Although role quality may be important, few researchers have developed instruments to measure this concept.

Another aspect of role context is role identity. Many people will use roles (mother, engineer, team captain, deacon) to describe themselves, suggesting that adopting the behavior of a particular social role may lead to adopting a corresponding role identity. The salience, or importance, of a particular identity for a particular individual may help explain the effect of role quality on well-being.

Historical and cultural contexts are also key to understanding roles in a life course perspective. Different cultures can define the same role in very different ways. Joel Savishinsky (2004), for example, examined the different meanings of the term *retirement* in the United States and India. Historical changes can also shape the expectations and norms associated with roles. Shin-Kap Han and Phyllis Moen (1999) demonstrated that the timing of retirement has been affected by a number of factors that have changed the average age of retirement and have also increased the variability in the timing of this role transition.

Gender and age, of course, are key contexts influencing role trajectories (Hostetler, Sweet, & Moen, 2007). A count of the total number of roles one holds may not be as important for well-being as having a set of roles that is normative, given an individual's age and gender. Other important ways to contextualize roles are by looking at resources.

## GENDER AND ROLES

Gender is a key context influencing role trajectories. Gender is clearly an organizing principle in most societies and shapes the behavior of individuals. Pervasive gender stereotypes both lead to and reflect prevailing gender roles, defined as differing expectations about the behavior of women and men.

In many societies, gender roles assign men primarily to public roles and women primarily to private roles. These behavioral expectations may be formalized in rules and laws, such as early 20th century laws that barred married women from being teachers in most U.S. school districts. Industrialization and modernization, however, led to changes in gender roles. As societies move through the demographic transition from conditions of high mortality and fertility to conditions of low mortality and low fertility, the status of women often undergoes change. Women no longer need to spend most of their lives engaged in bearing and raising children. Along with this demographic transformation comes change in the nature of employment due to modernization, such that more jobs require symbolic skills and are in traditionally female fields such as health and education and fewer jobs require physical strength and are in traditionally male occupations (Kleinfeld & Reyes, 2007).

In modern Western societies, where rules against women's participation in many public domains have been lifted, informal gender roles continue to produce gendered behavior. In many developed countries, for example, women are still primarily responsible for work in the home; this includes the work of care giving, which is still seen as more natural and appropriate for women (Moen, Robison, & Fields, 1994).

Gender roles help determine behavior, such as hours spent on housework, but also shape preferences and beliefs. Prejudice against gays and lesbians, for example, reflects both prejudice against same-sex relationships as well as prejudice against those who violate gender norms such that prejudice is strongest against effeminate gay men and masculine lesbian women (Lehavot & Lambert, 2007).

## FUTURE DIRECTIONS

Because of the wide use of the word *role* and its associated concepts such as gender roles and role strain, it is difficult to summarize the state of research in this area. The difficulty is compounded by the use of role concepts without reference to existing theory and research.

Research in several areas of psychology is showing creative uses of the role concept and role theory. A new perspective on multiple roles focuses on the role switching and role overlapping that most people experience in their everyday lives. Because social settings overlap, especially with new forms of communication, social actors are often enacting many roles in a short time frame. Author Karen Lynch (2007) urges scholars to look at the cognitive or mental strategies individuals use to manage multiple roles.

Role concepts are also being used in the study of personality. The Personality and Role Identity Structural Model connects role experiences, role identity traits, and general personality traits (Wood & Roberts, 2006). This positions the role concept not just at the juncture of society and the individual but also at the juncture of psychology and sociology.

Role identities continue to be of interest to researchers, especially in the area of gerontology. A promising intervention for persons with dementia provides individualized activities corresponding with highly salient role

identities (Cohen-Mansfield, Parpura-Gil, & Golander, 2006). Those for whom family was paramount might construct family trees; others might engage in activities related to a lifelong interest in sports. Other research in gerontology shows that formal volunteering moderates the negative effect of having few or no role identities in older adults (Greenfield & Marks, 2004).

Finally, several social work practice models have a central focus on social roles. Social role valorization has a long history in the disability field. In the United Kingdom, this model is based on the idea that society tends to identify some people as fundamentally "different" and of less value than others. Analysis of the disability role can be used to counteract the negative impact of the role. This model has been expanded to palliative care and a critique of the role of the dying person (Sinclair, 2007). Social role theory uses the concept of social role to improve adaptation and positive social functioning (Blakely & Dziadosz, 2007). More knowledge in academia about the possible practical uses of role concepts and theories could lead to another step forward in this area.

## SANDWICH GENERATION

**SEE** *Caregiving.*

## SAVING

*Saving* is accumulating disposable (after-tax) income that is not used for current consumption (i.e., spending) but set aside for future use. Saved income can be held as cash or in transaction accounts such as checking or savings accounts. Funds being saved also can be invested in stocks, bonds, mutual funds, retirement accounts, and real estate.

Individuals save for several reasons (Bryant & Zick, 2006). First, savings may be used to spread lifetime income evenly over the life course. For most individuals, income is relatively low while young, increases with age during the working years, and falls in later life as individuals work fewer hours or fully retire from the labor force. To avoid large disparities in the consumption standard attainable during different stages of the life course, an individual may borrow against future income while young, save during the peak earning years, and then use income saved in retirement.

Second, saving allows individuals to maximize lifetime consumption, or the spending and purchasing that one does over the life course. The nature of economic cycles is such that both prices and interest rates fluctuate over time. By spending or making purchases when costs are relatively inexpensive (from low prices, low interest rates, or both), an individual can maximize consumption on a given income. Conversely, by saving during periods of high prices or high interest rates, an individual can consume more in the future when consumption is relatively less expensive. At a very basic level, this is achieved when families purchase more of a good (e.g., breakfast cereal) when there is a sale; by purchasing additional units of the good for future consumption while prices are lower (and therefore not purchasing at the higher price), the family maximizes consumption.

Third, saving may be motivated by the desire to transfer wealth to future generations. Transfers may happen after death as bequests to children or grandchildren from estates or insurance. Transfers to children and grandchildren also may be made while an individual is still alive, in the form of funds for higher education or assistance with the purchase of a home.

Finally, savings may be motivated by the desire to minimize economic risk and protect against unexpected financial events. This precautionary saving can act as replacement income in the event of an income loss or reduction or as a buffer against unforeseen expenses such as medical costs due to major illness or injury.

### THEORIES AND RESEARCH ABOUT SAVING

Several theories have been proposed to predict saving (and consumption) behavior and explain differences in savings rates over time. Economist John Maynard Keynes proposed the absolute income hypothesis, the first and most basic theory of saving and consumption, in 1936. This theory posits that a positive relationship exists between current income and current consumption and

that higher income households will save a greater proportion of their income than lower income households. That is, as income increases, consumption also increases (although not necessarily in exact proportion to increases in income). However, Keynes hypothesized that the proportionate increase in consumption is smaller (and thus savings higher) for households with greater income (on average) because increases in consumption represents a smaller proportion of income for higher income households than for those with lower income. Although subsequent research has supported the absolute income hypothesis using data collected at one point in time, the hypothesis has not been supported when data tracking income and consumption over time are examined.

Two related theories, the permanent (Friedman, 1957) and life cycle (Ando & Modigliani, 1963) income hypotheses were developed to explain individuals' saving and consumption over the life course. According to these hypotheses, individuals allocate their financial resources, including saving and borrowing, over their lifetimes. Saving is motivated by the desire to spread consumption evenly over the life course; although income may vary over time, saving and borrowing based on an individual's projection of his or her lifetime income allows actual consumption to be relatively unaffected by current income. For example, a college student takes student loans to pay for college, anticipating that the increase in after-graduation income will allow the repayment of the loans. In later life, the accumulation of savings during higher income working years enables a relatively stable standard of living in retirement. Although subsequent research supports the idea that saving and borrowing are used to even out lifetime consumption, the positive relationship between current income and consumption indicates that current income, as well as lifetime income, shapes consumption and saving decisions.

## TRENDS AND PATTERNS IN SAVING

Although estimates of U.S. personal savings rates (i.e., the fraction of personal income that is not consumed) vary, their downward trend over the past several decades is clear. From an all-time U.S. high of 12.2% in the fourth quarter of 1981, the personal savings rate fell to near zero in the last quarter of 2007, the lowest level since the Great Depression. This decline, at a time when the large baby-boomer generation is aging, exiting the labor force, and consuming out of savings accumulated during previous years may result in a considerable economic downturn due to the inability of families to support current consumption levels. Additionally, the shift in employer-sponsored retirement plans from defined-benefit, in which retirement income was guaranteed, to defined contribution, in which the employee is responsible for saving and investment decisions, may threaten the financial security for many in the future. Taken together, the lower savings rate, relatively large cohort approaching retirement, and changes in pension plan coverage may substantially impact individuals' ability to maintain preretirement consumption levels later in life.

Although the overall saving rate in the United States has decreased, the magnitude of the decline varies across social groups. Of considerable concern is the disparity between the savings of low- and high-income families. In 2003 only 10% of the wealthiest 1% of families in the United States did not save, whereas more than 62% of families in the bottom 25% of the wealth distribution did not save (Kennickell, 2006). Similarly, families in the top percentile of the wealth distribution are more than 2.5 times as likely to have an established savings plan as families in the bottom 25%. There are racial disparities in savings as well; whereas 60% of all American workers are currently saving for retirement, only 45% of Black workers and 34% of Hispanic workers are actively saving for the retirement years (Helman, VanDerhei, & Copeland, 2007). These disparities are likely related to differences in the means and ability to save out of income, individual risk tolerance, and consumption preferences but may also be related to differences in access to formal savings vehicles such as employer-sponsored retirement accounts.

## RESEARCH CHALLENGES

One of the critical issues in research on personal savings is the manner in which governmental agencies calculate the average personal saving rate (Reinsdorf, 2007). The National Income and Product Accounts (NIPA) analysis of the National Bureau of Economic Research is a frequently reported source of savings rates. Although these estimates are widely used in literature on personal savings, some researchers argue that these rates underestimate the actual level of savings by omitting capital-gains income (the gain realized from the sale of an asset, such as stocks or bonds, at a higher price than it was originally purchased) and including both working people and retired people (who may be spending out of savings, rather than income resulting in a negative saving rate based on NIPA calculation).

Regardless of the exact rates, the downward trend in personal saving in the United States, as well as some other developed countries including Canada and Australia, is considerable. Scholars have proposed several reasons for this decline, including increases in personal consumption and consumer debt (Parker, 2000), in part due to the increase in the availability of credit card and nontraditional home equity lending (e.g. subprime, adjustable rate mortgages, revolving home equity lines

## INVESTMENT

Investing involves the purchase of a financial or physical asset with the intention of realizing a future return (i.e., an increase in the asset's value or a monetary payment). Investment can be used to both generate funds for the future and to safely mitigate the impact of inflation on savings. A wide variety of vehicles are used for personal investing, including stocks, corporate and government bonds, mutual funds, and real estate.

Acknowledging the trade-off between risk and return is key to investment decisions. Whereas low-risk investments such as U.S. Treasury bonds are relatively safe from any loss of principal (i.e., the original investment amount), they generate a relatively low level of monetary return. Conversely, a higher-risk asset such as corporate stock is subject to market downturn and principal loss, but has a greater potential return, particularly if held long-term. While a diversified investment portfolio consisting of both low and high-risk assets is generally suggested, the risk-return relationship can be utilized to maximize investment performance based on an individual's position in the life-course.

of credit). Other explanations include the aging of the U.S. population and expectations of continued stable macroeconomic policy (e.g., relatively stable inflation and economic growth) and social program support (such as Social Security) among young households. These factors all help to explain the significant decrease in the personal saving rate in the United States, but no comprehensive theory that sufficiently explains the decrease has been proposed (Guidolin & LaJeunesse, 2007).

Cross-national analyses of personal savings rates are complicated by substantial differences in the financial systems and institutional structures of different countries. For example, research indicates that American households save less than households in some other developed nations but that this decrease is tied to differences in retirement behavior and credit constraints (Kirsanova & Sefton, 2006). This use of individual rather than national data has provided some insight into the diversity in personal saving between citizens of different countries, but direct comparisons remain complicated.

### POLICY IMPLICATIONS

As the baby-boomer generation approaches retirement, the importance of saving becomes increasingly important. Several policy implications are related to the current state of personal savings in the United States. The development and implementation of government-sponsored financial education and savings incentive plans has been suggested to increase both awareness of the benefits of saving and the availability of saving options for consumers, particularly for low-income families. The inclusion of mandatory credit counseling for the successful discharge of personal bankruptcy in the Bankruptcy Reform Act of 2005 and the 2003 establishment of the U.S. Financial Literacy and Education Commission are examples of initial steps toward increasing financial education in the United States. To increase the availability of savings vehicles and encourage saving among low-income families, Individual Development Account programs have been established (Comptroller of the Currency Administrator of National Banks, 2005). These programs match the savings of low-income participants, providing additional incentive to save.

Another policy option directed at increasing the personal saving of American families is a shift from income-based to consumption-based taxation. Although a "spending tax," or tax on goods and services consumed rather than on income, could encourage saving by exempting income not used for consumption from taxation, there are several arguments against consumption-based taxes, not the least of which is the potential concentration of wealth among the already wealthy who are able to save and invest more of their income than those with lower incomes.

Although personal savings rates have declined over the past few decades, saving for major life events including retirement remains an important financial issue throughout the life course. Whereas previous generations were able to rely on employer-provided pensions and Social Security for resources in retirement, the shift away from employer pension provision and toward consumerism and easy access to credit creates a challenging environment for saving.

## SCHOOL TO WORK TRANSITION

The transition from school to work (STW) is a critically important juncture in the life course. Socioeconomic attainment is a long-term process starting in adolescence and encompassing achievement in school, the acquisition of educational degrees and other qualifications, and movement through the occupational career. The individual's completed level of schooling and the point of entry into the labor force are major determinants of subsequent occupational and income trajectories. Psychologically, the transition has significant implications for the development of identity. Finishing school and starting full-time work are key markers of the transition to adulthood, signifying adult status and maturity. Young people who have made the transition from *survival jobs* to *career jobs* are more likely to consider themselves adults, and to be viewed, as such, by others.

### FEATURES OF THE SCHOOL TO WORK TRANSITION

There are major differences in the character of the STW transition both within and across societies. The transition is facilitated when institutional connections between school and work are strong (Kerckhoff, 2003); these linkages vary considerably in contemporary modern societies. For example, high schools in Japan are linked to employers in the community, and recommend their students for the most desirable jobs in order of their academic performance (Rosenbaum, 2001). The apprenticeship system in Germany similarly functions to link students and jobs, as young apprentices' schooling and employment are effectively coordinated, mutually supporting one another, as the youth prepare themselves for entry into particular occupations (Mortimer & Krueger, 2000). The STW transition is much more difficult and prolonged in North America, where secondary schooling is not vocationally specific, credentials (that is, high school diplomas and BA degrees) are general, and youths are encouraged to go as far as they can in higher education (Kerckhoff, 2002). In these circumstances, attaining the next rung on the educational ladder assumes a much higher priority than vocational preparation.

High school students focus on getting accepted into the best college they can, rather than preparing for entry into the world of work. Their teachers and parents encourage this stance, fearing that premature coursework or other preparatory activities related to work might steer them away from college degrees. While approximately two-thirds of high school graduates enter college, many of these young adults are not successful in completing 4-year degrees. As a result, most young people in the United States enter the labor force (as high school graduates or college dropouts) without an educational credential that would signal to employers their capacity to pursue particular lines of work. Many have difficulties in finding acceptable jobs, and lower their sights as they encounter the realities of the job market (Johnson, 2002). Whereas high school dropouts are the most disadvantaged full-time labor force entrants, even the recipients of college degrees (approximately one-fourth of recent cohorts) often flounder from job to job as they try to obtain a better match between their own interests, occupational values and needs, and the experiences and rewards to be obtained in the labor force.

The term *school to work transition* implies a clear, discrete event: completing school and entering the usually full-time work role. However, as a result of changes in both education and work, as well as cultural shifts in the relative prominence and desirability of the youth and adult phases of the life course (Hartmann & Swartz, 2007), this once clear, predictable, and normative

transition has become increasingly delayed and disorderly among recent cohorts of youth in the United States. Instead of full-time immersion in school, followed by similar full-time involvement in work, the lengthy period of transition typically includes long-term involvements in both work and school. Ever-more young people are extending their formal educations through adolescence and into young adulthood. Postsecondary students are becoming older: In 2002, 39% of students who were enrolled in degree-granting institutions in the United States were older than 25 (U.S. Department of Education, 2002). Combining school and work is highly normative throughout the periods of secondary and postsecondary education; most students are employed during the high school years and during college (U.S. Department of Labor, 2000). Shared school and work roles begin in early adolescence—at about age 12 for most of the U.S. youth. Moreover, the transition from school to work is not unidirectional; many young people return to school after leaving and engaging in work full time (Shanahan, 2000). In fact, by age 26, 20% of youths have undergone the transition from school to full-time work at least twice (Arum & Hout, 1998). These trends partly reflect the general nature of educational credentials and the lack of clear connections between employers and schools in the United States, as well as the increasing importance of a college diploma among recent cohorts of youth.

Instead of defining the transition to work as a discrete event, it has come viewed as a long-term process. Patterns of schooling and working during adolescence have long-term implications for postsecondary schooling and wage attainments in early adulthood.

## THE SHARING OF SCHOOL AND WORK ROLES AND SOCIOECONOMIC ATTAINMENT

Most prior investigations of occupational attainment assume that young people make a sequential STW transition. The socioeconomic standing of the family of origin, as well as indicators of academic performance and attitudes toward school, are major determinants of a young person's highest level of schooling. Educational attainment, in turn, establishes credentials for more or less prestigious full-time jobs that are held after the completion of school. Yet, as mentioned before, most youths begin working in adolescence and often continue to be both workers and students during the STW transition. In the United States, the average high school graduate acquires nearly 1,500 hours of employment between his or her 16th birthday and graduation from high school, whereas the typical college graduate gains almost 5,000 hours of employment by the time of college graduation (Light, 2001). Students may work to save money for future education or other purposes, to assert themselves as more "adult-like" in the eyes of parents, teachers, or peers, and to buy clothes, music, or video games. They may also work to pay for educational and living expenses, especially during the college years.

Scholars disagree about the impact of various combinations of schooling and working during the STW transition on future economic attainment (Staff, Mortimer, & Uggen, 2004). One view is that combining work and school, especially during the high school years, ultimately undermines adult attainment because paid work limits time for homework, studying, and extracurricular activities and encourages delinquency and the use of drugs and alcohol. According to this perspective, employment should be discouraged and limited as much as possible prior to full-time entry into the workforce. An alternative view is that longer-term socioeconomic attainment is enhanced when paid work is effectively combined with periods of school attendance. Early work experiences not only benefit adult attainment through on-the-job training and skill development, but also promote *soft skills* that are not learned in the classroom, such as time-management, self-reliance, and other interpersonal skills that facilitate workplace interactions with supervisors, coworkers, and customers.

There is growing consensus that it is the pattern of investment in paid work prior to the completion of schooling that determines its positive or negative influence (Mortimer, 2003). For instance, youths who work intensively (conventionally defined as more than 20 hours per week) during the high school years report fewer hours of homework, lower grade point averages and standardized test scores, and a greater likelihood of dropping out of high school than youths who do not work or who work fewer hours. Research also shows that such intensive work hours during the high school years lessen the likelihood of postsecondary school attendance and the receipt of a college degree in young adulthood.

In contrast, limited involvement in paid work during the STW transition fosters academic progress and longer-term socioeconomic attainment. Moderate work during the high school years is associated with increased grade point averages and greater involvement in school activities than nonemployment. Furthermore, research shows that moderate work hours do not limit time for homework or other extracurricular activities (Schoenhals, Tienda, & Schneider, 1998). Moderate work hours over the duration of high school also increase the likelihood of obtaining a 4-year college degree. Jeremy Staff and Jeylan Mortimer (2007) found this outcome to be linked to continuity in employment patterns. Their analyses of data from the longitudinal Youth Development Study show that a continuous pattern of combining school with low-intensity work throughout

the STW transition accrues advantages during high school, postsecondary schooling, and early occupational careers.

It is important to note that preexisting individual differences in school performance, aspirations, socioeconomic background, ability, and motivation shape subsequent investments in paid work and school during the STW transition. For instance, youths from lower socioeconomic backgrounds work more hours when they are employed than their more advantaged peers (Entwisle, Alexander, & Olson, 2000). Moreover, poorly performing students with low educational aspirations have greater workforce involvement in subsequent years of high school than their better performing peers (Bachman, Safron, Sy, & Schulenberg, 2003). Some research suggests that paid work has little effect on school performance once prior differences in grades, aspirations, problem behaviors, and family socioeconomic standing are taken into account (Warren, LePore, & Mare, 2000). Other longitudinal research on young men shows that working during high school has little benefit for adult wages once differences in unmeasured traits (such as ability or motivation) between workers and nonworkers are adequately controlled (Hotz, Xu, Tienda, & Ahituv, 2002).

It is also important to consider whether distinct combinations of schooling and working during the STW transition have different consequences for future attainment, depending on the youth's own interests, motivations, resources, and capacities. In particular, there is evidence that heavy investment in paid work during high school may not be harmful for those youths who come from more disadvantaged backgrounds. Research shows that paid work increases the chances of high school completion for young, economically disadvantaged males (Entwisle, Alexander, & Olson, 2005). Among urban youths residing in impoverished neighborhoods, Katherine Newman (1999) finds that exposure to conventional adolescents and adults at work can serve as an entry to legitimate occupational career paths and may even encourage educational attainment. Similarly, among contemporary rural youth in hard-pressed farm families, early work experiences can build confidence and instill positive work values under conditions of poverty and economic distress (Elder & Conger, 2000). Staff and Mortimer (2007) find that steady work is especially conducive to the attainment of 4-year college degrees for youth who display limited educational promise at the start of high school. Furthermore, Jennifer Lee and Staff (2007) show that high intensity employment during high school does not influence dropout for those who have the greatest propensity to pursue such an employment pattern.

## TWO IDEAL TYPICAL SCHOOL TO WORK TRANSITIONS

Based upon what is known about the relations between work and school roles and what is known about how individuals choose various work and school patterns, contemporary young people can be classified into two ideal typical tracks with varying emphases upon school and work. These tracks commence as early as age 14 and 15 and continue as young people make the STW transition. Youths who come from more advantaged backgrounds, and who are more strongly oriented toward schooling, are more likely than their less advantaged counterparts to pursue steady work during high school (i.e., limited hours but near continuous duration) and they invest more in postsecondary education, especially in 4-year colleges (Staff & Mortimer, 2007), during the years following. In contrast, youths from more disadvantaged backgrounds, and those who have poorer grades and lower educational aspirations, are more likely to be employed intensively during high school. These more intensive workers have little likelihood of acquiring 4-year college degrees. These class-differentiated tracks, commencing at the start of high school and persisting through the transition to adulthood, have lasting implications for future socioeconomic attainment. However, when youth from lower socioeconomic backgrounds follow the first track, involving steady work during high school, their educational attainment and longer-term wages are enhanced.

## CONCLUSION AND FUTURE DIRECTIONS

In the contemporary United States, where institutional bridges between school and work are notably undeveloped and the sharing of school and work roles often begins in early adolescence, employment experiences appear to be an integral part of human capital acquisition during the STW transition. In decades past, young people typically made a sequential transition from full-time school to full-time work, a transition that could be characterized as a discrete event. There are two ideal typical routes that now characterize the more prolonged STW transition among contemporary cohorts of young people. One route involves less intensive employment during high school, followed by continued part-time employment and postsecondary educational investment, most likely in 4-year colleges. This pathway is more common for youths of higher socioeconomic origins, but is especially beneficial for young people of lower socioeconomic status. A second route involves early intensive work experience during high school that is less conducive to higher educational attainment. These workers are less likely to achieve 4-year degrees, irrespective of their parents'

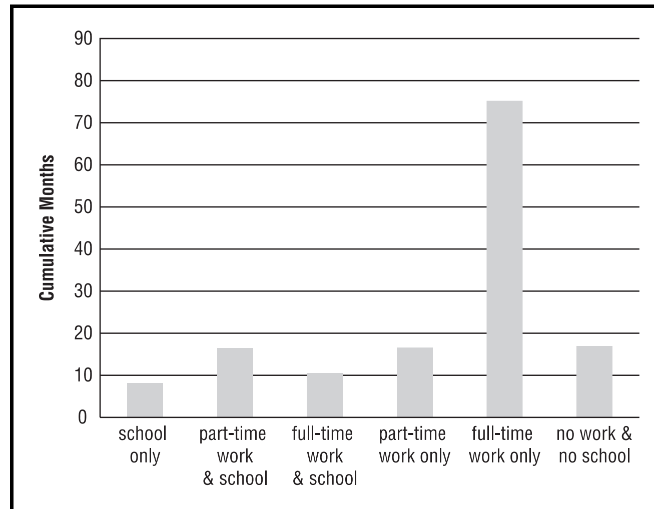

***Figure 1.*** *Cumulative Months of Work and School during the STW Transition (age 18–30).* CENGAGE LEARNING, GALE.

educational backgrounds. When they reach adulthood, these workers begin to show lower hourly wage rates than youths who worked less intensively in adolescence and were more likely to pursue postsecondary schooling in the years immediately following high school.

Whereas this review addresses patterns of temporal investment in work during the STW transition, little is known about the impact of the quality of early employment for educational and wage attainments on the quality of adult work and on adult occupational commitment and job satisfaction. For example, the presence of a supportive supervisor in the workplace may be especially important for youths whose own parents lack the experience and resources to effectively guide them toward higher education and jobs that will sustain a middle-class style of life. Positive work experiences, providing learning opportunities, skill development, and affirming one's role as worker may be especially important for the disadvantaged youth who may have few alternative sources of positive vocational identities, work values, and economic efficacy. Such experiences in the workplace could be particularly important in enabling youths of lower socioeconomic origin to make a successful STW transition, enabling them to find jobs that represent good fits with their interests, values, and capacities. High school guidance and career counselors, parents, and others concerned with the successful development of youth should be aware that early work experience has much to offer young people, particularly if their hours of work are restricted and if they learn to effectively balance schooling and employment through steady participation in the labor force.

# SEGREGATION, RESIDENTIAL

Residential segregation refers to the situation in which members of social groups live separately from members of other groups within a larger geographic entity. The term is most commonly used to describe the extent to which groups occupy distinct, separate neighborhoods within a city or metropolitan area. Cities can be segregated along many sociocultural dimensions, including social class, ethnicity, race, and even religion. In the United States, the most important dimension of residential segregation in terms of both prevalence and consequences is racial and ethnic. Of special interest is the spatial separation of racial and ethnic minority groups from non-Hispanic Whites. The spatial separation of populations can have profound consequences for a group's collective well-being as well as their inclusion or exclusion in the larger society. This is because resources are unevenly distributed across geographic space. Therefore, where one lives determines the safety of neighborhoods, quality of schools and housing, and availability of public amenities such as libraries and police stations.

## MEASURES OF SEGREGATION

The idea of residential segregation makes intuitive sense to most people. However, measuring segregation is complex because segregation can be conceptualized in multiple ways. Sociologists Douglas Massey and Nancy Denton (1988) identified five dimensions of residential segregation, each of which provides a different way of thinking about how race and ethnic groups are separated from each other within an area: (a) evenness, (b) exposure, (c) clustering, (d) concentration, and (e) centralization. *Evenness* refers to how groups are distributed over geographic space within an area—for example, the proportions of Whites and Blacks across all neighborhoods in a city. *Exposure* refers to a person's potential for contact with members of other groups. *Clustering* describes spatial distributions in which minority neighborhoods are tightly clustered to form a large contiguous area (as opposed to being dispersed throughout a city). *Concentration*, a closely related concept, captures the degree of crowdedness of a group within an area. Finally, *centralization* assesses whether a minority group is centralized around the urban core or spread out along the periphery of a city. The term *hypersegregated* is used to refer to areas where segregation scores are high on four out of the five dimensions.

Evenness and exposure are the two most commonly measured dimensions of residential segregation. Evenness is typically gauged by a measure known as the dissimilarity index. Values for the dissimilarity index range from 0 to 100, with values of 0 representing complete integration and 100 representing complete segregation. It is interpreted as the proportion of members of one group who would have to move—assuming that members of the other group remain where they are—in order to obtain an even distribution of the groups across an area. Examples of U.S. metropolitan areas where Blacks and Whites are highly segregated on the evenness dimension (values greater than or equal to 80) are Detroit, Chicago, Newark, and New York. Two common measures of contact are the exposure and isolation indices. The exposure index describes the probability that members of

group A will come into contact with members of group B. Values for the index also range from 0 to 100, with higher values representing a greater probability of one group coming into contact with a member of another group. Blacks have the least probability of exposure (i.e., exposure values less than 20) to Whites in the Los Angeles, Chicago, Detroit, Miami, New York, and Newark metros. The isolation index assesses the degree to which members of a group live in neighborhoods where the other residents are predominantly of the same racial or ethnic group (i.e., *ghettoization*). Unlike the dissimilarity index, the isolation index is sensitive to group size. Values are low if the minority group is small but high if the group is large. The range for the index is from 0 to 100, with 100 reflecting complete ghettoization. Metros where Blacks are highly ghettoized (values greater than 70) include Chicago, Detroit, Cleveland, and New Orleans.

## TRENDS IN RACIAL RESIDENTIAL SEGREGATION IN THE UNITED STATES

American cities were not always characterized by high levels of racial residential segregation. During the 19th century, non-Hispanic Blacks were less segregated from the majority group (i.e., White Anglo-Saxon Protestants) than White European immigrants (Lieberson, 1980). During the 20th century, segregation between Blacks and Whites increased and segregation of European immigrants decreased. By the 1970s and 1980s, Black–White segregation was so high that in some cities, such as Milwaukee, Cleveland, New York, and Los Angeles, the dissimilarity index was in the 80s and 90s (Massey & Denton 1987, pp. 815–816). Hispanic–White and Asian–White segregation have always been much lower than Black–White segregation. In fact, extreme Black–White residential segregation is one of the hallmarks of American society; no other developed, pluralistic society has segregation levels as high as those in the United States.

The overwhelming conclusion from the cross-national literature is that hypersegregation does not exist in the Canadian or European context (Huttman, 1991; Massey, 1985). Although segregation and ethnic clustering can be found in virtually every immigrant-receiving country, segregation levels do not approach those for Blacks and Whites in the United States. Not only is racial residential segregation lower in Europe, but where it does exist, the cleavage is not necessarily between Blacks and Whites. For example, geographer Ceri Peach (1996) examined the residential segregation of six major racial and ethnic minority groups in Great Britain. He found that Bangladeshis and Pakistanis were more segregated from British Whites than were Afro-Caribbeans or Africans. Blacks in Britain were the least segregated out of all six ethnic minority groups under study. Likewise, in Sweden, White and non-White immigrants have similar degrees of residential separation from Swedes (Linden & Lindberg, 1991). Socioeconomic differences between immigrants and natives, as well as cultural factors, have been posited to explain the patterns observed in Western Europe.

Studies based on the 2000 U.S. Census show that segregation between non-Hispanic Whites and minorities has declined throughout the 20th century. Black–White segregation in 2000 was at its lowest level since 1920 (Iceland, Weinberg, & Steinmetz, 2002). Yet there are regional variations in the decline of Black–White segregation across the United States. The Northeast and Midwest continue to have high levels of Black–White segregation, especially in former manufacturing cities such as Cleveland, Chicago, and New York, where housing is older (Cutler, Glaeser, & Vigdor, 1999). However, in regions with new housing and population growth, particularly the south and southwestern regions of the United States, Black–White segregation has declined markedly. Segregation among Asians and Hispanics has declined as well (Glaeser & Vigdor, 2001).

## THE CAUSES OF RESIDENTIAL SEGREGATION

A significant amount of scholarly attention has been given to explaining why residential segregation occurs and persists over time. Spatial assimilation theory is one of the leading frameworks used to understand processes of residential segregation (Alba & Logan, 1993). A central tenet of spatial assimilation theory is that spatial distance equals social distance. In other words, people want to live with others who are like themselves; spatial distance reflects some underlying social chasm between the separated groups that may be purely subjective or based on some real objective difference. The theory outlines a linear progression of spatial integration in which minority groups (and immigrants) initially start out in a state of geographic isolation from the dominant group (i.e., non-Hispanic Whites). Typically, minorities and immigrants will reside in poor central city areas where housing is cheap and one's neighbors are other minorities or immigrants. The theory assumes that this initial state of spatial separation is due to socioeconomic and cultural differences between minorities (or immigrants) and non-Hispanic Whites. Over time as minorities increase their socioeconomic status, they not only become more socially and culturally acceptable as neighbors, but they can also afford housing in predominantly White or racially mixed neighborhoods. These types of neighborhoods are more desirable because they tend to have better public amenities, have lower rates of crime, and are located in resource-rich suburbs. For

immigrants, acculturation—particularly the acquisition of the English language—along with increased socioeconomic status helps to diminish the cultural and socioeconomic gaps between native and foreign-born persons, thereby facilitating residential integration.

The spatial assimilation model has been criticized for its failure to explain the persistence of residential segregation among Blacks and darker-skin Hispanics (e.g., Puerto Ricans). Despite increases in income and education or cultural assimilation, Blacks and Puerto Ricans remain segregated from Whites. An alternative, although not necessarily contradictory, theory of residential segregation has been forwarded to explain the persistent segregation of Blacks and darker-skin minorities. Place stratification theory argues that residential patterns of different racial and ethnic groups reflect their relative standing in the larger society. In the United States, Blacks are at the bottom of the hierarchy, and race is a "master status," barring access to desirable, racially integrated neighborhoods (Charles, 2003).

The specific mechanisms for how race constrains the social mobility of Blacks and, by extension, other racial and ethnic minority groups are a hotly contested topic in the residential segregation literature. Three individual-level hypotheses have been influential: in-group preferences, racial proxy, and racial stereotyping. The in-group preferences thesis attributes residential segregation to varying degrees of ethnocentrism between the races. It is argued that all groups exhibit ethnocentrism and preferences for same-race and same-ethnicity neighbors. In the racial proxy hypothesis, it is argued that because Black neighborhoods are often associated with poorer amenities, inferior schools, and high crime, White avoidance of Black neighborhoods is not due to race per se but rather the desire to avoid disadvantaged neighborhoods and poor neighbors. Finally, the racial prejudice or discrimination thesis attributes racial residential segregation to active out-group avoidance or domination. It is believed that White prejudicial attitudes and racial discrimination cause Whites to avoid neighborhoods with Blacks and other racial and ethnic minorities.

## THE CONSEQUENCES OF RESIDENTIAL SEGREGATION FOR THE LIFE COURSE

Residential segregation can have negative consequences for individuals' life chances because resources are unevenly distributed across space. In general, majority-White, suburban areas tend to have better public amenities (such as well-maintained parks and playgrounds, safer streets, and high-quality public schools with well-trained teachers and smaller class sizes), economic resources, and higher-quality housing than non-White, central city areas. The geographic disparity in public resources stems from interactions among social class, race, and geography. Where one resides determines who one's neighbors are, which in turn affects the degree of political power, economic clout, and, ultimately, resources to which one has access. The high correlation between socioeconomic status and race means that middle-class areas will, on average, consist more of Whites than non-Whites. The overlap among race, place, and class means that, irrespective of a family's socioeconomic status, Blacks and other racial and ethnic minorities will, on average, reside in socioeconomically disadvantaged and segregated neighborhoods.

Research has shown that access to resources and amenities can affect health outcomes across the life course. For example, a study of neighborhood drug stores in New York City showed that pharmacies in non-White neighborhoods tend to carry fewer pain medications than those in predominantly White neighborhoods (Morrison et al., 2000). Another study found that grocery stores that stock nutritious food are less easily accessible for residents in segregated neighborhoods (Zenk et al., 2005). Segregated Black neighborhoods bear the burden of housing unhealthy establishments. Black neighborhoods tend to have a disproportionately high density of fast-food restaurants (Kwate, 2008)—no doubt contributing to the obesity epidemic among low-income minorities. Liquor stores and advertisements for unhealthy behavior, such as cigarette smoking and alcohol consumption, are also disproportionately concentrated in low-income, predominantly Black neighborhoods (Hackbarth, Silvestri, & Cosper, 1995).

The physical deterioration of the built environment (e.g., building and physical infrastructure, quality of transportation, and so on) often associated with poor, segregated neighborhoods also can have harmful effects on the health of children and adults. Poor housing conditions, for instance, can expose residents to lead and other harmful elements such as mildew and disease-carrying rodents (Hood, 2005). Residential segregation has also been shown to increase residents' exposure to airborne pollutants (Lopez, 2002), elevate the cancer risks associated with ambient air toxins (Morello-Frosch & Shenassa, 2006), and increase both infant and adult mortality rates (Polednak, 1993). Additionally, physical activity in segregated neighborhoods may be difficult due to the absence of walkable spaces or safe green spaces for children's play and recreation in segregated areas (Holt, Spence, Sehn, & Cutumisu, 2008).

Another way that residential segregation influences life course development is through exposing residents to violence. Violence is a regular feature of life for many residents of segregated urban neighborhoods in the United States. Children living in segregated neighborhoods experience frequent and ongoing exposure to guns,

knives, drugs, and random violence (Ofosky, 1999). Additionally, the burden of violence disproportionately falls on the shoulders of Black Americans. The homicide rate for African Americans ages 15 to 24 years in 1999 was 38.6 per 100,000 persons. This was twice the rate for Hispanics (17.3 per 100,000 persons) and 12 times the rate for non-Hispanic Whites (3.1 per 100,000 persons) of similar age (Krug et al., 2002, p. 11). In addition to mortality risks, living in resource-poor, segregated neighborhoods can have adverse effects on transitions into and out of different life stages. For example, ethnographic studies have shown that minority youths living in harsh, segregated neighborhoods where violence is an everyday occurrence may supplant mainstream norms of success with alternative norms such as sexual prowess, teenage pregnancy, and displays of aggression (Anderson, 1999). These alternative markers of social success may bring short-term satisfaction but often derail long-term transitions into adulthood roles, such as steady employment and marriage. Instead, youths may find themselves rotating in and out of prison, navigating the welfare system, and raising children without the support of a partner.

## (SUPPOSED) BENEFITS OF RESIDENTIAL INTEGRATION

Implicit in spatial assimilation theory is the idea that spatial propinquity helps to generate meaningful social relationships among neighbors. Coming into contact with people on the streets, on the subway, or at the supermarket does not provide opportunities to develop primary social relationships, nor does living in the same neighborhood guarantee that people would know their neighbors on a more intimate social level. However, coresidence in integrated neighborhoods is assumed to provide opportunities to develop primary social relationships through community activities and organizations. These primary social relationships, particularly with middle-class and non-Hispanic Whites, may have benefits for minorities in the form of job-generating social networks, a wider array of positive adult role models for children, greater social capital, and so on.

Despite the intuitively appealing premise that residential integration may foster beneficial primary social relationships between minority and majority group members and help to bridge social class, racial or ethnic, and cultural divides, the empirical evidence to support this notion is weak. Research shows that people's social support networks are not tied to neighbors within their neighborhood of residence. Neighborhood and family ethnographies from the Three-City Welfare Project show that the social support networks of poor families are not located in their neighborhoods of residence (Matthews, Detwiler, & Burton, 2005). One possible explanation for the lack of within-neighborhood social support networks is the density of multifamily residential units in low-income, segregated neighborhoods. The design of multifamily dwellings can adversely affect interaction patterns by discouraging social interaction and thereby increase residents' feelings of social isolation and impede the cultivation of strong social support networks (Evans, Wells, & Moch, 2003).

## POLICY ISSUES

The research evidence suggests that public policy can best ameliorate the negative effects of residential segregation on life course development in the short run by improving the physical conditions of segregated neighborhoods and minimizing public disorder. For instance, greater attention can be given to making segregated neighborhoods health-friendly by investing in safer parks and playgrounds, making streets more walkable for residents, and altering zoning laws such that there is a greater balance of healthy and unhealthy establishments in low-income, Black neighborhoods. Similarly, neighborhood development or renewal projects can improve community cohesion and strengthen within-neighborhood social support networks by directly incorporating building designs and land use that encourage socialization. In the long term, the goal of public policy should be to eliminate racial residential segregation. This would entail targeting the social and institutional mechanisms that perpetuate segregation—a feat that is, at best, daunting given the lack of consensus in the field regarding the root causes of segregation. However, recent declines in segregation are promising and suggest that the United States may potentially achieve low segregation levels on par with other developed, pluralistic countries.

# SELF-EMPLOYMENT

Self-employed persons are those who earn income from their trade or business, who set the terms of how, when and where they perform their work; and who assume all the risks and responsibilities of their entrepreneurial activities. Thus, self-employed persons include those who own businesses as sole proprietors or in partnerships, those who work as independent contractors, and those who work as consultants. The ranks of the self-employed include lawyers, tutors, plumbers, child care providers, cleaners, wedding planners, and Web site developers. The self-employed are a heterogeneous group, and to complicate matters further, individuals can be both employees and self-employed in different income-generating activities at the same time. Although the self-employed must still meet the demands of clients and contactors and cede some decision making to those with whom they contract, unlike wage work, to be self-employed means that a worker has some autonomy because he or she is not employed by another and that the individual derives an income from his or her own work effort. However, this autonomy can also be a source of instability, because nearly all self-employed workers are not afforded the same protections that are available to wage workers, such as social insurance, including unemployment, health and disability benefits, and labor contracts.

After several decades of decline, self-employment experienced a rebirth in the 1970s in industrialized countries. It is unclear whether the rise in self-employment is the result of a vibrant, entrepreneurial middle class or declining economic opportunities for the working class and those in nonprofessional occupations. The scholarly debate regarding the location of the self-employed in the social class structure is complicated by the heterogeneity of the self-employed. For some, self-employment is a means of obtaining upward mobility. However, the widely varying economic successes of the self-employed are linked to the gender, race/ethnicity, and the professional and nonprofessional status of the worker. It is an empirical question whether self-employment reduces or exacerbates existing inequalities found among wage-employed workers. Therefore, the role of self-employment is important not only for the life course of self-employed individuals, but also for understanding the state of the economy as a whole.

## MEASUREMENT ISSUES AND SELF-EMPLOYMENT

Just as defining self-employment is difficult, so is measuring it. Most data gathered on the self-employed in the United States are based on individual self-identification. The Current Population Survey (CPS), a monthly survey of employment and unemployment administered by the Census Bureau, is the most frequently analyzed dataset when it comes to self-employment. The CPS divides workers into four categories: government, private, nonprofit, and self-employed. If self-employed individuals indicate that their business is incorporated, they are reclassified as employees of their own company whereas the unincorporated are categorized as self-employed. The introduction of the questions related to incorporation in 1967 has created confusion regarding the accuracy of self-employment measures due to increasing rates of incorporation.

## RECENT TRENDS IN SELF-EMPLOYMENT

From the late 1940s to the 1970s, self-employment rates fell dramatically. However, since the 1970s the trend has been reversed in nonagricultural sectors. By 2003, 10.3 million U.S. workers were self-employed, primarily in construction, professional, business, and other services. In 2004 self-employed workers comprised 7.5% of the total U.S. workforce (Hipple, 2004). The incorporated self-employed tend to have advanced degrees whereas the unincorporated self-employed tend to have less than a high school diploma, indicating a large gap in the quality of self-employment. The self-employed also tend to be older than wage workers, with those 65 and over comprising 19.1% of the self-employed whereas only 2% of the self-employed are aged 16 and 24 (Hipple, 2004). Unlike older workers, who are more likely to have retired from wage employment, younger individuals typically have not yet acquired the necessary capital and managerial skills to start their own business.

The gender composition of the self-employed is unequal but changing. Although men are more likely to be self-employed, since 1975 women's participation has grown by 60%, compared with men's growth of 20% (Blau, 1998). The factors leading to and the economic returns from self-employment are linked to gender in complex ways. Professional status of the worker is key to understanding these linkages. Among professionals, women receive higher returns for skills if self-employed, compared with findings in wage-employed women. The factors leading to self-employment among professionals do not differ by gender, and women receive the same increase in earnings for becoming self-employed as do men (Budig, 2006). However, self-employment does not appear to reduce the gender gap in earnings that is found among wage-earning professionals. Among nonprofessional workers, the importance of gender is more pronounced (Arum, 1997; Budig, 2006).

The primary causes of women's self-employment in this group are family factors: number of children, marital status, and having a self-employed husband. None of these factors matters for men's self-employment among nonprofessionals. Gender occupational segregation is greatest among self-employed nonprofessionals, as is the gender gap in earnings. In contrast to professionals, among nonprofessionals self-employment appears to exacerbate gender earnings inequality. Thus, family factors powerfully shape women's self-employment in nonprofessional work and gender earnings gaps are largest among nonprofessional self-employment. In contrast, women engaged in professional self-employment are more similar to men and reap similar rewards from self-employment as men do.

Because self-employment is often described as a route to prosperity, understanding race/ethnic differences among the self-employed is important (Bates, 1997). Whites have higher levels of self-employment than Hispanics and African Americans, and this may result from some advantage among whites in asset accumulation and in consumer and lender discrimination. Family background and parental experience with self-employment are among the most important predictors of an individual becoming self-employed (Aldrich, Renzulli, & Langton, 1998). Because African Americans have historically had low levels of self-employment, the likelihood of subsequent generations of African Americans becoming self-employed is reduced. Stratification also appears

Data exclude the incorporated self-employed

Note: Detail for the above race and Hispanic or Latino groups will not sum to total because data for the "other races" group are not presented and Hispanics or Latinos are included in both the white and black populationt groups. Detail for other characteristics may not sum to totals due to rounding. In addition, data exclude unpaid family workers.

***Table 1.*** *Unincorporated self–employed, incorporated self–employed, and wage and salary workers by sex and selected characteristics, 2003 annual average.* CENGAGE LEARNING, GALE.

within groups regarding self-employment that could also be attributed to differential treatment in lending and consumer practices. Among Hispanic groups, Mexican Americans have low levels of self-employment whereas Cuban Americans have rates similar to those of whites. Asian Americans also tend to have higher rates of self-employment compared with other groups. Due to economic opportunity in ethnic enclaves, often resulting from discriminatory treatment in business arenas outside the enclave, some immigrant groups therefore tend to have distinctly higher rates of self-employment compared with the native born (Borjas, 1986). This illustrates how differences in access to economic and social mobility constrain different groups' participation in self-employment.

## THEORETICAL EXPLANATIONS

Which factors have contributed to the existence of self-employment and its resurgence over time? The Marxist (Karl Marx, German economist, 1818–1883) school of thought argues that the self-employed are part of the middle class, or petty bourgeoisie, because they own their

own businesses. Although some contention remains regarding what classifies an individual as petty bourgeois, Marxists argue that due to the tendency of businesses to concentrate into large firms, the middle class will eventually decline and become part of the working class. However, this is problematized by the resurgence in self-employment (Steinmetz and Wright, 1990). This theory has become less salient and useful over time for explaining the persistence of self-employment.

A second theory addressing the existence of the self-employed argues that capitalist economic systems require a healthy sector of self-employed to provide specialized skills and fill market niches not addressed by larger firms. Along with individual explanations such as the desire for upward mobility, larger structural economic factors also influence the rate of self-employment. The shift to a postindustrial economy has encouraged self-employment as a result of technological change, which allows for more decentralization of firms and increased opportunities for individual entrepreneurial ventures.

Technological change and economic decentralization also may explain increased self-employment rates. Some researchers suggest that the shift from a manufacturing to a service-based economy and the marginalization of nonprofessional occupations has encouraged the growth of self-employment. With the decline of the manufacturing sector in the United States and some countries in Western Europe, self-employment may provide a means of avoiding unemployment for displaced workers. Therefore, with an economic downturn or a rise in the unemployment rate, the number of individuals who become self-employed may increase. This is exemplified by the slight increase of workers becoming self-employed, 6.5% to 6.8%, during the sluggish economic period between 2002 and 2004 in the United States (Hipple, 2004).

Another explanation for the rise in self-employment focuses on the role of politics and the state in supporting small business ownership. Government policies have been increasingly directed at fostering self-employment by providing tax incentives and other programs designed to encourage small businesses. Comparing policies in the United States with those in Germany, McManus (2000) argues that the institutional features of labor markets and welfare states have important implications for quality of self-employment. The provision of social insurance and health care to Germany's small business sector provides more stability for the self-employed than in the United States, where social programs are not available to all.

## IMPLICATIONS FOR THE LIFE COURSE

The fate of the self-employed has tremendous significance for understanding economic conditions and their implications for the life course. Most researchers argue that its existence and size serves as a benchmark for measuring the state of the economy. A rise in the levels of self-employment may coincide with an economic downturn as individuals thrown out of work by recession seek other means for earning income. Others seek to understand the relationship of self-employment and earnings inequality. Under capitalist economic systems, it has been argued that the self-employed have the capacity to provide the economy employment for workers, generate new jobs, and stimulate innovation. The job creation potential of this economic sector has major implications for providing economic opportunities to women and immigrants. The self-employed also play an important political role in society through their general support of the capitalist system and democratic institutions. Although much more research is required to fully understand the role played by self-employment, this sector of employment has significant implications in both the short and long-term for the life course of individuals regarding economic and social mobility and for understanding the level of inequality in the larger economy.

# SEXISM/SEX DISCRIMINATION

Sexism and sexual discrimination are two of the primary reasons that gender inequality persists in the United States. The U.S. Equal Employment Opportunity Commission (EEOC) received almost 25,000 "charges of sex-based discrimination" in the 2007 fiscal year alone (EEOC, 2008). Sexism refers to attitudes and beliefs about people based on their sex. Often these prejudices are negative, such as the idea that women are incompetent, but these opinions may also be positive, such as the belief that women are nurturing. Sexual discrimination, in contrast, involves treating people differently based on their sex. For example, this may be the preference to hire men instead of women or to allow more women than men to enter a dance club.

These terms are frequently used to refer to the negative treatment or position of women relative to men. This approach makes sense. Because women are subordinate to men in most parts of the world, they are more likely to be the targets of sexism and sexual discrimination. However, men may be the targets as well. Because members of subordinate groups (e.g., women, gay men, and so forth) tend to be victims of gender bias and members of the dominant group tend to be perpetrators, sexism and sexual discrimination help preserve the system of male privilege and the subordination of women and nondominant masculinities.

If someone discriminates based on another person's gender, does that mean that he or she is sexist? The answer is not necessarily. Sexism and sexual discrimination often go together, but not always. Consider a male employer at an electronics store seeking a new salesperson. This employer may know that there are many women knowledgeable about electronics, but if he fears that his clientele will only buy from a man, then he will be hesitant to hire a woman, regardless of her credentials. His behavior, then, is discriminatory, even though he does not consciously hold sexist beliefs. It is possible that a person can have subconscious attitudes (implicit beliefs), which can influence behavior, even without the person being consciously aware of it (Quillian, 2006).

It is worth noting that sexism and sexual discrimination are actually misnomers. The two concepts technically focus on attitudes and behavior based on someone's sex, but what this concept really refers to is a person's gender rather than his or her sex. Sex is biology; gender relates to the meaning and behavior associated with being a man or a woman (Kimmel, 2008). Some of the most frequently measured forms of sexism are beliefs about how women are supposed to behave. For instance, should a mother work outside the home? Is it a woman's responsibility to care for the home? Can a woman be assertive and still be feminine? These beliefs have nothing to do with a woman's biological sex and everything to do with what it means to be a woman.

But why are some people sexist and why do some people discriminate? The simplest explanation is socialization—that is, the idea that people have been taught that certain behaviors are appropriate for one gender and other behaviors are appropriate for the other gender. (This assumes only two genders, a point that is contested by many gender scholars and intersex advocates; see Kimmel, 2008.) The extent to which one holds sexist attitudes is partly based on age, with people from older generations being more likely to hold "old fashioned" views about women (what is now called sexist) and younger people being likely to hold more egalitarian views. There is evidence for this argument, but the explanation is incomplete.

A related perspective is that people hold views about what is appropriate gendered behavior (i.e., their gender ideology) that agree with how they perceive their own gender (i.e., their gender role identity). This is because disagreement between someone's gender role identity and his or her gender ideology can cause confusion. For instance, if a man believes that masculine men are big and burly but he is small and delicate, does that mean he is not a "real man"? In contrast, agreement between someone's gender role identity and his or her gender ideology is validating. The result is that a masculine man is likely to support behavior that agrees with his ideas of masculinity (such as the male breadwinner role) and is likely to resist behavior that opposes it (such as married women earning an income).

A different set of arguments contend that sexism and sexual discrimination stem from some men's need to protect their position of privilege (Goldin, 2002). This practice may include men protecting their personal status or that of males as a group. Men are in the dominant social position, but not all men are as dominant as others. Masculinity, or manliness, helps determine which men are atop the hierarchy. Because of the privileges that come with appropriate displays of masculinity, some men are concerned that if their masculinity is questioned then they are somehow less of a man. In order to prove their masculinity to themselves and to others, they may denigrate and harass women or less masculine men.

Men as a group are in power; women are not. Sexism and sexual discrimination have been and continue to be used to prevent women from gaining power. From the perspective of those in power, it therefore makes sense to perpetuate gender stereotypes, even when there is overwhelming evidence invalidating those stereotypes. For instance, the common but erroneous stereotype that women are irrational implies that a woman should not

***Sexism in Advertising.*** *Pedestrians walk past large outdoor clothing advertisements.* SPENCER PLATT/GETTY IMAGES.

be a boss, a chief executive officer, or the president. If this stereotype is believed, then these positions are preserved for a man. This logic makes women less attractive as employees and keeps men "first in line" for the most desirable jobs (Reskin, 2001).

The consequences of sexism and sexual discrimination are felt by everyone, if for no other reason than that everyone has women in their lives. More specifically, the effects are seen in labor market inequality, such as the devaluation of the jobs predominantly held by women and the work women do, discriminatory hiring practices and job allocation, and different expectations; discrimination against mothers in hiring and promotion; the disproportionate amount of home, child, and elderly care done by women, along with the failure to either compensate workers for their labor or provide affordable alternatives; the medical field's disregard for women, as evidenced by women's exclusion from medical studies and absence from medical texts; and the disproportionate level of violence suffered by women at the hands of their partners. Biased treatment can also impact women's health, causing them to suffer from such ailments as depression, nausea, and headaches (Welsh, 1999, p. 183).

Although sexism and sexual discrimination impact women in all walks of life, the ramifications may be more severe for women of color and of lower socioeconomic status. These women not only face stigma and discrimination because of their gender but also because of their race and class. Oppression based on these statuses is multiplicative, not additive. This means that a Black woman does not face the same gender oppression as a White woman or the same racial oppression as a Black man. Instead, she faces unique experiences because she is Black *and* a woman. For instance, lower-class women of color, particularly immigrants, often work as domestics (lower-class men tend to hold other jobs), positioning them for exploitation, whereas upper-class women can use their wealth to reallocate their domestic responsibilities to women of lower classes (Amott & Matthaei 1996, p. 15). Young, lower-class Black women have the added stigma of being stereotyped as single mothers. Middle- and upper-class Black workers, in contrast, risk being "isolated" in a "corporate environment . . . that [is] inhospitable and alien" (Browne & Misra 2003, p. 501). Moreover, Black workers, regardless of age and class, must cope with the consequences of a long history of racial bias in the United States. Class and racial status also influence medical care, with lower-class and non-White patients receiving a lower quality of treatment than their wealthy White counterparts.

Sexism and sexual discrimination primarily impact women, but men can be victims too. For instance, current ideals of masculinity reward acts of risk-taking, aggression, and heterosexual sexual prowess while punishing behavior deemed to conflict with them. As a result, some men feel pressured into pursuing dangerous or even criminal behavior in order to prove their manhood. Men may also be harmed by the sexist belief that women and children deserve to be protected from danger first, leading men to be the last saved and the first to die.

A large proportion of the research on sexism and sexual discrimination considered in the United States focuses on what is going on here. It is therefore tempting to want to know how the situation in the United States compares to that in other countries. However, direct comparisons should be undertaken only with the utmost care. Cross-cultural comparisons are complicated by different definitions, data collection standards, and ethnocentrism.

Varying definitions and data collection standards are problematic because they make it difficult to ensure that measures of sexism and sexual discrimination are consistent and comparable across countries. For example, if country A defines discrimination as anything that creates a negative working environment, whereas country B says that the only thing that qualifies as discrimination is pressure from a superior to have sexual relations (Saguy, 2000, p. 1092), then it is meaningless to compare rates of discrimination across the two countries.

A second issue is how to apply one's own perceptions of sexism to other cultures without being too "ethnocentric." A single example should suffice to illustrate this problem. In 2004 France passed a law banning the wearing of conspicuous religious symbols in state schools. Although the law applied to all religious groups, there was a clear understanding that it was enacted to stop Muslim women from wearing headscarves. Two main justifications were given for the law. The first explanation was that headscarves were emblematic of Muslims' refusal to assimilate to secular French society. The second

contention was that headscarves were symbols of Islam's oppression of women. Some Muslim women agreed with this latter assessment, but many did not.

If the headscarf is considered only from a European/North American perspective, one could legitimately argue that it represents Muslim women's subordinate place in Muslim society (if for no other reason than that they are not granted the same freedom in attire as men). But if the decision is considered from the standpoint of many Muslim women, one could possibly see that maybe these women are not oppressed by the tradition. In fact, when asked, some women said that, for them, wearing a headscarf was a personal choice to follow cultural traditions and beliefs about what "was modest and right." This example demonstrates that before attempting to determine if certain cultural behaviors are sexist, it is necessary to have some understanding of that culture.

Even with the caveat that it may be ill-advised to compare sexism and sexual discrimination across cultures, it is clear that the treatment of women varies regionally. Norway, for instance, is known for its progressive policies promoting gender equality, whereas in Saudi Arabia women are forbidden from voting, driving cars, or being in public without a male relation. In many parts of the developing world the situation for women is even worse and is characterized by high rates of female infanticide and sex-selective abortion, poor nutrition, little or no medical care, and low life expectancies for those who survive childhood.

Because sexism and sexual discrimination persists almost everywhere in the world, further research on the subject must continue. Two likely areas of ongoing research are sexual harassment and the intersection of gender, race, and class. The trend of applying paradigms developed outside of gender of research is also likely to continue. Another area that deserves more attention is sexism and sexual discrimination against men. Although men are not the prime targets, to ignore them in favor of women would be both sexist and discriminatory.

# SEXUAL ACTIVITY, ADULTHOOD

People are born sexual and have the capacity for sexual activity throughout the life course. Sexual activity involves the behavioral expression of erotic feelings, typically for pleasurable or reproductive purposes but in some contexts for power and control. Sexuality is influenced by biological, psychological, sociological, and spiritual factors, within historical, cultural, and developmental contexts. Virtually all societies attempt to regulate sexual activity, with varying degrees of success. Individuals are presumed to be most capable of both fulfilling their sexual potential and conforming to social norms in their sexual behaviors when they are adults; thus, sexual activity is viewed as most acceptable for adults of legal age but before they become too old. This does not mean that children and older adults

are not sexual, but it does reveal that sexuality over the life course is socially constructed and socially controlled.

## THE NATURE OF HUMAN SEXUALITY RESEARCH

Sexology is the scientific study of sexuality. Given the private nature of human sexual behavior and the ways that societies attempt to control sexuality through laws and social norms, understanding and investigating the complex nature of human sexual activity requires multiple disciplinary perspectives and many types of research methods. Throughout the 20th century, sexologists sought to change the belief that sexuality was not worthy of serious attention by bringing a positivist scientific approach to the study of sexuality. Sexual science introduced survey and interview methods and laboratory research as a way to bring credibility to the investigation of behaviors, such as masturbation, homosexuality, oral sex, and sexual intercourse for purposes other than reproduction that had been condemned as sinful and deviant.

Alfred Kinsey (1894–1956) was the leading figure in conducting research in which Americans were asked about their actual sexual practices. His samples included 20,000 men and women who were surveyed and interviewed in the 1940s and 1950s (Kinsey, Pomeroy, & Martin, 1948; Kinsey, Pomeroy, Martin, & Gebhard, 1953). He demonstrated that people from all walks of life were willing to answer very personal questions about their most intimate behavior, including masturbation, orgasms, sexual intercourse, homosexual behavior, sexual responsiveness, extramarital relationships, and sex with animals. He found that many of the practices previously thought uncommon or perverse were widely practiced by ordinary citizens. His books were instant best-sellers, attesting to the public's keen interest in and desire for sexual knowledge and communication.

Kinsey and his associates also changed the conceptualization of homosexuality. They described sexuality along a continuum, with 0 being exclusively heterosexual, 6 being exclusively homosexual, and 3 being equally heterosexual and homosexual. They reported that 37% of men and 13% of women had experienced at least one sexual experience to orgasm with someone of the same gender and that 4% of men and 3% of women considered themselves lifelong homosexuals. The oft-cited and frequently challenged statistic that 10% of the population is gay came from one of Kinsey's findings, which indicated that 10% of White men had been mostly homosexual for at least 3 years between the ages of 16 to 55 (Carroll, 2007).

William Masters (1915–2001) and Virginia Johnson (b. 1925), a medical doctor and a psychologist, respectively, were among the first modern sexologists to conduct observational studies of people who volunteered to engage in sexual activity in their laboratory. In 1966 they published *Human Sexual Response*, in which they reported on their research with 700 volunteers they had studied engaging in sexual activities. Masters and Johnson measured physiological changes in the heart and of the sexual organs to study orgasmic potential and sexual response. Their research resulted in the four-phase sexual response cycle, consisting of the excitement phase, the plateau phase, the orgasm phase, and the resolution phase. They found that women experienced only one type of orgasm, through the direct or indirect stimulation of the clitoris. This finding was in direct contrast to Sigmund Freud's (1856–1939) theory of the vaginal versus the clitoral orgasm, with the vaginal orgasm characterized as a more mature and thus superior version. Masters and Johnson also found that women are capable of multiple orgasms, whereas males experience a refractory stage following ejaculation. That is, a male cannot be restimulated to orgasm for a certain period of time; the length of time is highly dependent on age, with older males experiencing a longer refractory period.

The National Health and Social Life Survey, conducted by Edward Laumann, John Gagnon, Robert Michael, and Stuart Michaels (1994), attempted to provide a more representative sample and thus improve on and update the Kinsey studies. After the U.S. government pulled its funding from this project due to policy makers' reluctance to fund the work, the researchers were forced to reduce the scope of the study. The final sample was much smaller than originally intended. It consisted of nearly 3,500 respondents between the ages of 18 and 59 and revealed that Americans were more sexually conservative in their behavior than Kinsey had reported. For example, Laumann et al. reported that the median number of sexual partners for men since age 18 was six, and, for women, it was two. They also found a smaller portion of married adults reporting infidelity than had been found in the Kinsey data: Only 25% of married men and 20% of married women reported that they had engaged in extramarital sex, whereas Kinsey's findings were 50% of men and 25% of women. Finally, the study challenged the Kinsey statistic about homosexuality: 2.8% of men and 1.4% of women described themselves as homosexual or bisexual. One possible explanation for the more conservative nature of the Laumann et al. findings is that they used a random sample approach, whereas oversampling of particular kinds of respondents, including those who were Northern, educated, White, and Protestant, among other characteristics, may have occurred in the Kinsey studies.

A study conducted by William Mosher, Anjani Chandra, and Jo Jones (2005), however, reported that the incidence of bisexuality is increasing among young

and middle-age adults, particularly for women. Eleven percent of women between the ages of 25 and 44 reported having had at least one sexual experience with another woman, and about 6.5% of men reported having oral or anal sex with another man. One conclusion from this study is that it is becoming more socially acceptable to openly discuss and experience bisexuality, particularly among recent cohorts of college-educated women.

Richard Parker and John Gagnon (1995) suggested that since 1980, the scientific study of sexuality has been reconceived by postmodern sex researchers. Several trends have greatly altered the way in which human sexual activity can and should be studied. One major trend is the global pandemic of HIV and AIDS and its disproportionate effect on women and children in developing nations. Another trend is the deconstruction of neat categories of heterosexual versus homosexual, which have been challenged by people who are bisexual, gay, and transgendered (i.e., people whose very identities are fluid and change across gender and sexual categories).

Postmodern sex researchers critique the 20th-century sexologists for their use of traditional scientific research methods (e.g., survey, interviews, and laboratory observations) that upheld conservative political values and normalized heterosexual middle-class behaviors. In contrast, postmodern researchers claim that new theories and methods are needed to account for how power and privilege structure sexual activity. Postmodern researchers critique sexology for its attention only to individual sexuality and its lack of attention to social change (Irvine, 2005). For example, when male pleasure is emphasized and privileged, women's expansive capacity for sexual pleasure is ignored; women learn to fake an orgasm, for example, in the service of male pleasure (Jackson & Scott, 2007). A postmodern feminist approach would reinterpret the Masters and Johnson finding of the myth of the vaginal orgasm by exposing how gender, sexuality, and power are intertwined.

## SOCIAL CONTEXTS OF ADULT SEXUAL ACTIVITY

Sexual activity in adulthood involves the variety of individual and relational experiences in which adults engage. People can be asexual and experience no sexual feelings, desires, or behaviors. People can also engage in autoerotic experiences such as fantasy and masturbation. Typically, however, sexual activity is defined relationally, by the partners with whom one engages sexually (Sprecher & Regan, 2000). The most socially acceptable form of adult sexual activity occurs in the context of a marital relationship. In most cultures throughout history, with notable exceptions, a heterosexual partnership is the key way in which people express their sexuality. As noted above, a significant minority of people also engage in homosexual behaviors and relationships, regardless of how they identify their sexual orientation. Finally, people can have sexual experiences with more than one person. These relationships can be open, in which partners in a primary relationship are allowed to have sexual contacts with others (e.g., polyamorist), or closed. Open relationships are sometimes referred to as *swinging*. A relationship in which secret sexual liaisons occur is characterized as infidelity, adultery, or having an affair.

In most European and North American societies, sexual activity is proscribed in the form of a monogamous relationship. Legal heterosexual marriage is the idealized form of this kind of relationship. Since the industrial revolution of the 19th century, marriage has represented a relationship in which feelings of romantic love and sexual behavior are expected to co-occur, though men were seen as the more sexually desirous and demanding gender. In the 20th century, however, marriage became more companionate and egalitarian, with women becoming freer to discover and express their sexuality.

Throughout history, variations have occurred to the socially and legally proscribed form of sexual activity as only occurring in marriage. For example, polygamy (whereby the husband has more than one wife) is common in many countries in the Middle East and parts of Africa (e.g., Iran, Nigeria, and Kenya) and is associated with the Muslim faith. Gender is an important distinction, though, in polygamous marriages. Although a man may have several wives, a woman's sexual behavior is restricted to her one husband, with severe punishments for transgressions. In European and North American societies, male and female infidelity is more acknowledged and tolerated, but a double standard still exists. Women carry the burden for nonmarital sex and suffer damage to their reputations, whereas men's sexual behavior is not as constricted by behavioral norms (Risman & Schwartz, 2003).

## DEVELOPMENTAL CONTEXTS OF ADULT SEXUAL ACTIVITY

By adulthood, most people have experimented with and faced challenges in establishing their sexual identity, orientation, and relational commitments. Sexuality, though, is best conceived of as an emergent process and not one that is settled or achieved by a certain age. The early years of adult life are characterized by initiating and experiencing various forms of sexual intimacy with partners, including dating, courtship, cohabitation, and marriage, as well as establishing one's sexual orientation. About half of the relationships that result in marriage also end in divorce, but most people who divorce also remarry.

Sexual orientation involves a range of feelings, thoughts, and behaviors associated with how people perceive their sexuality. In updating Kinsey's conceptualization, Fritz Klein (1990) described the following seven dimensions: sexual attraction, sexual behavior, sexual fantasies, emotional preference, social preference, self-identification, and lifestyle preference. The dimension of time is also considered in terms of a person's self-categorization in the past, present, and ideally. Thus, sexual orientation is reconceptualized as fluid and changeable over the life course, not a stable or fixed identity resulting merely from self-labeling or sexual behavior.

In addition to issues of sexual pleasure, relational fulfillment, and sexual orientation, there are other serious decisions to be made. Contraceptive and reproductive decisions that affect planned and unplanned pregnancies are central to sexual activity in adulthood. Another key concern is practicing safe sex to avoid sexually transmitted diseases (e.g., bacterial infections such as gonorrhea, syphilis, and chlamydia; viral infections such as herpes and human papillomavirus; and HIV or AIDS). People most likely to avoid making decisions on behalf of their reproductive and sexual health are those in compromised circumstances, including having sex for money, combining sexual activity with alcohol and drug use, having casual and unprotected sex, and experiencing sexual violence (Bowleg, Lucas, & Tschann, 2004).

Although adult sexual activity does not follow a uniform pattern, some research has shown that for married couples, sex is common and prevalent in the early years. Newlyweds report having sex about two to three times per week. The early phases of passion and intimacy in a new relationship can deteriorate over time, however, as the reality of adult life intercedes in the form of multiple and competing role expectations. Sexual activity tapers off when children are being reared and work and family demands compete with sexual desire (Schwartz, 1994). Unless passion is kept alive and rekindled, sexual desire in a committed relationship declines and may disappear altogether, with partners leading separate lives, experiencing infidelity, or divorcing (Schnarch, 1998).

Sexual relationships, then, require attention. This monitoring is especially important as people age and marriage endures. In midlife, menopause changes not only how the female body is capable of sexual response (e.g., vaginal drying), but the loss of hormones can dampen desire. Men also experience decreased desire and the physical changes that accompany aging, such as difficulty in getting and maintaining an erection. The prolonged use of alcohol and drugs also erodes sexual responsiveness and desire. In addition, the physical process of aging, in a society that prizes young, perfect bodies, can lead adults to feel less attractive and desirable as they mature.

Individuals and couples are advised to redefine the nature of sexual intimacy as they age. Sexual intercourse is only one way to express erotic potential. Heterosexual and gay and lesbian couples in established relationships report that deep kissing, hugging, erotic massage, intimate conversations, holding hands, taking showers together, and other established rituals are key parts of their erotic relationships (Sprecher & Regan, 2000). One of the advantages of adult sexual activity in a committed relationship in which couples are able to look each other in the eyes and take the time to fully experience their sensuality is that the culturally prescribed rituals of faking pleasure are no longer necessary (Schnarch, 1998).

Opportunities for partnered sex appear to be one of the biggest issues facing adults. Research also suggests that sexual satisfaction in midlife and beyond is linked to having a partner. Laumann et al. (1994) found that married couples reported higher levels of sexual satisfaction and pleasure than singles or those in extramarital relationships. Individuals who lived alone and those who were unmarried reported the lowest rates of satisfaction.

## THE RANGE OF SEXUAL ACTIVITY IN ADULTHOOD

Human sexual activity involves many ways in which adults act on their feelings and thoughts about sexuality. A large portion of adult sexuality is concerned with the reproductive potential within human beings, but sexuality is also about the pursuit of pleasure. Some individuals experience pleasure in socially accepted ways; others' experiences with sexual pleasure are more variant.

Sexually variant behaviors are characterized as *paraphilias*. They involve a desire for an erotic object that is unusual or different, with *different* being defined according to social and historical standards. For example, until 1973 the American Psychiatric Association defined homosexual behavior as a mental disorder. People who were caught engaging in homosexual behavior or diagnosed as homosexual could be arrested and institutionalized. Some stigma may linger about gay and lesbian people, but the myths of homosexuality as mental illness and social deviance have been debunked.

Paraphilias range from innocuous to harmful, that is, from certain behaviors such as having a fetish, in which no one is hurt, to behaviors such as pedophilia, in which there are criminals and victims. Paraphiliacs can be found in every race, social class, or ethnic group and are prevalent among people of every sexual orientation and intelligence level. The one demographic characteristic paraphiliacs have in common, however, is that they are disproportionately male (Carroll, 2007).

Certain paraphiliac behaviors (e.g., fetishes and cross-dressing) are typically harmless, particularly if they do not interfere with normal functioning and do not

harm another person. Others, such as exhibitionism and voyeurism, are nonconsensual and do involve a victim. Sexual masochism (feeling sexual pleasure from being humiliated or being forced to experience pain) and sexual sadism (feeling sexual pleasure from inflicting humiliation or pain on another) are experienced along a continuum, from dominance and submission sexual narratives and practices that are eroticized in heterosexual and homosexual relationships to very dangerous activities that could involve torture and death. Sadomasochism (S & M) is the ritualized experience of a master–slave relationship; a couple agrees on the dominance and submission script and uses an exit phrase if the role-play becomes too intense. The purpose of the exit phrase is to ensure that no harm comes to the dominated partner.

Pedophilia is an obsessive and predatory paraphilia, illegal in every country but practiced nonetheless. A pedophiliac is an adult who fantasizes or engages in sexual activity with a child under the age of 13. The typical pedophile is at least 5 years older than the victim. The majority of pedophiles (more than 90%) are males. Pedophilia is very difficult to treat or change (Carroll, 2007).

One of the major issues influencing contemporary sexuality is the way in which societies project values about sexual agency and the social control of sexuality. European and North American society projects an ambivalence that both celebrates and condemns sexuality. The mass media helps to construct and exploit human sexuality and its expression in adult intimate relationships. The media is saturated with contradictory messages and images that alternately take advantage of and repress sexuality. Agentic sexuality, whereby individuals are able to make wise choices on behalf of their own desires and express those desires in authentic relationships, is challenged in a society with such competing messages. How these messages are interpreted and sorted out is an issue for parents, educators, policy makers, and citizens alike.

Comprehensive sexuality education throughout the life course is a key remedy to the contradictory ways in which society exploits and represses sexuality. The scientific study of sexuality reveals that human sexuality is an emergent process, and the thirst for sexual knowledge does not end in childhood. Sexuality is primarily a relational experience, and adults grow and change through their sexual encounters with others. It is important for social institutions to provide all citizens access to new knowledge that has been generated from research so they can incorporate this knowledge into their own quests for sexual agency and authentic relationships.

# SIBLING RELATIONSHIPS, ADULTHOOD

The families of adults in American and European societies frequently are assumed to consist of parents, children, and spouses; siblings have been relatively invisible. As adult baby boomers' family experiences are studied, however, it has become clear that in that generation, with the largest sibships in the 20th century, sibling relationships are also primary. The stability of the sibling tie is emphasized by the fact that boomers will have fewer children to rely on than did their parents, are less likely to have a spouse because of their high divorce rates, and are less likely to have family members nearby because of their high rates of geographic mobility. Further, the need to provide care for frail elderly parents is becoming the norm; that role often reactivates dormant sibling relationships.

Addressing adult sibling relationships also makes visible certain overlooked aspects of adult life. For instance, because siblings are ''beyond the bonds of partnering and parenting,'' they force researchers to focus on a broader social network (Walker, Allen, & Connidis, 2005, p. 167). Siblings link one another to many other relationships, such as those with nephews, nieces, uncles, aunts, and cousins, as well as the network ties those kin make available to their family members (Matthews, 2005). Because relationships among adult siblings usually transcend household boundaries, they highlight family relationships beyond the household.

Before one can address some of the dimensions of sibling relationships, influences on them, and the consequences of those dimensions for the well-being of the siblings, it is necessary to define the sibling relationship. A sibling is a person's brother or sister. A sibling may have the same parents by birth (biological sibling) or through adoption or share only one parent (half-sibling). Some siblings have different parents: parents who may be married to each other in the case of a stepsibling or parents who may be cohabitating with each other in the case of a quasi-sibling. A sibling may be informally adopted in the case of fictive siblings. Most of what is known about adult siblings concerns biological siblings. More than 80% of adults have a living sibling (*General Social Survey Cumulative Datafile*, 1986). Sibships take into account all of a person's brothers and sisters. Sibships vary by number, gender composition (number of brothers and sisters), and birth order (position of each brother and sister relative to the others). Most research on adult siblings focuses on pairs of siblings rather than the whole sibship.

Most studies of siblings in adulthood use relatively small, nonrepresentative samples, with the exception of a few national samples, such as the National Study of Family and Households and the Netherlands Kinship Panel Study. Therefore, their findings rarely can be generalized.

## DIMENSIONS OF SIBLING RELATIONSHIPS

Despite the early Freudian emphasis on sibling rivalry, adult sibling relationships have many dimensions. Sibling relationships have been rated on specific emotional qualities such as closeness, conflict, separateness, indifference, and ambivalence. The emotional content of the relationship can be described in terms of its intensity (strength) and valence (positive and negative direction), but much of the research on adult siblings has been limited to feelings of closeness and conflict. The relationship also has been rated on the frequencies of behaviors that are engaged in, such as contact, provision of assistance, and companionship. Sometimes qualities and behaviors have been grouped into types of sibling relationships, such as intimate, loyal, and hostile (Gold, 1989). Various influences on the relationship have been studied. How close siblings live to each other and their frequency of contact with one another can be viewed as dimensions of the relationship but also as influences on it because both facilitate or constrain other aspects of the relationship.

## INFLUENCES OF EARLY LIFE-COURSE EXPERIENCES ON ADULT SIBLING RELATIONSHIPS

Adult sibling relationships are shaped by experiences earlier in the life course. For instance, it is known that differential treatment by parents of their children is destructive to the children's sibling relationships. Early differential treatment (parental ''favoritism'') also has a negative impact on the relationship in adulthood. Young adults whose parents showed different levels of affection toward them were more jealous of their siblings than were those whose parents were perceived to be equal in their affection (Rauer & Volling, 2007). Similar results apply to middle-age adults. In a study of more than 1,000 German men and women ages 40 to 54, the individuals who reported the best sibling experiences also reported that they and their siblings had been treated equally in childhood. The quality of the adult sibling relationship diminished both with increasing favoritism and with ''disfavoritism'' (Boll, Ferring, & Filipp, 2003).

Another example of the influence of earlier experiences on the adult relationship concerns the rarely studied tie between siblings with different sexual orientations. In one exploratory study, women ages 19 to 74 discussed influences on their feelings of closeness with their siblings. Lesbian women could trace their positive

relationships with their straight sisters to having received support from them when faced with parental disapproval after coming out (Mize, Turell, & Meier, 2004).

The death of a parent during a person's childhood also influences adult sibling relationships. Comparing the results of the death of a mother, father, both, and no death in childhood, Kristin Mack (2004) found that the death of parents results in more closeness but not more contact than in intact families. Maternal death in childhood results in less contact between adult siblings than does paternal death, most likely because mothers are typically the family "kinkeepers" who keep family members in contact with one another. The effect of parental death during adulthood is more varied: It draws some siblings closer together, whereas some become more distant.

## INFLUENCES OF SOCIAL CONTEXTS ON ADULT SIBLING RELATIONSHIPS

Sibling relationships are shaped by social contexts, both proximate (e.g., family, peer, and friendship groups) and distal (e.g., work organizations, historical setting, demographic conditions, and culture). For instance, in American and European societies the adult sibling tie is considered voluntary at the same time that demands are placed on it: Siblings are expected to be involved in one another's lives, be friends, and feel a sense of family commitment without asking too much of one another (Connidis, 2005). These conflicting expectations can generate feelings of ambivalence toward siblings.

Research on geographic proximity has shown that ethnicity, immigrant status, and education influence how close siblings live to each other, which in general declines through age 50 and then stabilizes. Individuals with more education and recent immigrants are more likely to increase their geographic distance from siblings over the life course. African Americans and people from large families are more likely to remain geographically close to siblings. Marital dissolution also increases geographic closeness to siblings. Contact with siblings follows the same pattern as geographic closeness with one modification: Women and Latinos also increase contact over the life course (White, 2001).

A large body of literature has examined exchanges of support and help between siblings. Shelley Eriksen and Naomi Gerstel (2002) found that race has little effect on the assistance and support siblings provide one another. Instead, gender, age, and social class influence the likelihood of providing care to siblings. Having a living parent also promotes sibling help. Marieke Voorpostel and Rosemary Blieszner (2008) found that when parents provide more emotional support, siblings exchange more practical and emotional support with one another. More practical support from parents, however, is related only to exchanges of more practical support between the siblings. Siblings also compensate for parents' lack of support when they have poor relationships with their parents. In this case siblings exchange more support with one another than they do when the relationship with parents is better.

Some influences on sibling relationships are the parent and marital status of siblings and the structure of the sibling group (birth order, number of siblings, gender composition), but their effects are observed mostly in early adulthood. In terms of birth order, older siblings are more supportive of their younger siblings than the reverse (Voorpostel, van der Lippe, Dykstra, & Flap, 2007), but this birth order effect disappears by middle adulthood (Connidis, 2005). Also, members of larger sibships exchange more affection, contact, and support within the sibship than do members of smaller sibships (White, 2001). Further, in young adulthood childless adults provide help to their siblings who have children. In regard to advice, in young adulthood it is siblings with children who share more, whereas childless sibling dyads are more likely to give advice later. Whether siblings have spouses or partners does not influence their exchange of support in Holland; it does in the United States, but in complex ways. Among siblings with different levels of education, those with lower levels of education show more interest in their more highly educated siblings than the reverse (Voorpostel et al., 2007).

Exchanges of help among siblings also depend on the type of help required, the gender and age of the siblings, and other characteristics of the sibling relationship. Voorpostel and Blieszner (2008) found that siblings exchange both practical and emotional support when the relationship is more positive and when there is more frequent contact. Voorpostel et al. (2007) found that sister–sister pairs are more likely to help with housework, give advice, and show interest in their siblings than are other gender combinations, but after age 36 those gender distinctions are less apparent.

Although Dutch men exchange practical support with siblings more than Dutch women do, women are more likely to exchange emotional support, but only with their sisters. Further, sibling relationship quality and contact are frequently more important for support among sisters than among brothers (Voorpostel & Blieszner, 2008), suggesting that whether brothers help one another appears to be independent of the relationship context. This seeming contextual detachment of support between brothers may illustrate a profound difference between female and male expressions of closeness (Matthews, 2005). Men may mask their care behaviors

intentionally to protect their brothers from breaking the normative "rules" of masculinity, in which men are expected to be strong and independent. Thus, in stories about brothers, men appeared insensitive to brothers who sought support because they asserted a controlling style, particularly when it came to practical support (Bedford & Avioli, 2006). This seeming insensitivity may be an act of caring in itself (Swain, 1989). Little research has been devoted to brothers.

## SIBLING INFLUENCES ON PERSONAL DEVELOPMENT

The sibling relationship in both childhood and adulthood influences adult development and well-being. In a prospective study of young non-Hispanic White American men that continued until the individuals were in their 50s, men who had a poor sibling relationship in childhood were more than three times as likely to develop major depression by age 50 than were men with better sibling relationships. This effect was independent of a family history of depression and the quality of relationships with parents (Waldinger, Vaillant, & Orav, 2007).

Siblings also may benefit one another as attachment figures (close others who provide solace in times of stress). Caroline Tancredy and R. Chris Fraley (2006) found that both twin pairs and nontwin pairs met the attachment criteria in young adulthood, although twins were more likely to do so. Also, the same factors contributed to becoming attachment figures among twins and nontwins, such as having spent time together as children and having shared interests, personal lives, or professional lives as adults.

Another sibling effect on well-being in adulthood derives from sharing in parent care. Attempts by individuals to correct sibling inequities in their care of parents resulted in distress to the primary caregiving sibling (Eriksen & Gerstel, 2002). Parent care also can offer opportunities for personal growth by forcing siblings to confront interpersonal issues that may have been avoided earlier through distancing. Sibling conflict in other contexts also offers opportunities for personal growth. Because the sibling tie cannot be dissolved, when faced with high levels of conflict, siblings have to develop strategies for regulating their own as well as another's emotions, including maladaptive expressions of anger and aggression (Bedford & Volling, 2004). In another study the most frequently named benefit stemming from conflicts in adults' sibling relationships was helping one's children and grandchildren manage their own sibling relationships, followed by gains in social competence and gains in one's self-understanding (knowing one's emotional limitations and talents and career choices; Bedford, Volling, & Avioli, 2000).

Siblings also contribute indirectly to the well-being of adults' romantic relationships. Amy Rauer and Brenda Volling (2007) found that young adults who were treated differently by their parents experienced distress in romantic relationships. They found that those adults' models of attachment contained representations of the self and the object of attachment that were more negative than were those of adults who received equal levels of affection from their parents.

## FUTURE DIRECTIONS

These research findings illustrate that the life course provides a meaningful framework for viewing sibling relationships. Spanning the whole of life, this relationship demonstrates the continuing interdependence of siblings as they move into and out of one another's inner circles; it also demonstrates how the changing social network of each sibling influences characteristics of the sibling relationship. Timing of events also may have an effect; early influences on the adult relationship, such as the death of a parent, differ when the event occurs later in life. The findings of research underscore the growing realization of the importance of siblings as both actual and potential sources of support in adulthood. In particular, siblings were seen to offer compensatory support in the absence of parental, spousal, or other resources as well as to make unique contributions.

In light of the growing importance of this relationship in later life, future research should focus on ways to maximize its support potential, such as by identifying potential socialization and intervention processes throughout the life course. For instance, it would be instructive to compare sibling support outcomes during various life transitions among different cultures as well as across different sibling constellations. Future research also should target all siblings, not only biological ones.

# SIMMEL, GEORG

***1858–1918***

Georg Simmel was born on March 1 in Berlin and died on September 28 in Strassburg, Germany (now Strasbourg, France). Trained as a philosopher, he also belonged to the first generation of German sociologists. After receiving a doctorate in philosophy at the University of Berlin (now Humboldt University) in 1881, he became a lecturer at that university in sociology, philosophy, ethics, art, and psychology. Not only were his lectures popular in the university, they attracted the intellectual elite of Berlin as well as many students from abroad.

Simmel was a founding member of the German Sociological Society, along with German sociologists such as Max Weber and Ferdinand Tönnies. By 1900 Simmel's work was well known throughout Europe, Russia, and the Americas, but his repeated attempts to gain a formal university position were unsuccessful. In 1901 he was granted an honorary position that placed him above the rank of lecturer but left him out of the mainstream affairs of the university. His Jewish heritage (despite his family's Protestant conversion) and especially his popularity outside of academia made him appear dubious to many of his colleagues and did not help to secure him a formal position early in his career. In 1914, only four years before his death, he became a full professor at the University of Strassburg.

## CONTRIBUTIONS TO LIFE COURSE RESEARCH

In contrast to some other sociological approaches, Simmel viewed society as neither an organism nor a convenient label for something that does not exist. Instead, Simmel pictured society as a web of reciprocal interactions (*Wechselwirkung*) among individuals and sometimes between people and the material world. Simmel's core notion of *Wechselwirkung* can be translated as both "reciprocal interaction" and "reciprocal effect and causation." To Simmel all social life consists of reciprocal interaction so that the actions and destinies of each element have an impact on the other elements. That notion allowed him to perceive that the modern individual has a strained relationship between what he called objective culture and subjective culture. Simmel saw the modern concept of individualization—the idea that individual people can and should have power and agency—as a part of subjective culture, but he was aware that the world outside the individual may develop its own dynamics (objective culture). Objective culture can have negative as well as positive unintended consequences for

***Georg Simmel.***

the life course of the individual. This perspective is echoed in the emphasis in contemporary life course research on the tension between human agency and social structure.

From that perspective Simmel defined the subject of sociology not as the study of society, community, or even groups but as the study of the modes or forms of sociation or, more literally, societalization (*Vergesellschaftung*), by which he meant the ways in which humans associate with one another and become interdependent. Throughout his work Simmel considered social actions not in themselves but in relation to particular structures and processes. For him sociology is the science that studies the processes of societalization.

That definition of sociology was a response to critiques from the historical sciences as well as from psychology that a science of society never would be established because it would fail to have a field of study of its own. To Simmel a sociologist's object of study should not be an entity called society but the intricate connections that give rise to society. As a result of his interest in the forms of association by which a mere sum of separate individuals undergoes the process of societalization to become something greater than that sum, Simmel was especially interested in the issue of individualization. He also considered historical change in individuals' group affiliations and in the life course stages of individuals' group affiliations. For instance, Simmel often discussed the impact of modern technologies, which in his view allow individuals to master their everyday tasks and help design novel forms of societalization in which individuals can pursue their goals and interests. He exemplified the pressure of objective culture when he discussed how modern technologies such as the telephone and new forms of transportation can become means in what he called the process of superordination and subordination. Essentially, he argued that technologies can end up controlling individuals. Subordination by objective culture in the form of a principle or a technological device can be seen as more disturbing than subordination to a group. To Simmel, subordination to a certain group still allowed a person to develop some form of individuality and express beneficial social bonds.

### SIGNIFICANCE OF SIMMEL'S WORK BEYOND LIFE COURSE RESEARCH

In addition to Simmel's contributions to understanding the modern life course and its implications, his work has remained relevant in many other areas in the social sciences. Simmel has been influential in the development of sociology, anthropology, and cultural studies. His ideas on individualization and reciprocal interaction have been critical to the contemporary understanding of modern life in big cities, the phenomenon of strangeness in debates on assimilation, personal and social interaction, modern sexuality, studies of social conflict, exchange theory, and qualitative data analysis in the social sciences.

## SINGLEHOOD

**SEE** Volume 3: *Singlehood.*

# SOCIAL CLASS

Most societies employ some system of hierarchical ranking, whether explicit or implicit, to make distinctions among their members. In stratified societies, individuals who occupy similar positions in the hierarchy are considered members of the same social class. Although the determinants of social class vary across societies, most modern societies base their rankings on some combination of occupation, education, income, and wealth. In addition to possessing greater financial resources, occupants of higher social classes tend to have greater access to power and authority, better living and working conditions, and better physical and mental health. Those who occupy higher-class positions in a given society typically distinguish themselves by adopting particular dialects, dress codes, leisure activities, manners, and other behaviors and traits that both signify and further their prestige. These behaviors and traits are cultivated to contrast with those of the lower classes, which are considered less culturally refined and therefore less desirable (Bourdieu, 1984).

The social class an individual belongs to typically has a great deal of influence on the shape and structure of his or her life course. As Max Weber's (1864–1920) concept of *life chances* implies, class plays a significant role in expanding or limiting access to a wide variety of experiences, goods, and conditions (Weber, 1946). This influence may be direct, such as when limited financial resources constrain an individual's ability to acquire goods or services that could improve quality of life (e.g., health care, legal services, higher education). Similarly, occupations at the higher end of the social hierarchy differ from those at the lower end in that they often offer greater stability of work and greater opportunities for promotion, as well as greater income.

However, the effect of social class on the life course can also be seen in much more subtle and insidious ways. Position in the social structure affects the very ways that people perceive the world, including the values that they emphasize, the opportunities that they encounter or consider feasible, and even the characteristics that they seek to instill in their children. For example, parents of lower-class children have been found to emphasize behaviors, such as obedience and good manners, that reflect the conformity required by their own class positions, whereas middle-class parents are more likely to emphasize self-direction (Kohn & Schooler, 1983). These traits are encouraged in children because they are likely to enable professional success in their respective milieus: Children who become factory workers will be rewarded for following rules, whereas children who become white-collar workers will be rewarded for innovation.

Social class is associated with a variety of outcomes across the life course. For instance, middle-class students often have better educational outcomes than do lower-class students. As Lareau (2003) has shown, this is not only because they have access to greater financial resources but also because they and their families have greater familiarity with the values, language, and culture of educational institutions; consequently, they are more likely to feel as if they *belong* in school (Ostrove & Long, 2007). Even seemingly personal decisions such as those involving marriage and child-bearing are associated with social class. Lower-class women are less likely than their middle-class counterparts to marry, a social fact that at least partly reflects the poor employment prospects of lower-class men in the modern economy (Edin & Kefalas, 2004). Lower-class women are thus more likely than middle-class women to have children out of wedlock; they are also, on average, younger than middle-class women when they become mothers. Indeed, middle-class women in industrialized societies are postponing motherhood longer than they have since at least World War II; they are also having fewer children (Hall, 1999).

Evidence is particularly compelling about the effect of social class on health throughout the life course. As Henry (2001) has noted, social class contributes to health inequalities in a variety of ways, including psychological mechanisms (e.g., cultural norms and habits, dispositions and cognitive styles, health knowledge); behavioral constraints (e.g., economic resources, barriers to access); and physical influences (e.g., environmental conditions, physiological stress, genetics). Further, the complex interactions of these mechanisms do not result in a simple difference between rich and poor. Instead, socioeconomic differences in health are gradational: The highest income group is healthier than the second-highest income group and so on (Marmot, 1999). A considerable amount of policy work has been devoted to finding ways to reduce inequalities in both the health outcomes and the health care experienced by members of different social classes.

## DEFINING AND STUDYING SOCIAL CLASS

Despite the importance of class to the organization of social life, no single definition of the term exists. Instead, social class has a number of distinct meanings. In everyday usage, it most closely approximates the idea of social prestige, as indicated by lifestyle and consumption patterns. Researchers, however, may use the term to signify one of three meanings. First, class may be used to describe a system of structured inequality, particularly with respect to economic and power resources. Second, class may mean an actual or potential social and political force, with the power to produce significant social change. Third, similar to the everyday usage of the term, class may be relatively synonymous with prestige, status,

culture, or lifestyles (Crompton, 1998). These multiple meanings can be traced back to those developed by Karl Marx (1818–1883) and Max Weber, whose works spawned the theoretical traditions that have been most important to the contemporary study of social class.

Social stratification, the systems of hierarchical ranking employed by societies, has long been a focal point of discussion and debate among intellectuals and philosophers. However, Karl Marx and his literary collaborator, Friedrich Engels (1820–1895), were the first to describe the motivating forces of the new social order that developed in the wake of the industrial revolution of the mid-19th century. Their work emphasized the social relations inherent to industrial production and linked these relations to the dynamics of social change (Rothman, 1999). Marx argued that each period of history was defined by two social classes that were in opposition to each other because of their different relationships to the *means of production* (the tools, equipment, materials, and infrastructure necessary to make products). In feudalistic societies, for example, the two classes were landowners and serfs; in slavery, they were masters and slaves. Under capitalism, the two classes are the *bourgeois*, those who own the economic resources, or capital, and the *proletariat*, workers who own nothing and thus can only survive by selling their labor. The dominant class in any period occupies an extremely advantageous position, which it both maintains and furthers by organizing the *ideological superstructure* (a society's laws, institutions, beliefs, art, values, and so on) to support the status quo.

Despite the considerable disadvantage of the proletariat under capitalism, Marx believed that it would eventually overthrow the capitalist system. To engage in revolution, however, members of the proletariat must recognize their collective predicament. To do so, Marx believed that the proletariat must move from being simply a *Klasse an sich* (a class unto itself) to a *Klasse fur sich* (a class for itself), in which its members are not only aware of the interests they share by virtue of their common location within the economic system but are self-consciously acting together to realize those interests. Marx believed that collective action by the proletariat would overthrow the bourgeoisie, resulting first in a temporary, transitional period of socialism and then settling into a permanent state of communism, in which the distribution of goods would be determined by each individual's abilities and needs.

Although class is obviously central to the Marxist conception of history and society, it is not defined clearly in Marx's writings. Wright (1985, pp. 26–38) argued that Marx referenced class in two distinct ways: structurally, as in the relationship to the means of production (i.e., ownership versus lack of ownership), and relationally, in that classes are defined by their opposing interests and antagonistic relationship. The two-class framework developed by Marx has also been criticized by some because it has been largely unable to account for the marked rise of the middle class(es) during the 20th century. How to incorporate this segment of society, as well as how to account for other developments in modern capitalism, has created considerable debate among neo-Marxist scholars. However, Marx and Engels' work spawned extensive analysis of industrial society, and all scholars of class analysis are thus indebted to them. They introduced many of the key issues on which the study of class and stratification has been based, particularly the concept of class as based on position in a specific productive system and the concept of class-consciousness.

Weber drew on Marx's work to develop a multidimensional view of stratification that extended beyond the Marxist emphasis on class relationships alone. Like Marx, Weber viewed social classes as groups of individuals who share a common market situation that significantly influences their life chances. However, he saw three types of market situation: the labor market, which divides individuals into employers and employees; the money market, which distinguishes debtors from creditors; and the commodity market, which distinguishes buyers from sellers. Participation in more than one market can result in simultaneous membership in more than one economic class. Further, Weber recognized that people without property had a range of skills and abilities that can significantly affect their social standing and life chances. In this way, his work allows more room for the incorporation of the middle classes than does the Marxist tradition.

Weber argued that there are actually three forms of social inequality under capitalism: economic inequality, status inequality, and power inequality. Status inequality is conceptually distinct from economic inequality but is often correlated with it, inasmuch as individuals and groups with the most economic resources often enjoy the highest status. What he termed *status honor*, but which is now typically called social status or prestige, reflected and was based on social values and ideals. Communities of people sharing a similar location in the status hierarchy comprise status groups; their commonalities are grounded in consumption patterns and lifestyles, as well as aspects such as ancestry, ethnicity, education, or occupation. Because status groups are aware of their commonalities to at least some degree, higher-ranked status groups develop exclusionary rules and practices to protect their position and maintain their privilege over time. Weber was less explicit about the nature and dynamics of power inequality. However, his identification of this third type of inequality as distinct from (if often overlapping with) economic and status inequality was significant and further contributed to his multidimensional model of social stratification.

***Blue-collar.*** *Assembly line workers install wheel well liners in the Ford F-150 at the Dearborn Truck Plant in Dearborn, MI. Manual laborers are often referred to as "blue-collar" workers.* AP IMAGES.

In contemporary social science, analysis of social class has typically assumed one of four forms: (a) the study of the emergence and perpetuation of (dis)advantaged groups within a society, with a focus on understanding and explaining a particular class; (b) the study of the consequences of class location, with a focus on understanding and explaining other phenomena (e.g., voting behavior) by examining the impact of social class; (c) the study of the development of class and status cultures and identities; and (d) the largely theoretical discussion of the significance of class processes, particularly with regard to their role in social change (Crompton, 1998, pp. 203–205). A large literature on social mobility has also emerged that examines the movement of individuals up and down the social class hierarchy, both across generations (intergenerationally) and within a single individual's lifetime (intragenerationally).

## THE CLASS STRUCTURE OF POSTINDUSTRIAL SOCIETIES

In some societies, little room is available for subjective interpretation about what constitutes a higher or lower social ranking. For example, the Hindu caste system in India is based on a division of labor and has informed the structure of Indian society for centuries. The caste system has historically determined the social interactions that members can have as well as the occupations they can pursue, although there has been some decline in the rigidity of observance in the modern business environment. However, in societies such as the United States where class divisions are not formalized, ideas about the precise location of class boundaries may vary.

Most models of contemporary stratified societies contain at least three classes: an upper class, a middle class, and a lower class. It is generally agreed that the most powerful and wealthy members of a society comprise the upper class, whereas those who have little to no power and property comprise the lower class. The middle class falls somewhere in between, consisting of those who may or may not exert power over others but who have at least some control over their own destinies through occupation, education, or property ownership. However, both the boundaries and the meaning of these social classes are subject to considerable debate. This is particularly so in societies with great economic, social, and cultural

complexity where there are few easily observable breaks in socioeconomic strata, such as the postindustrial United States (Eichar, 1989). Consequently, although most scholars of social class employ somewhat congruent theories, agreement on the proper operationalization of class remains elusive. For instance, some scholars conceptualize class as being primarily defined by relationships to power (e.g., Zweig, 2000), whereas others emphasize sources of income (e.g., Gilbert, 2002) or consumption patterns (e.g., Lury, 1997). This operational imprecision is also reflected in public opinion data. For example, polls have repeatedly shown that 90% or more of residents in the United States believe themselves to be somewhere in the middle of the class hierarchy (see, e.g., Baker, 2003; CBS News, 2007).

Most analysts of the modern U.S. class system divide it into a somewhat more complicated hierarchy, with each of the three main classes further divided into subclasses. The upper class, also sometimes referred to as the capitalist class (Gilbert, 2002), is in various models further subdivided into the super-rich and the rich (Beeghley, 2005) or the upper-upper and the lower-upper (Warner, Mecker, & Eells, 1960), or divided by the provenance of the wealth (i.e., those who were born into wealth, or old money, vs. those who became rich in their own lifetimes, or new money). The middle class is also often divided into two or three subclasses. These subclasses, which are organized roughly by individuals' educational attainment and the degree of autonomy they enjoy in the workplace, include the upper-middle, sometimes also called the professional class (Ehrenreich, 1989), and the lower-middle. Similarly, the lower class is also sometimes further divided, with scholars such as Coleman and Rainwater (1978) making distinctions between the *semipoor*, or unskilled labor and service workers with some high school education, and the bottom, those who are often unemployed and reliant on welfare. Many class analysts also include a fourth major class, the working class, which is located between the middle and the lower classes. This class, which is also sometimes called the upper-lower class (Warner et al., 1960), is typically made up of manual or blue-collar laborers who did not attend college. Some scholars also include workers in predominantly female clerical positions, or *pink-collar* workers, in this class.

As the multiplicity of these models suggests, a great deal of contention remains regarding which typology best captures postindustrial class structure. A similar lack of consensus exists surrounding the question of whether the unit of analysis for social class should be the individual or the family. For example, should a wife be accorded the same status as her husband if she does not work outside the home, or if her own class characteristics (e.g., education, manners) are different from her husband's? Similarly, should minor children be considered lower class, given their lack of power both within and beyond the family home?

Including women in class analysis has posed a significant challenge to social scientists since the 1970s. Prior to that, class analysis and social stratification in the United States and Europe was devoted almost entirely to studies of men (Sørensen, 1994). Women were considered peripheral to the main concerns of stratification theory because of their intermittent employment patterns outside the home and thus were classified according to the characteristics, particularly the occupational status, of their husbands. This conventional approach to class analysis took for granted that the family should be the appropriate unit for class analysis. However, married women's increasing involvement in the labor force led to criticism of the conventional approach's method of determining family class position, as well as its assumption that all members of a given family occupy the same position in the social structure (Acker, 1973). In what became known as the feminist critique of class analysis, some scholars argued for an individualistic model of class analysis in which the class positions of both men and women were determined individually, regardless of their marital status. Instead of conceptualizing the family as the unit of class analysis, then, this approach emphasized the class position of individuals. Although the issue of how the social scientific literatures on social class and stratification should incorporate women remains unresolved, the considerable debate it has generated has contributed to the development of a substantial literature on women's occupational mobility and disadvantage in the labor market, as well as on the status inequality that women may experience within the household.

In the last decades of the 20th century, some scholars began to argue that social class is of decreasing importance in shaping identity. These arguments reflect changes in the structure of work in modern industrial societies, including the decline in workers employed in traditional blue-collar industries such as heavy manufacturing, and the growth of jobs in the service economy (i.e., nonmanual workers in finance and retail services). These scholars argue that this upheaval in traditional class markers (e.g., clear distinctions in the status of white- and blue-collar work) as well as the individualization encouraged by increasing social fragmentation and an unstable labor market, mean that factors other than employment are becoming more relevant as sources of identity and social cleavage. However, other scholars strongly reject such arguments, asserting that social class remains both a salient source of identity and a highly relevant social force.

# SOCIAL EXCLUSION

**SEE** Volume 2: *Social Integration/Isolation, Adulthood.*

# SOCIAL INTEGRATION/ ISOLATION, ADULTHOOD

Social integration refers to the degree to which an individual is tied to other individuals, organizations and groups, and his or her community. These ties may be formal or informal. They may be objective (i.e., based on actual relationships) or subjective (i.e., based on individuals' perceptions of relationships). People who are not socially integrated often are referred to as socially isolated. Social integration both reflects and shapes the adult life course; social bonds emerge from the events and circumstances of people's lives, and those bonds affect people's lives because of the resources they bring.

## EARLY INTEREST IN SOCIAL INTEGRATION

The concept of social integration emerged from the work of the sociologists Ferdinand Tönnies (1855–1936) and Emile Durkheim (1858–1917), who were interested in the ways societies change as they progress from rural to urban. Tönnies used the term *Gemeinschaft* ("intimate community") to describe social integration in rural villages where people are closely tied by kinship and tradition and can be considered members of a single social group. In a Gemeinschaft, relationships are intimate and cooperative and individuals' interactions are guided by the interests of the group. As societies industrialize and urbanize, Tönnies argued, *Gesselschaft* ("impersonal association") emerges and weakens the integrated fabric of family and community. In a Gesselschaft, social bonds and long-lasting social relations are lacking and individuals' interactions are based on self-interest and material accumulation.

For Durkheim persons in both urban and rural areas have social bonds, but those bonds differ. Both types of

society have a collective conscience, a system of fundamental beliefs that tie people together and foster social integration. Rural communities are tied together by mechanical solidarity, that is, social bonds and integration based on common sentiments and tasks and shared moral values. Adults in rural societies have a deep and personal involvement with the community and with one another because they perform similar tasks. By contrast, urban communities, which are shaped by industrialization, are based on organic solidarity, in which individuals perform specialized tasks and rely on one another to perform those tasks. Social relationships thus are more formal and functionally determined in urban societies, but those societies still are socially integrated.

In his influential work *Suicide* (1951 [1897]), Durkheim examined the impact of social integration on individual well-being. He argued that geographic variation in suicide rates (high rates in some countries and low rates in others) are due to different levels of social integration and regulation. Insufficient levels of social integration lead to a high degree of individualism, and the consequent isolation results in higher rates of suicide. Durkheim also argued that excessive levels of social integration also lead to higher rates of suicide because individuals who are very highly integrated feel overwhelmed by the demands and regulations of society. However, this idea is largely unfounded because modern societies rarely have excessive levels of social integration (Johnson, 1965).

In a classic study Mark Granovetter (1973) examined the qualitative nature of social integration, emphasizing the importance of weak ties (acquaintances). Strong ties form among people as a result of long-term, frequent, and sustained interactions; by contrast, weak ties result from infrequent and more casual interaction. Granovetter argued that weak ties are more efficient for innovation and knowledge; strong ties include individuals so embedded in interaction that change is hard to come by. If two people have a strong tie, they are also likely to be strongly tied to all the members of each other's networks, and that creates high levels of overlap in their social integration. Weak ties, in contrast, are the building blocks and bridges for social integration between groups.

## DEFINING AND MEASURING SOCIAL INTEGRATION

Researchers draw a general distinction between structural (objective) integration and perceived (subjective) integration (Moen, Dempster-McClain, & Williams, 1989). Structural social integration refers to an individual's concrete involvement with other individuals, such as friendships, and with social groups, such as clubs and churches. Perceived integration reflects people's feelings about the depth of their connectedness to others, such as the sense of belonging. Another distinction is the social context in which integration occurs. N. Lin (1986) classified social integration as occurring at the community level, within social networks, and through intimate and confiding relationships. Another way of conceptualizing social integration is to think about variation across diverse social contexts. Some of the more common contexts are family, friendships, voluntary groups, civic organizations, the workplace, the local neighborhood, and the larger community. It is important to distinguish among these different types of integration because adults may draw on specific resources for different situational needs (Messeri, Silverstein, & Litwak, 1993).

A counterpart to social integration is social isolation, which refers to a lack of social ties, companionship, and connectedness. Like social integration, social isolation may be structural or perceived. Perceived social isolation sometimes is referred to as loneliness (Ernst & Cacioppo, 1999). Using survey information from 1985 and 2004 General Social Survey (GSS) data, M. McPherson, L. Smith-Lovin, and M. E. Brashears (2006) found that social isolation in the United States increased over that two-decade period. For example, the number of adults who said that they had "no one" with whom to discuss important matters nearly tripled. The connection between age and loneliness is contradictory. Some researchers find that loneliness is most intense during adolescence and young adulthood and then declines with age (Rokach, 2000). McPherson and associates (2006), however, found that a person's network size decreases with age; the older people are, the more likely they are to report that they have no discussion partners in their social network.

Research on social integration is confronted by a number of conceptual and measurement issues. First, the field lacks agreed-on measures of social integration; that means that researchers use a wide variety of measures, making comparisons across studies and data sources difficult. Second, this lack of precision in measurement reflects an underlying lack of conceptual precision. The term *social integration* is not used or accepted universally, and the following terms may be used interchangeably: social integration, social support, social networks, social capital, social isolation, social alienation, social ties, social relationships, social attachment, social disorganization, and social engagement. However, many of these terms, in particular *social support* and *social networks*, refer to specific concepts that although closely related to social integration, are distinct from it. This conceptual imprecision arises in part because research about social integration is carried out in several academic disciplines and because within disciplines, different researchers study different aspects of social ties.

A third issue in defining and measuring social integration is that the concept applies to individuals as well as social groups; for individuals, integration may be structural

or perceived. Thus, social integration may refer to a structural characteristic of an adult such as social support (House, Umberson, & Landis, 1988), a psychological characteristic of an adult such as social attachment (Kasarda & Janowitz, 1974), a structural characteristic of a small group such as social networks, or a structural characteristic of a geographic space such as social disorganization (Faris, 1955). A fourth issue is that similar concepts often are used to measure levels of integration; for example, higher levels of social ties indicate higher levels of social integration (Pescosolido & Georgianna, 1989).

Further development and refinement of the related concept of social capital eventually may rectify some of this conceptual confusion. The idea of social capital entered popular culture with the publication of *Bowling Alone: The Collapse and Revival of American Community* in 2000 by the political scientist Robert D. Putnam. Putnam argued that traditional forms of social integration—interpersonal ties, voluntary organizations, and civic participation—have had massive declines in involvement. Putnam made a distinction between two types of social capital: Bonding involves integration with individuals who have similar characteristics, whereas bridging involves integration with individuals who have diverse and often dissimilar characteristics. Putnam's work on social capital has been criticized and is not accepted universally in the academic community (Fischer, 2005).

The origin of the term *social capital* is debated (Portes, 1988). Although there is no universal definition of social capital—certainly a limitation of the concept—A. Portes (1988) provided a general definition that is accepted widely: Social capital is the ability of individuals to access and use resources and benefits as a result of their integration in social networks and social structures. Social capital is an extremely popular concept and is used extensively throughout the social sciences: The preface to a widely read edited volume on social capital states that "[s]ocial capital as both a concept and theory has drawn much intellectual interest and research in the past two decades. The attraction of the notion is perhaps in part due to the common understanding that as a social element it may capture the essence of many sociological concepts (e.g., social support, social integration, social cohesion, and even norms and values) and serve as an umbrella term that can be easily understood and transported across many disciplines" (Lin, Cook, & Burt, 2001, p. vii).

## CAUSES OF SOCIAL INTEGRATION AND SOCIAL ISOLATION

Social integration is important for well-being throughout the adult life course. However, the causes of adult social integration begin much earlier in the life course, generally during childhood and adolescence. Indeed, early life course experiences have an enduring impact on integration throughout the adult years and in later life. Research has indicated that four childhood and adolescent processes and experiences are reliable predictors of adult social integration. Those processes all limit the ability of children and adolescents to form social bonds, and those limitations persist into the adult years. All the processes generally are called family social capital (Coleman, 1988). Specifically, adults have lower levels of social integration if they experienced any of the following events as children or adolescents: parental divorce, geographic mobility (especially moves that require frequently changing schools), poor parent-child relationships, and socially isolated parents (Myers, 1999).

Although these earlier experiences persist into adulthood and shape social integration, life course variables in adulthood also have contemporary effects on social integration (McPherson et al., 2006). Historically, women always have had greater levels of social integration. This trend has continued, but the differences in social integration between men and women have been shrinking. Other factors important for social integration in adulthood are age (social integration declines in one's older years), education (higher levels lead to greater integration), race (Whites are more socially integrated), and marital status (those who are married are more socially integrated). One's community also influences one's level of adult social integration. Generally, social integration is lower if one lives in a poor neighborhood and a neighborhood with higher crime rates. These factors create stress, fear, and less psychological investment in one's community, all of which are linked to lower social integration.

## THE CONSEQUENCES OF SOCIAL INTEGRATION FOR THE ADULT LIFE COURSE

Life course researchers attempt to understand the opportunities, barriers, and social structures that shape individuals' life chances and well-being. The concept of social integration is integral to this understanding because social integration acts as a conduit for both tangible (e.g., money, help) and intangible (e.g., emotional support, intimacy, connections to opportunities) resources. Although measures of social integration and their equivalents are employed in almost all aspects of life course research, three research areas stand out in the importance they place on social integration: health, crime, and immigration.

Research shows that higher levels of social integration are associated with better physical and mental health

(House et al., 1988). This finding holds for diverse outcomes, including diabetes, hypertension, depression, self-rated health, and mortality. In general, higher levels of social integration provide (a) social support, such as information and help with tasks; (b) social influence, which may encourage health-enhancing beliefs and behaviors; (c) social engagement and attachment, for example, with friends and beneficial social institutions; and (d) material resources, which may facilitate preventive care and healthy behaviors (Berkman & Glass, 2000). Critics of research on social integration and health argue that too much attention is focused on structural aspects of integration. They propose that research should be directed at understanding the role of perceived integration and the qualities of relationships.

Building on earlier theories of social disorganization (Shaw & McKay, 1942), the social scientific study of crime emphasizes social integration and support at the individual, family, and structural levels. E. T. Cullen (1994) argued that that social integration and support should be an organizing concept for studies of crime. Social integration may provide a moral compass, an orientation toward family, a set of prosocial behaviors, coping resources, economic resources, and social control. Cullen (1994) argued that crime rates vary inversely with the level of social support across nations and communities. Research supports that statement and also finds that the beneficial effects of social integration on crime accrue to adults who are at the greatest risk of committing crimes: less educated persons and those with lower incomes. Unfortunately, structural and economic inequalities may create barriers to high levels of social integration among those adults who most need those resources to generate institutional controls (Messner & Rosenfeld, 2001).

The study of immigration has long employed concepts similar to social integration, such as assimilation, acculturation, and incorporation. Immigration research generally finds that as adult immigrants socially integrate into the new country, they learn the sociocultural ways of their new communities. As a result, immigrants receive the resources and benefits that social integration provides. Research on the benefits of social integration finds superior occupational, social mobility, and health outcomes for immigrants who can integrate comprehensively into their new communities. Immigrants who do not integrate socially may be viewed as the other group, be assigned to a lower socioeconomic position, and be marginalized and socially excluded.

Some scholars counter that social integration of immigrants does not have to be absolute and complete. Instead, successful social integration involves the combination of involvement in the mainstream institutions and organizations with one's familiar social and cultural practices. From this argument, the concept of social capital has crept into the theories and research on immigration. The benefits of social integration can be realized even when such integration occurs within a specific ethnic immigrant community if that community has established links and integration with mainstream institutions and organizations (Zhou, 2005).

## THE FUTURE OF SOCIAL INTEGRATION

Social integration is an important adult characteristic that shapes life course outcomes, such as those associated with health, crime, and immigration. Research also shows that social integration can be a stratifying variable because levels of social integration are not equal across individuals. One's ability to integrate socially in adulthood is the result of a wide variety of adult statuses and characteristics. Research finds that social integration, along with its negative counterpart, social isolation, is a function of a person's physical and mental health; occupational, marital, and economic statuses; race and ethnicity; age; geographic location and mobility; and neighborhood quality.

However, the concept of social integration is broad, and social integration can be measured in numerous ways. Some researchers have abandoned the term in favor of more popular terms such as *social isolation*, *social capital*, and *social networks*. Therefore, much work is needed if social integration is to remain a useful concept for research and not just a broad construct in the social sciences.

Three avenues should be pursued by researchers in the future. First, qualitative research should be conducted on social integration in adulthood to reveal its complex and dynamic causes and consequences. Research that relies on large-scale quantitative surveys often cannot capture the interpersonal and structural processes that shape social integration in adulthood. For example, qualitative methods such as open-ended interviews could help researchers understand fully how individuals weigh the costs (such as time and effort) and benefits (such as friendship and support) associated with social integration. The demographic variables typically used in quantitative research—age, race, education, gender—do not capture these more nuanced processes. Second, much theoretical and empirical work on social integration is focused on the very young (children and adolescents) and the very old. Equal attention should be devoted to adults.

Third, social scientists should address the policy implications associated with social integration and the disparities in them. Policy is a dominant feature of international work on immigration, such as the importance of quickly integrating migrants into their destination communities. In the United States policy efforts are pursued in the educational context, but those efforts are

focused mainly on child and adolescent social integration. For example, a review of outreach policies found that parental integration into a child's school and peer-group families is the stated goal of 75% of the federally funded programs that target low-income and racial minority students (Perna, 2002). Utilizing the life course perspective in this policy endeavor could be fruitful because it would show that social integration in adulthood has significant implications for life chances and well-being.

# SOCIAL MOBILITY

*Social mobility* refers to the extent to which the social position attained by adults is linked to the social position of their parents. Research on social mobility illuminates the degree of opportunity in a society, because it shows

whether and how advantages or disadvantages in family background contribute to one's adult social position. To that end, studies of intergenerational social mobility generally examine the extent to which *social destinations*, or the social position attained by adult individuals, are similar to or different from *social origins*, the social position of the adults' parents (and, in some studies, grandparents). Although social position can be defined and understood in different ways, the focus in mobility studies is on socioeconomic position (i.e., occupation, education, income, and wealth). The majority of sociological research on social mobility focuses on socioeconomic position as defined by occupational status or class and, in some studies, educational attainment.

For example, one seminal study compared father's occupation to son's occupation, with occupation categorized into the broad categories of farm, manual, or nonmanual, in various nations (Lipset & Zetterberg, 1956), and another investigated the impact of father's occupational status and educational attainment on son's educational attainment, first job, and current occupational status (Blau & Duncan, 1967). A large body of social mobility research has subsequently addressed questions about the linkages between childhood social origins and adult destinations, as well as questions about how these linkages may differ between, for example, nations, time periods, birth cohorts, individuals with different levels of education, racial/ethnic groups, and men and women. In answering such questions, social mobility research illustrates interdependencies between generations as well as some of the ways in which lives are shaped by key life transitions or contexts of time and place.

## DISTINGUISHING SOCIAL POSITIONS

The concept of social mobility assumes that societies contain social positions that differ meaningfully from each other. These positions are usually defined in socioeconomic terms, most often by occupation, and are often, but not always, assumed to be ranked in an inherent hierarchy. Social mobility is often described as "upward" or "downward" mobility in reference to comparing higher or lower occupations on this hierarchy. A fundamental theoretical difference among mobility researchers concerns how to distinguish occupations meaningfully.

Pitirim Sorokin (1959), a pioneer in social mobility research, suggested the existence of *vertical channels* of mobility in societies, and much work that followed was influenced by or compatible with this theory. Thus many mobility researchers conceptualized occupations as finely vertically gradated along an inherent hierarchy. For example, some research distinguishes occupations by ranking each one relative to the others in terms of occupational prestige, or similarly, on a vertical scale that measures occupations based on the average job holder's income levels and educational credentials.

In contrast, another approach to distinguishing occupations takes the perspective that mobility occurs within a structure of discrete social classes rather than a finely ranked hierarchy of occupational status or prestige. Proponents of this *class structure* approach generally view occupations as falling into relatively large categories (for an exception, see Weeden & Grusky, 2005). The large categories of occupations represent discrete social classes, the distinctions between which are not necessarily hierarchical. For example, the self-employed class may be distinct from other classes without necessarily being considered a higher or lower class position. Although hierarchy is not the most central concept in the class structure approach, it is still present—some classes are considered "lower" than all others, although the specific positions can vary between perspectives.

Within the class structure perspective, scholars have proposed defining the boundaries of the class categories in different ways. The most commonly implemented approach in current social mobility research is often known as the EGP class schema in reference to an early explication of the schema (Erikson, Goldthorpe, & Portocarero, 1979; see also Erikson & Goldthorpe, 1992). The EGP schema posits that class position distinctly shapes individuals' life chances such as through its association with specific employment conditions. It organizes occupations into class categories such that the occupations held by individuals in a given class involve similar labor market relationships (i.e., being an employer, self-employed, or an employee) and employment conditions. In particular, service or professional occupations, whose incumbents generally experience relative job security, regular advancement opportunities, and employer trust, are contrasted with working-class occupations, whose incumbents generally experience close supervision and earn a specified wage per hour of labor.

Although the EGP class schema is dominant in social mobility research, other researchers have proposed different ways of theorizing class distinctions. One such perspective, associated with the work of Erik Olin Wright (2005) and based on Marxist concepts of class, views classes as not only involving different employment conditions but also distinct and conflicting class interests. In Wright's class schema, occupations are divided into class positions with respect to class exploitation or, more specifically, with respect to incumbents' control of assets that Wright theorizes are the mechanisms of class exploitation—ownership of capital, skills or expertise, and authority. Consequently, employers are distinguished from employees, experts from nonexperts, and managers from nonmanagers (Wright, 2005; see Western & Wright, 1994, for an application to social mobility research).

## ABSOLUTE AND RELATIVE SOCIAL MOBILITY

Social mobility researchers generally make a conceptual distinction between *absolute mobility* (also termed *structural mobility*) and *relative mobility* (also termed *social fluidity*). Absolute mobility results from economic change in a society, such as shifts in job growth away from farm employment toward industrial employment. It thus results from changes in the distribution of available occupations between one generation and the next. If the proportion of higher status jobs increases in the children's generation compared to the parents' generation, all individuals in the children's generation, regardless of their class background, have a greater likelihood of upward intergenerational mobility than if the distribution of occupations remained unchanged.

Relative mobility, on the other hand, is the social mobility that remains after adjusting for differences in the distribution of occupations between parents and children's generations (i.e., absolute mobility). Relative mobility is considered a reflection of the degree of equality of opportunity in a society rather than a reflection of societal economic shifts. High relative mobility is thought to reflect a degree of equal opportunity because intergenerational movement between classes occurs when adults' class destinations are not tightly linked to their social class of origin (and the advantages or disadvantages it entails). Researchers in the United States have been most interested in relative as opposed to absolute social mobility. It is worth noting, however, that the destinations and life chances of individuals in a society are more strongly affected by absolute mobility than by relative mobility (see Breen & Jonsson, 2005, for a discussion).

## PATTERNS OF SOCIAL MOBILITY

Social mobility researchers may take different theoretical approaches to identifying social positions, but their findings nevertheless concur that significant constraints to relative mobility exist. Regardless of theoretical perspective, studies have demonstrated that the chances of achieving a particular status position as an adult depend significantly on one's social origins after absolute mobility is taken into account. In order to summarize this variation, researchers test statistical models representing various mobility patterns and select the model that they believe best summarizes the actual patterns observed in real-world data. A key pattern consistently identified by scholars is that the farther apart two classes or occupations are in a hierarchy, the lower the chances that individuals will experience mobility between them (whether upward or downward). Research findings also have illustrated a pattern of relatively high immobility in certain class positions; for example, children of the self-employed are likely to become self-employed adults (see Ganzeboom, Treiman, & Ultee, 1991, for a review).

In addition to the commonly identified hierarchy and immobility patterns, Robert Erikson and John Goldthorpe (1992) identified a pattern they termed *affinity*, in which certain classes have relatively high inter-class mobility whereas other classes have low inter-class mobility. They also identified a sector-based pattern such that mobility between agricultural and nonagricultural classes is unlikely. Erikson and Goldthorpe proposed a mobility model that incorporates affinity and sector in addition to hierarchy and immobility. Their model has been contested by others who argue that it understates the importance of the hierarchical component of social mobility (Hout & Hauser, 1992). Interestingly, regardless of the model of mobility, research suggests that mobility patterns are generally similar across nations. For example, a variety of research has demonstrated the presence of hierarchical mobility patterns across nations, and researchers utilizing Erikson and Goldthorpe's model have also found that it applies cross-nationally (see Hout & DiPrete, 2006, for a review).

## EXTENT OF SOCIAL MOBILITY

Although social mobility patterns may be generally similar between countries, the *extent* of mobility (i.e., the likelihood that an individual will experience social mobility or the frequency of social mobility) is a different question and one that has been extensively debated by social mobility researchers. Although many scholars expected the United States to demonstrate high rates of social mobility compared to European countries (due to perceptions that class is less important for life chances in the United States), an early cross-national social mobility study suggested that nonfarm mobility rates were similar among Western industrialized nations. This idea became known as the *Lipset-Zetterberg hypothesis* (Lipset & Zetterberg, 1956). This hypothesis was later reformulated by others to posit that, although absolute mobility rates may differ between industrialized nations, relative mobility rates are basically the same. This became known as the *FJH hypothesis* (Featherman, Jones, & Hauser, 1975). Subsequent research, however, has demonstrated that important differences exist between nations in both absolute and relative mobility rates. Although cross-national rankings comparing more and less mobile countries must be made with caution due to differences in data collection, research findings suggest that the United States falls toward the low end within a group of relatively high mobility countries, in which Israel, Sweden, Norway, Hungary, Poland, the Netherlands, and Canada are some of the more fluid nations. Countries exhibiting lower relative mobility rates include Great Britain, Italy,

Germany, Portugal, and Ireland (Beller & Hout, 2006; Breen, 2004; Breen & Jonsson, 2005).

In addition to addressing cross-national variation in the extent of relative social mobility, researchers also have examined differences in mobility rates within countries, including differences over time that could result either from cohort effects (changes that occur when older birth cohorts leave the workforce and are replaced by younger cohorts with different mobility experiences) or from period effects (changes in mobility that affect individuals of all ages during a given time period, such as a country's transition to post-socialism, for example). In most countries, relative mobility rates appear to have increased with time. Great Britain is an exception to this trend, however, as are Hungary and Russia (Breen, 2004; Breen & Jonsson, 2005; Gerber & Hout, 2004). One explanation for the pattern of increasing mobility over time within many countries concerns expanded access to higher education, thus granting educational opportunities even to persons with humble backgrounds.

## EDUCATION AND SOCIAL MOBILITY

Early social mobility researchers showed that educational systems contribute both to intergenerational social mobility and immobility because educational attainment plays a key role in the process of attaining an occupation. Individuals with advantaged social origins have relatively high chances of attaining a postsecondary education and vice versa. Because educational attainment is so important to occupational attainment, this link between social origins and educational attainment largely explains the link between social origins and social destinations. At the same time, however, many factors other than social origins shape educational attainment. The extent to which educational attainment depends on social origins constrains social mobility, whereas the extent to which it does not depend on social origins fosters social mobility.

In part due to its importance in the occupational attainment process, education plays a key role in mobility researchers' understandings of differences in rates of relative social mobility between countries and over time. Greater access to postsecondary education is associated with higher mobility rates in some countries, and the expansion of postsecondary education systems over time within a country can underlie rising social mobility rates over time in that country. Expanded access to postsecondary education increases relative social mobility if the linkage between social origins and destinations is weaker among individuals who achieve a postsecondary education, as research shows is the case in some countries (Breen, 2004; Breen & Jonsson, 2005; Hout, 1988). For example, an individual of disadvantaged social origins who earns an advanced educational degree is more likely to be upwardly mobile than an individual from the same background without the advanced degree.

Although societies that expand access to higher education tend to experience increased social mobility rates over time, there is evidence that this effect can weaken as more and more people earn a postsecondary degree. Also, whereas greater access to education is associated with higher social mobility in certain countries, other countries (e.g., post-socialist countries such as Poland and Hungary) achieve higher rates of social mobility for reasons not fully understood, despite comparatively low access to postsecondary education. Research also shows that mobility rates tend to be higher in countries with greater equality of educational opportunity (i.e., in countries in which educational attainment depends less on social origins) regardless of the extent of access to higher education. This pattern suggests that either equality of educational opportunity causes higher rates of relative mobility, or the same factors that foster greater equality of educational opportunity in a nation simultaneously foster social mobility (Beller & Hout, 2006).

## UNRESOLVED QUESTIONS IN SOCIAL MOBILITY RESEARCH

Many interesting questions about social mobility remain unresolved. One such question concerns how to capture the shared class position of families in measures of class origins and destinations. Although class origins and destinations can be measured in terms of the occupations held by individuals, many researchers theorize that individuals within families share a common class position. Researchers have particularly debated how to define the family-level class positions of married employed women. One position in this debate is that either the husband or the spouse with the dominant class position (i.e., the spouse with the higher position and/or stronger labor force attachment) defines the class position of all individuals in the family, regardless of whether the other spouse also has an occupation. Another view is that the class positions of families are jointly determined by both spouses. These two approaches yield different findings about women's social mobility, and the debate has not been adequately resolved (see Sorenson, 1994).

Although social mobility researchers have mainly debated the problem of determining shared family class positions with respect to class destinations, the problem is equally important when applied to social origins. It is widely accepted that social origins theoretically refer to family class background, not to fathers' class per se. In practice, however, researchers generally define social origins on the basis of a father's or head of household's occupation alone. Although some studies suggest that

both parents' positions matter for children's outcomes, the research consequences of measuring social origins without including mothers' positions have been difficult to assess, in part because of inadequate data on mothers' occupations.

The unresolved debate regarding family level class position is only one of many areas of social mobility research in which further progress remains to be made. For example, a number of scholars have called for social mobility researchers to move beyond descriptive research about social mobility processes (e.g., patterns and extent of mobility) toward more complex issues such as why mobility may be high or low in a given context, or the impact of structural factors that may affect mobility such as the clustering of men and women or racial groups within occupations, occupational segregation, labor market segmentation, or national policies. Although much interesting research remains to be conducted, the lessons of social mobility research to date compellingly illustrate the impact of intergenerational linkages for individuals' life chances and likewise illustrate the importance of national context, historical period, and educational attainment in mediating these intergenerational linkages.

## SOCIAL MOVEMENTS

Humans have always found ways to register their discontent, ranging in scope from jokes and complaints to sweeping revolutions. But in the modern world they have unprecedented access to arenas, resources, ideas, and know-how that allow them to form collective efforts known as social movements. Access to all these ingredients differs according to how old people are and when they were born.

Social movements are sustained and intentional efforts to foster or retard social changes, primarily outside the normal institutional channels encouraged by authorities. For instance, gay rights advocates have used a variety of tactics, from monitoring media portrayals of gay men and lesbians to challenging discrimination to pursuing marriage rights in the courts; at the same time, however, their opponents have tried to fight these efforts and roll back any gains resulting from them. Movements are *sustained* in that they differ from single events such as riots or rallies. Their persistence often allows them to develop formal organizations, but they may also operate through informal social networks. The intentionality of

these efforts links movements to culture and strategy: People have ideas about what they want and how to get it, ideas that are filtered through culture as well as psychology.

Movements have purposes, even when these have to do with transforming members themselves (as in many religious movements) rather than the world outside the movement. Although many scholars view movements as progressive, dismissing regressive efforts as countermovements, this distinction seems arbitrary and unsustainable. Finally, movements are noninstitutional, distinguished from political parties and interest groups that are a regular part of many political systems, even though movements frequently create these other entities and often maintain close relationships to them. Most movements today deploy some tactics within mainstream institutions, and "noninstitutional" protest itself is often quite institutionalized.

## GENERATIONS OF THEORIES

Theories of discontent have always reflected the form a protest was taking at the time, as well as each writer's own sympathies and political participation. In 17th- and 18th-century Europe, thinkers such as John Locke (1632–1704) and Jean-Jacques Rousseau (1712–1778) understood the collective expression of discontent primarily as a battle against tyrannical rulers. The economic and social dimensions of emerging nation-states were not yet distinguished from the political dimensions, so protest was seen as a political act. The concept of the social movement was not yet possible.

With accelerated urbanization in the 19th century, European intellectuals were increasingly alarmed at the regular rebellions of artisans, developing the concept of the *mob*. Crowds came to be seen as a form of madness that caused individuals to act differently than they would when alone. A more sophisticated generation of crowd theorists emerged in the mid-20th century, largely in response to communism and fascism, which were viewed as forms of mass society. Until the late 1960s the dominant view of protest overemphasized the noninstitutional dimension of movements, lumping them together with fads, panics, and other collective behavior. Explicitly or implicitly, crowds remained at the heart of this vision.

Everything changed in the 1960s. Social movements were everywhere, no longer populated by working-class persons but by middle-class faces. Because many of these movements were filled with young people, middle-age scholars often dismissed them as a sign of immaturity or youthful rebelliousness. Many scholars saw these young people as unsure of their identities and in search of an ideology that would provide one (Klapp, 1969). Conservative scholars saw the young populations of less developed nations with even greater alarm, viewing them as potential sources of revolution.

A generation of scholars more sympathetic to protestors prevailed from the 1970s to the late 1990s, highlighting the sustained dimension of movements by linking them to the core political and economic institutions and cleavages of society. No longer grouped with fads, movements were now nearly indistinguishable from political parties. They were thought to reflect deep structural (and objective) interests—especially regarding class, but also gender, race, and (eventually) sexual preference. What mattered most was how they mobilized resources and interacted with government.

Alain Touraine (1977) offered a perspective that linked contemporary movements to social change instead of organizational forms. He proposed that postindustrial societies experienced conflicts over cultural understandings, especially the direction in which a society's increasing self-control would take it. The technocrats of capital and government sought profit and efficiency as ends above all else, whereas protestors viewed these as mere means. They feared that society's goals—democracy, health, quality of life—were being ignored and crowded out. Touraine's vision helped scholars recognize the significance of new social movements, such as ecology, feminism, or gay rights, populated by a political generation less concerned with personal material benefits than its elders.

Inspired by the number of young people involved in the 1960s movements, scholars in the years since have used several different age-related concepts to understand how protest and age are related: youth movements, biographical availability, protest cohorts, and political generations.

## YOUTH MOVEMENTS

Young people have been associated with social change throughout human history. They are prominent actors not only in protest but in wars, revolutions, migrations, urbanization, and technological change. They raise anxieties in their elders, who are never sure that young people will be fully and properly socialized into existing norms, roles, and institutions. They are a frequent subject of moral panics, in which they are assailed for their supposedly deviant music, motorbikes, drugs, clothes, and other aspects of youthful lifestyles (Cohen, 1972). The concept of *youth movements* has proven useful for scholars who study anything from scouting to ethnic and religious groups.

With the expansion of higher education in the affluent world during the 1950s and 1960s, the similar concept of *student movement* emerged as a way of understanding youthful political participation (Lipset & Altbach, 1969).

Some analyses emphasized the ideas to which students were exposed, others their physical concentration, and yet others their lack of a direct economic role during a lengthening period of childhood and adolescence.

Placed together in the relatively sheltered environment of colleges and universities, students had what scholars later came to recognize as free spaces in which ideas about goals and tactics could develop while being sheltered from immediate repression by authorities. In such places, people can develop movement cultures, including an ideology, an emotional sensibility, optimism about change, a collective identity and sense of community, and tastes in tactics. Free spaces foster the democratic skills (public speaking, ability to compromise, and a sense of agency) considered vital to civic participation.

There was an echo of these ideas in the theories of *new social movements* (Melucci, 1980). Many activists in these movements were people in their 30s who had been involved in the student movements of the 1960s and were looking for less dramatic ways to pursue their political goals. Others were too young to have been active in the 1960s and were trying to avoid what they saw as the romantic, utopian hopes (and subsequent burnout) of the earlier movements. This new wave of movements tried to avoid creating media stars—by rotating leadership positions, for instance—and they tried to develop group procedures that encouraged input from everyone (sometimes dubbed the *feminist process*) to avoid even informal domination by a handful of leaders.

## BIOGRAPHICAL AVAILABILITY

The disproportionate participation by young people in many movements is sometimes interpreted as due to their biographical availability. In other words, they have the free time to participate. They are less likely to have a job from which they might be fired, small children to care for, or a spouse with whom they would like to spend time. Biographical availability implies that a person has few countervailing ties to counteract the pull of mobilization. Others have observed that many movements have a disproportionate number of students and the self-employed.

Such factors do not fully account for life course differences in participation, however. After all, retirees and empty-nesters may have as much biographical availability as young people, but it is not clear that their participation rises as a result (although there has been little research on this). Young people may be more likely than older persons to participate in high-risk, high-cost protest activities that might land them in jail or inspire violence from authorities.

Protestors tend to develop tastes in tactics that remain fairly stable as they change from movement to movement, even as they face successes and defeats that might suggest the need to change tactics (Jasper, 1997, pp. 174, 240). They attach moral worth to tactics; means are never viewed as neutral. Such tastes are often specific to cohorts and generations. College students who joined the U.S. civil rights movement, for example, retained a fondness for the kind of confrontational sit-in that they had pioneered, whereas older participants continued to favor marches and lawsuits.

The contrast between these two kinds of effect reflects the difference between aging life course effects and cohort or generational effects, which need to be combined for more robust models (Braungart & Braungart, 1986). College students in the 1960s may have joined the antiwar movement in part because of their biographical availability, but that participation in turn left them more politically radical than the generations that preceded or followed them.

## PROTEST COHORTS

Different people are recruited to movements at different times, forming distinct cohorts that are often age-related. Most protest groups contain rival factions, which may have different goals or different tastes in tactics (Jasper, 1997). Factions often develop as newcomers join a movement, demanding internal as well as external changes. Each new cohort reacts to the existing routines and sensibilities within the movement as well as to problems in the broader society. Movements may grow more radical because of new recruits bringing a more combative mentality to them or because these recruits have identities based on being radical, although other theories emphasize rebuffs by the state as the key source of radicalization. These new radical flanks can have advantages as well as disadvantages.

Nancy Whittier (1995) has described the impact of successive cohorts on the women's movement in Columbus, Ohio:

> Each micro-cohort entered the women's movement at a specific point in its history, engaged in different activities, had a characteristic political culture, and modified the feminist collective identity. Each defined the type of people, issues, language, tactics, or organizational structures that "qualified" as feminist differently. Presentation of self, use of language, and participation in political culture help to identify individuals with their micro-cohorts. (p. 56)

This kind of internal conflict can preoccupy or even destroy a movement, but it can also lead to innovation and clarification.

**POLITICAL GENERATIONS**

The idea that there are political generations marked by formative events is associated with Karl Mannheim (1893–1947), who was primarily concerned with the sources of human knowledge. The concept has remained useful as a way of understanding cultural meanings and collective memories, as events leave a special mark on those who, in late adolescence and early adulthood, are coming of age politically. Wars, revolutions, economic depressions, and other dramatic upheavals define political generations, as, in more modest ways, do smaller events such as a presidential campaign or the assassination of a significant social or political figure.

Mass migrations can also shape the experience of a generation in ways that affect its politics. For example, in the United States during the early and mid-20th century, African Americans left the rural south in large numbers for industrial cities, most of them in the North, generating resources and autonomy that helped produce the civil rights movement.

One key experience that shapes a generation is its political activity early in life. Considerable research has shown that those who were politically active in the generation that came of age in the 1960s have remained more politically active throughout their life course (Fendrich & Lovoy, 1988; Jennings, 1987; Whalen & Flacks, 1984). They remain more knowledgeable about politics and retain some of their early political leanings. They also are more likely to have personal identities that involve politics, the know-how to participate, and ties to social networks of others who remain politically active. Such networks provide both information and emotional encouragement to continued activism. Often, they move directly from one movement to another, related movement, taking their expertise with them; in other cases they remain active even when their movement is in the "doldrums" (Rupp & Taylor, 1987).

Of course, the existence of this political generation does not preclude age effects as well: Their participation has remained high but may also have been channeled into different mechanisms of action at different ages. The same people who, in 1968, were in the streets trying to shut down their universities might now be trying to bring about change by serving on their local school board. Again, age and generation effects interact.

## INTERGENERATIONAL CONFLICT

Although early theories of youth movements tended to see them as the result of immaturity and other psychological dynamics of participants themselves, more recent perspectives find real conflicts between generations. Structuralists tend to emphasize objective conflicts between generations and suggest that age is a core source of inequality in modern societies (Turner, 1989). A number of public policies affect the distribution of rewards and protections to people of different ages. Such policies deal with mandatory retirement ages, pensions, age-related competency, youth unemployment, school spending, and so on. Legislation may prohibit discrimination on the basis of age. Although all societies face issues of how to distribute honor and material benefits across age groups, these issues can inspire mobilization in a world of social movements. In the United States, war veterans and the elderly formed early movements to promote pensions and other welfare-state protections, and they continue to support other groups that pursue their interests.

Attitude surveys have been used in a more cultural approach to intergenerational conflict that emphasizes differences in basic values and political priorities. The largest research project along these lines stems from Ronald Inglehart's (1977) post-materialist thesis that generations of Europeans and Americans born after World War II (1939–1945) developed a feeling of security, or a freedom from warfare and material want, which allowed them to care more about their quality of life. Instead of placing priority on jobs and material well-being, they would criticize industrial society, hierarchy, and pollution in favor of greater political participation, peace, and a cleaner environment. The supposed generation gap of the 1960s and 1970s thus stemmed from differences in basic values. Later generations do not necessarily share the post-materialism of the 1960s generation, however, suggesting that there were special features of the period in which the latter came of age—a generational effect rather than a once-and-for-all change in history.

## FUTURE RESEARCH

A number of themes in current research on social movements are linked to life course research. For example, emotions, a popular topic for research, underlie many of the dynamics of age and generational effects. These might involve basic emotional commitments, such as those to families, friends, and fellow participants. They might involve different emotional reactions to grievances, which might differ by age in kind or intensity. Few have tested the popular stereotypes of younger people as having stronger emotional reactions, for instance, or of older people as more tempered by experience or family obligations. In addition, the events that define political generations are emotional as well as cognitive, often because of the moral shocks they trigger.

Because the current trend in movement research is to emphasize the ways that participants are involved in other institutions, research might investigate how these ties influence protest activities at different ages. Middle-age adults, for instance, might have positions of authority that they can use to further their ends without turning to extra-institutional outlets. The young and the old might lack such positions. The young might also lack resources that would allow them to pursue more institutionalized mechanisms, such as trade unions, again pushing them into noninstitutional means. Young people, however, might be more adept with newer media, such as the Internet, which has proven an efficient means for spreading information and mobilizing people. Research along these lines promises to overcome an unfortunate, inhibiting separation between research on movements and on more institutionalized participation.

Finally, life course research, with its frequent use of robust longitudinal techniques such as panel data, can redress weaknesses in movement research. Much of the latter depends on case studies of movements. When individuals are the unit of the analysis, they are often sampled on the dependent variable: participation. More research is needed comparing those who are mobilized with those who are not, at different points in their lives. Life course and movement research have the potential to interact in promising, fruitful ways.

## SOCIAL NETWORKS

Social network analysis (SNA) provides a direct means for examining the structural foundations of society. A social network is a collection of relationships—referred to as *edges*—connecting individuals, or aggregations of individuals (e.g., schools or businesses)—known as *nodes*. Analyzing social networks allows researchers to shift their focus from nodes and their characteristics to the spaces between them. SNA analysts examine the presence or absence of edges within the spaces between nodes and systematically analyze the patterning of those relationships within a studied population. SNA may include a variety of node types, including people, computers, places, and organizations; they focus on edges including friendship, trade, sex, shared memberships, and conversations. SNA draws on this variety of node and edge types to derive theories and methods that are equally applicable to all potential nodes and edges.

### A BRIEF HISTORY

Historically, social network analysis draws its roots from a range of academic disciplines—with mathematics, anthropology, and sociology playing especially important roles. Early research during the 1920s and 1930s in education research and observational developmental psychology began building the language of *sociometry* to describe formal properties of social organization within small groups (Moreno, 1934). Later anthropologists—along with others studying kinship in the 1940s and 1950s—dominated networks research with an aim to provide general models of the patterned relationships in kinship structures across a wide range of societies (White, 1963).

The 1970s saw a rapid increase in studies incorporating network ideas, shaped in large part by Harrison White and his students. Among the foundational pieces from this period was one of the most readily cited sociological findings—the *strength of weak ties* that demonstrated that people are more likely to benefit in job searches from their acquaintances than from their closer relationships. Granovetter (1973) argued the mechanism for this finding is based on strong personal relationships' likelihood of high redundancy. He shows that weak social ties are much less likely to overlap, therefore branching out into wider ranges of the population, and thus are more productive for seeking novel information.

Simultaneous and subsequent developments in network studies also arose in fields such as developmental psychology, education, communications, business, and most recently—physics and biology (Freeman, 2004). The past few decades have seen rapid growth in the volume of network studies produced and the range of topics they address—including the diffusion of innovations, the spread of infectious diseases, friendship and discussion networks, modes of social influence, interlocking boards of directors, and the evolution of academic disciplines. The formation of the *International Network for Social Network Analysis* and founding of the *Social Networks* journal helped consolidate these disparate scholars and range of topics into a relatively cohesive field (Wellman, 2000). Freeman (2004) provides an illuminating historical social network analysis of the development of the SNA field.

### A NEW PARADIGM?

Social science is driven primarily by only a few prevailing orientations to research—known as *paradigms*, which provide the frameworks within which scientists can produce individually testable theoretical propositions—referred to as *hypotheses*. Further, a paradigm also generally lays the ground rules for the criteria to evaluate those hypotheses—inferring particular methodological approaches. Network scholars have generated numerous theories that have been

readily incorporated into existing models of social science—such as the importance of social capital. Others have suggested that SNA provides only a new methodological tool kit for evaluating the variety of existing social theories. These new methods are important because, although many social theories are fundamentally relational in nature, current methodological approaches focus almost exclusively on individual, independent, unconnected nodes.

However, Wellman and Berkowitz (1988), among others, have consistently argued that SNA provides more than simply new theories and methods. Instead, they contend that the fundamental shift of researchers' focus from nodes to edges lays the foundations for a new research paradigm. Freeman agrees with this notion of networks as a new paradigm for social research, which he outlines as being demarcated by its: (a) focus on the structural properties of patterned links between actors, (b) empirical derivation of those patterns; (c) dependence on the graphical representation of those relationships—both intuitively and illustratively; and (d) use of complex mathematical/computational analytic methods (Freeman, 2004).

## GATHERING NETWORK DATA

To incorporate network ideas into traditional research methods, surveys of individuals can gather information about portions of their respondents' networks, simply treating this *local network data* as they would any other individual characteristic. Local network studies generally collect information about the focal individual—known as an *ego*—and their ties, such as the number and types of relationships they have, descriptions of the others—known as *alters*—with whom they have those relationships, and possibly details about the existing relationships between those alters.

Researchers interested in analyzing connections that extend beyond an initially sampled population typically expand their efforts in one of two ways. *Partial network data* not only collects information from index respondents about their alters, but also subsequently recruits those alters into the study and asks about their relationships—a process that can be repeated as many or few times as desired. Alternately, *complete network data* defines the boundaries of the population to be studied, then enumerates and describes all of the relationships within that entire population.

These three data collection strategies require vastly different techniques and amount of resources to gather (Morris, 2004). They each also produce substantially different types of data, which provide different options from the varied analytic strategies described below. The aims of the research can help the investigators consider these important tradeoffs.

## ANALYZING SOCIAL NETWORKS

The techniques available for SNA are numerous but can be classified roughly into measures that focus on node and edge composition, those that describe node position, and those that describe properties of the full network. Several handbooks detail the numerous strategies and the particular individual metrics available for SNA (Carrington, Scott, & Wasserman, 2005; Wasserman & Faust, 1994).

The first set of measures available provide a means for describing the relations between an ego and its alters. These measures capture properties that describe the composition and distribution of the nodes and edges in this bounded set. One such example calculates the density of ties, which compares the number of ties observed to the number possible. These composition measures can be calculated for local, partial, and complete network data, but the additional measures described later in this entry cannot be calculated for local network data.

When examining partial or complete networks, measures exist for describing both the position of an individual node in the network and characteristics of the entire network. Individual positional measures describe how a particular node is connected to all of the others. Centrality is a common class of measures capturing a node's position, which conceptually measures the node's comparative importance in a network. One conceptualization of centrality is based on how many edges a node has. In addition, the edges in a network can be thought of as pipes through which a *bit* can pass—such as an idea, money, or a disease. With this in mind, other variants of centrality determine the likelihood of a particular node being able to pass that *bit* to other members of the network, or the probability of a bit reaching that node (e.g., transmitting or contracting a disease, respectively). A key insight in network studies is that many individual position measures are not directly related to each other, even within a single class of measures such as centrality (i.e., having many friends is not the same as having the *right* friends) (Freeman, 1979).

Additionally, other measures focus on describing the patterns of connectivity in an entire network. One example of this type—*cohesion*—describes methods for identifying subgroups in a network that are more readily connected to each other than to the rest of the nodes in the network.

Another set of measurements assesses local composition patterns that are known to produce an impact on potential full network connectivity patterns. One of the most common of this type—*transitivity*—takes advantage

of the insight that a friend (*k*) of a friend (*j*) is likely a friend (of ego–*i*), and calculates the proportion of observed edges for all possible node-pairs (*i–k*) in an entire network, given the existence of two edges that share a node (*i–j* and *j–k*) (Holland & Leinhardt, 1972). Virtually all of the measures described here can be calculated separately for undirected edges (e.g., had a conversation) and directed edges (e.g., gave money to); many vary depending on whether analyzed as directed or not.

## NETWORK VISUALIZATION

Network data can be visualized just to illustrate the patterns found in the data, or they can be used as a means to assist in the discovery of those patterns. These visualizations typically use dots to depict nodes and lines connecting those dots to illustrate edges. Early network scholars manually produced visualizations; however, computer routines for producing these representations have become increasingly automated and are even being developed for displaying dynamic networks (Bender-DeMoll & McFarland, 2006). Network visualization techniques employ layout algorithms meant to suppress noninformative patterns, while drawing attention to the meaningful.

## NETWORKS AND LIFE COURSE RESEARCH

Many insights available using SNA have been slow to influence research not explicitly focused on developing network methods. This is largely because population-based studies common in social science use strategies to identify samples, which rarely are able to connect study participants to one another with any relationship information gathered. This limits analytic possibilities only to those developed for *local network data*. To overcome this limitation, institutional settings have been particularly attractive for network data collection, disproportionately including young people (e.g., in schools) and the elderly (e.g., in nursing homes or medical facilities). Further, because network data are often more intensive to gather, network data spanning long periods of extended observation are rare. Because of these limitations, existing work incorporating SNA into life course research typically focuses on networks immediately surrounding specific life course events, rather than network trajectories over the passage of time.

In adolescents, existing studies focus on key transitions and turning points that presumptively shape later life trajectories. For example, one substantial area of literature examines the important roles social networks play in teens' uptake and frequency of substance abuse. Network studies have confirmed that peer friendships substantially influence individuals' decisions to begin smoking and to use other substances. Perhaps more important for later health outcomes is the finding that those who do smoke, drink, or take drugs are more likely to subsequently choose friends who share those behaviors than those who do not (Kirke, 2004). As a result, having started, teens are then more likely to spend time with other teens who also abuse substances, thus decreasing their likelihood of quitting.

The time of sexual debut and subsequent sexual activity is another key transition that generally takes place in adolescence; it has been linked to a variety of later life outcomes. Therefore, many studies have examined the role teens' social networks play in determining the timing of sexual debut, and in regulating who might become potential sexual partners. On the latter point, for example, one study demonstrates that high schoolers' sexual partnering behaviors often adhere to unarticulated local configuration prohibitions (e.g., they do not partner with a former partner's current partner's former partner, described as *avoiding closed four-cycles*) (Bearman, Moody, & Stovel, 2004). This effectively creates *spanning-trees* in connecting most of the sexually active population to each other indirectly (through partners' partners' partners, and so on). This structure has direct implications for the potential spread of sexually transmitted infections in high schools, because those pathogens with long infectivity windows (e.g., herpes or human papillomavirus) are more likely to spread within adolescent populations than other pathogens with shorter windows (e.g., human immunodeficiency virus), which are likely to have a more limited spread because the timing of relationships readily breaks apart long singly-connected chains.

Some work addresses how social network patterns change over the life course, particularly in response to specific age-staged events. For example, studies of *dyadic withdrawal* demonstrate that networks of married and cohabiting people are more constricted than those observed before partnering, and likely increasingly overlap with their partner (Kalmijn, 2003). Furthermore, the segregation of social networks into age homogeneous clusters "reflect[s] institutional, spatial and cultural segregation associated with a tripartite life course" (Hagestad & Uhlenberg, 2005). These age configurations are especially exacerbated in nonkin relationships and slightly muted when limited to kin-only ties.

## NEW AGENDAS

Two of the most important ongoing areas of SNA work are developing methods for analyzing dynamic networks and generating statistical methods for analyzing network data. In addition to expanding the umbrella of SNA, these efforts are also likely to help bridge some of the gaps to more ready inclusion of network ideas into life course research. They happen to coincide with the completion of additional waves of several ongoing longitudinal studies

that have been collecting data for a number of years—such as the National Longitudinal Study of Adolescent Health, which has an explicit focus on gathering network data (Bearman, Jones, & Udry, 1997). Each of these advances combines to provide possibilities for researchers to explore how adolescent social networks contribute to outcomes later in life: both in terms of durability of previously observed behaviors and the contribution of behaviors not observed in respondents' adolescence. These new techniques and newly available data will also provide opportunities to examine how social networks change throughout the life course and the ways those changes differentially influence behavior and trajectories.

### USING NETWORKS FOR GOOD

Valente, Hoffman, Ritt-Olsen, Lichtman, and Johnson (2003) demonstrate that health promotion programs can strategically use the observed structure of social networks to enhance the spread of targeted information. However, the research remains inconclusive regarding how readily these strategies can be applied to efforts that are more general and whether they successfully transition from attitudinal shifts to behavioral change. Present uncertainties aside, more explicitly examining individuals' social network properties, and employing that knowledge in outreach efforts, at worst will help researchers better understand the potential that social networks hold for changing the relational contexts within which people experience critical life events. Further, these approaches may also provide key points of entry (relational, not temporal, although given the advances described earlier in this entry, in the best case scenario, perhaps a combination of the two) into individuals' lives to intervene for altering trajectories or providing alternative means for managing experienced events.

## SOCIAL STRUCTURE/ SOCIAL SYSTEM

The concept of the life course is predicated on an age-graded sequence of events and roles that are embodied in social structures; these structures vary from family relations at a personal or individual level to age-graded

educational organizations at the wider level. Such social structures can shape life-course experiences over time through such social institutions as marriage to shorter transitions in the life course, including those ranging from educational institutions to paid employment. These popular assumptions regarding the life course are nonetheless embedded in wider theoretical underpinnings developed by sociological approaches related to social systems and structures.

Social structure and the subsequent integration with social systems theory are longstanding sociological tenets. *Structuralism* is widely used in the social sciences and that stresses the causal force of the relations among components of an established *system* or in emerging properties with observable patterns. Its application to the understanding of the life course has, however, been less systematic and susceptible to theoretical discrepancies and unanswered criticism.

Various structural approaches are common to anthropology, sociology, psychology, and linguistics. In the first two disciplines, a distinct doctrine emerged that can be traced back to the work of Emile Durkheim (1858–1917) from the turn of the 20th century onward. Structuralism in anthropology in the 1950s and 1960s were inspired by Claude Lévi-Strauss (b. 1908), who was influenced by Durkheim's (1915) *The Elementary Forms of Religious Life*. Durkheim posited that some cognitive structures have the same forms as the components of social elements in everyday life. With more direct relevance to the life course, Mary Douglas (1921–2007) in her 1966 *Purity and Danger* studied social structures in traditional African societies, in biblical-era Judaea, and in modern society. Douglas also hypothesized that people with strong internal and external structural boundaries were more likely to honor clear rites of passage and the rules of taboo.

In sociology, structuralism has experienced a popularity of notable duration. Nonetheless, the underpinning theoretical frameworks have proved to be divergent. A number of early works from a structuralist approach addressed what is now the largely redundant concept of the life cycle. Compared with modern industrial societies, preindustrial communities were understood as displaying a less complex and relatively undifferentiated *cycle of life* and typically involved merely preadult and adult stages (although frequently subdivided into various age-graded sets)—a simple distinction that endured over generations. This basic differentiation was marked out by the near-universal phenomenon of rites of passage.

Writings that emerged from the structural functionalist school of sociology and anthropology enjoyed a noteworthy influence on the study of preindustrial tribal societies—one that accounted for rites of passage largely in social rather than psychological terms. Thus, Alfred Radcliffe-Browne (1891–1955), for example, focused on what he called the "ritual" prohibition that surrounded rites of passage in numerous societies and that served a positive function for African kinship systems among other sociocultural orders (Radcliffe-Brown, 1940).

Possibly the most significant framework, albeit with a significant degree of modification, was Erik Erikson's (1902–1994) eight-stage model of the life cycle. Erikson attempted to present the maturational relationship linking the biological, chronological, psychological, and social aspects of human progress through the life cycle as a fairly universal phenomenon. The most important aspect of Erikson's model, however, was the emphasis placed on the social context by way of significant structural relationships and institutions in which individual development occurred at any given stage. For instance, in the first year of life it was vital that the infant forged a bond of trust with his or her mother. In the next stage of life, the child ideally developed a level of self-control, which, according to Erikson, was important in the wider process of socialization and beneficial normative aspect of social control.

By the 1950s the exploration and account of social structures within sociology became connected more closely with systems theories. Such theories are largely differentiated in the extent to which they emphasize human agency and inherent normative structures in understanding the maintenance of sociocultural arrangements, as well as accounting for social change and transformation. However, the dominant sociological perspective in which the theoretical framework of social systems has been elaborated is that of structural functionalism. To be sure, one of the weaknesses of structuralism and social systems theory in its various forms has been its failure to provide a systematic account of the life course. Nonetheless, it has provided a broad framework by which to understand everyday life experiences in a range of institutional settings, including bureaucracies, educational establishments, the professions, and the family and small groups. It has also furnished insights into life experiences in the context of the dynamics of modernization, social evolution, economic change, and social disequilibrium.

Although structural functional theory has taken various forms, a few basic elements are central to its framework. Theorists who adopt this paradigm focus on the origins and maintenance of the integral and indispensible parts, structures, institutions, and cultural patterns that forge elaborate systems of norms, values, and behavior. In the most detailed formulation of social systems, Talcott Parsons (1902–1979) understood social life to be an aggregate of normative social structures and a functioning system that may vary from one society to another

according to levels of coherence, integration, and performance (Parsons, 1955).

Parsons's major contribution to the theoretical frameworks was in identifying four universal social functions that he deemed universal and indispensable if any social system was to survive ideally as a coherent and functioning whole: *goal attainment* (political and decision-making institutions that are designed to determine societal goals and priorities), *adaptation* (institutions geared to transforming the material environment), *latency* (institutions of socialization and social control), and *integration* (institutions that manage and coordinate numerous social structures and individual agents).

Although providing little by way of a systematic analysis of the life course, Parsons laid the foundations for further theoretical speculation and empirical work not least of all in identifying specific and universal socio-structural patterns that allowed people to make sense of life events and biographically structure their lives. For example, the family, for Parsons, was one of the most obvious institutions in this respect and provided a site of both latency and integration throughout life. The marriage and the establishment of the family of procreation, alongside the nurturing or early socialization of the child, denoted adult maturity and social responsibility for both genders. This was clear in Parsons's (1955) controversial account of the structuring of gender roles throughout the life course. He also maintained that in nuclear families the feminine role is expressive and the masculine, instrumental. Women thereby fulfill internal familial functions; men provide financial support and provide damilial adaptation to the society. The idea of the modern nuclear family, as well as other social institutions, being underpinned by the dominant value of instrumental individualism inspired other commentators in tracing the implications for declining extended family relationships (Beck & Beck-Gernsheim, 2004).

For Parsons, latency varies according to the evolutional stage of any given society. In premodern societies, this function tends to be carried out informally in everyday life in which typically the young learn by the instruction and examples of their elders. In modern societies, according to Parsons, socialization and social control become the preserve of formal educational institutions.

Parsons's discussion of latency also exemplifies how specific social structures or arrangement shape the life course at certain stages of life. Although clearly demarcated rites of passage take initiates from one stage of life to another and have a certain educational function for new responsibilities in premodern societies, in industrialized societies such responsibilities are more likely to be informed by new rights and duties framed in formal regulation related to specific ages. This clearly includes age restrictions related to voting, the age of consent, and marriage. Duties largely relate to civil responsibility in respect of codify laws.

Structural functionalist theories have also been applied to later life and are characterized by Elaine Cumming and Wiliam Henry's *disengagement theory* (1961) and again can be understood in terms of latency and integration. This theory implies that the major social passage in later life allows society to promote its own orderly functioning by removing older people from productive economic roles; such people welcome the opportunity to disengage at a time of declining physical and mental capacities.

Although the life work of Parsons was dedicated to establishing a coherent structuralist theory, his starting point was a general theory of social action in understanding relationships and behavior. In essence, this meant tracing any meaningful human conduct to four basic elements of ends, means, norms, and conditions that implemented action. Despite the attempt to understand social action, Parsonian and other system theories are relatively weak in conceptualizing and taking into account human agency. Thus were developed actor-oriented and dynamic systems theories, including Buckley's (1967), *modern systems theory*, Archer's (1995) *morphogenetic* theory, and the *actor-system-dynamics* (Burn, Baumgartner, & DeVille, 1985) that sought to rectify the perceived weakness of structural functionalism. In turn, few such alternatives systematically addressed the subject of the life course.

To conclude, the attempt to uncover structural determinants of the life course has been handicapped by disagreements among sociologists and anthropologists over the precise meaning of social structure. Without consensus about the important dimensions along which social structures vary, the focus of scholarship has been scattered and has not given rise to many systematic research traditions regarding the life course (although some works specialize in some aspects of it) or to relevant research in countries outside North America and Western Europe.

Other weaknesses are also observable. One problem highlighted in structuralist/social systems accounts of the life course is neglect of the so-called cohort effect, which points to the historical time and place in which experiences of the life course are forged. Another problem involves underpinning typologies: The "traditional" society amounted to a loose, catch-all typology, ranging from tribal groups, to settled agricultural societies, to large-scale feudal orders. This invariably weakened the opportunity to engage in systematic comparative accounts of particular concrete examples. No less troublesome was the typology of "modernity" in which structural/social systems theory was embedded. It is one that, in the

contemporary setting, appears increasingly redundant as a result of the emergence of late or post-modernity that is practically synonymous with the collapse of social structures and increasingly identified with discontinuity, reversibility, and flexible stages of life in respect to the life course.

# SOCIAL SUPPORT, ADULTHOOD

An old Beatles song states, "I get by with a little help from my friends." Most people rely on family and friends for a variety of resources, including help when needed, companionship, and intimacy. Social and behavioral scientists use the term *social support* to refer to the myriad ways that adults rely on and provide assistance to family and friends. The effects of social support on health and well-being have been intensely studied for more than 30 years. Results of those studies generally find that social support benefits physical and mental health and subjective well-being, but there are important definitional and substantive complexities as well.

## DEFINING SOCIAL SUPPORT

Defining social support as the ways in which family and friends assist one another is reasonable conceptually but of limited value for measurement. Early research devoted substantial attention to defining the boundaries of social support and developing ways of validly and reliably measuring it. In the early 21st century there is considerable consensus that two major dimensions underlie the many forms and functions of social support.

One dimension concerns the extent to which social support is an objective phenomenon versus a subjective sense that support is available and of high quality, leading to the distinction between received and perceived support (Krause, 2001; Lin, Ye, & Ensel, 1999). *Received support* refers to the forms and amount of support that individuals obtain from their families and friends. Because it refers to actual supportive transactions, received support is an objective measure, to the extent to which individuals are able to report reliably about it. *Perceived support* refers to individuals' evaluations of the support available to them—whether it is sufficient for their needs, whether it is readily available, and how satisfied they are with the amount and quality of support available to them. Most researchers report that the correlations between received and perceived support are very low (Krause, 2001). Thus, receiving large amounts of assistance from family and friends does not ensure that the recipient feels that support is of sufficient amount or quality. Conversely, many people who receive little or no social support nonetheless believe that more than enough high-quality support is available, if needed.

The second major dimension of social support concerns the specific kinds of assistance provided by family and friends. Three major types of support encompass most supportive transactions (Krause, 2001; Lin et al., 1999). *Emotional support* refers to the various ways that family and friends provide comfort, validation, reassurance, and understanding to the support recipient. *Instrumental support* refers to tangible forms of assistance such as help with meals, housework, transportation, and personal care. *Informational support* refers to the knowledge that family and friends provide to the support recipient. Each type of social support can be measured as either received or perceived. For example, emotional support can be measured in terms of the amount of support received in a given period of time or in terms of the individual's perception of the amount and quality of emotional support that would be available if needed.

## ANTECEDENTS OF SOCIAL SUPPORT

The primary prerequisite for social support is a network of close relationships from which support may be obtained.

Most adults marry and have children—although rates of both marriage and fertility have declined among recent cohorts and rates of divorce remain at nearly 50% of all first marriages (Bianchi, Robinson, & Milkie, 2006). Nonetheless, the majority of adults have family members who are both potential sources and potential recipients of support. Similarly, most adults report having two to five close friends on whom they can depend and to whom they confide their problems (Fehr, 2000). Thus, adults typically have a sufficient pool of family and friends who serve as potential support providers.

The composition of one's social network also has important consequences for receipt of various kinds of support. Simply stated, social networks can take one of four forms: absence of both family and friends, family-based networks, friend-based networks, and networks that contain both family and friends. Lack of family and friends obviously precludes supportive relationships. Conversely, the most functional networks, for purposes of social support, include both family and friends. The more interesting patterns are the two forms of single-source networks. In general, family-based networks provide support for longer periods of time than friend-based networks. On the other hand, friend-based networks typically have access to a wider range of resources than family-based networks (Fiori, Antonucci, & Cortina, 2006).

Although most adults have sufficient family and friends to lay the foundation for supportive relationships, not all people are able to sustain the close relationships required. A few adults lack social networks because of either external constraints or internal dispositions. External circumstances occasionally intervene to diminish social networks (e.g., deaths) or to produce networks that lack the capacity to provide social support (e.g., network members are too impaired to offer support). A minority of adults lack social networks because of their own inability to sustain close relationships. The inability to develop and sustain close relationships is strongly linked to a variety of psychological and social characteristics including attachment style (i.e., secure with and trusting of others vs. distrusting and insecure with others), narcissism, and lack of social skills (Sharabany & Bar-Tal, 1982).

It also is difficult to sustain supportive social networks if one lacks the capacity to provide support, as well as receive it. The norm of reciprocity that dictates a relative balance between benefits given and received in social relationships is strongly endorsed in Western societies (Uehara, 1995). Imbalances can take two forms: Overbenefited individuals receive substantially more benefits from their family and friends than they provide to them, whereas underbenefited people provide substantially more benefits to others than they receive from family and friends. Both forms of imbalance generate feelings of injustice. A long-term pattern of giving more than one receives typically generates feelings of resentment. Sustained receipt of more help than one gives leads to feelings of guilt and dependency. A defining characteristic of intimate relationships is that imbalances in benefits given and received are tolerated for longer than is the case in less intimate relationships. Nonetheless, even the closest relationships can be strained—sometimes to the breaking point—by long-term imbalances in receipt versus provision of social support. Unfortunately, individuals who are mentally or physically disabled invariably need more support from family and friends than they can reciprocate—now or in the future. Consequently, the support available to persons with long-term inability to provide support to others tends to dissipate over time.

## SOCIAL SUPPORT ACROSS THE LIFE COURSE

Although children can provide social support in only limited ways, important aspects of social support begin in childhood, as children are taught norms of commitment to family, sharing, and reciprocity. Perhaps most important, children observe supportive exchanges in which family members participate. Most children first experience the receipt and provision of social support at school and have peer-based social networks in which supportive exchanges are common by the time they are teenagers (Sharabany & Bar-Tal, 1982). Although relatively little research explores the early origins of social support, it is clear that most individuals are quite conversant in the provision and receipt of social support before adulthood (Gottlieb, 1991).

Although adults of all ages are engaged in complex patterns of providing and receiving support, the three major segments of adulthood are distinctive in the size and direction of supportive transactions (Silverstein, 2006). Young adulthood is typically characterized by high levels of receiving social support and relatively low levels of providing support outside the nuclear family. Although young adults typically do not live with their parents, the major flow of social support remains from middle-age parents to their adult children. Support from grandparents also is common during young adulthood. Both older generations typically send resources down the genealogical ladder to help young adults establish stable families and careers.

Middle age is characterized by very high levels of support provision and low levels of support receipt. During middle age, individuals typically provide more

support than they receive to both their young adult children and their aging parents. Health is typically good and resources peak in middle age. As a result, middle-age persons need and receive relatively little social support. During late life, the ratio of support given versus received changes again. Older adults receive more support, especially from their middle-age children, than they did when they were middle-age. Contrary to common stereotypes, however, most older adults remain intensely involved in providing support to younger generations in their families.

In contrast to family-based patterns of social support, patterns of support among friends change little across adulthood (Mulvaney-Day, Alegria, & Sribney, 2007). Support exchanges are more evenly balanced, in terms of the provision and receipt of support, at all adult ages than those observed among family members. The norm of reciprocity is undoubtedly the major explanation for this pattern. Family relationships may become strained if there is a sustained lack of balance between the provision and receipt of social support, but they rarely end as a result of imbalance. In contrast, friendships are less likely to survive when one friend consistently gives more than the other. These patterns reflect the social norms that family ties should persist over the life course—even in the face of long-term imbalanced support. In contrast, friendships are voluntary relationships that can end with relatively few costs.

## CONSEQUENCES OF SOCIAL SUPPORT

Massive amounts of research document the generally positive effects of social support for physical health, mental health, and well-being, but important distinctions and qualifications underlie this general conclusion.

**Received Support** The vast majority of research focuses on the effects of support received from family and friends. Type of support also is important. *Perceived support* and *emotional support* are consistently positively related to better physical and mental health and greater subjective well-being. They also are associated with the prevention of illness and disability (see Cohen, 2004, for a review) and quicker recovery from mental illness (Bosworth, McQuoid, George, & Steffens 2002; Nasser & Overholser, 2005). Evidence about *instrumental support* is more mixed, with effects differing depending on the outcome of interest. Clearly, receipt of instrumental support can be critical in preventing institutionalization of older adults and reducing the need for formal care arrangements (Bharucha, Pandav, Shen, Dodge, & Ganguli, 2004; Gaugler et al., 2000). Long-term receipt of instrumental support, however, has been reported in some studies to lead to decreased feelings of mastery and control and decreases in subjective well-being (Silverstein, Chen, & Heller, 1996; Wolff & Agree, 2004). Erosion of psychological assets in the face of sustained dependency is congruent with the norm of reciprocity. *Informational support* increases the range of coping resources utilized and thus indirectly benefits health and well-being. It has not been shown to directly benefit health, however (Krause, 1987; Stewart & Barling, 1996).

**Providing Support** Although the research base is small, evidence consistently demonstrates that providing support to others benefits not only the recipients but also the provider (Krause, Herzog, & Baker 1992; Lu, 1997). To date, studies of the effects of providing support have primarily examined mental health outcomes. When a loved one needs instrumental support for long periods of time and at high levels of volume, the support provider becomes a caregiver. In contrast to more typical patterns of providing support, care giving often harms physical and mental health (see Pinquart & Sorensen, 2007, for a meta-analysis). Thus, providing support to others—but only at moderate levels—benefits health.

**Methodological Issues** Several important methodological issues must be considered when examining the consequences of social support. First, the effects of social support need to be examined using longitudinal data, or data sources spanning relatively long time periods. Cross-sectional, or single point in time, studies not only fail to provide evidence that social support affects health at a later point in time, but their results are often misleading. It is not unusual, for example, to observe negative correlations between social support and health in cross-sectional studies. This pattern does not mean that support harms health; rather, it reflects the fact that sicker people need more assistance and mobilize their social networks to provide it. Thus, at any point in time, social support is likely to be related to worse health. When longitudinal data are used, however, investigators typically observe that high levels of support protect against the onset of illness and facilitate illness recovery.

Second, and also related to the need for longitudinal data, is the issue of whether social causation or social selection (or both) are responsible for the positive relationships between social support and health. The social causation perspective views social support as the causal agent and health as the outcome. The social selection perspective argues that healthier people are better equipped to develop and sustain supportive relationships. Evidence to date indicates that both processes operate (Johnson, 1991; Wade & Pevalin, 2004). Social selection is reflected in that, as the norm of reciprocity would predict, social support often dissipates in the context of

long-term need for it, but the dominant causal direction is from social support to health.

Finally, there has been long-term debate about whether the effects of social support on health are direct or interactive. Advocates for the direct effects hypothesis argue that social support is always an asset—even when it is not acutely needed, the availability of social support promotes health and well-being. The rationale for the interactive hypothesis is that social support is needed only in times of crisis and it is only in those situations that social support benefits health—a perspective known as the stress-buffering hypothesis. Logically, these are not mutually exclusive hypotheses, and research evidence supports both of them (Hays, Steffens, Flint, Bosworth, & George, 2001; Krause, 2006). In most studies, the direct effect of social support on health is positive and significant. The direct effect of social support on health also may mediate the effects of more distal antecedents of health and well-being. Yang (2006) reported that perceived social support partially mediates the effects of disability on depressive symptoms in late life. Similarly, in a longitudinal study of Swedish men, researchers found that neighborhood-based support mediated the effects of low income on ischemic heart disease (Chaix, Isacsson, Råstam, Lindström, & Merio, 2007). Many studies also report a significant interaction between social support and health, indicating that the effects of social support are stronger during times of crisis.

Given the strong relationships between social support and health, adults would be well-advised to sustain close, personal ties with family and friends. Beyond the pleasure involved, these relationships can help protect health and facilitate recovery when ill. From a policy perspective, it is important that policies support, rather than hinder, preexisting social ties.

# SOCIOECONOMIC STATUS

SEE Volume 2: *Social Class.*

# SOCIOLOGICAL THEORIES

A sociological theory is "a systematically developed consciousness of society and social relations" (Smith 1987, p. 2). Sociology is a multiparadigm science, having developed a number of important general theories. The term *general theory* is used to distinguish theories that aim at a full explanation of why and how societies exist from theories of the middle-range that aim to explain a particular phenomenon and theoretical orientations that serve as guides to research (the life course perspective is an example of a theoretical orientation). Sociological theories may be understood in terms of two competing but complementary commitments: A commitment to science and a commitment to justice. Commitment to science theories focus on discovering general principles of social life without assessing whether outcomes are ultimately just. Commitment to justice theories focus on describing, explaining, and critiquing socially produced inequalities and are frequently spoken of collectively as *conflict theory* because they assume that antagonistic interests are a fundamental feature of social life. Within these two commitments, one can identify a number of paradigms or theories grouped around a shared central concern as presented in Table 1. In addition to these two divisions, social theorists tend to describe a theory as macrosocial or microsocial in its orientation, that is, as concerned with large scale anonymous social structures or with individuals in interaction, and as focused either on agency or on structure.

## COMMITMENT TO SCIENCE: POSITIVISM

All positivist theories share five assumptions: the possibility of objective knowledge, the existence of universally applicable principles of social life, the unity of scientific method, the need for value neutrality, and the goal of creating formal expressions of social theory. The central problematic mission for modern positivism is to create a formal social theory that explains human social behavior and societal organization. Two key modern positivist paradigms are the primarily macrosocial paradigm of structural functionalism and the primarily microsocial perspective represented by exchange, rational choice, and social network theories.

**Structural functionalism** Structural functionalism offers a coherent formal theory focused on the relation between structure and agency, emphasizing structure as the shaper of agency and as functioning to ensure group survival. It proposes a triangular linkage of structure, function, and agency, a theme apparent throughout the work of its major modern progenitor, Talcott Parsons (1902–1979), beginning with his first major work *The Structure of Social Action* (1937). In structural functionalism, *structure* refers to collectively created arrangements generated out of ongoing group life, such as family, education, government, the Catholic church, and gender; *agency* (or action) is behavior undertaken by an individual actor, begun in a situation in which the actor is subject to certain conditions but also has some choice of means (Parsons, 1937) and *function* refers to the consequences of social structures for group life. For instance, gender patterns may be seen as functioning to provide a division of labor within the family. Over time, the concept of function has been elaborated to distinguish among manifest functions (the intended consequences of a structure), latent functions (the unintended consequences), and dysfunctions, which are counterproductive for the society (Merton, 1968). Central to the structural functionalist explanation of the relations among agency, structure, and function are the assumptions that the central dynamics of collective social life are those that serve to reproduce that life and that the conditions constraining agency are the dynamics that create conformity with what is already in place.

***Table 1.*** *An overview of sociology as a multiparadigm science. Boldface indicates that the theory is discussed in the article; italics indicate a middle-range theory.* CENGAGE LEARNING, GALE.

Parsons and his student and colleague, Robert Merton (1910–2003), offer five concepts essential to an explication of structural functionalist theory: social system, hierarchy of control, the functional prerequisites, institution, and status role. *Social system* describes society in terms of the interrelatedness of its parts or structures (the relationships among key institutions that include economy, politics, law, family, education, and religion). A social system is itself defined in terms of agency as "a plurality of individual actors *interacting* with each other" in a situation within normative limits (Parsons, 1951, pp. 5–6). The social system exists in an environment of other systems that affect action, *the hierarchy of control*, which includes nature, human biology, personality, other societies, and culture. All but the last of these extrasocial forces primarily affect the social system as destabilizers of pattern interaction; only the cultural system, the source of values and beliefs, works as a force for stabilizing those patterns.

Structural functionalists argue that if a social system is to reproduce itself, certain needs of group life—the functional prerequisites—must be effectively addressed. Parsons identifies four prerequisites, expressed in a model widely known by the acronym AGIL: *adaptation* to the physical environment in order to meet material needs; *goal attainment*, or collective agreements about priorities and the dispersal of resources; *integration* to settle conflicts between societal members; and *latent pattern maintenance* to transmit knowledge to and manage tensions among group members.

The work of meeting these prerequisites is done by institutions. A pivotal structure that links the social system, the agentic individual, and function, an institution is a complex arrangement of multiple status role sets and of norms, organized around satisfying one or more of the functional prerequisites. The concept of *status-role* incorporates the human actor into the social system. A *status* is a position in a system of relationships, most importantly a position in an institution; and a *role* is the behavior expected of someone in such a position. The interrelation of functional prerequisites, institutional structures, and individual actors in status roles can be conceptualized as shown in Table 2.

**Implications for the Study of the Life Course** Structural functionalism's emphasis on structure can inform the study of the life course in five ways. First, structural functionalism suggests understanding the life course as an institution meeting certain functions of the social system. The life course as an institution serves to meet the function of adaptation: If the primary structuring principle of trajectories across roles is age, then the institutions of the life course adapt to aging, the physiological change over time (a property of the biological system),

| **Adaptation** | **Goal Attainment** |
|---|---|
| Institution: economy<br>Status: worker<br>Role: perform assigned duties<br>Role Set: boss, customers, coworkers | Institution: government<br>Status: legislator<br>Role: to pass laws that will govern the use of society's resources<br>Role Set: fellow legislators,citizen constituents,lobbyists |
| Institutions: family, religion, education<br>Status: mother<br>Role: producing material and emotional stability in the home<br>Role set: husband, children, extended family, friends | Institution: court<br>Status: judge<br>Role: to determine facts and law in conflict between two parties<br>Role Set: plaintiff, defendant, lawyers, other judges |
| **Latent pattern maintenance** | **Integration** |

***Table 2.*** *Functions, Structures, and Individual Actors in Structural Functionalism. This table presents the institutions typically associated with meeting key societal functional prerequisites and suggests possible status roles within that institution.* CENGAGE LEARNING, GALE.

and to the functional needs of the social system. Indeed, the life course may be a meta-institution (a structure that transcends and connects existing institutions) linking the status roles a person plays over the lifetime to the four major functional prerequisites—for example, as a worker in the economy (adaptation); as a citizen in government (goal attainment); as a juror or claimant in the law (integration); or as a parent in the family or a student in education (latent pattern maintenance). This orientation allows one to see how an actor's individual choices over the life course sustain the social system.

Second, structural functionalism conceives of constraints on agency as beneficial for individuals rather than as a necessary sacrifice for the collective good. From Émile Durkheim's (1858–1917) classic formulation of *anomie*, or normlessness, as an unhappy condition—"all man's pleasure in acting . . . implies that by walking he advances. However, one does not advance when one proceed toward no goal . . . or the goal is infinity" (Durkheim, 1972, p. 175)—to the present, structural functionalism views socialization, the process of learning to take and play roles, as liberating humans from the chaos of unregulated desires and impulses. This perspective raises important questions about the de-standardization of the life course and whether the opening up of more options necessarily produces greater happiness.

Third, structural functionalism's elaboration of the experience of role-playing conceptualizes several themes in the life course paradigm, including linked lives and transitions. The experience of playing a role exemplifies the creative tensions in structural functionalism between agency and structure and the theory's significant emphasis on interaction as the fundamental form of the social. Actors do not perform roles alone; roles exist only in terms of relations to others because they arise out of one's having a position in a system of relationships. Within role theory as developed in structural functionalism, the key relationship is the *role set*, that is, the other persons (or positions) one must interact with in playing one's role. When those expectations come into conflict, the individual experiences *role strain*, the condition in which one cannot easily meet all the varying expectations of one's role set for a given status. *Role conflict* arises when two or more of the many statuses an individual occupies generate conflicting expectations, such as is suggested in the status label *working mother*. The experience of transition may be understood through the concept of *role exit,* the process of leaving a role or identity one has previously held for a significant length of time. Life course scholars see the individual trajectory as an age-linked movement from one role to another; structural functionalism's elaboration of the concept of role reveals complications and conflicts that surround both the experiences of duration and transition.

Fourth, structural functionalism offers a nuanced interpretation of the individual-history problematic through a multilevel analysis of the causes of social change. First, individual action may initiate changes in societal arrangements, when, as Merton (1968) points out in his theory of anomie, the goals of action upheld by the culture are out of alignment with people's access to socially sanctioned means to the goals. For instance, a socially-sanctioned goal is college attendance after high school graduation, the person who lacks the means to go to college at this juncture would experience anomie. This structurally produced stress can produce several kinds of individual nonconformity: improvising unapproved means to the goals (innovation), an empty following of means with no belief in the goal (ritualism), an abandonment of goals and means (retreatism), and an active critique of both goals and norms (rebellion). These various forms of nonconformity leach the system of the energy to reproduce itself, and for life course analysts, suggest an explanation of the ways individuals may repattern their trajectories away from conventional paths.

Fifth, social change occurs as an adjustment to changes in the environment of the social system or in other institutions. These adjustments can have a strong impact on the individual life course. For example, as biological changes lead to longer lives and more diseases of aging, the work of the adult family members is redefined to include caregiving to aging parents.

Structural functionalism argues that while structures change, functional prerequisites are a constant. This insight is useful for the cross-cultural or historical

comparative study of the life course, showing, among other things, how valued life skills may change across time and space. For example, to be dyslexic at the court of Charlemagne in the 8th century, where literacy was unnecessary, had little effect on one's life, but to be dyslexic in today's world potentially limits one's access to institutionalized means for achieving success.

**Exchange Theory, Network Theory, and Rational Choice Theory** Exchange theory, network theory, and rational choice theory share four key qualities, although each perspective is distinctive in important ways. First, they all represent a microsocial positivism, seeing individual action and interaction as the foundation of societal arrangements. Second, each builds on a particular social process or structure identified as critical and ubiquitous to social life. For exchange theory this is exchange, defined as an interaction involving the giving and receiving of tangible and intangible goods and services; for network theory it is social relations, understood as empirically observable ties that bind persons and groups to each other; for rational choice theory, it is the actions of rational actors undertaking projects in order to secure objectives judged important in terms of personal hierarchies of good. Third, all three have a studied indifference to the individual psychic processes of meaning-making, concentrating instead on visible activities common to all social actors. Fourth, they all strive for formal theoretical expression, as exemplified by exchange theorist George Homans's (1910–1989) propositions designed to predict behavioral outcomes, such as the success proposition: "For all actions taken by persons, the more often a particular person is rewarded, the more likely the person is to perform that action" (1974, p. 16).

Each theory elaborates the ways these fundamental processes and structures play out in social life. Rational choice theory generally shows human actors engaged in decision-making, assessing—for alternative courses of action—what resources they have, what costs they will incur, what benefits may accrue, and choosing the course that optimizes desirable outcomes. Exchange theorists argue that exchange shapes social structure by giving rise to norms that promote integration and by creating relations of power (Emerson, 1972; Molm, 2001). Group integration is facilitated by the norm of reciprocity, which makes possible indirect exchanges in which persons give in a context that does not allow for immediate repayment; such exchanges, Peter Blau (1977) argues, are only possible if there is a norm of trust, such as that of reciprocity, which says one will repay or be repaid in some equivalent manner at some future date. Power relations in society arise from situations of unequal exchange, where one actor needs something from another but lacks the resources or cannot afford to incur the costs to get it. The first actor may offer the second what Blau sees as subordination—an act of exchange Richard Emerson (1972) describes as creating power-dependence relations. An actor's dependence is determined by the extent to which an outcome the actor wants initiates an exchange with the other. For exchange theory, power-dependence relations are a force for social integration.

Rational choice arose out of utilitarian economics, came into sociology initially as a background presence in the assumptions of exchange theory and became institutionalized through the prodigious efforts of sociologist James Coleman who sought, in part, to craft a theory that would allow sociologists to evaluate a social system in terms of how well it met individual needs. Rational choice theory presents a model of the human actor making decisions by weighing the best means to achieve a self-selected goal. Three facts of human existence impinge on this decision-making: scarce resources (people do not have infinite resources in undertaking a course of action), opportunity costs (costs that result from other goals foregone), and institutional constraints (positive or negative sanctions facilitating some actions and hindering other actions).

Rational choice theory builds its analysis of structure through the concept of the aggregation mechanism by which separate actions by individuals combine to produce social outcomes (Friedman & Hechter, 1988)—outcomes that Raymond Boudon (1982) argues may sometimes be "perverse effects," that is, effects different from what the individual actors in their separate reasoning intended. For instance, individual actors rationally deciding to restrict family size and have only one child per couple can produce a demographic situation of an aging population without a sufficient younger generation to provide care and companionship for the older generation who find themselves 1 of 4 grandparents sharing a single grandchild.

Network theory approaches social structure by looking at the pattern of ties linking its members and at the intensity of those ties. These ties are conceptualized in terms of *deep structures*, patterns of relationship not immediately visible from a surface view of social life; *structural holes*, situations in which no connections exist between actors or groups; *social capital* (an idea initially advanced by Coleman), the resource of being connected to people; and *weak* or *strong* measured by time spent together, emotional intensity, degrees of mutual revelation, and exchange of reciprocal services.

**Implications for the Study of the Life Course** Exchange, rational choice, and network theories offer conceptual frameworks for analyzing the ways individuals make decisions that shape life trajectories—and for analyzing

the effects of these decisions on social structure. For example, individual life courses can be charted in terms of the individual's relation to exchange. In childhood, the individual gives affection and obedience in return to for care (material or emotional). The duration of childhood, defined by this exchange position, depends on both the industrial development of the society and the position of the family of origin within that society. The movement to adolescence is signaled by a sense on the part of all parties that the individual can now participate more equably in exchange, as he or she is able to offer labor and more formulated gifts of affection and service (thus, the driver's license becomes a resource in complex processes of exchange, as does access to the family car).

Adulthood is signaled in most societies by the expectation that the person will be a full partner in both economic and social exchange relations. The maintenance of long-term commitments, such as marriage, depends in part on the parties negotiating a mode of continuous exchange. From this perspective, the illness of a spouse is a major life crisis, disrupting agreed upon patterns of exchange. Retirement also creates crisis because as one moves out of formal economic exchange, one must discover new resources for exchange (e.g., grandparenting, hosting traditional events such as Thanksgiving) or risk an imbalance in power-dependence relations.

Applied to the life course, rational choice theory raises the question of whether the individual involved in making life decisions—to end one role, to begin another, to emphasize one role over another—is doing so in a rational manner as defined by the theory. Equally important is the issue of whether the concept of the life course is undergirded by an assumption of rational choice in decision-making processes—and if it is not, discovering what other processes are at work. The concept of the *aggregation mechanism* has important implications for the dialectic between individual action and social structure over the life course. For instance, there are numerous moments in economic history where an oversupply of workers in some employment sectors seems to have been the result of actors individually evaluating opportunities and rationally choosing a similar career (e.g., teaching or engineering). This "perverse effect" affects both individual life courses—for example, in the inability to find employment in what one has trained to do, disappointment, and irregularity in labor market participation—and social structure (e.g., a higher unemployment rate, too many teachers and not enough nurses, the need to offer retraining).

The major contribution of network theory to the study of the life course is the understanding that life course decisions are affected by social networks and the social capital they embody. For instance, labor market entry may be understood through Mark Granovetter's (1973) hypothesis about the strength of weak ties. Nan Lin (1999) shows that one is more likely to have a weak (rather than strong) tie to someone higher in the status hierarchy than oneself and the possession of this weak tie may prove to be the link that opens the possibility of employment.

## COMMITMENT TO SCIENCE: INTERPRETIVE THEORY

The central problematic of interpretive theory is to create a sociology that takes into account the distinctive human quality of acting on the basis of meaning. This focus gives interpretive theories a bias toward microsociology, the study of individual actors, which produces a secondary concern of how to relate individual action to macrosocial structure. While interpretive theory does not aim, as positivism does, at the production of formal theory, two theories in the interpretive paradigm, symbolic interaction and social constructionism, offer tightly argued statements linking individual action and societal organization.

**Symbolic Interaction** Symbolic interactionism has its primary origin in the work of philosopher George Herbert Mead (1863–1931) who was in debate with the radical behaviorism of psychologist John Watson (1878–1958) (which explains human behavior in terms of stimulus-response and conditioning). Mead sought to establish that mind and self can be studied as behaviors and are social in origin. Mead's work was given its formulation as a sociological theory by his student Herbert Blumer (1900–1987) in *Society as Symbolic Interaction* (1969). The foundational principle of symbolic interaction is that people do not simply respond to stimuli as do other animals. Instead, between stimulus and response, people interpret the stimulus—a process that involves taking the stimulus out of its context and making it an object by assigning meanings to it. People then respond to or interact with others on the basis of the meanings they have assigned. Furthermore, people are able to think and have a self by internalizing the social experience of communication; thus without socially experienced communication, thinking and self are not possible. Mead defines *thinking* as an internal conversation (carried on through the socially acquired symbols of language) and the *self* as a subject which is its own object. Both of these phenomena involve the ability of the individual to bring the social experience of other people into his or her own field of consciousness. This is done primarily through the human capacity for *taking the role of the other*, the process of imagining how the world and one's self look to other people. Essentially to have a self is to be able to see one's

own person as it is seen by other people; to think is to have a conversation between different parts of the self—an *I* that spontaneously proposes action and a *me* that reflects what others would say.

The ability to take the role of the other is not innate but is acquired through socialization, which occurs in three stages: *imitation*, in which a child mimics others without imagining what the action means for others; *play*, in which the child begins to imagine how he or she and the world actually appear to others and to take over some of others' meanings for action; and *game*, in which the child understands the various positions and attitudes of people involved in an activity and can synthesize those to create a sense of the way the community sees him or her and the world.

Society is composed of people engaged in symbolic interaction with each other: that is, people are always stopping and thinking, indicating to themselves what other people have said or done, and then responding. Because the majority of situations in which this happens are recurring, people build up a repertoire of indications and responses and may only experience "stopping and thinking" when a unique or problematic situation presents itself. Nevertheless, symbolic interactionism argues that the process goes on; it only seems automatic because of repetition.

**Social Constructionism** The definitive work in the development of social constructionism is Peter Berger's and Thomas Luckmann's *The Social Construction of Reality* (1966), a synthesis drawing especially on the work of phenomenological social theorist Alfred Schutz (1899–1959) and to a lesser degree on Mead and Durkheim. Social constructionism analyzes the paradox that humans produce a social reality that they come to experience as objective and independent of the producer.

Berger and Luckmann begin with an exploration of how people experience "reality" or things as "real." Following phenomenology (the branch of philosophy that deals with how the mind experiences the world), they argue that reality is conferred by the way consciousness *intends* toward—or pays attention to—an object. Different kinds of intention produce different realities—the everyday life world, the world of fantasy, the world of dreams, the world of scientific theorizing—and thus multiple realities are possible for every individual at any point in time. But the reality that concerns sociology is the reality of everyday life world that is produced by people intending toward the world in *the natural attitude of everyday life*. One feature of the intentionality of everyday life is that people are able to move between two states of consciousness: nonreflection, in which they look outward on the world, and reflection, in which they intend toward themselves, that is, toward their own consciousness.

Within the natural attitude of everyday life, people maintain and produce social reality through three moments in a process: externalization, objectivation, and internalization. Human beings externalize themselves—that is, project their thinking into the world—either through individual actions or group efforts. The products of those externalizations become objectivated in the world—experienced as existing as things in themselves independent of the persons who produced them. Those objectivated products are then internalized as independent realities, by their original producers, other people, and even across generations.

These three moments are ongoing and simultaneously occurring and are presented primarily through the medium of language. Primary socialization is thus the internalization of objectivated typifications—symbolic, usually linguistic, expressions of the essential features of a recurring phenomenon. Through socialization one acquires the relevant parts of the society's *stock of knowledge*, the *typifications* of phenomena, and *recipes* for action. Out of these and combined with group and personal experience, the individual creates a personal stock that guides action in a taken-for-granted manner "until further notice." Problems arise when the individual has experiences for which the stock of knowledge seems to lack adequate typifications or recipes.

These processes occur on the microsocial and macrosocial levels and, over time among larger groups and generations, produce *institutionalization*, the establishment of typified actions by typified actors in typified positions. As new generations question these massively institutionalized structures, *legitimations* are offered to explain why something is done the way it is. These legitimations lead to *reification*, the experiencing of a human product as something beyond human control. From a classroom syllabus to the U.S. Constitution, reification produces a situation in which people experience human products as having a reality beyond human control.

**Implications of Symbolic Interaction and Social Constructionism for Life Course Study** From the perspective of interpretive theory, the individual's negotiation of the life course involves various acts of individual consciousness and interpretation about which six hypotheses seem particularly significant. First, in early socialization the individual needs to acquire a self that has a sense of personal efficacy and achieving this depends in part on the quality of interaction with others. To navigate the life course, people need to see themselves as able to set and execute projects successfully in the world; attaining this self requires that others–particular and generalized–have defined them that way. If one belongs to a category of people defined by others as efficacious—that is, are constantly presented as leaders in cultural expressions such as

newspapers—the individual receives a sense that people like him or her can handle things. Conversely, the absence of such images can make the attainment of self-confidence harder.

Second, crises or turning points in the life course may be produced by failure in role-taking and the lack of an appropriate generalized other. Symbolic interactionism assumes that people unproblematically acquire the skill of taking the role of the other. This assumption is questioned by other theorists, most notably Schutz (1967), who argues that the concept of role-taking is based on the assumption of reciprocity of perspectives, which he believes to be flawed because were two persons to trade places, they would not see exactly the same thing due to differences in biography. This means that role-taking must be an imperfect process. Failures and negative experiences at various moments in the life course may have, as one cause, the inability to correctly take the role of a particular other or a generalized other (e.g., the student who finds they have failed to anticipate what would be on an exam). Thus an important consideration in the study of the life course must be the degree to which an individual can or cannot access the appropriate generalized other or has a wrong or inadequate generalized other for a situation. It can be hypothesized that many people's success—and the ability of professional classes to pass on status attributes to their children—results from their sharing the same generalized other as those in control, and, conversely, the failure of lower-class children may be due to a lack of a compatible generalized other.

Third, the model of primary socialization presented in symbolic interactionism may also be usefully applied to secondary socialization experiences. The stages of imitation, play, and game may describe one's initiation in to any new life stage including being a teenager, getting married, starting a new job, immigrating, or retiring.

Fourth, social constructionism urges a consideration of the life course in terms of the workings of consciousness and the organization of knowledge. If an individual is to have any experience of planful competence, he or she must have the time and space to step out of the demands of lived experience (i.e., of nonreflective consciousness) and switch to reflective consciousness, intending toward themselves as actors of a past or future state. (One cannot, by definition, reflect on the present because one only catches it in consciousness in a next moment—an axiom attested to by the experience of being asked if one is happy and having to stop and think.) Thus, planning in itself, which must involve reflection, may be emotionally frightening because it takes one away from living life.

This alternation between reflection and nonreflection affects a person's whole sense of duration. The time between transitions may at some fundamental level be unclear to an individual if these transitions are nonproblematic, because it was largely lived in nonreflection. Hence, older persons' statements that they do not "feel" older in their internal knowledge of themselves are a function of the inability of consciousness to actually reconstitute the lived, nonreflected upon experience of biologically growing old. Knowing where one is in one's life depends on being able to do acts of reflection that coordinate one's own being at a given moment with stages in the life course as outlined in the stock of knowledge of the society.

Fifth, the crisis nature of even happy transitions such as marriage or pregnancy can be conceptualized in terms of people moving into areas where their personal stock of knowledge is incomplete. Part of a transition involves figuring out how to fill in the perceived gaps in one's stock of knowledge. A person in transition may need to externalize with others about what lies ahead—for instance, expectant mothers in a waiting room or new mothers in a park. They will almost certainly try to discover what exists as objectivations in the culture for this moment—hence the enormous popularity of baby books and general self-help books. In addition, part of the stress of transition may be the feeling of needing to internalize too much too fast.

Sixth, the concept of *stock of knowledge*—and the attendant concepts of *typification* and *recipe*—help the life course scholar analyze the importance of birth cohorts, especially in a rapidly changing society. One of the things that happens across generations is that people do not share the same stock of knowledge. This difference intensifies the inherent problem in *the assumption of reciprocity of perspectives*. A knowledge organization approach may explain tensions between generations, such as with adolescents and parents. Entering a series of new worlds, adolescents find themselves lacking appropriate recipes for success and at the same time discover that their parents seem to be utterly clueless. Looked at from the social constructionist perspective, this seems less a baseless complaint than a descriptor; the parents simply do not have the knowledge that is needed. All of this is complicated by the fact that the development of a distinctive set of typifications is one of the ways that adolescents, or other groups, establish their own identity.

## COMMITMENT TO SCIENCE THEORIES: THEORIES OF THE MIDDLE RANGE

At least three middle-range theories deal with recurring themes in life course study: role theory, reference group theory, and social comparison theory. What these three theories have in common is that they have been

approached from both positivist and interpretive perspectives. The general social theory of ethnomethodology is a useful complement to role theory and has origins in both structural functionalism and social constructionism.

**Role Theory (and Ethnomethodology)** Role theory focuses on how individuals know what to do in a particular status role, which is a question that can be looked at from the perspective of structural considerations for the society or of interpretive problems for the individual. Role theory is based on the recognition that people spend much of their lifetime playing social roles (Biddle, 1986). From the structural functionalist perspective, *role* is understood as the behavior expected of someone occupying a given status in a system of relationships. In the interpretive view, the sense of one's status and role are much more open for negotiation and depend on signals from other people that have to be interpreted. The general thrust of role theory is more in the functionalist direction of role as a set of expectations that are fairly clearly understood or at least understandable, to which people seek to conform and monitor others and are monitored in terms of such conforminty and which are enforced by social monitoring.

Important work related to the question of how people know how to play roles and how they monitor each other is being done in ethnomethodology, a branch of interpretive theory pioneered by Harold Garfinkel (b. 1917). *Ethnomethodology* means "people's methods" and refers to the ways that people figure out what to do in given situations. According to Garfinkel (1967), the original question came to him when he was studying jurors: How did the jurors know that they were "doing juror"? Ethnomethodology suggests that people in everyday life situations appeal to norms in order to make sense of situations. This action of invoking a rule in a specific situation and holding oneself or others accountable for conforming to it constitutes the creation of social reality. A well-known example of ethnomethodological theory is the 1987 paper *Doing Gender* by Candace West and Don Zimmerman, which argues that while people are born with biological gender in some form, what matters socially is the gender category that is assigned to them, usually at birth. Most people pattern their life course, in part, by trying to engage in behavior that fits their gender category. This attempt to fit gender role behavior to gender category constitutes "doing gender." It is possible to talk about the "doing" orientation for a variety of roles, such as "doing student." The concept of "doing" and its attendant concept of accountability offer an important bridge between the fact of status and the execution of role. "Doing gender" can be seen in situations where groups of young women do "girl talk." There exists in that conversational moment expectations of what topics are appropriate, what tone is to be taken toward those topics, what gestures can be made (and the same is true of a group of young men doing "guy talk"). People occupy many status roles over the course of a lifetime, many of them simultaneously. As they try to meet the role expectations of any particular status, or balance the conflicting expectations of different statuses, people may experience role strain, role conflict, role confusion, role distance, and role exit.

**Reference Group Theory** Reference group theory dates to the first generation of U.S. sociologists in the work of William Graham Sumner (1840–1910) and Charles Horton Cooley (1864–1929), but it received an expansion and formulation in the 1950s with Merton's and Alice Rossi's (b. 1922) analyses of findings from Samuel Stouffer's (1900–1960) *The American Soldier* (published in 1949). Over its long use as a concept in American social science, the term *reference group* has spawned at least three different definitions (Shibutani, 1972). Essentially, however, all have in common the idea—central also to social comparison theory—that a reference group is a group that a person or another group takes as a standard for comparison in evaluating themselves, locating themselves in the world, and deciding whether to undertake or avoid certain courses of action. Reference groups are often typed in terms of how they are used by actors: A negative reference group is used to indicate conduct or attitudes one wishes to avoid; a positive reference group, to emulate; a comparative reference group, to get information about some significant dimension of one's own life (e.g., opinions, abilities, plans); a normative reference group, to get a guide to appropriate behavior within a given situation; and an aspiration reference group, to engage in anticipatory socialization.

**Social Comparison Theory** Social comparison theory has focused more on individual motivations and processes in making comparisons. Originally formulated by social psychologist Leon Festinger (1919–1989), social comparison theory began with the proposition that people are impelled to make comparisons in order to understand and evaluate the self, abilities, and opinions. This original concept of motivation has been revised to acknowledge that people may feel so impelled under some conditions, but under other conditions may find themselves presented with comparison data that they do not want (Suls, Martin, & Wheeler, 2000). This latter possibility underscores the enormous power of social comparison. Social comparison theorists have explored the kinds of groups that actors choose to make comparisons to and the conditions under which they choose groups defined as similar to themselves, groups defined as different, groups above themselves in status, and groups below themselves

in status. What emerges from the literature is a sense that, when they have the agency to do so, people are calculating and self-protective in their choice of comparisons.

**Implications for the Study of the Life course** The implications of role theory for the study of the life course have been suggested above: It offers a way to analyze people's experiences of duration and to conceptualize the experience of transition as involving a change in statuses and roles. An additional concept useful in considering the effects of age patterning over the life course is *role distance*, that is, the enactment by an individual in a particular status of behaviors intended to signal that the status does not reflect on her or his true self. The most typical examples of this given in the area's literature involve persons finding themselves momentarily in age-inappropriate roles. Ethnomethodology's concept of "doing" offers a useful lens for describing the work done by people in transition. (One of Garfinkel's first studies was of a young transsexual man in the process of changing himself into a woman.)

Reference group theory and social comparison theory are most significant in attempts to analyze how persons manage transitions. Social comparison theory, in particular, may offer insights into situations that might produce turning points. For example, a person might find themselves confronted with unsought and unwanted data about salary differentials between his or her job and those of another occupation; if the data are forceful enough and perhaps combine with other discontents, the person may feel more impelled toward major change. Reference group theory offers insights into at least one mechanism by which that transition may be planned and accomplished: the selection of an appropriate reference group to provide anticipatory socialization. The classic example is Merton's and Rossi's analysis of Stouffer, which found that enlisted men who eventually gained promotion to officer tended *not* to share the perspective of persons of their own in-group, other enlisted men, but to take on the perspective of the officer class. Changes in reference group may also account for an underexplored phenomenon in the life course—the inability of many immigrants to return to their native countries because their reference group has shifted. Equally problematic is the immigrant experience in which the actor holds to the original, but now irrelevant, reference group.

## COMMITMENT TO SCIENCE THEORIES: INTEGRATIVE THEORIES

The structuration theory of Anthony Giddens (b. 1938) is presented here as an attempt to integrate insights from interpretive theory and from structural functionalism. The concern of structuration theory is to resolve the agency versus structure debate by showing how social analysis can only be effective if both are given equal weight and their relationship understood as a dynamic duality: Social structure enables social action even as social action creates structure.

Structuration theory explores this duality by taking recurrent social practices as its object of study, that is, ongoing social activity patterned across time and space. Social practices are initiated by human actors or agents who are possessed of both consciousness and power. Consciousness is used by social agents not only to monitor the self, but also to monitor the conditions of their activity; power is their capacity for agency, their ability to affect the situations in which they act. But agents for the most part do not create social practices. Much of social practice consists of routines developed over time in response to people's needs for security and efficiency. Most of the time agents perform these actions with a nonreflective mode of *practical consciousness*. Thus, in general, agents reproduce rather than initiate social practices. Agents' actions, however, are always framed by social structures—rules and resources for engaging in practices, so that practices are patterned and similar across time and space.

Giddens (1984) identifies three main types of structures: signification, or the rules and resources of language that make communication possible and both constrain and enable what can be said; legitimation, or rules and resources that produce an ordering of values and standards; and domination, or rules and resources that make possible the exercise of power. These structures, originally arising from agents' needs for routinization, exist only in the moment when they are expressed in social practices, and never as external, determining forces. The concept of *social systems* refers to the most permanent features of social structure, expressed in highly regular and predictable sequences of social practice. Structuration may be seen in the transitional moment of the wedding: The agents (bride, groom, and families), in choosing the pattern of their wedding, even if that choice is to conform to very ritualized traditions, express agency as they reproduce those traditions and may also change structure as they choose to depart from those traditions.

**Implications for the Life Course** Structuration theory may provide a strategy for life course scholars' analyses of how an individual actor shapes a life course trajectory by exercising agency within the opportunities and constraints presented by social structure. The theory suggests that this analysis might focus on social practices, the recurring activities of actors across time and space; such a focus calls attention not just to moments of transition, when agency is high, but to the long periods of duration

when actors enact the life course through the social practices of everyday life, thereby reproducing the social structures that make that life possible. Similar to exchange theory, structuration theory points to the importance of trust in the conduct of social life; *trust* is seen here as an ultimate proof of structure. Action is possible because agents trust that a course of action will in all probability produce a given result, and that trust is based on a sense of prevailing rules and resources. It also seems possible to apply the concept of trust to moments of transition, especially voluntary transition. Here the individual agent must engage in what Giddens calls *discursive consciousness*, that is, one must consider the self as an actor in a situation and calculate what rules may apply and what resources may be forthcoming. This is possible in part because of the transposable rules (structures) that may be applied in a range of situations beyond those in which they were originally learned.

## COMMITMENT TO JUSTICE THEORIES (CONFLICT THEORY)

Commitment to justice theories look critically at socially produced inequalities and see theory as a means of creating a more just world. They describe society as an arena of struggle between unequally empowered groups—hence the description of them as conflict theories. This section describes three conflict paradigms: Marxian and neo-Marxian theory, modern feminist theory, and intersectionality theory.

**Marxian and Neo-Marxian Theory** Focusing critically on material inequality, Karl Marx (1818–1883) and Friedrich Engels (1820–1895) presented a model of society as located in history and divided into a substructure, the material economy of collective human work, and a superstructure, all other social institutions and the body of shared ideas, *ideology*. The substructure gives rise to economic classes, groups with different positions in their work arrangements, and the experiences and interests of classes in turn pattern the content of the superstructure. Throughout history the major classes have been an owner class, which claims as its property *the means of production* (i.e., the resources necessary to make goods and services), and a worker class, which, lacking access to the means of production, survives by selling its labor to the owner class by becoming a means of production. Class struggle between these two groups drives history. In the present historical moment, which is dominated by capitalism, the owner class (or bourgeoisie), in its unending pursuit of wealth through profit, engages in intensifying exploitation of the worker class (the proletariat).

Marx predicted that the revolution of the proletariat was inevitable as capitalists attempted to wring more and more profit out of labor by cutting wages and increasing hours and that such a system would give rise to a new postcapitalist phase in history. The revolution predicted by Marx and Engels has not happened. The central problematic of neo-Marxian theory is to explain why the revolution of the proletariat did not occur. Two different explanations are offered, one by the critical theorists of the Frankfurt Institute and the other by world systems theorists.

Neo-Marxian critical theory is the work of two generations of scholars. The first generation included Theodor Adorno (1903–1969), Max Horkheimer (1896–1973), and Herbert Marcuse (1898–1979), all of whom worked first in Germany and then in the United States after the rise of Nazism; the second, postwar generation works in Germany and its most prominent member is Jürgen Habermas (b. 1929).

The first generation of critical theorists addresses the lack of revolution by elaborating on Marx's concept of the superstructure. They describe their contemporary world as *an administered society*, that is, a nation-state organized to give the illusion of choice rather than real choice. This illusion is achieved by collaboration between government and capitalism. In classical Marxism, the state was seen as just another institution of the superstructure shaped by capitalism, but in critical theory the state becomes an active ally of capitalism. State and capitalism together employ the pathology of hyperrationality, that is, the use of reason to control rather than liberate people by giving people a false sense of options. Workers' capacity for independent thought is further subverted by the culture industry, the mass media that fills their time so completely that there is a loss of *negative space*, the space where people can imagine a world different from the one they are presented with daily. The ultimate product of the administered society is what Marcuse (1964) terms "one-dimensional man." The concept of one-dimensionality is meant to describe a person who is incapable of critique, who is poised for "the spontaneous acceptance of what is offered" (p. 74).

Adorno's (1950) analysis of the genesis of the authoritarian personality parallels Marcuse, but traces the loss of critical thinking to the disintegration of the family under capitalism. The father, rather than being an independent craftsman, is a wage slave and cannot provide an example of life competence for his children, who increasingly turn to charismatic political leaders to make up for this loss. Thus, for critical theorists, the revolution failed to materialize because the workers lost their capacity to think critically about their condition.

The second generation of critical theorists, lead by Habermas, tries to find some hope for change in this dark picture. Habermas argues that negative spaces, with their possibility for critical thought, persist in the *life world*, the world of face-to-face interactions in which people can know each other directly and arrive at a mutual understanding of their lived experience. He argues that they

will increasingly be presented with the *legitimation crises* of the modern democratic state brought on by the contradiction between its claims to aid the people and its structural ties to global capitalism. Legitimation crises may serve as catalysts for the critique and change of the capitalist world in place.

World systems theory shares some of the insights of critical theory, but it answers the question of why history has not evolved, as Marx and Engels predicted, by turning to conditions of the substructure. The primary fact about the organization of the substructure in the early 21st century is that the pattern is global capitalism. Capitalism has experienced unparalleled expansion by reaching out for world exploitation. World systems theory divides the mode of production in global terms, seeing a global division of labor: core areas of capital accumulation that control the means of production; semi-peripheral areas of technically skilled workers who provide the core with certain services; and peripheral areas of low-skilled workers who are used by the core as a source of raw materials and cheap mass labor. This global division of labor is marked by transnational elite solidarity on the one hand and working-class fractures on the other. These fractures are caused partly by a proliferation of organizational positions within production that lead some workers to identify with capitalists and partly by the growth of identity politics, which makes loyalty to other groups (e.g., race, religion) more significant than class identity. Finally, global capital expands markets in three ways: consumerism makes every human being a consumer (even small children); commodification brings value to products, things made to meet the immediate needs of people and not for sale, into the nexus of capitalist production and exchange (such as selling bottled water); and keeps working classes, semi-peripheral, and peripheral areas owing money to capitalists and thus subordinate.

**Feminist Sociological Theory** Feminist sociological theory derives from feminist theory, which has six broad branches: liberal, cultural, radical, materialist, psychoanalytic, and womanist. What follows draws primarily on materialist feminist and psychoanalytic feminism; the former is a reworking of Marxian theory and the latter of psychoanalytic theory.

All feminist sociological theory attempts to present an analysis of society and social relations from the standpoint of women. The first point that must be made, then, is methodological: Feminist sociological theory uses *standpoint epistemology*, that is, it founds knowledge on the assertion that all accounts of the social world are given from a particular location in society and are affected by that location.

From the standpoint of women, society is organized as patriarchy, a system of power relations designed to benefit men in all social arrangements. Feminist sociological theory focuses particularly on the arrangements of production and socialization. Its first approach to the organization of production centers on the everyday, taken-for-granted division of the social world into public and the private spheres—a division traceable historically to the industrial revolution. Social production occurs in both spheres; one key difference between Marxian theory and materialist feminist analysis is the latter's emphasis on the social significance of production done in the private sphere. Both spheres are deeply gendered. The public sphere, where the bulk of paid work occurs, belongs to men as their birthright under patriarchy; women are admitted increasingly but grudgingly as ongoing sexual harassment and pay inequity show. The private sphere, where the bulk of work is unpaid, is assigned to women; they are expected to perform homemaking tasks, which involves housework, reproduction of children, child care, emotional labor, meeting of sexual needs, health care, scheduling, money management, the production of sociality, aesthetic presentations within the house, and so on.

Dorothy Smith (b. 1926) offers a deeper look at this division of production by identifying a second division overlying the public and private division: the division of the world into *the local actualities of lived experience* and *the extralocal relations of ruling*. The local actualities are where material production is actually done and may be public or private; the relations of ruling is where elites interact to produce texts (documents, in the broadest sense) that serve to control the production done in the local actualities; contracts, wage laws, immigration laws, passports, licenses, diplomas, advertisements and so on are all examples of these texts. The relation between private and public and local actualities and relations of ruling may be pictured as shown in Table 3.

| | **Local Actuality of Lived Experience**—product here is material labor | **Extralocal Relations of Ruling**—product here is texts that govern production in local actuality |
|---|---|---|
| **Private** | All women doing work of home with only minimal assistance from men even if women also work in public sphere | Ceremonial appearances to enact heteronormativity—wife standing by erring husband is one typical enactment |
| **Public** | Most men and many women working but men paid more and have more access to more jobs | A few elite men's special province—very few women allowed entry |

***Table 3.*** *The Gender Division of Labor.* CENGAGE LEARNING, GALE.

This gendered division of labor handicaps women's attempts to move from the private to the public sphere and keeps them at a disadvantage in negotiating for wages. At the same time, the work of the home is at once romanticized and trivialized under patriarchy. The woman who works outside the home ends up doing "the second shift" at home (Hochschild & Machung, 1989).

The persistence of such a materially unfair arrangement is explained by the experience of socialization, which in all feminist sociological theory is understood as a deeply gendered process patterned by norms of patriarchy and by the institution of compulsory heterosexuality—that is, making heterosexuality and the heterosexual household the only acceptable way for persons to form homes and experience intimacy. Feminist psychoanalytic theory sees gender socialization as producing a male personality that is equipped for domination, the relationship in which the superordinate makes the subordinate an instrument of his will, a denial of the subordinate's independent subjectivity, and a female personality lacking the psychic energy to resist domination. This socialization is accomplished through differential experiences of and training in recognition, the process whereby one person acknowledges the agency of the other.

This differential experience results from the facts that "women mother" and social structure values men and women differently (Chodorow, 1978). Males are trained to win recognition; to do this, they must separate from the mother, accepting that they are different from the person who provided them with that earliest life-sustaining recognition. To do their duty by their sons, mothers must encourage them to separate at a very young age, leaving them a lifelong hostility toward women. In contrast, females are trained to give recognition as one way of experiencing agency. In adolescence, they are also encouraged to transform themselves from seekers of agency to objects of male desire—an encouragement their mothers are expected to aid in and that leaves the daughter feeling rejected.

**Intersectionality Theory** Intersectionality theory emerged from the joining of Feminist and Africana theory, especially in the work of Patricia Hill Collins (b. 1948). Its central problematic is to explain the way stratification works in the contemporary world. Intersectionality theory begins with the Africana theory conceptions that the essential societal unit is the group, understood as individuals who share a common experience that positions them in the system of social stratification, and that the essential dynamic in society is the interactions among such groups. These interactions, the relations between power and difference, shape history. The world today is organized by hierarchical power relations—a constellation of related practices in employment, government education, law, business, and housing that work to maintain an unjust system for the production and distribution of social resources. These hierarchical power relations reflect and reproduce a matrix of domination, the interaction of multiple practices of stratification, especially among the categories of class, race, gender, age, ethnicity, sexual preference, and global location. Intersectionality is the lived experience of embodying in one's person multiple dimensions of the matrix of domination. Being female and lesbian fundamentally affects the way one can create a family as opposed to the experience of being female and heterosexual; similarly, being female and poor affects the sequence in which one chooses to have children and marry in a way that contrasts with being female and professional class.

**Implications of Commitment to Justice Theories for the Study of the Life Course** The primary implication of commitment to justice theories for the study of the life course is that inequality matters. Inequality is produced by one's position in the system of production: for Marxian theory, the system of capitalism; for feminist theory, capitalist patriarchy; and for intersectionality theory, capitalist-racist patriarchy. Commitment to justice theories focus attention on the causes and consequences of inequality in the individual life course and the life course mechanisms by which social inequality is reproduced from generation to generation.

Classic Marxian theory would analyze the life course in terms of the individual's position in the substructure, beginning with a child being born into a family that occupies a particular position in the substructure—a position that in classic Marxian theory depends primarily on the father's work. This family position patterns interactions among family members and childhood socialization: Working-class parents value obedience in children because that is their experience of what secures them a place in the means of production; professional-class parents value initiative and verbal skills for the same reasons. The child's relationship to the institution of education will be largely dependent on the class position of the family. Adult experiences of sexuality, marriage, childbearing, transitions into and out of work, residence patterns, and the possibility or impossibility of retirement are shaped by position in the economic substructure.

The life course itself would be viewed as an ideology that bestows distinct life expectations to persons according to their location in the class structure. The purpose of life course ideology is to create a satisfied, nonrebellious working class that accepts that its life is as good as it could have hoped and that others who have better lives are entitled to this preferential outcome. Neo-Marxian critical theory would view many stages in the life course as products of the administered society, especially the illusions of choice about schooling, about workforce

entry, and about retirement. Critical theory sees these decisions as managed by a partnership among capitalism, the state, and mass culture to secure a passive workforce.

World systems theory calls attention to both the global nature of the substructural forces shaping individual life courses and the possibility of global mobility as a transition in the life of nearly every person on the planet. A phenomenon once typical of peripheral societies—being born to leave—now is potentially a part of planning in nearly all societies. But all capacity for intelligent individual planning may be corrupted by the erosion of negative space. The culture industry fills people's free time with innumerable images of the life course and becomes a part of many celebrations of life course transitions. For example, movies about weddings constitute an enormous and continuously profitable source of commentary on the life course. This is true not only for commercial films, but of films people make of their own weddings, as if the event would not be real if not captured in a form approved by the culture industry. Finally, life course transitions—birth, birthdays, marriages, anniversaries, graduations, new jobs, retirements, and death—are commodified into occasions to be marked by consumption.

Feminist theory highlights the different life courses of men and women. Under the ideology of patriarchy, women are socialized to a different set of life course expectations than men. Men within patriarchy understand that material success in the world (variably assessed by the classes under capitalism) entitles them and will bring with it the use of a woman. Women are socialized to measure part of their success as having a man who wants them, but that this alone is not connected to their material success—even though relation to a man brings with it a great deal of material responsibility. Men typically experience the self as competent and capable of independent action; women are more likely to experience the self as caring and generous. This means that for a woman, a successful life course requires someone to care for and look after. Women may also experience themselves as less capable of independent action, creating one danger in the female life course—the possibility of an abusive marriage, which the woman hesitates to leave because of lack of material resources, lack of confidence, and concern for how she would care for her children.

Intersectionality theory emphasizes that the life course is determined by the interaction among different vectors in the matrix of domination in an individual life, and that the relative importance of vectors may change over time. Class, gender, race, sexual orientation, and global position are all subject both to change and to change in significance. Gender may become less important as one becomes settled in one's intimate relations; race may affect one's class mobility; and class will almost certainly determine one's old age.

Theory comes from the Greek verb *therein* which means "to look at" or "see" and is also the root for *theater*, a place for viewing. Sociological theory, as a multiparadigm science, offers a variety of positions from which to view the life course. The structural functionalist position illuminates the way the life course functions as an institutional arrangement in the working of the social system. The micro-positivist perspectives—exchange, rational choice and network theories—depict the individual as a decision-maker navigating this institutional arrangement. The interpretive paradigm allows one to see how the individual subjectively arrives at and processes typified understandings of the life course and of their position in it at any given moment. The commitment to justice theories show how socially produced inequalities shape every moment of the individual's experience of the life course and that any generalization about the life course must be qualified in terms of the dictum that "inequality matters."

## STRESS IN ADULTHOOD

The term *stress* is widely used in everyday life, and even scholars have defined and used the term in different ways. However, researchers who study stress have arrived at a general consensus in the definition of the concept. *Stressor* refers to life circumstances that disturb or threaten to disturb the patterns of everyday life. Stressors initiate a process of adaptation to the demands of life. The degree of adaptation required depends on characteristics of the stressor, such as its intensity or duration. Adaptations that evoke changes in psychological and physical functioning are referred to as *stress responses*. The *stress process* refers to people's ongoing adaptation (changes in physical, social, and psychological functioning) to the demands of life. In other words, the stress process is an ongoing system of adaptation to the ups and downs of everyday life; stressors are antecedents of the stress process; and stress responses are the outcomes of adaptation.

### THEORETICAL PERSPECTIVES ON THE STRESS PROCESS

Theoretical perspectives on the stress process emphasize different aspects of the relationship between an individual and his or her physical and social environment.

**Biological Perspective** The biological perspective considers the underlying physiological responses people exhibit when exposed to stressors. Author Walter Cannon (1929) wrote that the body physically prepares to handle a stressor by mounting a short-term defensive response to meet an immediate threat to physical safety. When the brain detects a potential threat, it sends an alert through the

central nervous system directly to major bodily systems (e.g., circulatory, respiratory). In response to this alert, the systems release hormones, called catecholamines, to help the person defend against the threat. This response is commonly referred to as the fight-or-flight response. The catecholamines (e.g., adrenaline) trigger processes that provide energy needed by the body to protect itself by either fighting off the threat or running away. Once the threat ceases, the brain signals the release of different hormones (e.g., noradrenaline) prompting the body to return to its normal resting state (i.e., homeostasis). This physiological response is adaptive, allowing people to successfully manage short-term physical stressors (e.g., a charging woolly mammoth, pulling a child out of deep water, running a race).

Hans Selye (1956) recognized that psychosocial stressors also could trigger the fight-or-flight response and that many stressors may endure over long time periods. Thus, he hypothesized that the body needs an alternative response to fuel a prolonged defense. Selye proposed that an alternative, neuroendocrine stress response meets this need. The brain initiates the release of a different type of hormone (i.e., glucocorticoids) that actually triggers the breakdown of proteins and excess body fats to fuel the body's longer-term response to stressors. However, without adequate recovery time between stressors, the body cannot replenish its supply of excess fats and proteins and will burn up essential body cells, eventually leading to physical illness.

The current perspective on the biological stress response suggests that the normal state of an individual is ongoing adaptation to his or her environment. Referred to as *allostasis*, this ongoing, self-regulating adaptation promotes a balance between complex bodily systems and the demands of a changing physical and social environment. In this sense, responding to a stressor is a within-person, self-regulating process that brings physiological systems back into balance. However, repeated physiological adjustments in response to a lifetime of physical and psychological stressors exact a physical cost on the body, referred to as *allostatic load* (McEwen & Stellar, 1993). It is the physical wear and tear from prolonged or continuous activation of the stress response that increases the risk of physical and mental disease and disorder (Seeman, McEwen, Rowe, & Singer, 2001). Current depictions of the stress response posit an interrelationship between the central nervous and endocrine systems, providing a more complete picture of the integrated pathway by which stressors affect health outcomes. Essentially, the initial response to a stressor is the activation of the central nervous system, with the endocrine system providing a more protracted response to stressors.

The way an individual interprets the surrounding physical and social environment affects the way he or she feels about the current situation. These feelings may prompt physiological changes through two physiological pathways: the central nervous system and the hormonal system. These feelings may also initiate behavioral changes or coping strategies to adapt to the situation. The physiological changes may initiate a change in the functioning of the immune system, which in turn may increase disease susceptibility.

**Sociological Perspective** The sociological perspective on the stress process focuses on the naturalistic causes of stress or, more specifically, on the social and environmental conditions that serve as sources of stress that then influence individual well-being (Pearlin, 1999). From this perspective, key questions relate to the social conditions (e.g., social positions, roles, and challenging life course events) that trigger the physiological stress response and how the availability and distribution of resources affect people's ability to successfully manage stressors. Stress is viewed as a dynamic and ongoing set of interrelationships between the individual and his or her social environment. Although unique circumstances do occur and do affect individuals, research into social stress is concerned with the difficult or threatening circumstances confronted by groups of people who share similar social and economic attributes, that is, the social patterning of stress. Research on social stress also examines the consequences of stress for individual well-being, especially for mental health.

**Psychological Perspective** Whereas the sociological perspective examines the social conditions that create potentially stressful situations and the consequent social patterning of stress and well-being, the psychological perspective emphasizes the internal cognitive and behavioral processes that account for individual variations in response to stressors (Lazarus, 1999). In this sense, the psychological perspective provides a bridge for understanding how life circumstances and physiological responses together affect individual health and well-being. The psychological perspective emphasizes the ways personality and biological factors combine with environmental conditions, allowing people to make meaning of the current situation with respect to individual well-being. Simply put, if an individual perceives a situation as stressful, it is a stressor. Thus, despite similarities among people experiencing a particular stressor, individuals respond uniquely to each situation. A key assumption of psychological perspectives on the stress process is that the ways people think about and interpret the circumstances of everyday life changes their physiological response to those circumstances.

**Integrated Perspective** Although several perspectives are used to study stress, a common goal for all of them is gaining an understanding of how individuals adapt to the changing circumstances of daily life and the impact of that adaptation on well-being across the life course. Rather than being at odds with each other, integrating findings from different perspectives has the potential to provide a more complete explanation of the stress process and to more effectively delineate the impact of social stress on individual health and well-being (Wheaton, 2001).

## TYPES OF STRESSORS AND THEIR EFFECTS ON WELL-BEING

Selye (1956) proposed that anything that initiated a stress response constituted a stressor. Such a broad definition, however, makes it difficult to systematically study the individual components of the stress process. Thus, social stress research categorizes sources of stress to examine their distinct origins and develop better methods for further investigating their consequences. Social stressors are challenging conditions emerging from the social contexts of everyday life, including traumas, life events, chronic demands and strains in specific life domains (e.g., work and at home), and minor interruptions to one's daily routine (daily hassles). Typically, physical stressors (e.g., environmental exposure to hot or cold weather) and psychological stressors that focus largely on one's perceptions of a social stressor (e.g., ruminating and reliving past situations, or catastrophizing about a current situation) are not considered types of social stress.

**Trauma** Extreme events that both overwhelm a person and disrupt the life course (e.g., a violent crime, war, or a life-threatening illness) are referred to as traumas. The magnitude and suddenness of these events may disrupt a person's mental and physical well-being long after the occurrence of the event (Pearlin, 1999).

One often-studied trauma is combat exposure or war stress. Beginning after World War II (1939–1945), systematic research documented the effects of combat exposure on psychological health. This research led to the establishment of posttraumatic stress disorder (PTSD) as a psychological condition (Fontana & Rosenheck, 1994). PTSD is an anxiety disorder observed in persons who have been exposed to an extreme stressor. In addition to its immediate detrimental impact, war stress has the potential for both ongoing disruption to the life course and onset of PTSD symptomatology late in adulthood. The effects of wartime trauma extend beyond people with direct combat exposure. Similar disruptive and long-term effects have been found in both children of military parents (Shaw, 2003) and nonmilitary relatives of military adults. PTSD and other severe psychological disorders also have been associated with exposure to other trauma conditions, including natural disasters and severe physical injury.

**Life Events** Life events are discrete, observable, and objectively reportable changes that require some adjustment on the part of the individual experiencing them. Examples include marriage, divorce, death of a loved one, and loss of a job. Exposure to life events, particularly undesirable and uncontrollable events, is associated with increases in psychological distress. A long research tradition linking life events and depression provides compelling evidence for a direct link between life events and onset of major depressive disorder, especially the onset of one's first major depressive disorder (Kendler, Karkowski, & Prescott, 1999). Stressful life events have also been linked to negative physical health outcomes such as coronary heart disease and other physical disorders, including rheumatoid arthritis (Zautra et al., 1998) and AIDS or HIV (Leserman et al., 1999). Although several studies provide strong support for a link between life event stressors and physical disease and disorders, the findings must be interpreted with caution, as it may be the combination of life events with other factors (e.g., ongoing life difficulties, social support, current health status) that influence health outcomes.

**Chronic Stressors** Chronic stressors are persistent or recurrent life difficulties, including strains in particular areas of life (e.g., job demands and family responsibilities), conflicting social roles (e.g., being a parent and worker), or excessive complexity in everyday life. Chronic stressors activate a prolonged immune response that may lead to physical diseases, including those that suppress immune response (e.g., infection), as well as those that overactivate the immune response (e.g., allergic and autoimmune responses). The open-ended nature of chronic stressors (not knowing when, or if, the stressor will end) may deplete biological, psychological, and social resources and thus be particularly influential in increasing the risk of distress and disease.

Job strain, or the combination of high job demands and low control over those demands, is a typical example of a chronic work-related stressor that contributes to negative psychological and physical outcomes. The effects of job strain may be particularly harmful in high-strain jobs, such as those for service workers and machine-paced operatives (Repetti, 1989).

Caregiving for loved ones is another source of chronic stress. The responsibilities of a primary caregiver include meeting the demands of caring for a loved one with a serious illness as well as the emotional burdens associated with the loved one's increasing physical and mental

impairments. Leonard Pearlin, Joseph Mullan, Shirley Semple, and Marilyn Skaff (1990) referred to the cascading burden of caregiver stress as *stress proliferation*, or managing both primary stressors of caregiving (e.g., tending to the patient's meals, medications, and hygiene) and secondary stressors (i.e., additional demands unrelated to the person's illness). Role strains and resentments are examples of secondary stressors that may emerge when children care for an aging parent (Suitor & Pillemer, 1993).

Although chronic stressors are a distinct type of stressor, there is often an interrelationship between types of stressors. Ongoing job strain may lead to an acute life event, such as job layoff. Alternatively, an acute life event such as a divorce may give rise to ongoing financial difficulties. Thus studies that focus on a single type of stressor may understate the harmful effects of stressors.

**Daily Hassles** Daily hassles are defined as relatively minor events arising out of day-to-day living, such as a last-minute change on a work project or a flat tire. Although they may not have the same impact as a life-altering event, daily hassles do significantly influence daily health and psychological well-being. Studies of daily stress and health provide a unique opportunity to examine the unfolding process of stress adaptation within a person (i.e., how the same person responds to changing conditions) by documenting how a person's reactivity (i.e., how likely he or she is they are to experience distress) fluctuates. Daily diary studies, in which people record their experiences and their reactions to them, offer insight into the dynamic interplay between stressor exposure and reactivity and how the two combine to affect daily health and well-being (Almeida, Wethington, & Kessler, 2002).

To put it another way, everyone has good days and bad days. On good days, a person may be less reactive to experiences; on bad days, he or she may be more reactive. Daily studies also consider how the characteristics of a stressor may trigger different responses, both for the same person and for different groups of people. One study found that the type of daily stressor affected variations in mood (Bolger, DeLongis, Kessler, & Schilling, 1989). Of the 10 categories of stressors studied, interpersonal tensions were the most upsetting for both men and women.

In a follow-up study, David Almeida and Ronald Kessler (1998) found that although exposure to stressors was associated with higher levels of distress for both husbands and wives, wives reported more stressors overall than did husbands. In addition, family demands, arguments with a spouse, arguments with a person besides the spouse, transportation difficulties (e.g., traffic jams, car trouble), and other demands (e.g., those of relatives or friends) were more strongly related to distress for wives than for husbands, whereas work overloads, arguments with children, and financial problems were more strongly related to distress among husbands than among wives.

**Associations among Types of Stressors** Stressors rarely occur independently; one stressor may trigger a number of subsequent stressful experiences. Chronic stressors may lead to more daily hassles or life events. Even minor stressors can increase in intensity by accumulating and disrupting other aspects of a person's life or usurping resources needed to manage subsequent circumstances. Thus, considering the association among the stressors in a person's life is important to understand the effects of stress on health and well-being. For example, ongoing financial strain following a divorce or job loss may be more damaging to individuals health than the actual event itself.

## COPING WITH STRESSORS

Coping typically refers to the things that people do to manage the ups and downs of life. Coping includes both the cognitive and behavioral strategies people use as well as the resources they apply in managing the demands of life.

**Coping Strategies** There are two primary coping strategies: problem-focused and emotion-focused. Problem-focused coping refers to efforts directed at resolving or removing the source of the stressor—for example, taking an alternate route to work to avoid traffic caused by road construction. In contrast, emotion-focused coping strategies address the negative emotions and feelings of distress triggered by a stressor. Rather than feeling frustrated or angry at traffic delays due to construction, a person may tell him or herself how easy the ride to work will be when the road is finished, or use the time to think about the pleasant things that she or he will do when they arrive at home. In these examples, the stressor is unchanged, but the negative reaction to the stressor dissipates.

Much research on coping examines which emotion-focused and problem-focused strategies are effective at minimizing the impact of stressors. Emotion-focused coping strategies are often associated with *increased* distress (Penley, Tomaka, & Wiebe, 2002). Passive coping strategies—for example, avoiding difficult situations rather than dealing with them—have been found to be associated with higher levels of depression and psychological distress. Denial as a coping strategy (e.g., ignoring worsening symptoms or saying that a personal problem "is not real") also may be maladaptive for chronic illnesses because it does not allow for learning to manage the long-term stressor (Burker, Evon, Losielle, Finkel, &

Mill, 2005). In contrast, however, denial may have positive effects for people dealing with certain short-term stressors by diverting attention from the stressor until it has passed. For example, one study found that avoidant coping was most effective in dealing with the stress of donating blood (Kaloupek, White, & Wong, 1984).

Problem-focused coping strategies, such as seeking social support and problem solving, tend to be favored in individual-oriented Western nations. Problem-focused strategies have been associated with better outcomes for patients dealing with a variety of illnesses and also with helping a patient's partner psychologically adjust to his or her loved one's illness (Chandler, Kennedy, & Sandhu, 2007). In general, however, most effective coping responses, particularly to severe stressors, involve multiple strategies (Folkman, 1997).

**Coping Resources** Coping resources are assets people have that may alter their reaction to stressful circumstances. In other words, resources are not the things that people do (e.g., strategies) but rather the things they can apply to meet the needs and demands of challenges. Coping resources may be internal (i.e., within the person) or external (i.e., outside of the person).

*Internal resources* refer to psychological resources that may help or hinder how people cope with stressors. Personality traits are an example of internal resources. Enduring personality traits are typically associated with differing coping strategies. Personality traits are often conceptualized as consisting of five main dimensions: neuroticism, extroversion, openness, agreeableness, and conscientiousness (McCrae & Costa, 1986). In terms of use of coping strategies, emotion-focused coping tends to be used by those with high levels of neuroticism, as well as by those who are open and agreeable. Extroversion and conscientiousness, as well as agreeableness, have been associated with the use of problem-focused coping strategies (Penley & Tomaka, 2002). It is possible that these personality characteristics themselves may serve to either exacerbate or buffer the effects of stress. For example, in an experimental study in which participants were assigned a stressful cognitive task (giving a speech on a controversial topic), people who were extroverted, open, agreeable, and conscientious were more satisfied with their performance on lab tasks than those with high levels of neuroticism. Neurotic individuals also reported more negative emotions such as anxiety, fear, and self-disgust (Penley & Tomaka, 2002). A similar pattern emerges in response to chronic stressors.

Other personality traits also may modify the impact of a stressor. For example, an optimistic disposition buffers the effects of stressors for patients suffering from chronic diseases perceived to be uncontrollable (Fournier, de Ridder, & Bensing, 2002). Whether a person sees events as within his or her control (*internal locus of control*) or outside of his or her control (*external locus of control*) has been shown to affect people's responses to stressors; an internal locus of control is more effective in coping with stressors. Negative events are more strongly correlated with anxiety for people with external, as opposed to internal, locus of control (Sandler & Lakey, 1982).

***Figure 1.*** CENGAGE LEARNING, GALE.

*External resources* refer to the available tangible and social assets people can apply to offset the impact of potential stressors, such as money, social characteristics, and social resources. In their seminal work on the structure of coping, Pearlin and Carmi Schooler (1978) found that certain social characteristics had an impact on coping. For example, pronounced differences were found between men and women. Women were more likely to use coping responses that increased distress, such as selective ignoring, whereas men were more likely to use psychological resources that actually diminished stress reactivity in response to life problems, such as optimism. Additionally, lower socioeconomic status was associated with increased exposure to hardships and more reported stressors. People with lower socioeconomic status were also less likely to possess the necessary resources to buffer the negative distress associated with these hardships. The availability and type of social resources also may contribute to coping differences. *Social resources* refer to the people in one's social network, such as family, friends, and coworkers, who may offer tangible assistance and emotional support.

Some evidence suggests that the potential buffering effects of resources depend on the type of stressors being faced. For example, findings from a study conducted in

England examined the links between psychological resources and illness-related death (Surtees, Wainwright, & Luben, 2006). Findings suggested that a strong sense of mastery was associated with lower rates of death due to cardiovascular disease, whereas a sense of coherence, the belief that the things that happen are manageable and meaningful, was associated with lower rates of cancer death. In a separate study conducted in the Netherlands, researchers found that the psychological resource of self-esteem lessened the effects of cancer and arthritis on depressive symptoms, whereas the psychological resource of mastery lessened the effects of only diabetes on depressive symptoms (Bisschop, Kriegsman, & Beekman, 2004). In contrast, having a partner, an important social resource, lessened the negative psychological effects of a variety of chronic diseases.

## INTERDEPENDENCE OF SOCIAL RELATIONSHIPS AND THE STRESS PROCESS

Considering the interdependence between individual experiences and the experiences of close others is important for understanding both the stressors that people experience and their responses to those stressors. Most human behavior takes place in the context of relationships with others. In virtually every study examining human happiness, satisfying close relationships are an integral component of well-being (Berscheid, 1999). Glen Elder (1999) referred to the interdependence of social relationships as *linked lives*, where the individual life course is influenced by experiences and life transitions of other social relationships. Because of these interdependencies, social relationships play an important part in the individual stress process. Social relationships make it easier to handle the challenges of life, offering emotional and tangible support during difficult situations. Indeed, supportive relationships are associated with decreased risk for morbidity and mortality (Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002).

**Family Relationships** Each stage of the life course is both the consequence of prior experiences as well as the antecedent for subsequent life experiences (Spiro, 2001). Thus, early family life is important for understanding people's responses to stressful experiences. Family interactions establish both the initial trajectory of the life course as well as patterns for managing life experiences. First, biological families determine a person's genetic endowment, which lays the foundation for lifelong characteristics such as disposition or temperament and for predispositions to health conditions such as depression or heart disease. Family relationships and family environments influence the individual stress process in other ways as well, including exposure to different types of stressors, selection of coping strategies, and development of social skills.

Rena Repetti, Shelley Taylor, and Teresa Seeman (2002) considered the long-term effects of growing up in a "risky" family. These authors defined risky families in terms of their relationship interactions, specifically those that have high levels of conflict and aggression or relationships that are cold, unsupportive, and neglectful. Ongoing exposure to conflictual family relationships can literally change the underlying physiological mechanisms for handling even routine challenges by continually activating the stress response. This chronic activation may lead to later deficits in physical health, such as coronary heart disease. These life experiences contribute to early wear and tear on the body, or allostatic load.

Families also may influence the individual stress process by modeling coping strategies and patterns for handling day-to-day life experiences. Once established, coping patterns are difficult to change. Repetti et al. (2002) suggested that growing up in families with high levels of conflict or anger results in the use of less adaptive coping strategies, such as those that focus on reducing tension or escaping from intense emotions rather than dealing with the stressor itself. Although escape from the angry situations in the home may be adaptive for their immediate safety, over the long run these avoidant coping strategies may result in other costs such as social problems with peers and difficulties in problem solving.

Finally, the family environment may influence the development of children's social skills. Repetti et al. (2002) found that children who grew up in risky families had problems processing emotions. Emotion-processing skills are essential for engaging in healthy relationships with others. High levels of conflict in the home may sensitize children to respond to social situations with negative emotions such as anger and anxiety. In adolescence, these children may demonstrate less control over their emotions and less understanding of emotions. Because children model the social behavior that they learn at home, they may develop unhealthy ideas about how relationships work. Indeed, there is evidence that the children of cold, unsupportive, or neglectful parents continued to experience problematic and unsupportive relationships throughout their life (Repetti et al., 2002).

**Romantic Relationships** Studies often find that married people tend to enjoy physical, emotional, and economic advantage, compared to their unmarried counterparts (Coyne & DeLongis, 1986). Romantic relationships can be an important source of social support. For example, one study found that support from a spouse was more strongly associated with life satisfaction and

positive mood than support from friends or family (Walen & Lachman, 2000). This suggests that there may be something unique about the kind of support that a spouse can provide. Unfortunately, interpersonal relationships are not always supportive and may actually be a source of strain. Relationship conflicts are among the most potent of stressors, evoking strong psychological and physiological responses in both men and women (Bolger et al., 1989). Exposure to high levels of stress also may have an impact on the quality of one's relationships. Thus, whereas having a supportive spouse may ameliorate the impact of stress, ongoing exposure to stress may also strain relationships.

**Peer Relationships and Friendships** Friendships are another type of close social relationship that may modify the individual stress process. Social networks that include supportive friends are one of the best predictors of overall life satisfaction and physical health. The presence of a supportive friend has been associated with lower cardiovascular reactivity in response to acute stressors (Kirschbaum, Klauer, Filipp, & Hellhammer, 1995). Similar to romantic relationships, friendships can be sources of both support and strain. Negative interactions with friends are more predictive of depressed mood than supportive interactions.

Much of the literature on the relation between friends and one's stress level has examined the role of friendships during adolescence and young adulthood, particularly in undergraduate samples. Friendships are particularly important during this time in life—perhaps even more important than family relationships. For example, a study that examined first-year college students adjusting to school life found that increased social support from friends, but not the family, was associated with better adjustment (Friedlander et al., 2007). Thus, friends can be a great source of support for managing stressors.

Epidemiological studies on the health of older adults provide substantial evidence that social integration and social support contribute to longevity. In a review of the protective effects of social support from friends and family and the health of older adults, Seeman (2000) suggested that it is the pattern of support received, rather than the source of support, that contributes most to health outcomes. Thus, social support that is perceived as critical, demanding, or conflictual has a negative effect on both morbidity and mortality rates in older adults.

Research on the influence of friends and well-being during middle adulthood is limited, comparing the influence of friends to the influence of others (e.g., spouse or relatives). For example, Pamela Jackson (1992) found that for married parents who are employed full time, spousal support lessened the depressing effects of all types of life strain whereas the support of friends was limited to specific domains (i.e., marital, economic, and health). Additionally, under high-stress conditions, such as those for people diagnosed with AIDS, for example, family support was found to be more important than support from friends (Crystal & Kersting, 1998). In summary, although the importance of friendships on individual health and well-being may be an important resource for managing the individual stress process, additional research in this area, particularly during adulthood, is needed.

## PHYSIOLOGICAL PATHWAYS BETWEEN STRESSOR EXPOSURE AND DISEASE

As described in part above, psychosocial stressors are risk factors for a broad range of physical diseases. Stress-related illnesses include minor physical ailments, such as colds, allergies, back pain, and headaches, as well as severe diseases such as coronary heart disease and cancer. Research has thus focused on the specific physiological processes linking stress exposure and disease.

The physiological response to stressors involves direct stimulation of the central nervous system and a hormonal relay system among three main organs: the hypothalamus and the pituitary gland, located in the brain, and the adrenal glands, located at the top of each kidney. Both the central nervous system and the hypothalamic-pituitary-adrenal (HPA) axis play a vital role in linking stressor exposure to physical health outcomes (Cohen & Herbert, 1996; McEwen, 1998). Much of the research on the link between psychosocial stress and health has focused on the cardiovascular and immune systems, as these two systems are directly involved in the etiology of several disease processes (Cohen & Manuck, 1995).

**Coronary Heart Disease and Stress** Coronary heart disease is the leading cause of death in European and North American populations (Brydon, Magid, & Steptoe, 2006) and is gaining momentum in developing countries. Epidemiological evidence suggests that psychological stress has a profound effect on cardiovascular functioning and the development of coronary heart disease globally (Rosengren et al., 2004). A rich literature documents the association between psychosocial stressors and incidence of heart attack in Western countries. However, an increase in both coronary heart disease mortality and psychosocial stress among eastern European populations, especially middle-aged men (Weidner & Cain, 2003), suggests that the health risk of psychosocial stress extends beyond the border of Western societies. An international study on the association between

psychosocial stress and heart attack in 24,767 people in 52 countries provides evidence for the association (Rosengren et al., 2004). The study found that for people reporting their first heart attack, stressful life events, general stress, and financial stress were more frequent compared to controls. The findings were consistent across regions, genders, and ethnic groups.

Reactivity to stressors is thought to account for the relationship between exposure to psychosocial stress and coronary heart disease. High stress reactivity increases vascular inflammation (atherosclerosis), which in turn leads to a build up of plaque in the arteries (arteriosclerosis), in turn increasing the likelihood of heart attack (myocardial infarction) and stroke. Stress reactivity also increases production of platelets. Platelet activation releases substances into the blood stream that adhere to arteries, which results in plaque buildup and may also account for the association between reactivity to stressors and coronary heart disease (Brydon et al., 2006). Laboratory studies examining the association between reactivity to acute stressors and atherosclerosis find that people who are more reactive to acute lab stressors demonstrate more evidence of cardiovascular disease (Barnett et al., 1997; Player, King, Mainous, & Geesey, 2007).

**Psychoneuroimmunology and Stress** The immune system protects the body from foreign materials, such as bacteria and viruses, by releasing antibodies and white blood cells into the circulatory system. Psychological stressors increase the risk of illness and disease by altering the immune response, making the body less able to defend itself against foreign materials. Research examining these associations since the late 1980s has provided a much clearer understanding of the process (Kemeny & Schedlowski, 2007).

The strongest evidence for a direct link between psychosocial stressors and the etiology of physical disease comes from studies on stress and viral infections, such as colds and the flu (Cohen, Tyrrell, & Smith, 1993). In these experimental studies, healthy volunteers answered questions about life stress and were then inoculated with a virus to examine the impact of stressors on health outcomes. After several days, health symptoms evaluated through both self-report and physiological measures (i.e., blood draws) suggested that exposure to psychosocial stressors increased susceptibility to upper respiratory infection. An association between stressor exposure and other infectious diseases has been documented in both laboratory studies (Kiecolt-Glaser & Glaser, 1987) and in studies on the progression of immune diseases, including HIV and rheumatoid arthritis. Findings from these studies support the idea that exposure to both acute and ongoing stressors contributes to a worsening of health conditions and disease symptoms.

## CONCLUSION

All people, regardless of age, gender, or social situation, face changing life circumstances and are therefore engaged in a process of ongoing adaptation. A life course perspective suggests that researchers study people of varying social and economic backgrounds at different life stages (e.g., childhood, adolescence, adulthood) to identify the kinds of challenges they are facing and the processes they are likely to use in dealing with those challenges. There are several reasons why this life course perspective is vital in the study of stress. First, adverse early-life circumstances (e.g., poverty, abuse, neglect) have both immediate and long-term effects. Second, adaptation to severe, unexpected events may be very different depending on the timing of the event—consider the implications, for example, of the loss of a job in young adulthood compared to the loss of a job near retirement age. Finally, the frequency and type of life circumstances people face as well as the impact on the life course are likely to vary by age, socioeconomic status, gender, and culture. Thus, the study of stress and the life course emphasizes the importance of examining people engaged in ordinary activities of everyday life, so as to enable the understanding of how life circumstances account for exposure to various types of stressors and, in turn, how the availability of resources to combat these stressors contributes to variability in individual health and well-being.

# SUICIDE, ADULTHOOD

Suicide refers to the willful taking of one's life. A life course perspective on suicide helps to address two fundamental questions about the causes of suicide: (a) Are there individual-based factors such as lifelong depression that affect suicide risk independent of stage in the life course, and (b) to what extent do the common transitions in adulthood, such as marriage, parenthood, and employment, predict suicide risk?

## THE PSYCHIATRIC PERSPECTIVE ON SUICIDE

The most well-researched area in adult suicide is the linkage between certain psychiatric disorders and suicide risk. Most suicides result, in part, from a serious psychiatric disorder. For example, in a review of 3,275 suicides, researchers found that 87.3% of the victims had been diagnosed with a mental disorder prior to their death (Arsenault-Lapierre, Kim, & Turecki, 2004). Similarly, E. Clare Harris and Brian Barraclough (1997) systematically reviewed 249 research studies. Of the 44 disorders investigated, 36 were found to significantly raise the risk of suicide. Table 1 provides a summary of the average risk for suicide among people experiencing selected psychiatric disorders in which at least nine studies linking the disorder and suicide were available. For example, on average, major depression increases the risk of suicide 20.4 times, whereas schizophrenia increases it 8.5 times.

| Psychiatric Disorder | Increased Odds of Suicide for Persons With the Disorder vs. Controls | Number of Research Studies | Number of Persons Studied |
|---|---|---|---|
| Eating Disorder | 23 | 13 | 1,300 |
| Alcohol Dependence and Abuse | 6 | 32 | 45,000 |
| Opioid Dependence & Abuse | 14 | 9 | 7,500 |
| Schizophrenia | 8.5 | 38 | 30,000 |
| Major Depression | 20.4 | 23 | 8,000 |
| Bipolar Disorder | 15.1 | 14 | 3,700 |
| Dysthymia | 12 | 9 | 50,000 |
| Mood Disorders | 16 | 12 | 10,000 |
| Epilepsy | 4.9 | 12 | 6,500 |
| Suicide Attempts by self poisoning | 40 | 11 | 8,000 |
| Suicide Attempts, any method | 38 | 9 | 2,700 |

***Table 1.*** *Average risk ratio for selected psychiatric disorders.* CENGAGE LEARNING, GALE.

Substance abuse disorders are among the best-researched disorders. A recent meta-analysis of 42 comparable research studies found that substance abuse disorders increased the risk of suicide above that experienced in the general population as follows: alcohol use disorder 9.7 times, opiate use disorder 13.51 times, intravenous drug use 13.73 times, mixed drug use 16.85 times, and heavy drinking 3.51 times (Wilcox, Connor, & Caine, 2004). A different meta-analysis calculated an annual suicide rate of 193 per 100,000 persons among those with anxiety disorders, including the posttraumatic stress and panic disorders (Khan, Leventhal, Khan, & Brown, 2002). By contrast,

| Group | 1950 | 1960 | 1970 | 1980 | 1990 | 2000 | 2004 |
|---|---|---|---|---|---|---|---|
| White Males | | | | | | | |
| 25–44 | 17.9 | 18.5 | 21.5 | 24.6 | 25.4 | 22.9 | 23.8 |
| 45–64 | 39.3 | 36.5 | 31.9 | 25.0 | 26.0 | 23.2 | 26.1 |
| Black Males | | | | | | | |
| 25–44 | 9.8 | 12.6 | 16.1 | 19.2 | 19.6 | 14.3 | 13.7 |
| 45–64 | 12.7 | 13.0 | 12.4 | 11.8 | 13.1 | 9.9 | 10.1 |
| White Females | | | | | | | |
| 25–44 | 6.6 | 7.0 | 11.0 | 8.1 | 6.6 | 6.0 | 6.6 |
| 45–64 | 10.6 | 10.9 | 13.0 | 9.6 | 7.7 | 6.9 | 8.5 |
| Black Females | | | | | | | |
| 25–44 | 2.3 | 3.0 | 4.8 | 4.3 | 3.8 | 2.6 | 2.9 |
| 45–64 | 2.7 | 3.1 | 2.9 | 2.5 | 2.9 | 2.1 | 2.2 |
| Ratio of Male 25–44 to Female 25–44 Suicide Rates | 2.7 | 2.64 | 1.95 | 3.0 | 3.8 | 3.8 | 3.6 |

***Table 2.*** *Suicide rates per 100,000 By gender, race and age group, adult, 25–64 population, USA, 1950–2004.* CENGAGE LEARNING, GALE.

annual suicide rates for the general population in developed nations typically range between 10 and 20 per 100,000 persons.

Schizophrenia, a condition marked by perceptual distortions of reality including auditory and visual delusions, generally begins to take hold in early adulthood. In case-series studies, an investigator follows a group of people diagnosed as schizophrenic and determines the proportion that die through suicide at follow-up some years later. A review of 30 such studies determined that, on average, 37.7% of male and 27% of female schizophrenics had committed suicide by follow-up, typically 5 to 15 years after the onset of the study. In contrast, only 1 to 2% of the population of developed nations dies through suicide (Lester, 2006).

One investigation exploring the relation between various psychiatric factors and suicide risk involved a large, 18-year study that tracked the lives of 444,297 persons in Denmark, including 21,169 who committed suicide during the study period. Researchers found that the group with, by far, the highest risk of suicide was former mental patients during the first 8 days of being discharged. Their risk of suicide was 278 times that of nonmental patients (Qin, Agerbo, & Mortensen, 2003).

That biological factors are involved in the transmission of psychiatric disorders across generations is consistent with findings on suicide risk within families. For example, persons who committed suicide in the Denmark study were 3.5 times more apt to have had a first-degree relative who also had committed suicide, relative to similar people in the general population.

Although the psychiatric perspective explains much of the variation in adult suicide risk, it does not fully explain secondary variation (or subgroup differences) in risk, such as the large gap in suicide rates between men and women, and the considerable variation in suicide rates over time and among geographic units such as cities, states, and nations. Work on other risk and protective factors needs to be considered to fully understand the causes of adult suicide.

## INDIVIDUAL-LEVEL RISK AND PROTECTIVE FACTORS

**Gender** In what approaches something akin to a social science law, adult males tend to have a suicide rate that is between 2 to 4 times that of adult females. Data on U.S. suicide rates between 1950 and 2004 by race or ethnicity and gender are provided in Table 2.

Researchers have advanced many hypotheses to explain the gender differential in suicide, with these hypotheses drawn from prior research on gender differences in behaviors and attitudes. These behaviors include

factors such as alcoholism rates, which are higher among men, and men's greater knowledge about and ownership of firearms. There are also gender differentials in help-seeking behavior for mental disturbances, such that females have a greater tendency to seek professional help for psychiatric problems. Females also generally have more extensive support networks than males (Stack, 2000). Although these factors help explain the gender gap at one point in time, additional factors are needed to explain trends.

Table 1 shows that the suicide gender gap in the United States changed between 1950 and 2004. For White persons ages 25 to 44, the male to female suicide ratio decreased from 2.7 in 1950 to 1.95 in 1970. From 1970 it increased to 3.6 in 2004. Sociological analysis of this curvilinear relationship has been done both in the United States and in 17 other developed nations. The main explanation for it is that after a critical mass of women enters the labor force, cultural definitions of women's (and men's) role in society change. Cultural approval of women working while raising children was relatively low in the 1950s and contributed to feelings of role conflict between homemaker and worker. However, as the proportion of working women increased, culture defined the working mother in positive terms, lessening any guilt feelings about tension between the worlds of work and family. There is corresponding growth in supportive cultural institutions and patterns such as day-care centers and greater male involvement in housework and childcare. Unfortunately, male suicide rates have held steady or increased as female rates have decreased. This male response is related to declining opportunity for men to enter and advance in managerial professional careers (Stack, 2000).

**Race** Whites generally have had a suicide rate that is double that of African Americans. However, this pattern is somewhat weaker for young adults (see Table 2). The best available national database on suicide is the National Mortality Followback Survey (National Center for Health Statistics, 2000). It contains detailed information on 9,869 adult deaths (ages 18 to 64), including 948 suicides. An analysis of this database found that controlling for 18 other contributing factors, including age and depressive symptoms, White adults were 1.85 times more likely than minorities to die through suicide.

Several explanations have been advanced for the race–suicide relationship. The first such argument posits that societal discrimination against African Americans has contributed to a particular response, the externalization of aggression. Given the history of racial discrimination in the United States, Blacks are more apt to blame others than themselves when confronted with stressful life events. As a consequence, Black homicide rates are five or more times those of Whites. A second argument notes that tolerance of suicide, suicide acceptability, is considerably lower among Blacks than Whites. Finally, religiosity levels are higher among Blacks than Whites. Religions tend to condemn suicide (Stack, 2000).

## LIFE COURSE EVENTS AND SUICIDE IN ADULTHOOD

Suicide rates increase from childhood to adulthood. During the adult years there are life events that act as risk and protective factors for suicide. The more well-researched life events include several regarding measures of social integration, an individuals ties, and social and interpersonal networks that provide emotional support and, hence, reduce suicide risk. Marriage, parenthood, living alone, migration, as well as economic strain, which is shown to increase suicide risk in adulthood, are all areas that have been given specific attention in their relation to suicide prevalence (Stack, 2000).

**Marital Status** During adulthood marriage is a powerful protective factor against suicide. A review of 789 research findings from 132 studies published over 115 years found that 78% demonstrated a link between divorce and increased suicide risk (Stack, 2000). For example, in Austria, divorced persons had a suicide rate of 128.6 per 100,000 compared to 30.5 per 100,000 for married persons. The ratio of the divorced to married rate, the coefficient of aggravation (COA) of 4.22 is in the typical range for adult men in the United States. The COA for men in the United States ranges from 4.58 for men ages 40 to 44 to a low of 3.53 for men ages 60 to 64. For adult American women, the COA varies from a high of 4.15 for women ages 25 to 29 to a low of 2.10 for women ages 60 to 64.

**Cohabitation** Although there is little research on the protective effect of cohabitation on suicide risk, what does exist suggests that cohabitation does not protect as much against suicide as marriage. For example, in Denmark, cohabitants have a risk of suicide 1.54 times higher than married persons, whereas single persons have a risk 3.17 times higher than that of married persons (Qin et al., 2003).

**Living Alone** Living alone contributes to suicide through minimizing emotional support from intimate relationships. An analysis of the National Mortality Followback Survey determined that after controlling for depressive symptoms and 17 other predictors of suicide, persons who lived alone were 1.58 times more likely to die through suicide than those not living alone (National Center for Health Statistics, 2000).

**Parenthood** Dating back to early research conducted by French sociologist Émile Durkheim (1858–1917), sociologists have documented the tendency for married persons with children to have a lower rate of suicide than married persons without children. For example, in Denmark, parents with a young child are 50% less apt to commit suicide than parents without a young child (Qin et al., 2003). Ties to children can increase purpose or meaning in life and increase the odds of going on with life in the face of adversity—for the sake of one's children.

**Migration** Persons who migrate, especially over long distances, break ties with friends, extended family, coworkers, and other sources of social support. Although not as well-studied as marital ties, migration tends to be related to suicide risk. For example, controlling for depression and 17 other predictors of suicide, an analysis of the National Mortality Followback Survey determined that persons who changed residence in the previous 12 months were 4.32 times more likely to die through suicide than persons who did not move (National Center for Health Statistics, 2000).

**Religiosity** A large body of sociological research has found that the higher a person's level of religiosity, the lower their suicide risk (Stack, 2000). Religions tend to condemn suicide as a sin, promote social networking and support among coreligionists, and offer a variety of beliefs (e.g., a pleasant afterlife), which can act as coping mechanisms in times of adversity. For example, in the National Mortality Followback Survey, controlling for the effects of 18 other predictors including depression and living alone, persons who reportedly were active in religious activities had an 18% lower probability of dying through suicide (National Center for Health Statistics, 2000).

**Socioeconomic Status** Measures of economic strain generally raise the risk of suicide by creating an environment marked by hardship and disappointments. Variation in risk of suicide among adults is associated with variation in income levels. For example, a large, over-time study of suicides in Denmark determined that persons in the lowest quartile in income were 5.52 times more apt to die of suicide than persons in the top quartile in income (Qin et al., 2003).

**Job Demotions** The limited research on downward social mobility indicates that job demotions increase suicide risk. An analysis of the National Mortality Followback Survey determined that persons who were demoted at work had a suicide risk 5.06 times greater than those who were not demoted in the past 12 months (National Center for Health Statistics, 2000).

**Unemployment** Being out of work raises the risk of suicide independent of depression and other predictors of suicide. For example, marked differences exist in London, England, where the suicide rate of the unemployed was 73.4 per 100,000 compared to 14.1 per 100,000 for the general population. Controlling for 12 other socioeconomic predictors of suicide, unemployed persons in Denmark were 18% more apt to die through suicide than fully employed persons (Qin et al., 2003).

**Opportunity Factors** Suicide rates reflect contextual factors that provide the opportunity for suicide attempts. For example, an analysis of the National Mortality Followback Survey found that, controlling for depression and 17 other predictors of suicide, persons who had a gun available in their homes were 3.41 times more apt to die through suicide than persons with no gun available (National Center for Health Statistics, 2000).

## COMMUNITY-LEVEL PREDICTORS OF ADULT SUICIDE

Many of the individual-level predictors of suicide risk have been used to predict the suicide rates of cities, counties, states, and nations. For example, divorce rates of the 50 American states, in each of five census years during 1940 to 1980, were the single best predictor of state suicide rates (Stack, 2000). At the community level, divorce rates measure not only low levels of social integration among the divorced members of the state but also problems in intimate relationships (including marriage) in general. For example, the classic work of Durkheim (1966/1897) on suicide took divorce as an index of a trend in society toward individualism, where people pursue their own self-interests and are guided less and less by traditional ties to groups such as marriage, religion, and other institutions. It should be noted that divorce rates are often found to be correlated with other characteristics of states such as income level, but the association between divorce rates and suicide rates remains strong even after these covariates are controlled.

**Imitation** At least 105 studies to date have explored the association between the appearance of widely publicized suicide stories and suicide rates. Evidence supporting the existence of imitation or copycat effects includes a study based in New York City around the time of the publication of Derek Humphry's (b. 1930) *Final Exit* in 1991, a book advocating suicide among terminally ill persons by plastic-bag asphyxiation. Researchers found that suicide by this method increased by 313% and that 27.3% of these suicides were found with a copy of the book next to

them. However, many studies report no copycat effect. Among the most likely stories to trigger copycat effects are those concerning well-known celebrities such as entertainers and political officials. A meta-analysis of 419 research studies on copycat suicides determined that investigations that explored the impact of the suicide of a well-known celebrity were 5.27 times more apt than other studies to report a copycat effect (Stack, 2005).

## PREVENTION AND TREATMENT POLICY

In 2002 an estimated 877,000 persons committed suicide worldwide. In response to suicides, many countries have developed suicide prevention and treatment programs. Prevention programs include suicide educational programs in the schools, education of primary care physicians regarding suicide risk assessment, and general public education through the media concerning signs of suicide risk. Treatment programs have included pharmacotherapy using antidepressants or antipsychotic drugs and psychotherapy, including alcoholism treatment programs and cognitive-behavioral therapy. Means restrictions programs have attempted to lower suicide rates by limiting access to highly lethal means of suicide (e.g., gun control). The effectiveness of these suicide prevention and treatment programs is rarely evaluated. Based on the limited evaluation research available to date, some of the more promising suicide prevention strategies are further educating primary care physicians so they are more able to detect suicide risk and the restriction of lethal means of suicide (Mann et al., 2005). Evaluation research of media education and school-based suicide prevention programs is needed to fully assess their effectiveness in preventing suicide.

Treatment for suicidal persons with mental disorders, such as schizophrenia and affective disorders, includes both drug and talk therapies. Lithium has been used for more than 50 years as a biochemical treatment for persons with affective disorders (including borderline personality disorder). A meta-analysis of 31 research studies, which collectively covered 85,229 persons, found that the overall risk of suicide among those treated with lithium was 4.91 times less than those not treated with lithium (Baldessarini et al., 2006). A review of 32 of the most comparable and rigorously designed studies (randomized trials) found similar results: 1,389 patients with mood disorders (including forms of depression and manic depression) were randomly assigned into a lithium treatment group and placebo-receiving group. The probability of death through suicide was 74% less in the lithium treatment groups (Cipriani, Pretty, Hawton, & Geddes, 2005). Still, even with lithium treatment, persons with psychiatric disorders had a relatively high suicide rate.

Suicide rates do not vary considerably during the adult years of the life course. However, adults have a much higher rate than children. In turn, midlife male rates are considerably lower than those of elderly males. Within the stage of midlife, however, groups with relatively high suicide risk include persons diagnosed with manic depression or schizophrenia, divorced persons, persons who are demoted in or lose their jobs, persons who migrate long distances, Whites, and males. The average age at suicide is 44. Hence, whereas the elderly have a higher suicide rate, people in midlife account for the majority of suicides in the United States. This social fact is expected to begin to shift as the large cohort of baby boomers enter their retirement years beginning in 2012. As the proportion of elderly approximately doubles over the next generation, the mean age of suicides is expected to be much higher. As a consequence, adults in midlife will account for a lower proportion of suicides than they do at present.

## TECHNOLOGY USE, ADULTHOOD

**SEE** Volume 2: *Media and Technology Use, Adulthood.*

## TIME USE, ADULTHOOD

Time is an essential resource in modern life. More Americans say they are concerned about the lack of time than say they are about the lack of money. Benjamin Franklin's adage that "Time is money" has taken on a new meaning, with the advantage of time being that it is equally distributed to everyone (at least in the short term). How a society uses its time provides a behavioral window on its values and attitudes, and time use data identify the important lifestyle changes that occur across the life course, especially as one takes on the social roles of spouse, parent, or other caregiver.

### MEASURING PEOPLE'S TIME USE

One of the challenges in studying how individuals use their time is measuring the use of time. Researchers use a variety of methods to measure time use: direct observation (shadowing), on-site verification, "beeper" studies, and respondent recall or estimates, among others. Prior to the 1960s most information about time use was obtained from surveys that asked respondents to estimate the hours they typically spend on some activity such as working or watching TV. These self-reported measures were often subject to errors in estimation and recall, and this method provided relatively little information on daily activities not included on the survey.

Researchers thus have begun to depend more on the time-diary method, which enables them to assess more precisely the time one spends in all daily activities. More important, time diaries suggest a somewhat different set of conclusions about almost all aspects of daily life (decreased free time, increased sleep, among many others) than research using time estimates or other measures (see Robinson & Godbey, 1999, for evidence of counterintuitive trends in increased free time, childcare, and fitness activity in society).

In the time-diary method, respondents provide complete accounts of what they do on a particular day and for the full 24 hours of that day. Respondents take the researcher step-by-step through their day, describing everything they did from the time they woke up until midnight of that day. The researcher also learns about where people spent their day, whom they were with, and what other activities they were involved in during their main activities (multitasking). Because these data are intended to represent complete accounts of daily activity, diary data can be used to generate estimates of how much societal time is spent on the complete range of human behavior—from work to free time, from travel to time spent at home. Because they are complete, diary data can address most issues about various policy implications of daily activity in society, from the time children spend doing homework, to the amount of sleep people get, to how much they are working long hours.

**Features of the Time Diary** The time-diary approach follows from the first American diary study, done as part

of the most extensive and well-known of diary studies—the 1965 Multinational Time Budget Study (Szalai, 1972). In that benchmark study, roughly 2,000 respondents ages 18 to 64 in urban employed households from each of 12 different countries kept a diary account of a single day, with each day of the week equivalently represented; in subsequent U.S. studies all seasons of the year were covered as well. The purpose of this research design was to ensure that the data truly were a representative snapshot of American life, both during weekdays and weekends, as well as throughout the calendar year.

Respondents using the time diary sometimes have some recall difficulties, but these are small compared to the task of making estimates of past time use over a long time period. The diary keeper's task is to recall all of one day's activities in sequence, which may be similar to the way most people store their activities in memory. Rather than having to consider a long time period, the respondent need only focus attention on a single day (i.e., yesterday). Rather than working from some list of activities whose meanings vary from respondent to respondent, respondents simply describe their day's activities in their own words. The open-ended nature of activity reporting means that these diaries are also automatically geared to detecting new and unanticipated activities (e.g., in past decades, aerobic exercises and use of e-mail, VCRs, and other new communications technologies).

The diary technique also provides respondents minimal opportunity to distort activities in order to present themselves in a particular light. They are not told about a study's interest in one activity or another, because the diary is a simple record of any and all activity. Some respondents may wish to portray themselves as hard workers or light television viewers, but to do so they must fabricate the activities that precede and follow it. Further, a time-diary represents a one-day account, and on any given day respondents likely realize that on a particular day they may work less or watch television more than usual. Moreover, respondents are not pressured to report an activity if they cannot recall it or do not wish to report it.

In sum, the time diary is a microbehavioral technique for collecting self-reports of an individual's daily behavior in an open-ended fashion on an activity-by-activity basis. In this way, the technique capitalizes on the most attractive measurement properties of the time variable, namely:

- All daily activity is potentially recorded and must sum to 1,440 minutes of the day.
- The "zero sum" property of time is preserved, so that if time on one activity increases, it must be balanced out by decreases in some other activity.
- It uses an accounting variable, time, that is maximally understandable to participants and accessible in memory.
- The open-ended activity reporting allows one to detect new and unanticipated activities.

## EARLIER DIARY SURVEYS IN THE UNITED STATES

There have been roughly decade-interval (1965, 1975, 1985, 1992–1995, 2003–2005) time-diary surveys from which to make trend comparisons, although time-diary interviewing has generally moved from face-to-face personal interviews to telephone interviews and from "tomorrow" diaries to "yesterday" diaries (rather than asking participants to keep a leave-behind diary to be filled out tomorrow, asking them simply to recall what they did yesterday).

**1965 U.S. Time-Use Study** In the fall of 1965, as part of a multinational time-use study, the University of Michigan Survey Research Center (SRC) surveyed 1,244 adult respondents, ages 18 to 64, who kept a single-day "tomorrow" diary. The interviewer visited respondents and explained the procedure then left the diary to be filled out for the following day. The interviewer then returned on the day after the "diary day" to collect the completed diary.

**1975 U.S. Time-Use Survey** In fall 1975, the SRC surveyed 1,519 adult respondents and 887 of their spouses, who provided retrospective "yesterday" diaries. These respondents were subsequently reinterviewed in the winter, spring, and summer months of 1976, mainly by telephone.

**1985 U.S. Time-Use Survey** In 1985 the SRC collected single-day diaries from more than 5,300 respondents employing the same basic open-ended diary approach as the 1965 and 1975 studies, using personal, telephone, and mail-back diaries for either yesterday or tomorrow.

**U.S. Time-Diary Collections in the 1990s** Two diary studies were conducted by the SRC by national random digit dial telephone procedures between 1992 and 1995, one with 9,386 respondents and the second with 1,200 respondents. All interviews in both phases used the retrospective diary (or yesterday) method for the previous day. Two further yesterday studies were conducted by the University of Maryland, one in 1998 ($n$ = 1200) and the other in 1999–2001 ($n$ = 978).

**2003–2005 Bureau of Labor Statistics Diary Study** The Bureau of Labor Statistics has collected over 60,000 daily diaries continuously since 2003, using the telephone

## PATTERNS OF TV VIEWING

National trend data in the United States indicate that television has had more of an impact on daily time use than any other household technology and that it continues to account for more than half of Americans' free time. Moreover, time spent watching television has been minimally reduced since the advent of the Internet and other new IT. Early multinational data indicated that television initially drew time away from "functionally equivalent" activities such as movies, radio, and print fiction—and more recently from newspapers. It also appears to have drawn time from activities that are less clearly functional equivalents, such as sleep and grooming (see Robinson & Godbey, 1999).

The main increases in viewing time occurred in the 1970s, apparently related to the availability of color television, although television has made persistent but smaller inroads on free time since that time. As was true in that period, time-diary studies show that less television time is correlated with less time working and traveling, so that people who are at home more do more viewing. Television time has been named as the daily activity people would give up if something urgent occurred.

As shown in Table 1, TV viewing is rated as more enjoyable in "real time" in the diaries than in general, and falls in the middle of other leisure activities. However, Kubey (1992) indicated that was not the case the longer TV is viewed. These quantitative results stand alongside other lasting effects of TV outside of time that have been alleged (at least in the United States). These include (1) decreasing the number of manufacturers and producers, due to the concentration of mass advertising; (2) increasing the fear of crime; and (3) fostering a multitude and democracy of voices that has led to "post modernism." Another cause for concern came from Putnam's (2000) link of TV viewing with long-term declines in social capital in the United States. Other works whose titles give a pessimistic appraisal of TV's effects include Mander's (1978) *Four Arguments for the Elimination of Television* (1977), Postman's *Amusing Ourselves to Death* (1985), and Kubey's *Television and the Quality of Life* (1990). Only the latter is based on actual viewer feedback, finding viewers rated themselves as more passive and using less concentration than for other activities. More upbeat views can be found in Bianculli's *Teleliteracy* (1992), Johnson's *Everything Bad is Good for You* (2004), and Neuman's *The Active TV Audience* (1988), the latter again being the only one based on viewer feedback.

### TRENDS AND PATTERNS IN TIME USE

Figure 1 shows a list of the 22 main uses of time recorded in prior research on the right and a standard set of predictor variables on the left that are used in studies of time use. In most studies, the activities or uses of time (such as work or TV viewing) are dependent variables, or the behavior to be predicted, whereas the demographic characteristics (such as gender and marital status) are the independent variables, or the predictive factors. Researchers can the assess the extent to which the six categories of background factors can predict the four major types of time: contracted (paid work) time; committed (family care) time (mainly divided into core housework and cleaning, childcare, and shopping); personal care (sleeping, eating, and grooming); and the remaining activities that comprise free time (dominated by TV viewing, which takes up almost half, as noted below).

The predictor variables are grouped into six categories in Figure 1:

1. Birth factors: The factors one is born with (e.g., gender, race, and age).
2. Status factors: The factors that reflect one's social standing (e.g., education, income, and occupation).

| Demographic/ Background Factors | Time Uses |
|---|---|
| BIRTH FACTORS | A. CONTRACTED TIME |
| a) Age | 1. Paid Work |
| b) Gender | 2. Work Commute |
| c) Race | B. COMMITTED TIME |
| STATUS FACTORS | 3. Housework |
| d) Education | 4. Child care |
| e) Income | 5. Shopping |
| f) Occupation | C. PERSONAL CARE |
| ROLE FACTORS | 6. Sleeping |
| g) Employment | 7. Eating |
| h) Marriage | 8. Grooming |
| i) Children | D. FREE TIME |
| LOCATION FACTORS | 9. Religion |
| j) Region | 10. Organizations |
| k) Urbanicity | 11. Social events |
| l) Dwelling type | 12. Visiting |
| TEMPORAL FACTORS | 13. Fitness activity |
| m) Year | 14. Hobbies |
| n) Season | 15. TV |
| o) Day of week | 16. Radio/recordings |
| GEOGRAPHY/CULTURE/ETC. | 17. Reading |
| p) Country | 18. Home communication |
| q) Technology | 19. IT |
| | 20. Rest/relax |
| | 21. Free travel |
| | 22. Total travel |

***Figure 1.*** *Time/Activity categories and their major background predictors.* CENGAGE LEARNING, GALE.

3. Role factors: The various roles one undertakes and performs (e.g., as an employee, spouse, or parent).
4. Location factors: The effects of where one lives (e.g., by region, living in urban vs. rural areas, type of housing).
5. Temporal factors: What year, season, or day of the week is being reported.
6. Geo-cultural factors: Such as the country lived in or access to technology.

Attention to these six sets of factors demonstrates the ways that time use is powerfully shaped by social factors such as life course stage, gender, and access to social and economic resources. In terms of the main trends in U.S. time use since 1965 (the "year" variable on the left side of Figure 1), most notable overall activity increases are found in childcare, TV viewing (see sidebar), and fitness activities. The most notable decreases are found in paid work for men, housework for women (men's housework, by contrast, has nearly doubled), eating, and reading (mainly of newspapers). The main shifts occurred between 1965 and 1975.

There is little evidence in these diaries of other expected changes—even those considered to be common knowledge, such as historical increases in average paid work hours or decreases in free time, childcare, social visiting, relaxing, or (non-newspaper) reading—or of age per se as a major predictor of time. Among the key findings obtained are:

1. Age: Between the ages of 18 and 64, the main age differences are predicted by role factors, such as those due to the increase in housework and childcare that accompany marriage and parenthood. One major shift is the decline in paid work time by those ages 55 to 64, many of whom are taking early retirement. Another is that those under age 30 are going to college in greater numbers than in the past.
2. Gender: The largest shift here is the above-noted activity of housework, whereby men's share increased from 15% in 1965 to 35% today (with the notable exception of laundry). This is part of a larger picture of increased "gender convergence" and "time androgyny," in that women are doing more of the activities that men dominated before, primarily for paid work but also for the former "male" activities involving education, TV viewing, and fitness activity. In contrast, the gender gap in childcare, grooming, reading, and hobbies has declined.
3. Race: Since 1965, Blacks have consistently spent more time in grooming, religion, and TV viewing, whereas Whites spend more time in housework, reading, and visiting. Thus there is little closing of the race gap to parallel the closing of the gender gap. Moreover, the above differences by race are not explained by education or other demographic differences between the races.
4. Education: There is an increasing tendency for a greater number of work hours and less sleep for the college educated, along with higher figures for reading and attending social events (such as the arts or sporting events). By far the most dramatic educational difference is for lower levels of TV viewing among the college educated; the amount of time college-educated people spend watching TV is about half of that for those with less than a high school degree.
5. Income: Differences by income parallel those for education and are often a function of education.
6. Occupation: Again, these differences largely reflect related education differences.
7. Employment: Whether one is currently employed is probably the most significant predictor of time use, particularly as work hours increase. Sleep is the major activity affected; housework and childcare are cut by a third, and TV viewing decreases dramatically as well.
8. Marriage: Getting married also reduces most free-time activities, mainly due to increased housework

and other family care activities (but more for wives than for husbands).

9. Parenthood: Surprisingly, having children has less time effect than getting married, but it still means more housework and shopping and less free time and TV viewing.

The other sets of predictor factors on the left of Figure 1 seem to have much less impact than those above, and those that are found tend be a function of them, such as higher TV viewing in the South due to lower education levels there. Few notable regional differences emerge, nor is there much evidence of a more hectic lifestyle in more urban areas. Outside of less housework among dwellers of apartments or trailers, housing type has little relation to ways of spending time little effect of seasonal differences is found, much as for regional differences that may reflect climatic/weather differences. There are major and obvious differences by day of the week, with weekends meaning decreased work and more time for sleep and TV.

Another primary factor that is often linked to time use is technology. Although the development of so-called time-saving appliances in the 20th century might lead one to believe that time use has changed as a result, the few time studies conducted to date suggest that consumers seem to use their "hassle-saving" features instead—that is, to increase outputs from the technology rather than to save time (Robinson & Godbey, 1999).

**Cross-National Results** Finally, research reveals surprising convergences across most of the more than 30 countries studied (some identified below), although most of them are developed, Western societies in Europe, which can afford to conduct expensive time-diary surveys. For example, Bittman (2000) found similar increases in free time since the 1960s in other countries, much as in the United States. In an analysis of all productive activity (contracted and committed time together) in 12 countries, Goldschmidt-Claremont (1995) found the same basic equality of men and women in overall hours spent on such activities. Another study found the same pattern of increased father childcare across six Western countries since 1990 (France being a notable exception), much as was reported in a 2004 study (Gauthier, Smeeding, & Furstenberg, 2004) for many other countries over this period. Robinson and Godbey (1999) found many similarities in both the trends and predictors of time use in Japan, Russia, and Canada. Gershuny (2000) extended these results to more than 15 other countries.

National trend studies of time use indicate that TV has had a greater impact on daily use of time than any other household technology (see sidebar) and that it continues to consume almost half of free time, at least in the United States. TV use appears to have not been greatly displaced by the Internet and personal computers.

Main gains in viewing time occurred in the United States in the 1970s, coincident with the arrival of color TV, and it has made persistent but smaller inroads on free time since then. As was true in the late 1960s, these diary studies show that lower TV time is correlated with more time at work and more travel and that TV is viewed more by people who are at home and who have more free time. Early casualties of TV, such as sleep and reading, are now correlated with more viewing.

## POLICY ISSUES AND TIME

Because time diaries cover all daily activities performed by individuals in a society, they might be thought to have immense policy implications. However, it is often the case that time itself is less the issue than how the time is used or valued. The "fun meter," displayed in Table 1, shows differences in how people rate the enjoyment they get from various daily activities, when asked on the left-hand column "in real time" (when they were doing it in the diary) or when asked to think about a particular activity in general on the right. Although the two ratings correlate highly, there are exceptions (such as the low rating for TV in general vs. its higher rating in real time, as discussed below and in the sidebar).

For example, in the case of the division of housework between men and women, Table 1 shows that both men and women rate housework low in terms of enjoyment, yet women continue to do twice as much of it. However, it is hard to imagine what type of policy would offset this imbalance, outside of providing counselors to help individual couples to make better arrangements for themselves.The "take back your time" movement (de Graff, 2003) has proposed that American workers stop all paid work after mid-October, so that their total annual work hours would be equivalent to those of European workers. Yet Hochschild (1997) found in one company that it was other workers themselves who sabotaged innovative family-friendly policies to reduce work hours. The National Sleep Foundation has raised alarms about sleep deprivation as a national crisis, although time diaries show no decline in sleep since the 1960—which holds steady at the legendary 8 hours per night. The "turn off your TV" movement has designated one week per year for people to leave their sets off and to instead participate in more potentially gratifying activities. However, Table 1 suggests that, although people rate TV in general as relatively low on the fun meter, the programs they watched on the diary day rated far higher in enjoyment.

**On a Scale from 10 = Enjoy a Great Deal to 0 = Dislike a Great Deal. (1985 and 1975 National Data from Robinson and Godbey 1999, Appendix O)**

| (1985 Diary Average = 7.0) | 1975 General (Average = 6.8) |
|---|---|
| 9.3 Sex | |
| 9.2 Play sports | |
| 8.7 Playing/reading with children | 8.9 Child care |
| 8.5 Church, religion | |
| 8.5 Sleep | 8.6 Play with children |

| 4.8 Health care, doctor | 4.2 Clean house |
| 4.7 Car repair | |

***Table 2.*** *Activity enjoyment ratings in time diaries vs. in general.* CENGAGE LEARNING, GALE.

Of all the potential policy issues related to time use, perhaps what is most impressive is the largely anecdotal data on the meager, marginal outputs that workers produce and obtain for their inputs of work time. These data largely suggest that the same work productivity can be achieved with 20 to 50% less time spent on the job (Parkinson, 1962; Schor, 1991; Schuman, Walsh, Olson, & Etheridge, 1985) and that many workers put in simple "face time" to impress their employers.

This inability of diary data to speak to the quality of people's lives and to guide policy to improve that life quality remains the major limitation of time use research and a major area for future studies. The findings reported in Table 1 represent an important first step toward gaining more nuanced insights into time-use statistics, but a new study design—such as a representative ethnography that combines observation with representative sampling (Robinson & Meadow, 1982)—could provide more enlightened insights. Diary data allow researchers to document what people are doing, yet scholars need to find out more about why, with whom, for whom, and to what ends adults are using their time.

# TRANSITION TO ADULTHOOD

The transition to adulthood is the period in the life course that bridges childhood and adulthood. This transition stage is defined by exits from roles that support and foster childlike dependence (e.g., student), entries into roles that confer adult status (e.g., parent), and the acquisition of stage-specific, developmental skills such as the development of one's personal identity. This stage has been called "demographically dense" (Rindfuss, 1991) because it is defined by a large number of transitions into and out of roles in a relatively short period of time. The transitions are pivotal in individuals' lives, distinguishing it as a stage of life during which individuals are most likely to experience self-described key, turning-point life events that involve family and relationships, education, and work (Elnick, Margrett, Fitzgerald, & Labouvie-Vief, 1999).

Industrialization has influenced the transition to adulthood by increasing society's need for a more highly educated workforce. In turn, in more industrialized countries, education is prolonged and transitions to careers and family roles are delayed. Industrialization has variably influenced the world's nations; in turn, the age span over which the transition to adulthood occurs and the specific criteria that characterize an *adult* vary culturally and historically. This variation principally reflects differences in the degree to which childhood is distinguished from adulthood, the range of opportunities for entry into the labor market, and the availability of resources during this transition stage, in any given culture. In contemporary industrialized nations, this transitional stage spans a wide age range: the later half of the teens, the decade of the twenties, and even into the early thirties. In less industrialized countries, transitions to adulthood are more likely to reflect traditional and homogeneous pathways beginning and ending at younger ages.

## DEFINING AND MEASURING THE TRANSITION TO ADULTHOOD

The transition to adulthood is typically defined by a specific set of role transitions: completing formal education, moving out of the parental home, entering the labor force, getting married, and becoming a parent. These events have a normative sequence; for example, young people are expected to finish their education and establish their work lives prior to marrying or having children. Thus, a "successful" transition to adulthood occurs when an individual completes school, moves out of his or her parents' home, establishes employment, gets married, and becomes a parent (Settersten, Furstenberg, & Rumbaut, 2005).

Yet, individuals' transitions to adulthood are influenced by a range of factors beyond macroeconomic forces, including shifts in the roles of social institutions (e.g., family and schools), social norms, and social values that, in turn, determine and constrain role opportunities. Transition to adulthood experiences vary across individuals in whether or not a role transition is completed, the age at which it occurred, the extent to which it occurred at the normatively expected age, and whether or not it occurred in the normative sequence. Variation in the transition to adulthood also occurs because of personal agency; people act in their own behalf to maximize their well-being, weighing the costs and benefits of choices and options (Schwartz, Côté, & Arnett, 2005).

The role-based definition of the transition to adulthood reflects sociological and demographic perspectives. Psychologists offer an alternative definition of transition from childhood to adulthood. Instead of focusing on social roles, this perspective focuses on the specific life skills that individuals acquire at specific stages of life. Drawing from the developmental theory of Erik Erikson (1950), life span psychologists classically view the stages and ages referred to as adolescence and young adulthood, stages 5 (ages 12–17) and 6 (ages 18–35), as the transition to adulthood. Respectively, during these transitional years individuals are confronted with two challenges—the resolution of one's personal identity and the establishment of intimacy with others. A successful transition to adulthood, therefore, results in a personal sense of self and the ability to simultaneously merge and maintain oneself with another in a love relationship.

Contemporary theorists have expanded the psychological perspective on the transition to adulthood to include a stage between adolescence and young adulthood, "emerging adulthood" (Arnett, 2000). This stage of life is defined by individuals' lack of formal

commitments to social roles. Rather, the stage is defined by psychological markers of adulthood: accepting responsibility for the consequences of one's actions, deciding on personal beliefs and values independently of parents or other influences, becoming financially independent from parents, and establishing a relationship with parents as equal adults (Arnett, 1997). In other words, the developmental task of this age period is gaining self-sufficiency. Therefore, from a contemporary and psychological perspective, the transition to adulthood is a three-stage process through which individuals move at varying rates and with varying degrees of resolution of the respective life tasks associated with adolescence, emerging adulthood, and young adulthood (Tanner, 2006).

The sociological and psychological perspectives differ in their definitions of the transition to adulthood. From a sociological perspective, role transitions are indicators of becoming an "adult." Some empirical research supports this idea. For example, financial self-sufficiency and taking on family roles (marriage and parent) have been associated with feelings of "being an adult." In addition, expectations for taking on adult roles are associated with increasing age through the twenties. The psychological perspective refutes the position that social role transitions are the sole markers of adulthood. This position is supported by studies that demonstrate that only small proportions of people see role transitions as relevant criteria for adult status, while most people favor psychological criteria of adulthood, such as accepting responsibility for self (Arnett, 1997). Still other research suggests that chronological age, the social roles one holds, and psychological gains each contribute to feelings of being adult. However, it is important to highlight that age, roles, and psychosocial maturation are not independent; rather the three are closely intertwined. For example, the number of roles an individual acquires increases with age; and, as age increases, individuals' perceptions of their psychosocial maturity increases, as well (Galambos, Turner, & Tilton-Weaver, 2005).

## HISTORICAL CHANGES IN THE TRANSITION TO ADULTHOOD

The transition to adulthood is different for contemporary cohorts versus prior generations due to changes in the economy and related shifts in social values and norms. The economy defines key dimensions of the school-to-work transition including the types and availability of job opportunities for young people and the education and training requirements for these jobs. In the United States over the past 200 years, the economy shifted from an agrarian to an industrialized economy. In the industrialized nations, economies are increasingly organized around providing services, generating information, and supplying energy. In response, labor market needs increased the demand for a more educated workforce.

The recent macroeconomic reshaping of the labor market has had specific effects on individuals' transitions into adulthood. First, the time between childhood and adolescence has been elongated. Demands for more education prolong young adults' time spent in the student role, delay entry into labor force, and subsequently postpone entry into marriage and parenthood. Second, the traditional sequence of transitioning from student to worker to spouse and parent no longer defines a normative experience. Holding both "student" and "worker" roles concurrently has become more common. Also, trends indicate that there is an increase in out-of-wedlock childbearing and childbearing within cohabiting unions. The extent to which a group of transition-stage individuals are in different roles, experience transitions at different ages, and go through transitions in different sequences determines the heterogeneity of the transition to adulthood in that population, a measure labeled *entropy* (Billari, 2001). Entropy analyses confirm that transitions to adulthood are growing more heterogeneous and that there is variation in entropy across countries (Fussell, Gauthier, & Evans, 2007).

Changes in social values and social norms have accompanied macroeconomic shifts and have also influenced changes in the transition to adulthood (Smith, 2005). In industrialized countries, social values have come to place a greater emphasis on gender egalitarianism, self-actualization, and self-fulfillment. Contemporary cohorts are less religious, less connected to social institutions, and more pessimistic about society and people in general. All together these changes reveal an *individualization* of life pathways and movement away from proscribed, socially sanctioned transition sequences. Current generations also have a different relationship with the economy than prior generations have; both in their own perceptions and in terms of real dollars, current generations fare financially less well than prior cohorts.

## CROSS-CULTURAL VARIATION IN THE TRANSITION TO ADULTHOOD

The contemporary pattern of transitioning to adulthood varies between countries as a function of their economic advancement and other social and political trends. At one end of the continuum, industrialized nations (i.e., United States, Canada, Australia, Japan, and Western Europe) comprise a cluster of countries considered economically advanced and socially and culturally similar. Findings have demonstrated similar entropy patterns across the three countries: very little heterogeneity at ages 17, a quick rise and high heterogeneity through the late 20s, and then a gradual decrease through the late 20s

and 30s. Despite the political, social, and economic similarities in these nations, life course researchers have also detected some differences that reflect the nations' distinctive social values and policies. Transition to adulthood patterns in the United States differ from those in Canada and Australia in that marriage occurs at younger ages, and marriage and parenthood remain more closely tied, perhaps due to higher religiosity in the United States. The result is that the transition to adulthood is less variable and more compressed temporally in the United States than in Canada and Australia (Fussell et al., 2007).

The United States is considered a moderate example of the trend in prolonged and non-traditional transitions to adulthood. European countries with advanced economies are the countries with the longest delays in entries into marriage and parenthood (Douglass, 2007). In Italy a relatively old age at first birth has contributed to a below-replacement level fertility trend, perhaps due to the fact that marriage and parenthood remain closely linked. Additional variation arises between Mediterranean and Scandinavian countries in that, similar to in the United States, Scandinavian youth tend to leave home to live alone or cohabitate with roommates. Young adults in Mediterranean nations leave home later and tend to move in with a romantic partner, commonly with intentions to marry and have children. This one difference explains, to some extent, the increased risk for poverty during the transition to adulthood in countries in which a period of time is spent cohabiting between living with parents and living with a marriage partner. The increased risk for poverty is explained by the decreased likelihood of living with a full-time wage-earner, more common among cohabitors who are more likely to be students or employed only part-time. Comparatively, occupational stability and full-time wage earnings accelerate transitions to marriage and parenthood.

In Latin American countries there is also great variation in transitions to adulthood. In Argentina, a country with a developed economy, the delay in transitions has been observed, but is relatively limited to the proportion of the Argentinian population that can afford a college education and thus experience a delayed entry into the labor force. Independent living is relatively rare in Argentina; the majority of transition-stage individuals who are not married or cohabiting live with their parents or families. Reasons for living with family during the transition-stage are rooted in Latino and Catholic traditions placing high value on family responsibility (Galambos & Martinez, 2007).

Evidence for the broad trends depicting contemporary shifts in the transitions to adulthood varies across Asian countries as well. In China, college students' transitions to adulthood resemble transitions to adulthood in the United States. However, very different patterns are evidenced by Chinese young persons who live in rural villages and/or regions with largely agrarian economies. Agrarian-based economies offer young adults opportunities to enter the local labor market via family- or local-owned businesses, primarily requiring manual labor. Providing young people with employment opportunities that favor manual labor and skill over higher-education affords young people an opportunity to earn a living wage, and thus reduces the likelihood of delay in marriage and parenthood associated with educational attainment (Nelson & Chen, 2007).

In less industrialized countries there is a weaker association between prolonged time spent in education and delays in transitions to marriage and parenthood. In Mexico, for example, there is some evidence of a link between college attendance and delayed entries into marriage and parenthood, but the delays are not as long and the pattern reflects the patterns and behaviors of only a minority proportion of the transition-stage population. The rate of college participation for 16- to 29-year-olds is 25% in Mexico, compared to 55% in Spain, two countries considered close in cultural and social values. Despite the similarities in culture, transitions to adulthood in Spain conform to Mediterranean patterns of late home-leaving and delayed transitions into family formation. In contrast, the average age of home-leaving in Mexico is 18 to 19, followed closely, on average, by transitions to marriage and parenthood. One possible reason for early home-leaving and the lack of postponement of family roles is the lack of a shift toward egalitarianism at the cultural–level that has accompanied industrialization in the United States. The result, despite higher levels of educational attainment, without equality afforded to young women to enter the labor market, women do not delay transitions to family roles to pursue education or careers in their 20s (Fussell et al., 2007).

In non-industrialized countries researchers have found high levels of homogeneity in the timing of life course transitions between mid-adolescence and age 30. In six developing countries—the Dominican Republic, Ghana, Columbia, Kenya, Peru, and Cameroon—there is evidence of increasing levels of educational attainment, yet educational attainment does not fully account for the economic forces that are shaping transitions to adulthood in these countries (Grant & Furstenberg, 2007). In developing nations, the move toward a delayed and varied transition to adulthood is shaped by factors other than educational expansion. As is the case with Mexico, lack of movement toward egalitarian gender roles and lack of a labor market that provides rich opportunities to young people has thwarted delays in marriage and

parenthood (except for a small proportion) despite increasing rates of participation in college.

## WITHIN-CULTURE VARIATION: SOCIOECONOMICS, SOCIAL NORMS AND VALUES, FAMILY RESOURCES, AND CUMULATIVE ADVANTAGE

Within-culture, sub-group and individual-level variation in duration and sequencing of the transition to adulthood exists as a function of access to and involvement in tertiary education and the advanced economy. Within the United States, social class differences have been cited as a key source of variation in pathways through the transition to adulthood. These differences have been observed and reported across countries reflecting different pathways between the middle-class versus working-class, and the college-educated versus high school–educated (Furstenberg, 2008). These observations suggest that the contemporary conceptualizations of transition to adulthood may, at least, neglect the experiences of the poor, less educated, working class.

The labor market currently favors educated young people from higher social class backgrounds, by granting "time off" from labor market participation to build human capital and accumulate education opportunities. In the United States, the half of the population that does not go on to college after high school—the Forgotten Half—not only earn lower salaries when they enter the labor market in their late teens and 20s compared to their college-educated peers, but they also experience slower acceleration in their salaries across their life spans. In addition to the economic inequalities, they miss the normative experiences of the age period that afford freedom from role stress and responsibility if only for a brief period of the life course. Not experiencing a period of being in-between childhood and adulthood for a prolonged period of time may result in different life course pathways for those who delay commitments to adult roles and responsibilities versus those who make commitments early in adulthood, without a period of exploration prior to commitment. For example, it may be the case that spending time exploring a range of professional and personal options during the early adult years before making commitments may lead to better marriage and career choices, and greater preparedness for the parental role. Given the recency of the new transition to adulthood patterns, future studies will be required to test for differences in outcomes associated with different transition to adulthood patterns.

Within countries, sub-groups vary with respect to the access they have to higher education. Across societies, racial and ethnic minorities and non-native born populations typically face the most severe obstacles to high

***Graduation Ceremony at Brown University.*** *A group of Brown University undergraduates cheer as they exit through the Brown University gates prior to Brown's graduation ceremony in Providence, RI.* AP IMAGES.

levels of educational attainment. In the United States, for example, enforcement of Affirmative Action programs decreased in the 1970s and 1980s resulting in large and increasing gaps in educational advancement between whites and African Americans (Corcoran & Matsudaira, 2005). Both high school and college graduation rates are higher for Whites and Asians compared to Hispanic, Black, and Native Americans, resulting in variation in the age of entry into the transition to adulthood.

Sub-group variation also has been attributed to immigration status. Studies of educational trajectories and attainments of immigrant versus native-born students inform our current understanding of processes that may underlie differences in transition patterns between immigrant and native groups. Mollenkopf and colleagues (2005) collected data on a sample of second-generation immigrant and native-born White young adults (i.e., ages 18 to 32) in New York City and surrounding areas. The second-generation immigrants were the children of

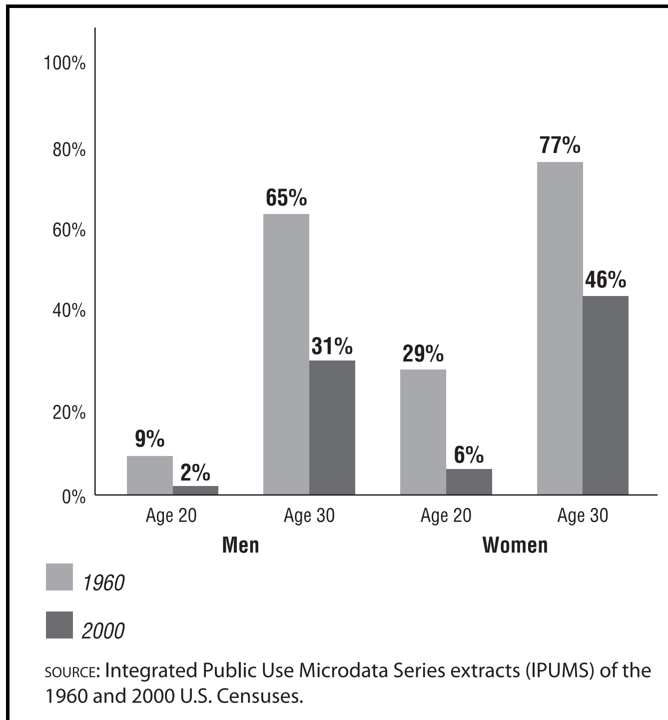

***Figure 1.*** *Percent completing transition to adulthood in 1960 and 2000 using traditional benchmarks (leaving home, finishing school, getting married, having a child and being financially independent).* CENGAGE LEARNING, GALE.

parents who immigrated to the United States after 1965. The research revealed much variation in the rate of college enrollment among these young people; for example, Chinese and Russian immigrants enrolled at higher rates than native Whites. This difference has been attributed to the influence of family value for education attributed to these immigrant groups, manifesting in high parental expectations for achievement, and child adherence to such expectations. Immigration selectivity has also been advanced as a factor leading to these differences; the characteristics of those who immigrate to the United States may be the same factors that lead them to achieve educationally and financially.

Differences between immigrant and native groups of transition-stage adults in the United States are not only reflected in educational attainment, but also in the proportion of each group that makes transitions to marriage and parenthood between ages 22 and 32. As a function of longer periods of time spent as students, the trend demonstrates later ages at marriage and first birth among immigrant Chinese and Russian groups (they are more likely to delay these role transitions). By contrast, Dominican, Puerto Rican, and native-born Black persons made these transitions at younger ages (Mollenkopf, Waters, Holdaway, & Kasinitiz, 2005).

Subjective accounts of "success" in the transition to adulthood vary as a function of sub-culture. Native-born Blacks are more apt to describe success in terms of meeting basic needs, staying alive, staying out of jail, having fun, meeting one's material needs, being the boss (having power), and having stability. In contrast, native-born Whites and Chinese and Russian Jewish immigrant groups—those with higher levels of education and upward mobility—reported that success was realized not only through the attainment of education, career, and money, but also the achievement of higher-order human needs such as awareness of future goals, being happy, being a good person, and making the world a better place (Mollenkopf et al., 2005).

Family support for semi-autonomy plays some role in the prolongation of the transition into adult roles of adult children. One key assumption of the sociological perspective holds that family resources provide a safety net during the transition to adulthood and provide for a period of semi-autonomy during which transition-age youth can extend their role as student and delay adult self-sufficiency (Osgood, Foster, Flanagan, & Ruth, 2005). Parental socioeconomic resources affect the timing of a young person's transition to adulthood (Sandefur, Eggerling-Boeck, & Park, 2005). Parental resources operate both directly and indirectly. First, parents with richer economic resources can contribute to their children's educational attainment directly, by paying for tuition. Second, parental socioeconomic resources affect children indirectly, as parent's social background may affect a child's socialization, peer group, and attitudes toward education—each of which contribute to a child's educational trajectory and, in turn, delayed marital and parental transitions (Osgood, Ruth, Eccles, Jacobs et al., 2005). Socioeconomic differences also may be transmitted through parental expectations for secondary education, which explains some variance in post-secondary attainment (Furstenberg, 2008).

## FUTURE DIRECTIONS

Contemporary studies of the transition to adulthood indicate that, in many countries, the transitions to adulthood are taking longer and are less likely to reflect the "traditional" sequence of role transitions. The growing complexity in young people's pathways to becoming adult reflects an increasingly composite global economy and world. Consistent with these global changes, life course researchers are embracing theoretical frameworks that capture the multidimensionality of the contemporary transition to adulthood. There is momentum across disciplines to establish a more integrated, less disciplinary-divided definition and theoretical frame for study of this salient period of the life course. As new complex frames and methods evolve, studies of macro–micro forces that shape

individual-level transitions, intergenerational and bidirectional shaping of transitions, and integrations of the subjective nature of the transition to adulthood are expected to paint a dynamic portrait of the transition from child to adult (Gauthier, 2007). Some scholars have advocated for a human development framework to integrate multidisciplinary perspectives of the transition to adulthood, and one that bridges theoretical and applied goals (Settersten, 2007; Tanner, 2006).

In sum, the transition to adulthood is a stage of life that, for individuals, varies as a function of a broad range of factors, some macro- (e.g., such as the changing economy) and some micro (e.g., parent financial contributions). For some, the contemporary transition to adulthood reveals great opportunities for growth, development, and the accumulation of resources and attainment of roles. For others, economic and institutional barriers, as well as developmental histories, present challenges to optimizing pathways during these critical years.

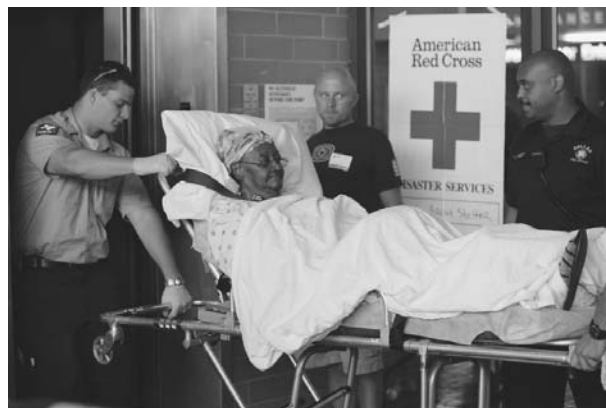
# TRAUMA

Trauma is the extreme psychological distress that a person experiences when exposed to severe adversity. Although experiencing trauma is relatively uncommon

for most people over the course of a given day, year, or developmental stage, studies show that the majority of the population experiences trauma at least once over the course of a lifetime. Experiencing trauma can lead to long-lasting, negative consequences for both mental and physical health, yet not everyone who is exposed to trauma suffers equally. The long-term impact of trauma depends on many factors, including the nature of the trauma-inducing event, the developmental stage and coping resources of the person exposed, and the social and cultural context within which the event occurred.



***Refugee.*** *A hurricane Katrina refugee from New Orleans is transported by paramedics to a Dallas shelter. Texans opened their schools, hospitals, and sports arenas to some of Hurricane Katrina's most desperate refugees, offering them a chance to recover from the trauma of the event, regain some normalcy, and decide their next move.* AP IMAGES.

## THE DEFINITION AND DISTRIBUTION OF TRAUMA

The term *trauma* originates from the Greek word for "wound." Whereas physical trauma is defined as a wound to living tissue caused by an external force, psychological trauma is the mental and emotional distress that results from experiencing extremely threatening life events. The distress that is associated with trauma is described as an overwhelming sense of fear, helplessness, or horror. Events, or stressors, that can lead to trauma responses are called *traumatic events*. Traumatic events are distinguished from other stressors by their heightened seriousness or severity. According to the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition) of the American Psychiatric Association (1994), a traumatic event is an experience that involves actual or threatened death or serious injury, or a threat to the physical integrity of self or others. The *ICD-10 Classification of Mental and Behavioral Disorders* of the World Health Organization (1992) refers to a traumatic event as that which is of an exceptionally threatening or catastrophic nature, which is likely to cause pervasive distress in almost anyone. The term *trauma* is often used to represent both the traumatic event and the initial distress that it causes.

Examples of traumatic events (or traumas) include sudden events, such as exposure to natural or manmade disaster, or witnessing violent crime, as well as events that are more chronic in nature, such as participation in combat or being the victim of physical or sexual abuse or assault (Wheaton, 1996). Traumas also can be characterized by their scope of influence. For instance, some traumatic events, such as natural disasters, affect entire populations simultaneously, whereas others, such as exposure to physical or sexual assault, primarily affect individuals in isolation.

Traumatic events differ with regard to their prevalence. The most common forms of trauma over a lifetime include witnessing someone being injured or killed, being exposed to a natural disaster, and experiencing a life-threatening accident or illness (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995; Krause, Shaw, & Cairney, 2004). Population-based studies of trauma suggest that the lifetime prevalence of exposure to any trauma among adults is more than 50%, with the majority of those who have been exposed actually reporting more than one type of trauma exposure.

The lifetime prevalence of most of the relatively common traumas is higher among men than women; however, some forms of trauma have higher rates among women, including rape, sexual molestation, and childhood abuse and neglect (Breslau et al., 1998; Kessler et al., 1995; Norris, 1992). Evidence of race differences in the prevalence of exposure to traumatic events is mixed, with some data showing higher rates of most traumas among Whites (Norris, 1992), and other data showing no race differences for most traumas, and higher rates among non-Whites for violent assaults (Breslau et al., 1998). Exposure to violent assaults is also more common among persons of low socioeconomic status (Breslau et al., 1998).

Some age differences in the prevalence of exposure to trauma are also apparent. Not surprisingly, lifetime trauma exposure appears to be positively associated with age for young and middle-age adults (Kessler et al., 1995). Among older adults, however, additional years of life do not appear to result in higher levels of lifetime trauma (Krause et al., 2004). Other studies have estimated rates of trauma exposure by age and have found the highest rates between the ages of 16 and 20 years (Breslau et al., 1998). After age 20, exposure rates tend to decline for most forms of trauma; however, rates are stable and actually increase for some forms of trauma, such as the unexpected death of a loved one and natural disaster (Breslau et al., 1998; Norris, 1992).

## THE LONG-TERM IMPACT OF TRAUMA

Virtually everyone exposed to a traumatic event experiences some degree of distress in the immediate aftermath (O'Brien, 1998). This trauma response typically entails intense feelings of fear and helplessness arising from the appraisal that one's life or sense of self has been fundamentally threatened (Resick, 2001). Following this immediate response, however, most people are able to cope effectively and recover satisfactorily. Nevertheless, for a substantial number of people, the distress caused by a traumatic event lingers and can lead to the development of mental, as well as physical, health problems over the life course.

The vast majority of studies of the long-term impact of trauma focus on mental health problems. The mental disorder most commonly associated with trauma is posttraumatic stress disorder (PTSD). PTSD is a pathological stress response syndrome with symptoms that include (a) "re-experiencing" the traumatic event through flashbacks and nightmares, (b) avoidance of stimuli associated with the trauma and a numbing of responsiveness, and (c) excessive arousal (American Psychiatric Association, 1994). In order to meet the threshold for a PTSD diagnosis, these symptoms must persist for at least one month and must cause "clinically significant" impairment in social functioning. In adults, estimates of the prevalence of PTSD among those exposed to a traumatic event range from 8% to 20% (Breslau et al., 1998; Kessler et al., 1995).

Other mental disorders that are associated with exposure to traumatic events include substance abuse, depression, and anxiety disorders. Often, these disorders co-occur with PTSD. Kessler and colleagues (1995) estimated that 79% of women and 88.3% of men with PTSD have at least one other mental disorder.

A growing number of studies have also raised the possibility that trauma has adverse long-term effects on physical health (Krause et al., 2004; Shaw & Krause, 2002). Data from these studies show significant associations between exposure to traumatic events earlier in the life course and subsequent physical health outcomes such as poor self-rated health, acute and chronic illnesses, and functional disability. At least two possible explanations for these associations have been proposed. First, exposure to trauma may impair one's psychosocial resources, such as personal control beliefs and social support, which themselves are strong determinants of physical health (Shaw & Krause, 2002). In addition, exposure to trauma may lead individuals to engage in negative health-related behaviors—such as smoking, substance abuse, or poor weight management—in attempts to cope with the ongoing distress associated with a trauma (Irving & Ferraro, 2006; Resick, 2001).

## FACTORS INFLUENCING THE IMPACT OF TRAUMA

A particular event is traumatic only to the extent that victims appraise the event as extremely threatening (Van der Kolk, McFarlane, & Weisaeth, 1996). Therefore, it is one's interpretations of the meaning of an event that largely dictate its long-term impact. Characteristics of a traumatic event that may influence its interpreted meaning, and thus its long-term impact, include its perceived intendedness and whether the victim is oneself or another person. For example, Kessler and colleagues (1995) found that events that are natural (e.g., natural disasters), unintentional (e.g., accidents), and impersonal (e.g., witnessing death or injury) are less strongly associated with PTSD than are events involving intentional interpersonal violence (e.g., combat, rape, and physical abuse). Therefore, it appears that events that cause people to perceive themselves as deliberate victims may have a stronger long-term impact than events involving immediate harm to others or events that are perceived to be natural or accidental.

Other determinants of the long-term effects of a traumatic event involve characteristics of the victim. Figuring prominently in this regard is the victim's stage in the life course. Both the stage in the life course at which a victim was originally exposed to a trauma, as well as a victim's current life course stage, are important to consider. Research findings regarding which life course stage is associated with the most harmful impacts are somewhat equivocal. Many investigators believe that exposure to trauma during childhood is especially harmful (Irving & Ferraro, 2006; Shaw & Krause, 2002). This is because childhood is viewed as a particularly vulnerable developmental stage, when the foundations for key psychosocial resources that are essential for effective functioning in adulthood, such as perceptions of control over one's environment and the ability to form and maintain meaningful and supportive social relationships, are being developed. The feelings of helplessness and insecurity caused by traumatic events could permanently impair the development of these key psychosocial resources.

Despite evidence of the strong and enduring negative consequences of childhood trauma, however, other research suggests that exposure to trauma at other stages of the life course may be even more damaging. In particular, research by Krause and colleagues (2004) found that traumatic events encountered during young and middle adulthood (i.e., between the ages of 18 and 64) exert the greatest negative effects on health. However, this research does not indicate whether the greater level of harm

caused by trauma encountered during these stages is due to something characteristic of these developmental stages or to the particular types of trauma that are likely to be encountered during these stages.

Trauma encountered during old age does not appear to be associated with negative health outcomes. This may be because the extensive life experience of elderly individuals better prepares them to anticipate and cope with the consequences of a traumatic event.

A person's stage in the life course is also important for understanding the long-term impact of trauma because the interpreted meaning of a traumatic event is likely to evolve over time. For instance, the impact of trauma encountered during childhood may not be apparent until much later in the life course because a child may not have the cognitive capacity or life experience to fully appreciate how threatening an event actually was until adulthood. Furthermore, the developmental stages encountered during late life may also influence the effects of trauma encountered many years earlier. For example, many people, as they enter old age, consciously strive to evaluate, integrate, and make sense of the experiences they have encountered over the course of their lives. In the process, they may learn to reconcile or overcome the negative effects of earlier trauma by reaching an understanding of the experiences they have had, and perhaps even forgiving the perpetrators of their traumatic experience. Alternatively, during these final stages of life, some traumatic experiences that have not been effectively coped with previously may resurface and lead to a reoccurrence, or delayed onset, of posttraumatic disorders (Aarts & Op den Velde, 1996).

Finally, the social environment surrounding a trauma victim also influences the long-term impact of the event. For example, the meaning attached to a particular event is heavily influenced by social context. This is evident from changes in the ways in which American society has viewed the use of physical force as a form of discipline by parents. Over the course of the last century, Americans have progressed from viewing corporal punishment as normative and morally sanctioned to viewing it as abusive and condemning it. Therefore, older cohorts who were exposed to childhood physical abuse may have interpreted these events differently than do younger cohorts, and this may influence the long-term psychological impact of such an event (Shaw & Krause, 2002).

Factors in the social and cultural environment are also important for the recovery process. Strong and supportive relationships with others are thought to be a primary defense against the negative long-term effects of trauma (van der Kolk et al., 1996). In addition, the presence of cultural rituals for coping with some forms of trauma (e.g., funerals) are also helpful in the recovery process.

## CURRENT RESEARCH AND POLICY ISSUES

Despite the tremendous growth in recent decades in knowledge regarding psychosocial trauma and its potential long-term effects, more research is needed. Exposure to traumatic events is an inevitable part of life. However, the more that is known about how people respond to trauma, the more effective societies will be at promoting healthy recovery.

Several specific issues are high priorities for future research. First, most studies focusing on trauma have been limited to mental health outcomes of traumatic events, such as PTSD and depression. Further examination of the extent to which trauma leads to physical health problems, and how exactly exposure to trauma affects physical health, is greatly needed. Second, although researchers have begun to examine the effects of multiple exposures to trauma throughout the life course (Breslau, Chilcoat, Kessler, & Davis, 1999; Turner & Lloyd, 1995), further investigation into the joint and cumulative effects of multiple exposures to trauma at different points in the life course is critical. Third, a relatively new area that is ripe for further examination is posttraumatic growth. A growing body of research has revealed that for many individuals, the process of struggling with extreme adversity actually leads to improved functioning (Linley & Joseph, 2004). Nevertheless, it remains unclear how common such growth is or what factors are likely to facilitate it. Finally, research is needed to better understand the public health impact of large-scale traumas that affect entire groups of people simultaneously, such as natural disasters, wars, and terrorist attacks. More research is needed to better predict who in the population is most vulnerable to trauma-induced mental and physical health problems in the wake of such events.

Current policy challenges related to trauma involve devising ways to prevent posttraumatic illnesses among those who are exposed. Because exposure to many traumatic events is unavoidable, prevention policies that focus on secondary, rather than primary, prevention are likely to be most productive. For example, policies are needed to ensure that those who must be exposed to trauma (e.g., emergency response personnel) are adequately trained. In addition, following exposure to traumatic events, early intervention with efforts to stimulate healthy coping is thought to be effective at limiting long-term damage. Therefore, policies that reduce barriers to seeking mental health treatment and otherwise facilitate early intervention programs for those who are exposed to trauma are greatly needed. This may be especially true in developing countries that currently lack the critical resources needed to launch extensive prevention efforts but whose rates of exposure to many traumas (e.g., disasters) far surpass those in developed countries (Van de Kolk et al., 1996).

## UNEMPLOYMENT

Individuals are officially defined as unemployed if they are seeking paid work but are unable to find a job. The unemployment rate is obtained each month from the Current Population Survey of U.S. households, conducted by the Bureau of Labor Statistics. The official unemployment rate is computed by dividing the number of people unemployed during a survey week by the total number of people employed and unemployed during the same week (excluding those under 16 years of age, institutionalized persons, and persons on active duty in the armed forces). The denominator is referred to as the civilian labor force; thus the unemployment rate shows the fraction of the labor force that is unemployed, not the fraction of all people who are unemployed.

### UNDEREMPLOYMENT

The unemployment rate is usually considered to be an underestimate of labor market weakness because it does not include people who are underemployed in one of three ways: (a) those who are employed only part-time when they need and desire full-time employment; (b) those who are employed at a low-paying job that requires less skill or training than they possess; and (c) those who have become discouraged workers because of a lack of job opportunities, training opportunities, or services that enable them to work, such as child care and public transportation. Such difficulties lead them to accept economic inactivity rather than to register as unemployed or actively seek jobs because their prospects for regular employment appear to be bleak. Members of the first two groups are included in the labor force, but not counted as unemployed; members of the third group are not counted as a part of the labor force, because actively seeking a job is required for them to be considered unemployed in official statistics.

### EXPANDED MEASURES OF LABOR UNDERUTILIZATION

Policy-makers and the public-at-large would benefit from having greater knowledge of the full extent of the level of underutilization of people who are available for work. It is widely acknowledged that the official unemployment rate understates the number of persons who are negatively affected by labor market conditions, and that it is not the best estimate of the nation's economic health. For example, it is likely that in inner city areas with limited job opportunities, the number of discouraged workers is higher among young minority men (Wilson, 1996). The monthly publication of a single unemployment rate fails to report on the rates for different age and racial and ethnic groups, the number of part-time workers who desire full-time jobs, and the duration of unemployment that is experienced. The 2006 Bureau of Labor Statistics, as reported in Nelson (2007), provides six alternative measures of labor underutilization that should be reported along with the official unemployment rate; they include the addition of discouraged workers, involuntary part-time workers, and marginally attached workers (see Figure 1).

### CROSS-NATIONAL COMPARISONS OF UNEMPLOYMENT

The unemployment rate is often used as an indicator of a nation's economic health. The U.S. rate is often compared

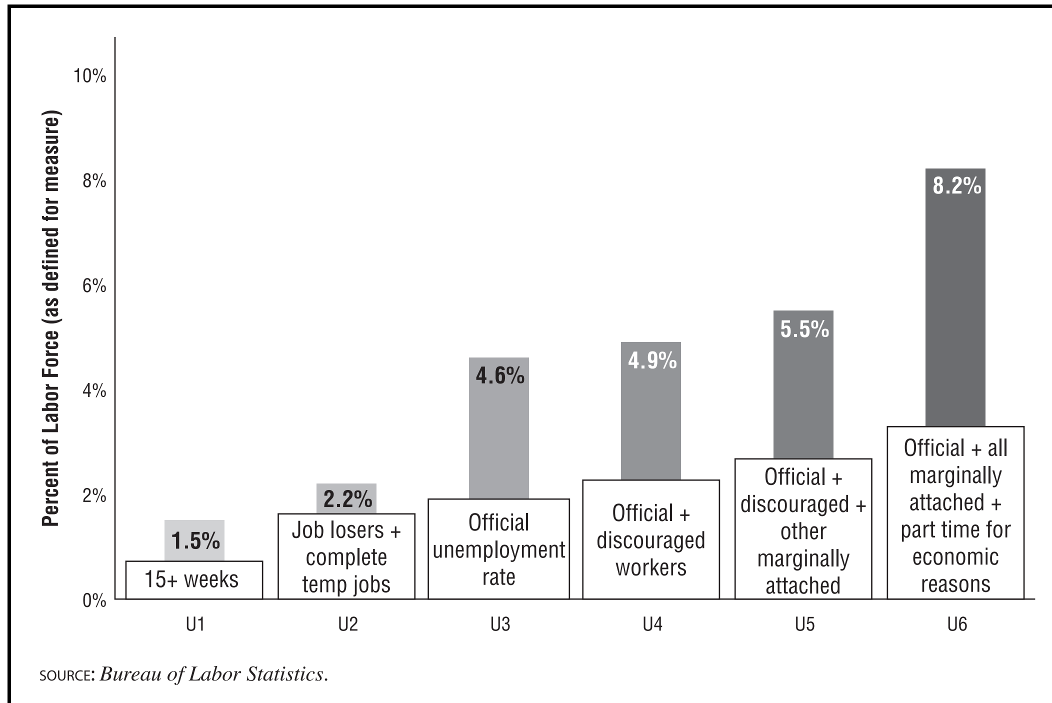

***Figure 1.*** *Alternative measures of labor underutilization, United States 2006.* CENGAGE LEARNING, GALE.

with that of the industrialized countries of Canada, Australia, Japan, France, Germany, and Italy. Since 2001 the United States has had a relatively low rate, coming in either second to Japan, or third behind Australia. The highest rates are for Germany and France. In all these countries, highest rates are for teenagers (Bureau of Labor Statistics, 2007a).

## U.S. DEMOGRAPHIC GROUP COMPARISONS

In the United States unemployment rates are calculated for several demographic groups, enabling subgroup comparisons. While unemployment characterizes all age groups to some extent, it is highest for teenagers and young adults aged 20 to 24 years. The unemployment rate is lowest for adults aged 45 to 55 years. In general, women have lower rates than men, but married women have higher rates than married men. With respect to race and ethnicity, Whites have the lowest unemployment rates, followed by Asian Americans, Hispanic or Latino Americans, and African Americans (Bureau of Labor Statistics, 2007b). These differentials are due to a number of factors, such as educational level of each group and job opportunities in area of residence (Wilson, 1996).

## CAUSES AND GENERAL EFFECTS OF UNEMPLOYMENT

Unemployment rates largely reflect the workings of a market economy, especially technological changes in industrial production and corporate reorganization or relocation to minimize costs. It is the unemployed workers, however, who experience income loss, anxiety, reduced self-esteem, loss of social contacts, heightened smoking and alcohol use, lower quality nutrition, postponed health care, family conflicts, and illness.

## EFFECTS ON HEALTH

Extensive research has been conducted on the health impact of economic downturns and unemployment (Perrucci & Perrucci, 1990). Research based on state and county unemployment rates and its effects reveals a relationship between economic downturns and aggregate rates of negative health symptoms. Research focused on the link between unemployment and health has been conducted on both broad, general samples of unemployed workers as well as on workers displaced by specific plant closings. For general samples of unemployed workers, studies conducted at one point in time and studies that take repeated measurements across time demonstrate the development of mild levels of distress or increases in levels of psychological distress subsequent to unemployment.

Workers who have been displaced by a specific plant closing in a community experience greater health impacts than workers drawn from a general sample of unemployed persons (Perrucci & Perrucci, 1990). The difference is probably because of (a) the impact that a plant

closing has on a community's economy, reducing the chances for reemployment; (b) longer periods of unemployment for workers in a depressed local economy; and (c) greater economic strain resulting from longer periods of unemployment.

## EFFECTS ON FAMILIES AND COMMUNITIES

Families with unemployed members have significantly lower marital adjustment, poorer marital communication, and lower satisfaction and harmony in family relations. Also, children whose fathers are unemployed are more likely to experience infectious disease as well as illness of longer duration in comparison with children whose parents are continuously employed. Even for continuously employed fathers, children whose fathers feel considerable job insecurity are more likely to experience illness than children whose fathers feel very secure in their work positions, suggesting that the anticipation of joblessness affects health (Margolis and Farran, 1981).

The effects of unemployment can reach beyond the individual worker to affect entire communities in situations where tax revenues are reduced and needs for additional public social expenditures increase. Several case studies of unemployment indicate that the loss of economic security usually adversely affects the social cohesiveness of communities as the unemployed workers lose faith in the economic system and become dependent, precluding redevelopment of their communities. Cutbacks in public services, such as education and police protection, reduce quality of life and impair the community's ability to attract new families and new employers.

## GAPS IN RESEARCH KNOWLEDGE

Research on the way in which unemployment affects health points to three explanatory factors: First, and perhaps most important, is income loss and the threat to future financial security; second, is the loss of meaningful work and self-esteem; third, is the lack of social support from friends, kin, and community. These factors have been studied in the context of the stress process. Learning more about who is vulnerable, when in their lives they are vulnerable, and why some vulnerable people become resilient in the face of stress is an agenda for future research (Broman, Hamilton, and Hoffman, 2001).

## UNEMPLOYMENT AND POLICY CONSIDERATIONS

Unemployment is an economic problem and much more. Its impact on individuals, families, and communities results in human and social costs that require a public response. A consideration of the nature and effectiveness of current public policy on unemployment and assumptions about patterns of economic change in the future also encourage a policy response.

Current policy assumes that unemployment is a normal and unavoidable cost of a growing, changing economy operating in a free market. A growing economy requires change, and change leaves behind those individuals who lack the needed human capital (education and skills) and those firms that cannot compete in the marketplace. The challenge is how to get corporations to accept some of the costs of unemployment that now jeopardize workers and their communities.

There is evidence that current unemployment insurance and severance pay or continuing job-related fringe benefits, especially health insurance, is inadequate for most displaced workers. Also, when unemployment occurs during a recession, or by plant closings by a major employer in a small community, there is also a decline in the availability of community resources to assist displaced workers. Current policy attempts to assist those whose jobs have been moved overseas through the Trade Adjustment Act of 2002 and Title III of the Job Training and Partnership Act of 1983, but both serve relatively few displaced workers. And as corporations continue to move or initiate operations abroad, workers will experience job insecurity as well as loss.

There are at least four general policy initiatives that could be considered. First, a policy initiative should be job-centered, with a focus on creating and maintaining jobs through stronger federal legislation to place the human and social costs of unemployment at the center of economic decision-making. Companies should be required to provide sufficient reason in closing their plant(s) before federal permission is granted to do it, particularly if the closing would devastate the individuals and communities involved.

A second policy initiative should expand unemployment benefits available to displaced workers, and it should set uniform standards for states to follow to deliver benefits. These benefits would be particularly effective if combined with an adequately funded program that coordinates job retraining and relocation expenses.

A third policy initiative should provide social services to unemployed workers and their families while they are participating in retraining and relocation programs. Such assistance would help workers to better cope with job loss, and it would help spouses and other family members to obtain advice, training, and agency referrals to help the entire family deal with unemployment.

Fourth, as the creation and export of jobs overseas continues, the federal government should undertake a jobs program, implemented through state and local governments, to hire the unemployed into meaningful and valued jobs in communities across the country. These workers

could assist with vital community services in underserved areas of education, health care, and other community-based services, while benefiting from gainful employment and a sense of contributing to the community.

## UNIVERSAL HEALTH INSURANCE

**SEE** Volume 2: *Policy, Health.*

## VOLUNTEERING, ADULTHOOD

Volunteering is a form of altruistic behavior. Its goal is to provide help to another person, group, organization, cause, or the community at large, without expectation of material reward. Volunteer work is not to be confused with informal helping, which is unpaid service people provide on a more casual basis, outside of any organizational context, to someone in need, or care work, which is normally associated with kin relations and consists of face-to-face help provided to an individual toward whom one feels some kind of social responsibility. Volunteer work does, however, include advocacy, which is a form of service that is very close to social activism. Advocacy organizations seek to influence the outcomes of public or private decisions on issues that affect the fortunes of the organization's clients or broader constituencies.

When people think of a volunteer, they almost always imagine someone who is making a sacrifice to help another person, an organization, or a cause. Although most people agree that individuals can benefit from their volunteer work, they must not volunteer for the purpose of gaining those benefits and would, it is assumed, continue to volunteer even if those benefits disappeared. In the public mind, then, volunteer work is not simply unpaid labor but unpaid labor performed for the correct reason. *Good works* are inspired by virtues such as generosity, love, gratitude, loyalty, courage, compassion, and a desire for justice: any benefits are a byproduct.

According to social surveys, just over a quarter of Americans age 16 years or older will have volunteered at some point in the past 12 months, but the likelihood of having done so and the specific volunteer activity in which they engage vary considerably across social groups. Volunteers tend to be more highly educated (about 20% of high school graduates volunteer compared with 43.3% of college graduates); they are more likely to be White, female, working part-time, married, parenting school-age children, and frequent church-goers. Some people volunteer just a few hours in the course of the year, whereas others contribute several hours a week steadily; the latter group is composed disproportionately of those who are not in the labor force, such as homemakers, students, and retirees (U. S. Bureau of Labor Statistics, 2006).

Volunteerism is more common in the United States than most other advanced industrial societies, mainly because of the religiosity of the American people. A comparison of two otherwise quite similar countries substantiates this argument. The volunteer rate in the United States is higher than the rate in Canada. After country-level differences in frequency of attendance at religious services are controlled, however, the Canadian rate exceeds that of the United States. The same could be said for Sweden and Norway because they, too, have higher rates of volunteering than the United States after frequency of religious services attendance is controlled for. This is because much of the volunteer work in the United States is performed on behalf of religious organizations (Curtis, Baer, & Grabb, 2001).

## VOLUNTEERING OVER THE LIFE COURSE

Life-course patterns in volunteering are quite evident in Figure 1, which uses Current Population Survey data from 2006 (U.S. Bureau of Labor Statistics, 2006). The columns show the percentage of each age group who volunteered at all during the previous 12 months.

Life-course variation in the number of hours volunteered among those who volunteer follows a different pattern: The number of hours volunteered per year is highest among those age 65 or older, followed by those age 55 to 64 years. Volunteers between 16 and 34 years contribute the fewest hours.

**Teenagers and Young Adults** Teenagers are often portrayed as rather self-centered, preoccupied with material possessions, and uninterested in community affairs, political activities, or helping others. In addition, many of the voluntary associations that sponsor and organize volunteer work are relatively inhospitable to teenagers, the one major exception being religious organizations. The teenage years would therefore appear to be a wasteland as far as volunteerism is concerned. In the United States, at least, teenagers show considerable interest in volunteering mainly because schools, churches, and other youth-oriented institutions encourage or, in some cases, require community service of their young people. Numerous studies show that the habit of volunteering tends to be passed from one generation to another. The mother's volunteering is more influential than the father's, due partly to her greater efforts to integrate her children into her own activities and partly to the fact that she is more likely to volunteer for child-related activities than the father (Wuthnow, 1995).

By volunteering early in life, people acquire experience and skills that establish the groundwork for volunteering in later life. In many respects, middle-age volunteers are simply young volunteers who have aged. From a human development perspective, it is no surprise that adult volunteers are more likely to say they volunteered in youth. However, young adults in their early 20s experience the time-pressure of multiple commitments and engage vigorously in a wide variety of leisure-time pursuits—a lifestyle not normally associated with doing volunteer work and this stage of the life course tends to mark a low point in volunteering.

The most popular form of volunteering among younger Americans is in connection with youth development organizations, followed by civic and community groups and environmental organizations. They are less interested than are older people in working in connection with a church (Lopez, 2004). Although young people are less interested in more routine forms of advocacy volunteering, they turn out in greater numbers for the kind of "high-risk activism" associated with protest movements. They are more available for this kind of work (their free time is relatively plentiful, social obligations are few, and, for those in school or college, work commitments are flexible), but the thrill of risky volunteering, which appeals to young people, should not be overlooked. They are also more likely than older people to take on high-adrenalin work, such as search and rescue or emergency squad volunteering.

**Forming a Family** Most Americans get married for the first time in their 20s. When looking at the possible influence of marriage on volunteering, it is important to bear in mind the several different ways people can be single. Compared with married people (and controlling for age), those whose spouses who have died are the least likely to volunteer, followed by those never married and those who are divorced or separated. Significantly, when frequency of religious service attendance is controlled for, the positive effect of marital status disappears, probably because marital status is associated primarily with volunteering in connection with a religious organization (Musick & Wilson, 2008).

Married couples tend to behave similarly when it comes to volunteer work: Freeman (1997) found that 59% of men married to women who were volunteers were volunteers themselves, compared with only 10% of men married to women who were not volunteers. Seventy percent of women married to men who volunteered were volunteers themselves, compared with only 16% of women married to men who did not volunteer. Furthermore, respondents married to spouses who volunteered contributed more hours than respondents married to spouses who did not volunteer (Hook, 2004).

**Who Has the Most Influence?** Spouses have a reciprocal positive effect on each other's volunteer hours; this influence is stronger when spouses are volunteering in the same domain, and the influence of the wife is stronger than the influence of the husband. Interestingly,

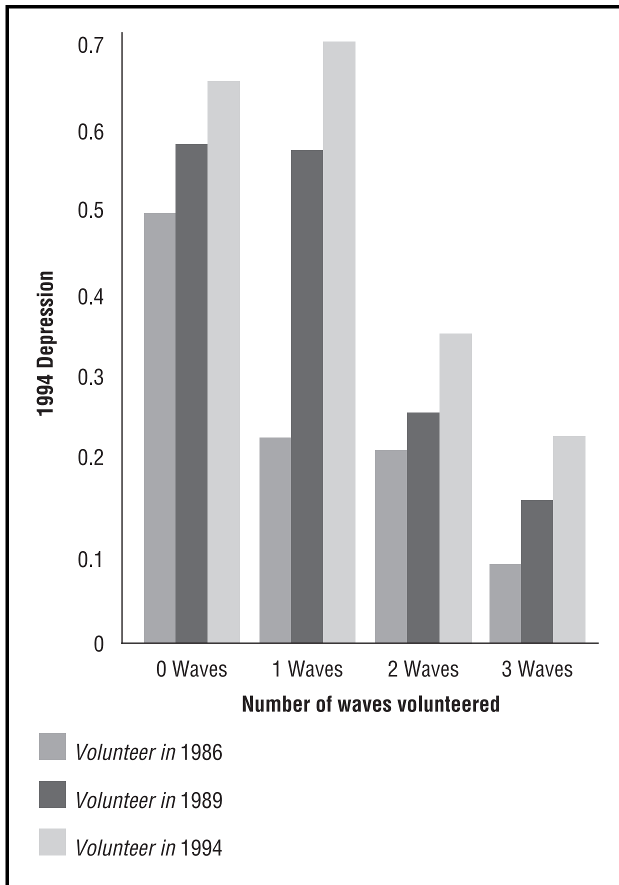

***Figure 1.*** *Percentage of each age group who volunteered at all during the previous twelve months, 2006.* CENGAGE LEARNING, GALE.

unmarried couples living together (i.e. cohabiting) have *no* influence on each other's volunteer behavior (Rotolo & Wilson, 2007).

**Volunteering with a Spouse** Spouses clearly influence each other's volunteer behavior, but it does not necessarily follow that they volunteer together. One survey found that remarkably high proportions of married volunteers (41.4%) were accompanied by their spouses. Husbands were more likely to say they had volunteered with their spouses than wives did. Surprisingly, the tendency to volunteer together did not increase with age. Among the married couples who were volunteering, frequent church-goers were most likely to be volunteering together (Musick & Wilson, 2008).

**Becoming Parents** Newly married couples tend to have low volunteer rates, but this is mainly due to the fact that any children they have are young and that young children inhibit their parents' ability to do much outside the household other than paid work. After they reach school age, however, children act as a social magnet for their parents, drawing them into a wider range of activities outside the home, including volunteer work. Parents of school-age children have a stake in maintaining organizations and activities that cater to their children and that, as individuals, they could not provide on their own, such as sports teams and scout troops.

The influence of children on their parents' volunteering is felt most keenly by mothers, who bear most of the responsibility of looking after children. According to Current Population Survey data, both mothers and fathers are more likely to volunteer if their children are between 6 and 13 years of age—and this pattern does not vary based on gender of the child. Compared with findings in parents of children ages 2 years or younger, parents of children between 6 and 13 years of age are much more likely to volunteer—but mothers are especially likely to do so. The influence of children ages 14 to 17 years on educational volunteering is also stronger for mothers than fathers. Both mothers and fathers of children ages 2 or younger are less likely to volunteer than married couples who have no children, but the deterrent effect is stronger for mothers than fathers (Musick & Wilson, 2008). In short, gender makes a difference regarding the influence of children on volunteering: Young children deter their mothers more than their fathers and school-age children involve their mothers more in volunteer work than their fathers.

Parental status and the gender of the parent also make a difference as to what the volunteer does. The Current Population Survey asks volunteers to report their main activity or job as a volunteer. For example, only 5.5% of men without children volunteered as a coach or referee compared with 18.9% of men with children younger than 18, but their volunteer rate for this activity was nevertheless higher for women whether they have children under 18 (4.2%) or not (1.8%).

The positive influence of school-age children on volunteering in midlife is conditioned by available free time. Full-time workers find it more difficult to volunteer than part-time workers; women with part-time jobs are more likely to volunteer and volunteer more hours than women working full-time, especially if they have school-age children. Full-time work, however, lowers the probability of volunteering and the number of hours volunteered but less so for mothers with school-age children (Musick & Wilson, 2008).

**Volunteer Work in Later Life** People become steadily less likely to volunteer as they enter old age and volunteer for fewer organizations. However, the hours contributed by each volunteer increase until he or she enters the ranks of the *oldest old* (75 years of age or more). According to

2006 Current Population Survey data, among those who volunteer at all, the median annual hours is highest (104) for the over-65 age group and lowest for 25- to 34-year-old age group. This age profile is found in most industrialized societies that gather such volunteer data. Interestingly, older people (i.e., those 65 years old and older) are somewhat more likely to say they became a volunteer by approaching an organization (43.4% compared with 40.8% of volunteers as a whole). Although this difference is small, it suggests that older people are more likely to take the initiative as a way of finding rewarding activities in their old age.

As far as volunteer preferences are concerned, older people favor volunteer activities in which they can help on a one-to-one basis and see the fruits of their labor immediately. Not surprisingly, older people are also drawn to volunteer work that targets other older people. In the 2006 Current Population Survey data, religious volunteering was the most popular choice among older people. Age also positively influenced volunteering for social and community service organizations, health, civic, political, and professional organizations. However, people older than 65 were less likely than younger people to volunteer for education or youth services, environmental or animal care organizations, and public safety organizations (U.S. Bureau of Labor, 2006).

**The Effect of Retirement on Volunteering** Many Americans plan to take up volunteer work in their retirement. The data suggest, however, that continuity is the predominant pattern: People tend to maintain the habits they had before retirement, but they modify them in light of their new circumstances. If they volunteered in middle age, they volunteer in old age and, in all likelihood, increase the number of hours they contribute. If they did not volunteer in middle age, they are unlikely to take it up when they retire. Those who do begin volunteering after retirement are more likely to be White, highly educated, in good health, and, above all, strongly religious and married to a spouse who is also volunteering (Zedlewski, 2007). Much also depends on what retirement means for the person: Older people who have fully retired volunteer the most hours, followed by older people who have retired but returned to work, followed by full-time workers who have not yet retired (Musick & Wilson, 2008). Once again, the interweaving of influences from several life domains—a hallmark of life-course analysis—helps shape the amount and direction of volunteer work.

## THE BENEFITS OF VOLUNTEERING

A growing body of research indicates that volunteering is good for the physical and mental health of the volunteer. Volunteers have lower early mortality rates, possess greater functional ability, and are less likely to feel depressed. Up to a certain point (around 100 hours per year), more volunteer work means more positive health outcomes. Long-term volunteers also seem to enjoy more benefits. For example, an analysis of the American Changing Lives data over three waves (1989, 1992, and 1994) showed that respondents who volunteered in all waves had fewer depressive symptoms than those who volunteered only once (Musick & Wilson, 2003). From a life-course perspective, it is interesting that older volunteers receive the greatest mental health benefits from doing volunteer work, no doubt because it provides them with physical and social activities and a sense of purpose at a time when they are losing social roles. It is also likely that older volunteers have more discretion over their volunteer work and contribute more of their volunteer time to religious organizations, both of which increase the likelihood of positive health benefits (Musick & Wilson, 2003).

## POLICY

In the United States and other countries, such as Canada, the United Kingdom, and Australia, it is official government policy to promote volunteerism. Governments have come to regard volunteer work as a valuable adjunct to publicly provided services such as education, recreation, health care, and social services and an important stimulus for wider engagement in the community through political and civic organizations. In 1993 the United States established the Corporation for National Service to coordinate federal and state organization and promotion of volunteerism. Among the initiatives pursued by the Corporation are Senior Companions, to encourage volunteer work among the elderly, and Americorps, to engage teenagers and young adults in helping others. Service-learning curricula, in which high school students perform community service in return for academic credit, have recently spread throughout the United States, their aim being not only to improve educational quality but also to encourage a long-term commitment to helping out in the community.

# WORK–FAMILY CONFLICT

Work–family conflict (WFC) refers to the situation in which the responsibilities and expectations of an individual's work roles interfere with the performance of his or her family roles—or vice versa. The work–family literature has burgeoned in the wake of large numbers of women and mothers entering the workforce since the 1970s. This research, which is based largely on the scarcity principle that individuals have finite resources that become overtaxed by multiple role responsibilities, takes one of two broad approaches. The first approach focuses on specific manifestations of WFC, as when employment or job characteristics interfere with specific family activities such as parenting or marital quality. The second approach focuses on experiences of WFC more broadly and the putative causes and consequences of these generalized experiences. This entry focuses on the latter of these two approaches because the full scope and breadth of WFC has direct effects on individuals at most stages in the adult life span, and it has untold potential effects for individuals' children and other family members as well as for coworkers and employers.

## WFC: THE EVOLUTION OF A CONCEPT

Jeffrey Greenhaus and Nicholas Beutell (1985) defined WFC as "a form of interrole conflict in which role pressures from work and family domains are mutually incompatible in some respect" (p. 77). Building from this basic definition, a substantial literature in the fields of sociology, psychology, organizational behavior, management, and family studies has conceptualized WFC as a stressor. As such, WFC is believed to interfere with individual health and well-being, marital quality, family functioning, and fulfillment of job expectations.

There have been two primary innovations to the WFC concept since Greenhaus and Beutell's influential definition. The first primary innovation is the idea of directionality. Michael Frone, Marsha Russell, and M. Lynne Cooper (1992) argued that work-to-family conflict, or the extent to which work pressures impinge on family responsibilities, was conceptually and operationally distinct from family-to-work conflict, or the degree to which family responsibilities impinge on work responsibilities. Frone, John Yardley, and K. S. Markel (1997) then demonstrated the empirical distinction between work-to-family and family-to-work conflict and subsequently developed an influential model of the work–family interface, which emphasizes the reciprocal and bidirectional relationship between work-to-family and family-to-work conflict.

The directionality issue is interesting because it is in direct contrast to the original conceptualization of WFC. Greenhaus and Beutell (1985) specifically argued that WFC is inherently nondirectional until a decision is made to resolve one of the pressures contributing to the conflict, at which point directionality takes form, a situation sometimes referred to as work interference with family or family interference with work. This consideration of directionality creates conceptual confusion between WFC, conceptualized as a discrete occurrence of mutually incompatible role responsibilities, and work–family interference. Nevertheless, two separate meta-analyses have concluded that work-to-family and family-to-work conflicts are distinct yet bidirectionally interrelated. It is now standard practice in most research to conceptually and empirically separate work-to-family and family-to-work conflict.

The second primary innovation revolves around typologies of WFC. Greenhaus and Beutell (1985) originally speculated that WFC takes three primary forms: time-based (e.g., missing work because of a sick child or inclement weather keeps a child from school), behavior-based (e.g., treating family members like a subordinate at work), and strain-based (e.g., a person being short-tempered with his or her children following a bad day at work) conflict. However, only recently have researchers given serious

consideration to these different types of WFC. Whereas some reviewers of the work–family literature question the utility of different types of WFC (Bellavia & Frone, 2005), others conclude that there is useful evidence supporting the distinction of some types of WFC—particularly time- and strain-based conflict (Geurts & Demerouti, 2003). Some researchers suggest that differentiating time-, behavior-, and strain-based conflict is important because they may have different antecedents and consequences, thereby requiring different intervention strategies (Carlson, Kacmar, & Williams, 2000). Greenhaus, Tammy Allen, and Paul Spector (2006) expanded the original typology to differentiate energy-based conflict from strain-based conflict, whereby the former reflects physical or emotional exhaustion and the latter reflects the transfer of negative emotions or feeling states (e.g., stressed or cranky). The utility of differentiating among different types of WFC is not yet resolved and awaits focused empirical and theoretical analysis.

## MEASURING AND STUDYING WFC

In a review of the industrial-organizational psychological and organizational behavior literatures, disciplines central in studying WFC, Wendy Casper, Lillian Eby, Christopher Bordeaux, Angie Lockwood, and Dawn Lambert (2007) noted that 85% of WFC studies used survey methods. Several studies of WFC have been based on nationally representative samples such as the National Study of the Changing Workforce (NSCW), a sequential panel study that began in 1977 and was refielded in 1992 and 5 years thereafter by the Families and Work Institute. Other national data on WFC come from the Midlife Development in the United States survey, which was originally fielded in 1995. In addition to these nationally representative studies, a large number of studies have been conducted with industry- and company-specific samples of workers.

WFC research is almost exclusively cross-sectional. Casper and colleagues (2007) noted that only 6% of WFC studies conducted in the past 25 years have followed individuals over time. Studies based on longitudinal data have produced results that are consistent with the general view of WFC as a stressor. Frone and colleagues (1997), for example, found that elevated levels of family-to-work conflict predicted the onset of incident hypertension (i.e., high blood pressure) over a 4-year time horizon. Similarly supportive of the stress perspective, other researchers have documented that elevated levels of WFC predicted health declines over time (Grant Vallone & Donaldson, 2001). These few longitudinal

studies notwithstanding, surprisingly little is known about the antecedents and consequences of WFC over time.

Measurement of WFC has relied almost exclusively on self-reports that are either self- or interviewer-administered. Lois Tetrick and Louis Buffardi (2005) identified five to six measures of WFC most commonly used in the literature since the mid-1990s. They pointed out that there is substantial variation in the degree to which self-report measures have demonstrated construct validity, indicating that they actually measure WFC.

Some concern has been expressed that measures of WFC are inherently problematic because they overlap with outcomes of interest such as psychological strain, marital quality, and job satisfaction (MacDermid, 2004). Others question the structure of items assessing work-to-family conflict and family-to-work conflict and raise concerns that the absence of parallelism could create the impression that one direction of conflict is more common than the other (Bellavia & Frone, 2005). Still others have been critical because common measures do not capture the conceptual difference between WFC, such as the simultaneous occurrence of incompatible pressures in work and family domains, from work–family interference or the extent to which experiences in one domain impede activities in the other (Carlson & Grzywacz, 2008). Some investigators have developed proxy reports whereby knowledgeable counterparts report on levels of WFC for a focal individual, such as a spouse (Small & Riley, 1990); however, proxy measures are infrequently used. The infrequent use of proxy measures is driven, at least in part, by the fact that WFC can occur at both the social (and observable) and psychological (and nonobservable) level, suggesting that proxy reports can only capture a portion of WFC.

## FINDINGS FROM WFC RESEARCH

The WFC literature is large and spans multiple disciplines. Since the late 1990s, there have been no fewer than 10 narrative reviews of the work–family literature. Most of these reviews provide summaries of the antecedents and consequences of WFC (Bellavia & Frone, 2005; Eby, Casper, Lockwood, Bordeaux, & Brinley, 2005). Additionally, there have been several quantitative reviews of the WFC literature (Allen, Herst, Bruck, & Sutton, 2000; Byron, 2005). Interested readers are encouraged to consult these. In this entry, a few main findings are emphasized that are likely to be of particular interest to life course researchers.

**WFC across Time** Relatively little research examines WFC across either historical or developmental time. In terms of historical trends, evidence from the NSCW indicates that levels of WFC increased among American workers in the late 20th and early 21st century and that this increase is not attributed to growth in the proportion of women in the labor force and increases in dual-earner families (Winslow, 2005). On the developmental side, in light of the absence of longitudinal studies of WFC, there is limited ability to determine whether WFC changes across the adult life span. Based on cross-sectional data, Joseph Grzywacz, David Almeida, and Daniel McDonald (2002) reported that both work-to-family and family-to-work conflict increased and then declined across adulthood, with both directions of WFC peaking between the ages of 35 and 44.

Drawing on birth cohort data from Sweden, Gunn Johansson, Qinghai Huang, and Petra Lindfors (2007) reported significant differences in WFC among 43-year-old women, depending on life course employment patterns: Women with more intensive and persistent employment coupled with late childbearing generally reported greater WFC than those who began parenting earlier while working part time. Deborah Carr (2002) reported cohort differences in the effects of work–family trade-offs on psychological well-being. Despite these and other studies using birth cohort studies or a life course approach, there is a substantial need to better understand whether experiences of WFC have changed over time and how the ebb and flow of work and family responsibilities across the adult life span may contribute to age-related differences in WFC.

**WFC across Social Groups** Gender is a dominant focus of WFC research, both historically and substantively. The historical focus arises from the reality that WFC research is rooted in the large-scale shift of women and mothers of young children into the labor force. Although women and mothers have always been in the labor force, particularly women from minority and working-class families, the substantial increase in labor force participation among White middle-class women stimulated a large amount of research questioning the degree to which problems arise from women's employment. The substantive interest in gender differences in WFC arises from a theory suggesting that the worlds of work and family are inherently gendered and that gender-specific constructions of these worlds would create unequal experiences of WFC. Joseph Pleck's *(1977) asymmetrical boundary hypothesis*, or the view that women and men will have different patterns of WFC because of socialization patterns that assign responsibility for family to women and responsibility for work to men, exemplifies the gender argument made by several researchers.

Despite strong theory that indicates otherwise, there is only mixed evidence of gender differences in WFC. One review concluded that "there is little support for differences across basic characteristics that are typically examined such as gender" (Bellavia & Frone, 2005, p. 118). Likewise,

another study reported that "there is no clear pattern in terms of the relative importance of work or family domain predictors for men's and women's work-family conflict" (Eby et al., 2005, p. 181), although those authors did conclude that gender is deeply engrained in work–family relationships. Kristin Byron's (2005) conclusion from a meta-analysis is that there is little evidence that experiences of WFC differ between women and men. Research acknowledging that women are overrepresented in some occupations whereas men are overrepresented in others and that uses gender-neutral measures of WFC are needed to resolve the inconsistent pattern of results observed in the WFC literature.

The WFC literature has been criticized as being overly focused on individuals who are valued by the labor market, that is, White, middle-class individuals working in professional jobs (Lambert, 1999). Little research examines WFC among members of racial and ethnic minority groups or compares experiences of WFC across racial and ethnic groups; such research is sorely needed. Evidence from the 1997 NSCW suggests significant racial and ethnic variation in WFC (Roehling, Jarvis, & Swope, 2005). Research that treats race and ethnicity as more than control variables would improve theoretical understanding of WFC—recognizing that cultural beliefs likely shape the relative salience of work and family and the importance of integrating these domains (Korabik, Lero, & Ayman, 2003). On a more practical level, in light of the growing diversity of the labor force in the United States and around the world, research that documents and seeks to understand racial and ethnic variation in WFC is needed to ensure that all workers benefit from governmental and occupational programs designed to help workers effectively integrate their work and family lives.

Likewise, location in the social hierarchy has not been adequately handled in the WFC literature. Jody Heymann (2000) characterized jobs occupied by lower-class individuals as requiring nonstandard and erratic work hours and lacking necessary benefits (e.g., child sick leave) and argued that these types of jobs create WFCs that exacerbate health disparities. This basic argument has strong face validity, but there is little attempt to document social class or socioeconomic inequalities in WFC or to consider the degree to which WFC contributes to difficulties experienced by lower-status families. The few studies on the topic find that higher-status workers, as indicated by education and occupation, report more rather than less work-to-family conflict (Schieman, Whitestone, & Van Gundy, 2006). Single mothers report high levels of WFC (Avison, Ali, & Walters, 2007), but whether this is attributable to family structure or socioeconomic hardship remains uncertain. More research is needed to firmly determine whether the WFC is unequally shared in the social hierarchy and the potential role of WFC in contemporary social problems such as health disparities.

## CONCLUSION

Evidence from the large multidisciplinary literature suggests that WFC is a pressing social problem in need of policy solutions. Diane Halpern (2005), in her presidential address to the American Psychological Association, described WFC as the issue of our time. WFC is an issue confronted by most workers, regardless of whether it is the new parent transitioning back to work, the midlife individuals sandwiched between children and aging parents, or the older worker laying plans for retirement. Echoing Halpern's claim, the National Institute for Child Health and Human Development has created a network of researchers to develop and test policies and organizational practices that reduce WFC. Workplace flexibility, particularly management strategies that give workers control over when and where job-related tasks are performed, is believed to be invaluable for minimizing WFC. Similarly, systematic training of supervisors and managers to help them be more supportive of employees' lives outside the workplace also offers promise for minimizing WFC. These types of strategies help adults respond effectively to legitimate demands that arise in daily life, such as needing to drive an aging parent to a health care appointment or meeting with a child's teacher to resolve a learning or behavioral problem. The short- and long-term consequences of strategies to reduce WFC remain unknown, but researchers and policy advocates believe that they will produce healthier and more content workers, better-functioning families, and more productive organizations.

The WFC literature has developed substantially since the 1980s with contributions from several disciplines. Despite the breadth and depth of the literature, substantial room remains for advancements and new areas of research. Longitudinal research examining WFC over time is needed, as is research devoted to documenting and understanding secular trends in WFC. Advancements in measurement tools are needed to better capture WFC while remaining attentive to problems that arise from exclusive reliance on self-report data. Finally, focused research on understudied segments of the population, such as economically disadvantaged families and members of racial and ethnic minority groups, is needed. Focused research attention in these areas will deepen understanding of WFC and contribute to the creation of workplace and public policies that promote adults' ability to integrate work and family.

# ZNANIECKI, FLORIAN

## *1882–1958*

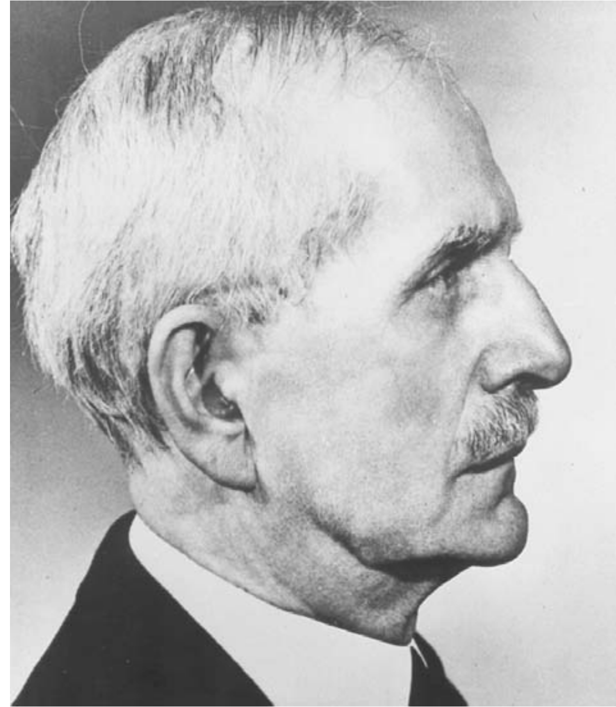
Florian Witold Znaniecki was born on January 15 in Świątniki near Włocławek, Poland; he died on March 23 in Champaign, Illinois. A sociologist, social theorist,

and philosopher of culture, he taught at the Poznań University (1920–1939) and the University of Illinois (1940–1958). Together with William I. Thomas of the University of Chicago he published *The Polish Peasant in Europe and America* (1918–1920), considered an early examination of what would later be called the life course. Another of his notable works is *Cultural Reality* (1919/1983), which outlined his theory of human action and values. Recognized as an eminent sociologist of education, he directed the Education and Social Change project at Columbia University's Teachers' College from 1930 to 1933. In 1956 he was elected as President of the American Sociological Association.

Znaniecki was one of the first sociologists to consider the two-way process by which society is maintained through the actions of individuals while, at the same time, the actions of individuals are shaped by society. This duality is central to sociology in general and to the study of the life course in particular. Znaniecki focused on culture and emphasized its construction by individuals as social agents. His work provided the conceptual and empirical foundations for the development of life-course studies.

Znaniecki's approach to understanding the relationship between society and the individual emerged from his theory of cultural systems, which he developed in *The Method of Sociology* (1934), *Social Actions* (1936), and *Cultural Sciences* (1954). In Znaniecki's view, culture encompasses multiple systems—social, economic, hedonistic, technical, cognitive, aesthetic, and religious—that are composed of different values and constructed by human activities. Within the cultural system, social systems are crucial for their perpetuation and development. Social systems encompass social actions, relations, roles, and groups. The "humanistic coefficient" of cultural systems refers to their meaning and axiological significance in the experiences of individuals as members of various groups. To Znaniecki, the individual "self" is not independent but exists with the humanistic coefficient as an object of the active experience of others and of the individual him- or herself. In short, individuals are constructed by their participation in cultural systems as social values and social agents. Znaniecki's works relating to individuals as cultural and social persons include *Wstèp do socjologi* [Introduction to Sociology] (1922), *The Laws of Social Psychology* (1925/1967), *Socjologia wychowania* [The Sociology of Education] (1928–1930), *Ludzie terázniejsi a cywilizacja przyslósci* [People of the Present and the Civilization of the Future] (1934), *The Social Role of the Man of Knowledge* (1940), and *Social Relations and Social Roles* (1965).

Znaniecki combined data from individual life histories and the study of social groups to identify major types of



***Florian Znaniecki.*** **COURTESY OF THE AMERICAN SOCIOLOGICAL ASSOCIATION.**

social personalities, which are formed through the interactions between individuals and social circles. He argued that three kinds of social circles are particularly relevant in the formation of social personalities: educational, occupational, and companionable. Social personality is the cultural, constructionist view of the individual. Znaniecki distinguished four major components of the social person: the *reflected self*—the way individuals believe members of their social circle view them; the *social position,* including social standing (the rights of being recognized as socially valuable) and economic status; the *social function,* comprised of obligations such as objective tasks and moral integrity; and finally the *reconstructed self,* which is independent from the social circle and is both autobiographical (related to one's memories) and one's ideal (or the desired self that one projects into the future).

Znaniecki believed that social personality evolves throughout the life course, because each new social role introduces new experiences and leads to the development of new active tendencies. The extent to which social tendencies developed early set life trajectories varies across individuals. What develops is the tendency toward either a stable and predictable life course or a changeable and unpredictable one. Personality is conceptualized not as a reflection of one's inborn biological or psychological

characteristics but as shaped by social and cultural context. Particularly important in the early part of the life course is the emergence of person-creating tendencies, that is, tendencies to form one's person according to a unique pattern. An individual's social biography is actualized in various social circles through these person-creating tendencies.

Znaniecki conceived of the individual life course very differently from those who built on the basic framework of biological maturation. He took into consideration the influence of social circles and developed a role theory that took into account the dynamic interplay between society and individual, in contrast to those who either emphasized the ''self'' as the dominant element of roles or who highlighted the social structural aspects. For Znaniecki, the social role is a purely cultural phenomenon, involving the active participation of the performer and other individuals as social agents. An individual's participation in social life in terms of role performance implies four components: the social person, social circle, duties, and rights. Znaniecki's work contributed to the study of the historical evolution of various social roles: of men of knowledge, educators, religious and political personas, as well as to the study of marital and erotic relations, mother–child relations, fraternal relations, and friendships.

***Elżbieta Hałas***

A groundbreaking reference work in life course studies — a field within modern sociology that provides an interdisciplinary examination of the convergence of individual life pathways with social structures — the *Encyclopedia of the Life Course and Human Development* explores major stages of human development. Organized into three volumes (Childhood and Adolescence, Adulthood, and Later Life), the nearly 400 signed entries in this set examine how enduring experiences, major transitions, and events such as having children and childcare, education, stress, marriage, career, addiction, friendship, disease, spirituality, and retirement influence and affect an individual's life course.

The 500 to 7,000 word entries are written by nationally renowned subject specialists and peer-reviewed by the editor-in-chief, Deborah Carr, and an editorial board of academic experts specializing in life course sociology and human development. Each article concludes with a bibliography pointing users to recent books, journal articles, board-approved Web sites, and proven classics to facilitate further research. The *Encyclopedia of the Life Course and Human Development* covers research methodologies and key data sources, and includes a glossary, thematic outline, annotated bibliography, and cumulative index. Individual entries are enhanced with graphs, charts, and tables, as well as photographs which complement, clarify, and add detail to the text. The set opens with a preface written by the editor-in-chief and each volume contains an introduction to that life stage written by a board member. By bringing together a wide range of information and perspectives on each of the three major stages of life, this set provides students with a basic research guide to life course studies and human development to use along side primary course materials. This set is also a useful reference tool for scholars and practitioners in the fields of life course sociology, developmental psychology, and gerontology.

The *Encyclopedia of the Life Course and Human Development* broadens Gale's collection of encyclopedias in the Macmillan Social Science Library, making it a companion to the *Psychology of Classroom Learning: An Encyclopedia*, the *Encyclopedia of Sex and Gender*, the *Encyclopedia of Race and Racism*, and the *International Encyclopedia of the Social Sciences*.

# *Introduction to Volume 3, Later Life*

Many students become interested in the social sciences because they want to know how people live their lives—their work lives, their family lives—and they also want to know why people make the choices they do. People who have meaningful experiences and relationships with grandparents and older relatives often become interested in the study of aging. College students often bring stories to the classroom about how their grandparents (and great grandparents) grew up in dramatically different times and as a result had different life experiences that seem unfamiliar to young people today. Grandmothers had far fewer opportunities to earn college degrees and have careers compared to today's young adults. Grandfathers often were the sole breadwinners in their households providing stable wages and a modest standard of living that benefited their families. These kinds of stories are familiar and expected. However, what is also true is that stories that students share about their older relatives are wide ranging. For example, some tell stories of grandmothers who worked and raised children by themselves, or great uncles who never married. Life course scholars agree that all of these diverse life experiences contribute to variations in later life experiences and statuses. It has been the work of life course scholars to disentangle complex relationships between history and biography in order to learn how each generation is different from all others and why there are differences within each generation.

One of the most significant demographic trends in the United States has been the aging of the population. The number of older adults in the United States—defined as persons ages 65 and older—will more than double in size from 2005 through 2050. The number of working-age Americans and children will increase more slowly than the older population, and will shrink as a proportion of the total population. In the United States, and nearly all developed nations, declining fertility rates and mortality rates have led to a large increase in the older adult population, both in relative and total size. This trend is well described in several entries in this volume (see both Age Structure and Population Aging in this volume). The "graying" of the world's population has inspired a large body of research and theorizing about the latter part of the life course. The life course paradigm has provided a guiding framework for much of this research. The entries in Volume 3 summarize much of the best life course scholarship that has led to a greater understanding of later life. I will next provide an overview about how we might think about defining later life. Then, I'll discuss several of the major trends in aging research that are described in this volume.

## WHAT IS "LATER LIFE"?

The definition of later life is itself a subject of debate. Typically later life, or "old age," is considered to begin at age 65. However, beliefs about what constitutes "old age" vary across time and place. In nineteenth century America, when it was much less common to encounter 60 and 70 years olds, defining old age to begin at age 55 may have been more appropriate. Even today, among the younger populations of the world such as those in South Asia and Africa, researchers define old age as 50 or 55+ or even younger. My own research in Nepal has shown that significant physical impairments are common among people as young as age 45 and 50, especially among Nepalese women. I have met women who appear be in their 80s because their skin and teeth are weathered and they are stooped over, their backs appearing "broken" due to years spent doing arduous farm and household labor. When interviewed, these women report they are decades younger than they appear to be. If the goal of defining old age is to direct attention, policy, and resources to those in need—the definition of old age might account for declining physical health. However, if one were to take physical health alone as a mark of old age—age 65 might be too young of a definition—especially in the United States and other wealthy nations, where a great many adults live impairment-free throughout their 60s and 70s (see "Disability and Functional Limitation, Later Life" by Martin).

Definitions of age may also encompass individuals' own perceptions and self-evaluations. It is not uncommon to "feel" decades younger than the chronological age on a driver's license (see "Age Identity" by Westerhof). This may be especially true of baby boomers who might still identify with a youthful 1960s identity that encompassed the then-revolutionary ideals of peace, self-expression, and free love. By and large, however, a definition of 65+ remains useful to researchers because policies, such as Social Security, use age 65 to define cut points for age-related benefits and services.

## THE RISE OF THE "THIRD AGE"

One of the most significant trends in aging research is the recognition that later life, whatever definition is used, is not a time of inevitable decline. In their entry "Theories of Aging," Norella Putney and Vern Bengtson write that disengagement theory, which emphasizes the necessary withdrawal of older persons from social life, has largely been refuted by empirical research. Instead, this theory has been supplanted by activity theory and continuity theory, which stress the importance of active engagement in the social world for optimizing well-being in later life. As a result of this theoretical shift, there has been an explosion of research on topics such as creativity and wisdom (both in this volume). We learn from these entries that later life can be a time of psychological *growth*, rather than decline or stability. Also in this volume, we describe the time that older adults spend doing volunteer work (see "Volunteering, Later Life" by Burr) and traveling (see "Leisure and Travel, Later Life" by Gibson). All of these topics can be summarized using the label of Third Age. Third age represents the point of view, among scholars and laypersons, that later life can be a time to set new life goals and create new meaning. One only has to spend some time using Google and key words like "seniors and art" and "seniors and travel" to know that older adults are an active, vital community.

## SOCIOBIOLOGICAL INFLUENCES ON AGING

Another important trend in aging research is increasing multidisciplinarity of ideas and research, especially the use of both social and biological perspectives to better understand aging. Sociologists, economists, epidemiologists, psychologists, physicians and many others have engaged with one another to investigate the interrelationships among social status and biology in later life. This volume documents the improved physical health of the older population compared to years past. At the same time, there are new health problems in later life that are growing in importance such as diabetes and dementias, both of which are topics covered in this encyclopedia. In addition to social explanations for the trends in health and

well-being, there has been increased scholarly attention to biological influences over the life course on later life health (see "Genetic Influences, Later Life" by Gavrilova & Gavrilov).

Greater longevity or lengthening of the life span and better health have also reorganized the social world of older adults. For example, as people live longer and healthier lives it is possible to occupy roles for prolonged periods of time. Thus, we have seen an increase in the amount of time one spends in some roles such as retirement (see "Retirement" by Williamson & Higo ). Also, time spent on various family roles such as the grandparent role and the great grandparent role has increased (see "Grandparenthood" by Szinovacz). Another consequence of greater longevity is a rise in the variability of roles as not only the time spent in roles increases but also the incidence of new roles increases. For example, one of the notable features of the lengthening life course is that more and more older persons are continuing their education during their post-retirement years (see "Lifelong Learning" by Hamil-Luker). Finally, men and women are more likely to have more complicated combinations of roles than in the past. As a result there are many men and women who experience psychological stress from role overload and role strain (see "Stress in Later Life" by Kahana, Kahana, & Hammel). This trend may be particularly true among older caregivers who take on care of a spouse or partner (see "Caregiving" by Silverstein).

## NEW DATA, NEW FINDINGS

Glen Elder (1985), a sociologist who is considered the architect of the life course paradigm, has observed that that theoretical developments combined with new methodological tools and data have spurred considerable growth in later life scholarship over the past four decades. Many of the authors in this volume credit advances in research in their respective areas to availability of new data; especially longitudinal data (see the composite entry "Data Sources, Later Life"). It is difficult to determine what kinds of behaviors or statuses may be apt to change as one ages when data are from one point in time (referred to as cross-sectional data). With cross-sectional data, older people are compared to younger people at one point in time and it is tempting to attribute any observed differences from these data as being related to aging. It is not possible to disentangle age, period and cohort effects with one wave of data. For example, in her entry "Religion and Spirituality, Later Life," Linda George writes that although older people appear more religious than younger people in cross-sectional studies, only longitudinal data (where individuals are interviewed at various points in their lives) can truly reveal whether and how individuals change as they age. Many entries in this volume describe a similar "data dilemma" (see "Sexual Activity, Later Life" by Waite, Das, & Laumann) that has only recently progressed due to the availability of new data.

Two important types of longitudinal data are described in this volume. First, there are long-term longitudinal studies that follow people over many stages of life. For example, The Wisconsin Longitudinal Study (WLS) follows a sample of Wisconsin high school graduates from the class of 1957 from ages 18 through late life. With longitudinal data such as these, it is possible to understand how early family formation and career choices affect later life outcomes such as retirement and health. Other longitudinal studies begin at later points in the life course such as the Health and Retirement Study (HRS). The HRS interviews people at regular, frequent intervals (every 2 years) so that the dynamics of change associated with aging can be better understood. The importance of data such as the HRS should not be underestimated. HRS data have been widely used since the study began in 1992. The HRS has led to similar studies in Europe (see "Data Sources, Later Life: English Longitudinal Study of Ageing [ELSA]" by Marmot & McMunn). Also, many entries in this volume report on findings from the HRS. It has been a monumental data collection effort, offering rich data over time on a wide range of topics. While the HRS initially focused on the aging experiences of the generations that preceded the baby boom generation, younger birth cohorts have been added to the HRS study. So, new information about the baby boom cohort have become available to researchers recently. This design—where multiple cohorts are followed over time—is an important advance in aging research.

## A FINAL NOTE TO THE READER

I began this introduction by discussng about the predictability of life transitions and the importance of one's history in shaping his or her later life chances. Yet I also noted the incredible diversity of experiences from one generation to the next and also within a given generation. When asking authors to prepare their entries for this volume, we asked them to include comments about this diversity. As a result, the entries in this volume discuss generational differences, cross-cultural differences, and differences by age, gender, social class and race within the United States. It is our hope that readers will find the entries in this volume to be informative about both major trends and patterns over the life course yet also provide many unexpected findings.

## ACTIVE LIFE EXPECTANCY

One of the defining features of the 20th century was a steady increase in life expectancy, accompanied by rapid population aging—a trend that is expected to continue into the foreseeable future as more individuals survive to older ages, and fertility rates remain low. Accompanying the growth of the older population is an increasing need for support services for individuals with physical limitations and disability. Active life expectancy is a measure researchers have developed that can succinctly describe the average amount of time one is expected to live with disabling conditions in a population. It provides a basis for understanding the time individuals in a population are likely to need support from others or be in need of health care.

### DEFINING ACTIVE LIFE EXPECTANCY

Active life expectancy is a summary measure of population health, which integrates age-specific disability and mortality into a single measure, indicating the average number of years of life expected to be spent active after a specified age. The remaining life expectancy is inactive. When life expectancy is divided into these states, *active* years are usually defined as years lived without a specifically defined disability, whereas *inactive* years are usually defined as years lived with a disability. The inactive years are not necessarily lived at the end of life, and can be distributed throughout the remaining lifetime. The term *inactive* is not meant to imply complete physical incapacitation. Definitions of *inactive* vary from having any difficulty performing normal tasks to having severe limitations that would make it difficult to live independently in a community setting and provide self-care. The accompanying figure shows an example of active and inactive life expectancy in the United States at age 65 in 1980 and 1990. As seen in Figure 1, the sum of the active and inactive (sometimes labeled *disabled*) years is life expectancy at a specific age.

Active life expectancy tends to be used synonymously with the term "disability-free" life expectancy—both of which are subsets of the broader term *healthy* life expectancy. Whereas active life expectancy is usually defined as life without some form of physical limitation or disability, healthy life expectancy can be defined as life without a disease or impairment such as diabetes, cognitive loss, obesity, or hypertension.

As with other life table-based measures, active life expectancy measures are not affected by the composition of the population; therefore, the results can be compared over time or across populations, assuming similar measurement of disability or health state. Like life expectancy, active life expectancy does not represent the actual experience of a real population, but rather the number of years a hypothetical life table population would live in active and inactive states if it experienced the observed mortality and morbidity rates.

Active life expectancy data are used by official government publications in the United States, Europe, Asia, and the World Health Organization (WHO), as well as by journalists and public health researchers around the world. It can be used for several purposes including: to provide a summary description of mortality and morbidity for a population; to indicate health inequalities for subgroups in a single population; to make comparisons

## LIFE TABLE

A life table shows the life expectancy of individuals at different ages. It is a series of calculations based on age-specific mortality rates that summarize the effect of mortality on the number of survivors at a given age, and the expected length of life after that age. Life table measures are valuable because they are succinct indicators that reflect mortality conditions across the life course and are unaffected by the number of people in each age group in the actual population, making them comparable across populations and subgroups of the population. Life tables are usually based on mortality data for a short period of time rather than for a real cohort of people throughout life. Because of falling mortality rates over time, actual life expectancy lived by generations has usually been higher than the life expectancy at birth from the life table in the year of their birth.

across populations; to monitor changes in the health of a population; and to asses the contribution of specific risk factors to population health outcomes and thus inform policy debates. *Years of inactive life* can provide an indicator of the average time individuals will need health care or social or institutional support, and is a measure that can also be used to provide a sense of the magnitude of the potential or realized impact of public health programs or other health interventions.

It should be noted that there is no single number alone that is considered the active life expectancy of a population at a given moment because the value depends on the definition of *active* and the method used to calculate the estimate. The definition of *active* can vary from study to study. When the estimate covers all ages, general definitions of disability are used; with older individuals, the definition of disability (also referred to as inactive) is often related to the ability to care for one's own needs independently based on scales that gauge one's capacity to perform various activities of daily living. In addition, inactive years can be further subdivided by levels of severity from the debilitating (e.g., being unable to bathe oneself or eat without assistance) to the more mild (being unable to go shopping or manage money, for instance), depending on the extent to which the disability limits participation in normal roles and daily activities.

### METHODS OF CALCULATION

The first and most commonly used approach to calculating active life expectancy is the prevalence-based life table method, also known as the Sullivan method (1971), named after its designer. This method, developed in the late 1960s, combines age-specific disability, or another indicator of health status prevalence, with the life table functions derived from a set of age-specific mortality rates, to divide the life table years lived into active and inactive. This method remains the most widely used since cross-sectional data on the prevalence of disability and mortality have been readily available. There are multiple advantages to Sullivan's method: (a) it has a straightforward protocol that does not require special software; (b) it can be applied to cross-sectional disability data (a one-point-in-time observation) that are more available than panel surveys (multiple observations); (c) only moderate sample size in the disability survey is required to produce reliable age-specific prevalence estimates; (d) an abridged life table is sufficient for mortality information because the method is not sensitive to the size of the groups; and (e) prevalence-based methods are less influenced by survey design and model assumptions than longitudinal approaches. For a detailed description of this method see *Health Expectancy Calculation by the Sullivan Method: A Practical Guide* (Jagger, Hauet, & Brouard, 2001).

There are some limitations and disadvantages to this widely used approach. The biggest disadvantage is that this method provides little information about the process of health change, which figures into the estimated length of healthy life. Increases in healthy life could come from reductions in the onset of disability, improvements in recovery from disability, or changes in mortality. Second, it may not be a sensitive indicator of change over time because the prevalence of disability may not change as quickly as disability incidence rates. Finally, mortality rates are usually assumed to be the same for both active and inactive individuals, and this assumption is not likely to be accurate. The Sullivan method has been widely used around the world in order to compare change in health or disability over time, differences across countries, and differences within countries.

Building on the Sullivan approach, the WHO uses a measure called *disability-adjusted life expectancy* (DALE). This measure weights different levels of disability as less than full years based on severity, as well as the duration of the disability, so the years lived do not really add up to the total length of life expectancy. This approach is based on cross-sectional data and thus has all of the same limitations as the Sullivan approach; however, it has been used in international comparison studies because the WHO collected relevant data for this measure. The WHO used the DALE measure to compare the health

of 191 member state populations in their Global Burden of Disease publications (Lopez et al., 2006).

Incidence based methods estimate active life using longitudinal data that indicate changes in health or disability state over time. Analysis of active life expectancy based on longitudinal data from a panel study of the population is of increasing importance as researchers investigate the causal mechanisms driving changes in population health. Disability is based on incidence, the new occurrence of a condition at a follow-up interview, and thus is focused on recent health events rather than lifetime events. Mortality among the active is also estimated separately from mortality among the inactive based on the panel study, allowing variation in mortality to be reflected in the estimates of active life expectancy. The data input into the life table are the age-specific transition rates that reflect bidirectional transitions between the active and inactive states as well as to death from either an active or inactive state. This is the theoretically preferred method of estimating active life expectancy and has more potential to provide useful information about the processes of disability onset, recovery, and death.

However, this analytic approach is significantly more complicated to model. The major difficulty in adopting this approach is that it requires extensive longitudinal data, with a substantial sample size in order to model the onset of and recovery from disability and transitions to death. The model is also somewhat sensitive to the assumptions underlying the estimation process such as the functional forms of the transition schedules. Several methods have been developed to analyze longitudinal data including: a hazard model approach (Crimmins, Hayward, & Saito, 1994); an algorithm based on Markov chains called IMaCh (Liévre, Brouard, & Heathcote, 2003); a Markov transition model; and a Bayesian Monte Carlo estimation technique.

## RELATED CONCEPTS

Additional summary measures of active life expectancy have been developed using similar conceptual approaches. In the 1940s the concept of *years of life lost* was developed to assess the health burden associated with deaths prior to the age of average life expectancy based on a simple calculation of the number of deaths multiplied by the life expectancy at the age at which death occurred. More recent measures of life lost have incorporated information on years lived in a disabled state and the time lost to death. For example, in 1993 the WHO introduced *disability-adjusted life years* (DALY) to summarize the effect of both premature death and disability, with each DALY representing one year lost of nondisabled life. The DALY is a health gap measure that identifies years lost to lower quality of life, as well as death. One criticism of the DALY is that it is based on an arbitrary definition of ideal health, with subjectively defined disability weights.

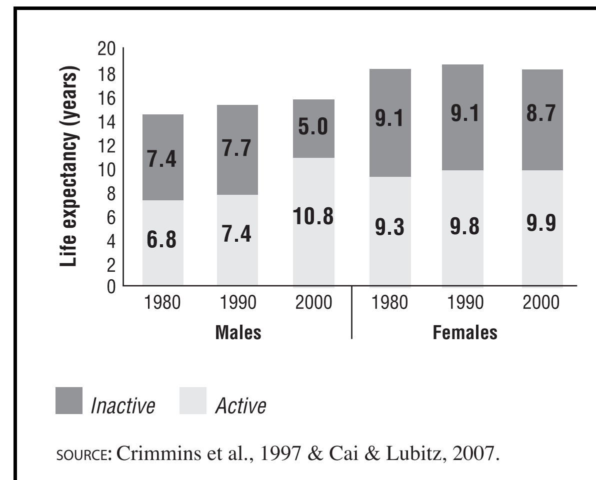

***Figure 1.*** *Active life expectancy at age 65 for the United States. (Crimmins, Saito, & Ingegneri, 1997; Cai & Lubitz, 2007.)* CENGAGE LEARNING, GALE.

DALYs have been used to compare health care cost-effectiveness, with recommendations based on a cost per DALY gained. Both the DALY and the DALE (described earlier) can be used to link potential disease-specific and risk factor interventions with population health outcomes.

*Quality-adjusted life years* (QALY) is usually used as a quantifiable measure of the impact of a medical intervention. In this measure, each year in perfect health is assigned the value of 1.0, each year of non-perfect health (e.g., disabled or otherwise physically limited) is assigned a fractional value relative to its impact on quality of life, and death is assigned a value of 0. The values assigned for non-perfect health are the subject of some debate, and can be calculated by several methods including what follows: the time-trade-off method, where respondents choose between remaining ill for a period of time or being restored to good health with shorter life expectancy; the standard gamble method, in which respondents choose between remaining ill or choosing a risky treatment that has a chance of restoring health or killing them; the visual analog scale in which individuals rate ill health on a scale from 0 (*death*) to 100 (*perfect health*); or the EuroQol EQ-5D questionnaire, a classification system based on dimensions such as mobility, pain, and anxiety (Murray et al., 2002). Multiple question responses can be collapsed into a single health state utility score. Additional information about each of these methods can be found in the *Global Burden of Disease and Risk Factors* report (Lopez et al., 2006) and the WHO's *Summary Measures of Population Health* (Murray et al., 2002).

## TRENDS IN ACTIVE LIFE EXPECTANCY

Active life expectancy became a popular measure with rising interest in whether there has been a compression of morbidity. (Compression of morbidity refers to the concept of pushing all the illness and disability of one's life into as small a time period as possible.) This interest has grown with increasing focus on the quality, as well as the quantity, of life. Many analyses have addressed the issue of how changes in total life expectancy are divided into changes in active and inactive life. A compression of disability or morbidity would be an increase in life expectancy resulting in a greater proportion of life lived active or without disability; an expansion of disability or morbidity would be an increase in the proportion of life lived in the inactive state or with disability or morbidity. It is also possible that both changes occur together, proportional increases in both active and inactive life expectancy, resulting in no change in the relative proportion of life years lived disabled or nondisabled. Understanding which of these scenarios is occurring can potentially have an important impact on planning for the health and support needs of a society, and is of increasing importance as the proportion of the population at older ages increases.

Cross-sectional estimates of expected life that is free of bedridden disability and institutionalization were first attempted in the 1960s. These first estimates of the expectation of healthy life showed increasing healthy life expectancy between the years 1958–1966, whereas life expectancy as a whole did not change. Between 1970 and 1980 life expectancy in the United States increased by about three years and most of the increase was in years of disability. Studies for the mid-1980s through the mid-1990s suggest that disability, particularly severe disability, has declined over this time period, leading to overall increases in active life expectancy. Trends in England and Wales, Canada, and France have been similar to those in the United States: Before 1980 increases in life expectancy were concentrated in disabled years; after 1980 life expectancy in the active state accounted for the majority of the increase in life expectancy.

A small number of studies of trends in active life expectancy based on longitudinal data have been published to date and these are limited to analysis of the older population. Results appear to be similar to studies for the whole population based on cross-sectional data that indicate increases in active life expectancy and decreases in life expectancy with severe disability from the mid-1980s through the late 1990s (Cai & Lubitz, 2007). In addition to calculating estimates of active life expectancy, longitudinal (or over-time) analyses of active life expectancy also investigate trends in disability onset, recovery, and mortality, helping to explain the ways in which the processes leading to disability prevalence may be changing over time. Studies suggest that there have been declines in disability onset through the mid-1980s and the mid-1990s as well as decreases in mortality for both those who are disabled and those who are not.

## DIFFERENCES IN ACTIVE LIFE EXPECTANCY BY SEX, RACE, AND SOCIOECONOMIC STATUS

Researchers have used active life expectancy to summarize differentials in disability and mortality for different subgroups of the population. For example, many studies have addressed differences in active life expectancy by gender, socioeconomic status, and race. Women generally have longer life expectancy than men, and when disability is defined in a yes-or-no fashion, studies show that women tend to have both longer active and longer inactive life than men. Most studies show that women live a greater proportion of their longer lives with disability. In studies where disability severity is taken into account, such as those based on the DALE measure, the proportion of remaining life in disability is more similar for both sexes. This could result from men spending less time with disability, but having more severe disability, which is more heavily weighted in the DALE calculation.

Health expectancy indicators are comparable across groups with different age structures, and are useful for comparing socioeconomic differences across groups, or over time. Socioeconomic differences in active life provide a summary indicator of the effects of inequality on health or disability. Most studies find that people who have lower socioeconomic resources have shorter life expectancy and live a greater proportion of their lives in a disabled state. Differences by social class in expected active life are usually larger than differences in total life expectancy. Reducing socioeconomic differences in active life has become a public health goal in many countries. Trends over recent decades suggest that differences between low and high socioeconomic status groups have been growing, led by increased morbidity differentials (Crimmins & Saito, 2001). Although many different measures of socioeconomic status are used in the literature, education level is the most common measure because it does not generally change after adulthood, and it is not affected by poor health in later life, as income or occupation might be.

In the United States race and ethnic differences in active life expectancy have become an important area of inquiry as these are, of course, highly related to socioeconomic differences. African Americans in the United States have a shorter active life expectancy and a longer disabled life expectancy (Hayward & Heron, 1999). Race and gender also appear to interact; a number of studies conclude that African American women live a notably greater percentage of their lives with disability than

African American men, who have the shortest life expectancy and largest numbers of life years lost.

## INTERNATIONAL COMPARISONS

Measures of active life expectancy have been developed for many countries around the world, led in part by the *Réseau Espérance de Vie en Santé* (REVES) International Network on Healthy Life Expectancy and the Disability Process, and the WHO. The WHO's major contributions are part of a larger initiative called The Global Burden of Disease, which was an attempt to summarize and compare the health needs of countries all over the world. Efforts have been made by researchers to harmonize data collection on disability and health measures in surveys across countries, and many new studies are designed with international comparisons in mind.

International comparison studies by academics generally use the Sullivan method or DALE to calculate expected years active and inactive, as well as the proportion of remaining life expected to be lived in an active state. Precise rankings of countries on active life expectancy are difficult to make, as residents of different countries may evaluate health problems differently and different definitions of disability are employed in different surveys.

Rankings of countries on active life made by the WHO generally parallel rankings of life expectancy. More developed nations report both longer lives and more years active; less developed countries report shorter lives, with a smaller percentage of remaining life expected active. For example, the WHO estimated years of healthy life lost in different regions of the world and found developed countries average about 8% of healthy life lost (of a 77 year life expectancy), while a comparable measure for sub-Saharan Africa is 15% (of a 50 year life expectancy) (Mathers, Sadana, Salomon, Murray, & Lopez, 2001).

Large variations in active life expectancy exist between regions within national borders as well. In Australia, for example, active life expectancy can vary by as much as eight years across states; a comparison of small regions in Canada found differences of active life expectancy as large as 11.5 years; in both Spain and France studies examining active life expectancy in the 1980s and 1990s found increases of up to 4 years in some regions, and declines of 4 years in other regions (Robine, Jagger, Mathers, Crimmins, & Suzman, 2003).

Active life expectancy can be affected by lifestyle and behavioral choices, physical activity, social interactions, random events such as accidents or catastrophic health problems, and preventable strategies to avoid injurious situations. Recovery can be affected by these issues as well, in addition to medical interventions and the availability of compensatory services.

## SUMMARY

Active life expectancy can provide a succinct indicator of the health and mortality of a population as well as a summary of differences within populations, changes over time, or differences between countries. Trends in active life expectancy appear to show increasing length of active life expectancy, especially when severe disability is used to define inactive, and little change over time when mild disability is used to define inactive. Early 21st-century trends suggest widening differences across socioeconomic classes. A valuable summary of information on the concept of active life expectancy, methodological approaches, and empirical findings can be found in *Determining Health Expectancies* (Robine et. al, 2003), which is written and edited by the members of the REVES International Network on Health Expectancy and the Disability Process.

# AGE, PERIOD, COHORT EFFECTS

Life course and human development research has long concerned itself with time-specific phenomena that can be represented in age, period, or cohort (APC) effects. The search for these effects—APC analysis—permeates sociological, demographic, and epidemiologic studies of aging and the life course. Because APC analysis has the unique capacity to depict the entire complex of social, historical, and environmental factors that shape individual life courses, its importance for constructing and refining theory, measurement, and analysis can hardly be overstated. This entry briefly introduces the intellectual history of various conceptual and analytic issues in contemporary APC analysis, discusses the consequences and implications of misspecifications of APC effects in previous studies, reviews the state-of-the-art development of APC models in recent research, and concludes with the challenges that remain for studies of APC phenomena in human societies.

## DEFINITIONS OF AGE, PERIOD, AND COHORT EFFECTS

Age, period, and cohort effects all refer to some type of time-related variation in the phenomena of interest, yet they carry distinct substantive meanings.

*Age effects* are defined as variations associated with different chronological age groups brought about by physiological changes, accumulation of social experience, and/or role or status changes. Age effects, therefore, reflect biological and social processes of aging internal to individuals and represent developmental changes across the life course. This can clearly be seen in the considerable regularities of age variations across historical time and place in many outcomes such as mortality, fertility, disease prevalence and incidence, schooling, employment, marriage, and family structure. The identification of age changes is especially important in studies of health and aging because age has been shown to be the most important source of variation in vital rates and has frequently been used to understand the etiology of diseases (Hobcraft, Menken, & Preston 1982).

*Period effects* are defined as variation over time periods or calendar years that influence all age groups simultaneously. Period effects subsume a complex set of historical events and environmental factors such as world wars, economic crises, famine, epidemics and pandemics of infectious diseases, public health interventions, and technologic breakthroughs. Shifts in social, cultural, economic, or physical environments may in turn induce similar changes in the lives of all people at a given point in time. Thus, period effects are evident from a correspondence of changes in demographic events and social and epidemiologic conditions that are expected to influence these events.

*Cohort effects* are defined as changes across groups of people who experience an initial event such as birth or marriage in the same year or years. Birth cohorts are the most commonly examined unit of analysis in demographic and aging research. A birth cohort moves through life together and encounters the same historical and social events at the same ages. Birth cohorts that experience different historical and social conditions at various stages of their life course, therefore, have diverse experiences. Conceived as the essence of social change (Ryder, 1965), cohort effects arise when each succeeding cohort carries with it the imprint of physical and social exposures from gestation to old age that bear on its members' fortunes in a way specific to that cohort. Cohort effects thus represent the effects of formative experiences that subsume both the effects of early life

conditions and the continuous exposures to historical and social factors throughout the life course.

Conceptually distinguishing APC effects is theoretically important in three ways. First, it is crucial for attributions of etiology or social causation. Age effects represent aging-related developmental changes in the life course, whereas temporal trends across time periods or birth cohorts reflect exogenous contextual changes in broader social conditions. Second, this distinction also relates to the generalizability of research findings. In the absence of period and cohort effects, age changes are broadly applicable across individuals in different time periods and cohorts. However, differences among periods and/or cohorts indicate the existence of social forces and exposures affecting changes that are period and/or cohort specific. Third, to the extent that these effects serve as aggregates and proxies for different sets of structural correlates, the distinction is especially valuable for better understanding and identifying the underlying social and environmental factors that are amenable to modifications.

## THE HISTORY OF AGE, PERIOD, AND COHORT EFFECTS

Although studies of age and time variations have long existed in the history of science, those that jointly consider age, period, and cohort variations as distinct entities appeared in the scholarly literature only relatively recently. Examinations using APC analysis are most common in demographic studies of human population and have been most rigorously developed in analyses of mortality (Hobcraft et al., 1982). The earliest attempts can be found in descriptive studies of 19th-century English death rates that clearly indicated the importance of cohort variations, relative to period variations, in projecting mortality (Derrick, 1927; Kermack, McKendrick, & McKinlay, 1934). The relevance of this approach was then recognized in subsequent epidemiologic investigations of public health issues, the earliest of which is the well-known study on tuberculosis mortality conducted by Frost (1939). Frost's study emphasized the influence of early life conditions, rather than current conditions, on cohort experiences for a disease that has long latency. The usefulness of APC analysis demonstrated by these early studies and the convenience of using simple indicators that are widely available in many kinds of data facilitated the quick spread of APC analysis not only in the demography of mortality and fertility but also in the epidemiology of diseases. Although APC analysis has taken root in these two fields relatively independently of one another, the common interest and similarities in the development of analytic techniques unite them as one cottage industry.

Early studies mostly relied on descriptive analyses such as graphical displays of age-standardized or age-specific data by time period or birth cohort. They are useful for providing *qualitative* impressions about temporal patterns, but they provide no *quantitative* assessment of the sources of change. The question of how these factors simultaneously operate to shape the observed patterns require the use of statistical regression modeling (Kupper, Janis, Karmous, & Greenberg, 1985). The first successful implementation of a statistical model for APC analysis was by Greenberg, Wright, and Sheps (1950), who found statistically significant variations that can be attributed to all three effects.

The APC accounting or multiple classification model was more fully developed by Mason, Mason, Winsborough, and Poole (1973) and has served for over three decades as a general methodology for estimating separate APC effects using conventional linear regression models. Mason and associates also formally defined the model identification problem that is induced by the unique relationship between the three variables: period = age + cohort. A vast literature in demography, biostatistics, and sociology subsequently used this methodology, with only the solutions to the identification problem varying (Hobcraft et al., 1982). Differences among these solutions often produce ambiguous and inconsistent results. Researchers do not agree on methodological solutions to these problems and have concluded that APC analysis is still in its infancy (Kupper et al., 1985; Mason & Wolfinger, 2002).

## DISENTANGLING AGE, PERIOD, AND COHORT EFFECTS: ILLUSTRATIVE EXAMPLES

Disentangling APC effects in empirical analysis is without a doubt an arduous task. Failure to attend to this confounding problem, however, can constitute model misspecification and seriously bias one's understanding of the true social and biological processes that generated the observed data. The following examples illustrate this point by showing how omitting one or more factors leads to differences in inference.

First, some widely embraced images of the baby boom cohorts do not mean the presence of cohort effects. For example, the *boomers* have been frequently conceived of as the innovators rewriting the rules and remaking society. They have also been thought of as the *Me Generation,* which consists of self-indulgent consumers obsessed with health and youth and rely on products such as Botox or Viagra to fight against the effects of biological aging (Hughes & O'Rand, 2004). Although it is intuitively appealing to attribute these as cohort effects, they could have been driven by other forces that are independent of cohort effects, such as period changes. One key assumption on which the expectation of cohort effects rests is that individuals do not change their attitudes and behaviors in response to changes in political, economic, or social context over time. It is possible that

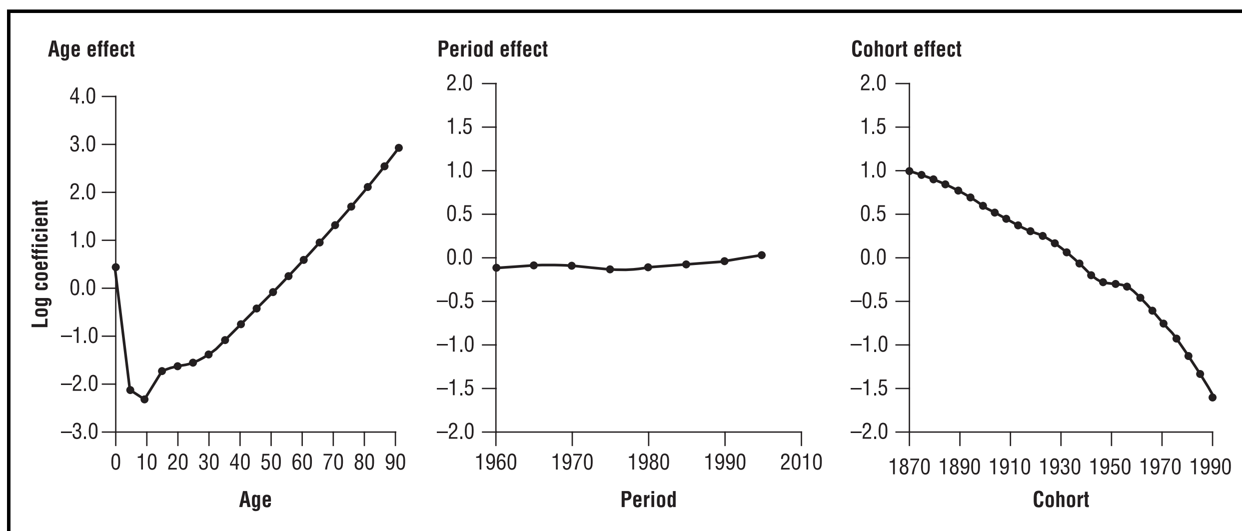

***Figure 1.*** *Hierarchical APC model estimates of age, period, and cohort effects on U.S. verbal ability: GSS 1972–2000.* CENGAGE LEARNING, GALE.

the characteristics observed in the baby boomers have resulted from their adaptations to period conditions. Such period conditions could have also changed other cohorts in a similar way.

Consider another case in which one omits cohort effects in studies of temporal trends in adult mortality in the United States. Substantial mortality declines in the United States for a large part of the past 100 years have been widely documented. However, the sources of mortality reductions in the most recent 50 years are not well understood. Empirical investigations are usually confined to changes in age and/or period trends. The cohort effect is less frequently tested. If it is present, then it implies that certain assumptions currently employed by demographers and other social scientists can be misleading. For instance, it is frequently assumed that rates of mortality declines over time are equal across birth cohorts. It is also assumed that these declines depend on rates of change in period-specific conditions such as economic advance and health care technology that are independent of birth year. These assumptions ignore cohort effects and greatly simplify estimations, but they are increasingly inconsistent with the accumulating evidence of cohort differences in a variety of health outcomes that predict mortality. Recent APC analyses, conversely, relate these temporal patterns of mortality to specific demographic components by delineating APC effects (Yang, Fu, & Land, 2004). They provide new evidence of persistent cohort differences in mortality rates—namely, the substantial survival improvements across most birth cohorts. As shown in Figure 1, the most striking finding is the dominance of cohort effects in explaining recent trends of mortality reductions. Period effects are generally small or modest when birth cohort and age effects are simultaneously controlled in the analysis. Thus, the role of cohort effects in recent mortality declines suggests that the assumptions employed in previous studies are untenable. This undeniably has serious implications for measurement and analysis in future research.

A third example is confounding cohort and aging effects in the life-course study of mental health. Is old age depressing? Most cross-sectional studies found that depression changes with age. However, findings are inconsistent with regard to the direction of this relationship. This inconsistency has been referred to as a *scientific myth*. Cross-section data, however, do not substantiate real-time aging as a risk factor for depression, nor do they suggest true life course changes of individuals. More important, age and birth cohort differences are confounded and cannot be disentangled with observations obtained at a point in time. Using longitudinal data with multiple follow-ups and statistical models that distinguish the age and cohort effects, Yang (2007) found evidence of substantial cohort variations in age trajectories of depression. Earlier cohorts have higher levels of depression on average (Figure 2), which are largely due to their lower levels of education and income relative to more recent cohorts. Taking this cohort effect into account explains away the aging effect.

## AGE-PERIOD-COHORT MODELS: NEW DEVELOPMENTS AND CHALLENGES

The conventional linear model of additive APC effects (Mason et al., 1973) has been the most widely used model

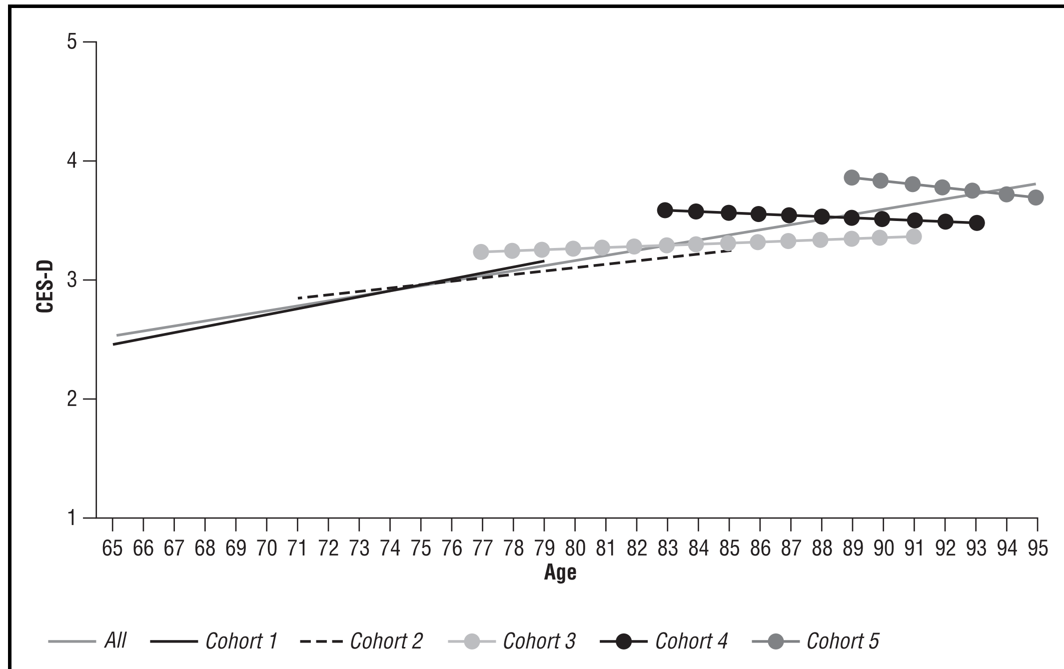

***Figure 2.*** *Expected Growth Trajectories and Cohort Variations in Depressive Symptom (CES-D) Scores.* CENGAGE LEARNING, GALE.

for analysis of tabular population level data. As mentioned already, one has to resolve the identification problem by imposing certain identifying constraints to estimate such a model. The most common approach to solving this problem is to place at least one equality constraint on two or more of the age, period, or cohort coefficients. For example, one can constrain the effect coefficients of two adjacent age groups, periods, or cohorts to be equal to identify the model (see, e.g., Mason & Smith, 1985; Yang et al., 2004). The main criticisms of this approach and its variants are that (a) different equality constraints yield different effect coefficient estimates but identical model fit and (b) estimates of the effect coefficients and thus of the patterns of change across the age, period, and cohort dimensions are sensitive to the choice of the identifying constraints that depends on strong a priori or external information that rarely exists or can be well verified (Mason & Wolfinger, 2002).

The problem with much of the extant literature is that there is a deficiency of useful guidelines on how to conduct an APC analysis. Rather, the literature often leads to the conclusion that it is either impossible to obtain meaningful estimates of the distinct contributions of age, time period, and cohort to the study of social change or that conducting an APC analysis is an esoteric art that is best left to a few skilled methodologists. New models and methods have been developed to redress this situation for three common research designs in social science research. These developments not only have better addressed the limitations in conventional APC models but also have extended the reach of APC analysis to a new family of models. They consist of (a) a new statistical estimator, called the Intrinsic Estimator, for estimating the conventional APC multiple classification models for the aggregate population level data on occurrence/exposure rates (Yang et al., 2004); (b) a hierarchical or mixed (fixed and random) effects model for repeated cross-section sample surveys with multilevel data (Yang & Land, 2006; Yang, 2006); and (c) a hierarchical or individual change model for accelerated longitudinal cohort data (Miyazaki & Raudenbush, 2000; Yang, 2007).

The APC identification problem is inevitable only under the specification of conventional linear models of fixed APC effects that are assumed to be additive. However, additivity is only one approximation to the process of how social change occurs. The models described above in items (b) and (c) bypass this problem by specifying nonlinear models for multilevel data, thereby allowing researchers to capture the contextual effects of cohort membership and historical time on a wide range of social demographic processes. In addition, the possibility of testing explanatory hypotheses using these kinds of models greatly enhances researchers' ability to construct theories about the specific social forces that produce general cohort and period trends.

The developments summarized above mark the beginning of a new era of APC analysis. New models and methods

are needed for testing other theories of social change. Two prominent examples (Hobcraft et al., 1982) that need additional methodological development are (a) *cohort-inversion models* that suggest that cohorts experiencing exceptionally adverse or beneficial events early in life will respond inversely later in life and (b) *continuously accumulating or evolving cohort effects models* that suggest that, contrary to what conventional linear models assume, cohorts are continuously exposed to influences that alter their developmental trajectories over the life course. There currently are few, if any, statistical models with which to apply these conceptually appealing models. The development of such analytic devices and tools thus should be a priority for future research.

# AGE IDENTITY

The concept of age identity refers to the inner experience of a person's age and aging process. Age identity is the outcome of the processes through which one identifies with or distances oneself from different aspects of the aging process. In scientific research a person's age identity is measured with questions such as "How old do you feel?"; "To which age group do you belong?"; and "How do you perceive and understand your own aging process?"

Age identity belongs to the domain of the subjective experience of aging. Key measures of age identity thus are subject to personal biases and misinterpretation, yet researchers in the field of gerontology have long taken the personal experience of one's own age and aging process to be a subject worthy of investigation. Different aspects of age identity have been studied empirically since the 1950s (Barak & Stern, 1986). There are two reasons why it is important to study this topic. First, age identities, however biased they may be, have important consequences for individual development over the life course. Second, age identities represent visions of aging that come from older persons. It is important to highlight these perspectives in research, as they are not paid much attention in contemporary society.

## FEELING YOUNG

Consistent with the saying that "you're only as old as you feel," one of the most widely replicated findings in age identity research is that older individuals tend not to feel old. In 1986 S. R. Kaufman conducted a series of in-depth interviews about the personal experiences of aging. Despite changes in their physical and social functioning, many older persons had a strong inner experience of continuity that was not affected by their rising chronological age. Kaufman concluded that older people have an "ageless self." Many older persons also do not feel that they belong to the elderly age group and tend to see

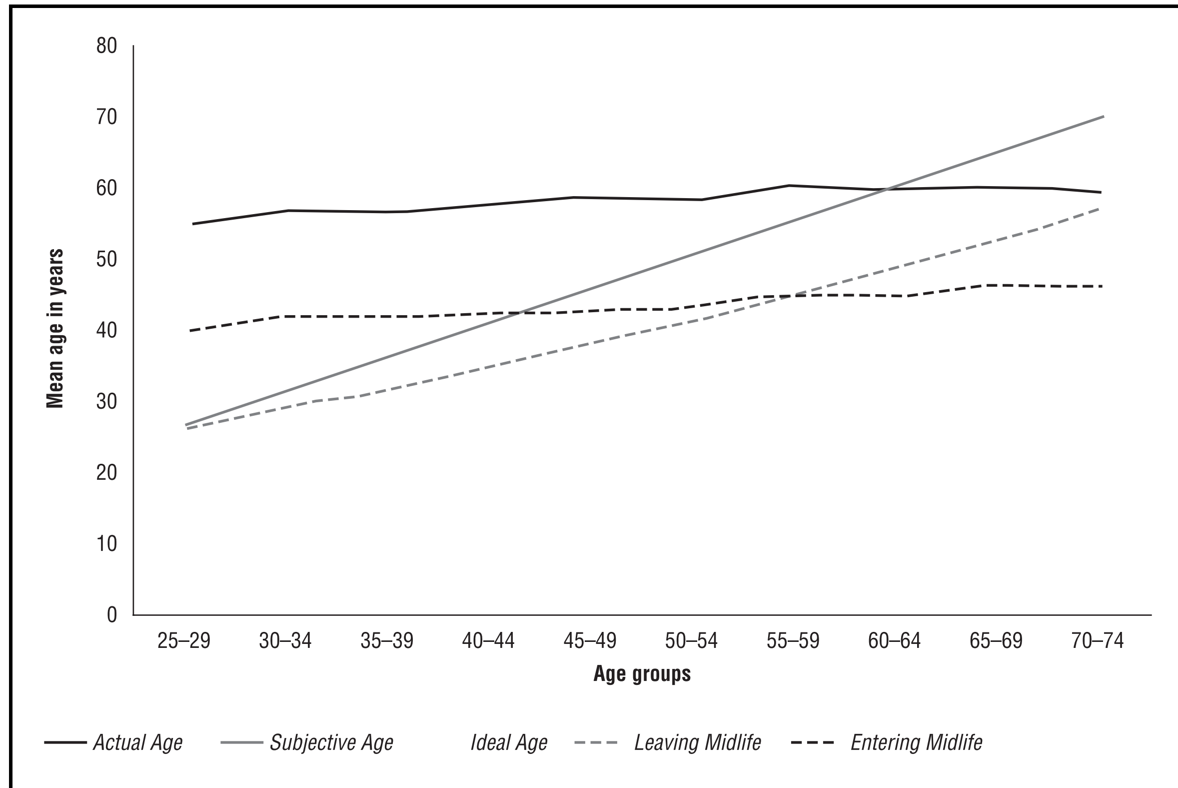

***Figure 1.*** *Different aspects of age identity as compared to actual age.* CENGAGE LEARNING, GALE.

themselves as doing better than their peers. In general they see themselves as an exception to the general belief that aging is related to decline.

Many studies have shown that older individuals feel younger than their chronological age. Figure 1 illustrates this phenomenon by using data from the study on Midlife Development in the United States (MIDUS), one of the few nationally representative American surveys that have measured age identity. The figure shows the mean actual age and the mean subjective age for 5-year age groups. It can be seen that in the youngest age group (25 to 29 years old) there is almost no discrepancy between one's actual age and one's felt age. Each consecutive age group has a younger age identity, up to the oldest individuals, who feel about 13 years younger than their actual age. This pattern has been found consistently in studies comparing different age groups (Barak & Stern, 1986, Westerhof, Barrett, & Steverink, 2003). However, when the same individuals are followed over time, it is found that not all individuals experience an increase in perceived youthfulness; unhealthy people tend to feel less young (Uotinen, Rantanen, Suutuma, & Ruoppila, 2006).

To understand why older people tend to feel younger than their actual age, it is useful to look at the standards individuals use in judging their subjective age. An important standard is people's ideal age: how old individuals want to be. This is an important standard because it provides information about how satisfied older persons are with their chronological age (Uotinen et al., 2006). It can be seen in Figure 1 that the average ideal age is much lower than the chronological age. On average, persons in the oldest age group (70 to 74 years old) want to be almost half their actual age and therefore appear to be very unsatisfied with their age. It also can be seen that individuals on average want to be younger than they actually feel.

Another standard that individuals use in judging their own subjective age are their ideas about when a person enters or leaves a certain stage in the life course. Individuals who participated in the MIDUS study were asked to report the age at which they believe men and women enter and leave middle age. On average, midlife was believed to start at age 44 and end at age 59. In each age group, the mean ideal age is below the age of entering middle age and the mean subjective age is below the age of leaving middle age. Individuals want to be younger than midlife and do not feel older than midlife. It can be concluded that individuals have much younger age identities than their objective age, and their norms about midlife provide support for these perceptions.

## PSYCHOLOGICAL PROCESSES

How can this bias toward younger age identities be understood? Life-span psychologists have described the phenomenon of feeling younger than one's actual age as resulting from a process of adaptation to age-related changes (Sneed & Whitbourne, 2003). When individuals are confronted with age-related changes such as the loss of paid employment and the onset of physical decline, they may strive to maintain their existing identity. For example, when an individual who sees himself as an athlete is confronted with limitations in his physical mobility, he may strive to overcome those limitations by exercising and thus maintain his identity as an athlete. This process is called assimilation. Conversely, an individual may react to new experiences by changing her identity, a process called accommodation. In this case the athlete may give up her identity and search for a new one, for example, being an artist or a writer. From this developmental perspective, feeling younger than one's actual age is the result of an assimilation process that maintains an existing identity.

From a psychological perspective, researchers have argued that motives such as self-continuity and self-enhancement may shape age identity. Self-continuity refers to the desire and motivation to remain the same person over time. Identifying with the younger ages one has been thus results in a feeling of consistency with one's past. Self-enhancement refers to the motive to maintain or increase a positive image of oneself. Youthful identities are a way to satisfy this desire in a culture that associates aging with decline and associates youth with vigor and physical attractiveness, reflecting prevailing negative cultural images of old age in American society.

## CULTURAL CONTEXTS

According to modernization theory, cultural changes create a social context in which youth is a more valued status than old age. For example, historically, the status of older persons declined as a result of increases in literacy and the dissemination of information through formal educational systems and the mass media, which deprived the elderly of their traditional advantage in knowledge. Because there were no systematic observations on age identities in earlier historical periods, it is impossible to assess whether modernization resulted in an increase in the youthfulness of the identities of older persons. However, cross-cultural studies have shown that there are differences in age identities that are based on the way modernization processes unfolded. Although individuals in many cultures tend to feel younger than their actual age, the discrepancy and the age differences are less pronounced in European and Asian cultures than in the United States. For example, a nationally comparative study showed that 74-year-olds feel about 8 years younger in Germany, compared with 14 years in the United States (Westerhof, Barrett, & Steverink, 2003). These differences were attributed to differences in welfare systems and individualistic values resulting from differences in the modernization process in the two countries.

## INTERINDIVIDUAL VARIATION

The focus on average age identities across large groups of persons conceals the fact that there is also clear variability between individuals. Although about three-quarters of Americans feel younger than their actual age, the MIDUS study shows that 15% feel about the same age as they actually are and that 10% feel older than their chronological age. How can this individual variation be understood?

From a life-course perspective, cultural norms provide guidelines for what is considered the optimal chronological age at which life transitions should occur. For example, people judge whether marriage, parenthood, or retirement happens on time or whether an individual is too young or too old for it. In general, when there is a cultural age norm for a particular transition, one can expect that those who experienced that transition will feel older than those who did not. The most consistent evidence for this line of reasoning is found for physical health. Individuals who have poorer health have a less youthful age identity than do their age peers who are in better health (Barrett, 2003). In a culture that largely equates aging with physical decline, individuals tend to use their physical health status as an indicator of their personal aging process. A few studies have examined other life-course transitions, such as the empty-nest phase, retirement, widowhood, and grandparenthood. Although the findings are inconclusive, they tend to confirm that these transitions and their timing in the life course are related to older age identities.

However, life-course transitions tend not to occur at a single uniform age. Life-course theorists have documented that the timing and nature of transitions vary with one's social position, such as socioeconomic status, gender, and race. For example, persons of lower socioeconomic status (less education, less income, and lower-status jobs) experience a pattern of cumulative disadvantage over the life course as well as a temporally more compressed life course; that is, they experience life transitions during a shorter, more densely packed period. Thus, one might expect that persons from backgrounds with lower socioeconomic status have older age identities in that they experience health problems and major transitions such as marriage, parenthood, and grandparenthood earlier than do their wealthier peers. This has been found in many studies. The relative health disadvantage of those with lower status is the most important explanation for this finding (Barrett, 2003).

From a feminist perspective, it has been argued that women in Western cultures suffer from a double standard of aging. Whereas aging comes with grace for men, it comes with disrespect and disregard for older women.

One therefore might expect that women will try to escape this double standard by overstating their own youthfulness more than men do. Few if any empirical studies provide support for this hypothesis, however. Similarly, one might expect that ethnic minorities feel older than Whites, as they have disadvantages similar to those of persons in lower socioeconomic positions. Growing older might pose double jeopardy to aging ethnic minorities that might make them feel even older. However, few studies have assessed this proposition rigorously.

## INTRAINDIVIDUAL VARIATION

Life span psychologists emphasize that the aging process is multidirectional and multidimensional; in other words, there is a balance between gains and losses in different life domains, such as family, health, and personal development. Therefore, it might be expected that one's age identity is more complex than a simple snapshot measure of whether one feels older or younger than one's chronological age.

Qualitative studies of age identities have revealed that individuals perceive both losses and gains in their personal aging process (Keller, Leventhal, & Larson, 1989). In a nationally representative study of middle-age and older persons in the Netherlands, respondents completed two sentence stems: "what I like about getting older . . ." and "what I don't like about getting older . . ." (Westerhof, 2003). Negative perceptions of aging mainly concern physical and social decline. Physical decline is experienced in terms of increasing vulnerability, a loss of vitality, and complaints about specific functional losses such as losses in mobility, vision, and hearing, which are attributed to normal aging. Social losses pertain to the death of loved ones, the loss of independence, and the loss of respect in society. Positive perceptions of one's own aging process were found mainly in social and psychological functioning. The increasing freedom and autonomy, the continuity of relationships, and the birth of grandchildren are the most important social gains, whereas increases in life experience, wisdom, and tranquillity are the most frequently mentioned psychological gains.

In an effort to incorporate these more complex aspects of age identities into gerontological research, researchers have developed and used multidimensional instruments. For example, the frequently used cognitive age measure (Barak, 1987) characterizes subjective age as feel-age ("I feel as though I am . . ."), look-age ("I look as though I am . . ."), do-age ("I do things as though I am . . ."), and interest-age ("My interest are mostly those of a person of . . . years"). Although the answers to these questions are related, individuals may have a feel-age that is different from their look-age, do-age, or interest-age.

New multidimensional measurement instruments have been designed to capture perceptions of different aspects of the aging process. For example, Steverink, Westerhof, Bode, and Dittmann-Kohli (2001) developed an instrument for measuring the experience of one's own aging in terms of physical decline, social loss, and continued personal growth. Older persons experienced more physical and social decline in their aging process than did middle-aged persons and also felt that they had fewer opportunities to continue their personal growth.

In addition to exploring the different domains that shape age identities, researchers have investigated the ways in which social context affects those identities. Symbolic interactionism is a sociological framework that focuses on the ways individuals present themselves in different social interactions in their daily lives. Nikolas Coupland and Justine Coupland (1995) reported a case study of May, a 79-year-old woman. In a conversation with a woman her own age, May presented herself as active and independent, resisting stereotypical images of older persons. In a conversation with a 38-year old woman, however, May suddenly offered a negative portrait of herself, confirming stereotypical images of being old and dependent. These different ways of presenting oneself are related to who has the initiative in the interaction and to the infantilizing mode of communication of the younger partner.

## THE IMPORTANCE OF AGE IDENTITY FOR LIFE-SPAN DEVELOPMENT

As a potentially biased interpretation and characterization of one's own aging process, age identity has important consequences for one's further life-span development. Psychological theories of self-continuity and self-enhancement suggest that one's age identity is typically younger than one's chronological age and that younger age identities are related to mental health and well-being. Many studies have supported this expectation (Barak & Stern, 1986; Steverink et al., 2001). Well-being often is taken as the outcome of successful aging; thus, these studies suggest that age identities are related to a successful outcome of the aging process. However, existing studies have not shown definitively whether age identity influences mental health or mental health affects age identity in later life.

Research shows persuasively that good physical health is one of the strongest correlates of youthful age identities. Although physical health may affect age identities, the causality also may be reversed: One's age identity may affect one's physical health later in life. Studies have shown that more positive self-perceptions of aging and more youthful age identities are related to better health over time and even to longevity (Levy, 2003).

Perceptions of one's aging process have important consequences for one's further psychological development,

physical health, and even mortality. However, individuals' denial of aging may contribute unwittingly to the perpetuation of cultural beliefs about old age as a period of decline at the societal level. It is therefore important to construct identities of old age that are positive in and of themselves.

# AGE SEGREGATION

*Age segregation* refers to the separation of age groups in society. This separation may be physical, in terms of spatial location, or social, in terms of social networks and supports. The separation of age groups can reduce contact between younger and older persons. Because segregation separates members of groups, age segregation may perpetuate stereotypes between generations by limiting opportunities for them to interact. Age-segregated social networks limit the exposure of individuals to others who are not their age. At the same time, age-homogeneous social networks may be perceived as biased or discriminatory because social networks serve to integrate individuals into the greater social context and provide opportunities.

## AGE SEGREGATION AND THE LIFE COURSE

The impact of age segregation varies across the life course. Segregation from other age groups is quite high for younger persons due to the time they spend pursuing education. On entering the workforce, age segregation decreases. As individuals age and retire they may once again become more separated from other age groups. Hence, exposure to age segregation is most common at the younger ages and then later in life. With the aging of the baby-boom cohort and the growth in sheer numbers of older persons, scholars and practitioners are increasingly interested in "age integration," the bringing together of persons of all groups as well as the breaking down of age-based structures in society (Riley & Riley, 2000). By understanding how social structures shape lives, life course researchers are able to distinguish a transition to an increasing degree of age integration in social contexts such as education and work (Riley & Riley, 1994).

Age segregation occurs at multiple levels in society. Individuals are embedded in social contexts. Those social contexts tend to shape their access to other individuals and resources in society. It is well established that individuals are attracted to and associate with others who are like themselves. The principle of homophily suggests that individual's social networks are sorted by characteristics including age, race, and gender. This tendency toward homogeneous networks implies that individuals who are dissimilar will be less likely to maintain relationships (McPherson, Smith-Lovin, & Cook, 2001). Although social networks are likely to be age homogeneous, family-based social supports will vary over the life course (Burt, 1991). Younger adults may turn to their parents for social support. As they age, the focus may shift from parents to their own children.

In the life course context, transitions may be either gradual or discrete. Age is an example of a gradual component of change across the life course and marital status is an example of a discrete transitional stage. Because age is closely related to marital status, the spatial clustering of groups (such as younger married couples in suburbs) can contribute to age segregation in social networks (Kalmijn

& Vermunt, 2007). Age boundaries tend to be stronger among younger adults and women. Possible explanations for this include increased age integration associated with the transition from school to the workforce and the persistence of gender roles associated with child rearing. Although age segregation may be distinguished in terms of individual and group-level network characteristics, age segregation can also be identified in spatial contexts such as residential communities or occupational distributions.

## MEASURING AGE SEGREGATION

Age segregation can be measured using traditional spatial segregation measures as well as through social network analysis. Typically, the preferred method depends on the dimensions of age segregation being measured and the focus of the particular study. The analysis of residential segregation is based on characteristics that may be either ascribed, such as age or race, or achieved, such as economic status. Researchers have refined a number of measures of residential segregation based on the spatial distribution of characteristics.

Scholars of residential segregation distinguish between five distinct dimensions of segregation: evenness, exposure, concentration, centralization, and clustering (Massey & Denton, 1988). One of the best-known measures of residential segregation, the index of dissimilarity, is a measure of evenness. In the age segregation context, it would measure the extent to which different age groups are distributed among dimensions such as neighborhoods or occupations. The index of dissimilarity ranges between zero and one (zero representing no segregation and one representing complete segregation) and is often interpreted as the proportion of one group that would have to move between areas (or occupations) to create an even age distribution.

Other commonly used measures of segregation include the isolation index and correlation ratio, which measure exposure. The isolation index could be used to measure the extent to which one age group has contact with another age group in an area. The correlation ratio measures the degree to which an area is composed of age-homogeneous units. In segregation studies, measures of concentration, centralization, and clustering are related concepts representing the physical space occupied by a group and the adjacency of the group's space to other groups. Researchers have increasingly recognized that no single summary measure fully characterizes all dimensions of spatial segregation (Reardon & O'Sullivan, 2004).

Examining the composition of individuals' social networks, the people they have contact with and to whom they turn to for social support, is another approach to the measurement of age segregation. Data on social networks can be presented descriptively, either in summary tables or through diagrams. Networks diagrams facilitate the visualization of the connections between individuals. There are a growing number of statistical methods used in network analysis (see Wasserman & Faust, 1994).

## CAUSES AND CORRELATES OF AGE SEGREGATION

Age segregation has cultural, social, and spatial contexts. Many Western cultures tend to focus on "youth culture." This focus highlights the language, tastes, and consumption of younger cohorts (Hagestad & Uhlenberg, 2006). A cultural focus on youth may overshadow cohort differences in socialization experiences and exaggerate differences between age groups.

There are both voluntary and involuntary causes of social and spatial age segregation. Voluntary segregation often occurs at the individual or group levels in relation to social networks (or spatial location) and may offer group members supports they might not have access to in the larger society. Involuntary segregation occurs when individuals and groups are denied access to resources or opportunities because of their age. Generally, voluntary and involuntary age segregation can be cast in terms of individual preferences versus age discrimination. In both cases, differential status is assigned to groups based on their age.

Age segregation can occur at any stage of the life course but is most likely at the youngest and oldest ages. Educational and socialization activities are primarily age-segregated for the young. An aging population has contributed to the development of age-segregated retirement communities as well as leisure activities. Involuntary age segregation can be based on either legal justification or socially condoned discriminatory behavior. Examples of involuntary age segregation include mandatory retirement ages as well as the increasing use of long-term care facilities to house the oldest old.

Because social networks are relatively homogeneous, individuals embedded in age-segregated environments will have limited exposure to individuals unlike themselves. They may be unaware of disparities that exist or lack the means to overcome them. For aging adults, an additional consequence of age segregation may be a shrinking social support network. By maintaining ties to family members across generations, older adults are able to increase their age integration and levels of social support (Hagestad & Uhlenberg, 2005).

## PHYSICAL AND PSYCHOLOGICAL CONSEQUENCES OF AGE SEGREGATION

The consequences of age segregation will depend on whether the segregation is at the micro level (individual's

connections and membership in social group) or the macro level (society and social institutions; de Jong Gierveld & Hagestad, 2006). Some key institutions associated with age segregation include education, work (retirement), and leisure (Riley & Riley, 2000). At the individual (micro) level, age segregation is contrasted to age integration and associated with social isolation. At the macro level, age segregation may not necessarily be bad for a group. The type of institution associated with the age segregation and whether the segregation is voluntary or involuntary will influence the consequences of segregation.

Successful aging has been associated with both age segregation and integration. Age-segregated communities are often marketed as life style communities, highlighting amenities and active lifestyles (McHugh, 2003). At the same time, older persons may interact with younger age groups through volunteer activities at schools or in the community. Many large universities increasingly offer programs that encourage lifelong learning. In fact, university towns often seek to attract retirees. Voluntary age segregation is generally associated with successful aging, leisure, and active retirement. The rise of age-segregated retirement communities suggests that voluntary segregation can serve a supportive function for elders. These aging "enclaves" may offer support, social capital, and economic opportunities. Yet voluntary age segregation may also represent a disconnect with previously active social networks and general social disengagement. In this situation it can have negative effects on the individual, including psychological stress or depression.

In an involuntarily segregated context, groups may have little or no contact with each other. This lack of contact between groups contributes to the negative consequences associated with segregation through both lack of exposure and unequal access to resources. Many of the negative consequences of segregation result from the extent to which involuntary segregation is embedded in the social fabric. As an individual ages, there may also be cumulative effects of advantage or disadvantage that have accrued over an individual's life course. For example, the cumulative effects of an individual's gender, race, ethnicity, or economic status may mean that some individuals are advantaged as they age whereas others may need more supports. For the less advantaged, age segregation may exacerbate their lower levels of social integration, poorer health, and greater potential for loneliness and depression.

## AGE SEGREGATION AND INDIVIDUAL EXPERIENCES

The segmentation of the life course into three broad periods (education, family and work, and retirement) that are associated with established social institutions has contributed to age segregation over the life course (Hagestad & Uhlenberg, 2005). As the workforce ages, ageism, or age discrimination, at work becomes a greater concern. Traditionally older workers would socialize younger workers, teaching them how to function in the workplace. With the increasing prevalence of technology, younger persons may have stronger skills (Uhlenberg & de Jong Gierveld, 2004). Older workers are more likely to have stronger credentials, whereas the changing nature of the labor force may make younger workers more attractive to employers (MacLean, 2006). Both older and younger workers experience more stereotyping and less power than middle-aged adults (Nelson, 2002).

The aging of the baby-boom cohort has raised concerns about age segregation and discrimination. To the extent that residential patterns are associated with the family life course, unmarried younger adults are more likely to cluster in urban areas whereas married couples may move to suburban areas to raise their families. Older adults may age in place, either in a neighborhood or community. In rural areas, the out-migration of younger age groups may leave the older generations behind. The absence of stable, ongoing interactions between age groups can contribute to a lack of age integration that, in turn, may contribute to increased ageism (Hagestad & Uhlenberg, 2006).

Increases in age segregation may have important consequences for the well-being of community members. To the extent that segregation contributes to discrimination, the consequences of age segregation can have significant physical, psychological, and financial costs for both individuals and communities.

## THE FUTURE OF AGE SEGREGATION

Age segregation is most likely to occur in the early and later stages of the life course. Children are segregated in school by age. Cohorts of children progress through the educational system together. Age integration increases as young adults enter the workforce. On retirement, older adults may have fewer nonfamily connections, and, outside their family interactions, the age integration of their social networks may decrease. With the population aging and the increasing proportion of older persons in many developed societies, researchers and policy makers will need to understand the factors that contribute to both age segregation and age integration over the life course.

Some important research issues to be addressed include the costs of age segregation for communities and societies, whether age-restricted residential communities create or decrease support for elders, and whether increased life expectancy and aging populations will contribute to greater segregation. Such studies should also assess the heterogeneity of social networks across the life course. It has been suggested that greater age integration

in a society will promote a more civil society (Riley & Riley, 2000; Uhlenberg & de Jong Gierveld, 2004). A better understanding of the costs and benefits of age segregation across the life course will enable researchers and policy makers to better address the future consequences of age segregation for both individuals and society.

## AGE STRUCTURE

Age is one of the most significant dimensions of the composition of a population. There are important links between the age structure and the social structure of a society. Understanding the age structure provides insight into the history and future potential of a population. There are several measures and methods for summarizing the age structure of a population and for making comparisons across populations and time.

Demographers use the term *age structure* to describe the distribution of people in a population by age. The current distribution of the population by age is the result of past patterns of mortality, fertility, and migration in a population and evolves over time as those processes change. Populations often are referred to as being young or old. Although those terms do not have precise definitions, a young population is generally one in which a large proportion of the people are below working or reproductive age and there is a large potential for future population growth. In contrast, an old population is one in which a relatively large proportion of the people are past working age and the growth rate is small or potentially negative.

### POPULATION PYRAMIDS

A common way to depict the age structure of a population is through the use of a population pyramid. These figures consist of bar graphs showing the proportion of the total population in each age group (usually presented in 5-year age groups) by sex. The bars are arranged horizontally with males on the left side of the *y* axis and females on the right side. In this manner population pyramids summarize both the age structure and the sex structure of the population in a single visual image.

A population that is growing rapidly will have a younger age structure than will one that has a slower growth rate. This can be seen in the shape of the population pyramid, which has a classic pyramid shape with a wide bottom and a narrow top. The youngest age groups constitute the largest proportion of the population, and each age group is larger than the one above it. This shape comes about primarily as a result of high levels of fertility that add new members to the youngest

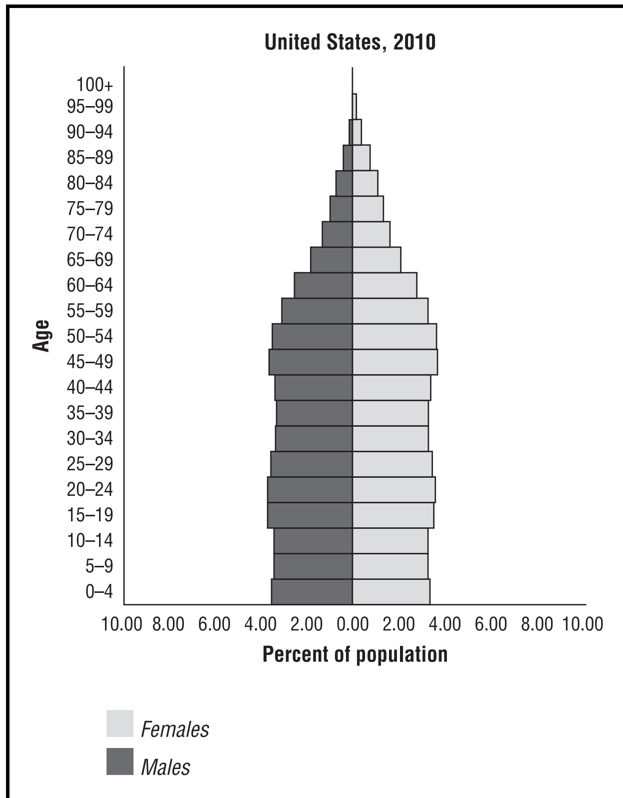

*Figure 1. An estimated population pyramid for the United States.* CENGAGE LEARNING, GALE.

age group. As the younger members age, they enter the reproductive years and, even if fertility rates are falling, create a large number of future births.

A population that is growing more slowly will have a more rectangular shape that represents a relatively even distribution of the population across age groups. In these countries, the base of the pyramid is narrowing and there is little difference in cohort size from one age group to the next. As fertility and mortality levels fall, this rectangular shape emerges. Some populations experience zero or even negative growth. In these cases the base of the pyramid is smaller than the upper age groups because fertility is below the replacement level. (That means that the total fertility rate of an area is not high enough to replace the population.) This creates a pyramid shape that is more barrel- or football-shaped: narrow at the bottom and the top with a bulge in the middle.

## DEPENDENCY RATIO

Another way to summarize the age structure of a population is through the calculation of a dependency ratio. The dependency ratio compares the size of the non-working-age population, both young and old, with that of the working-age population. The age range used to define working is most commonly ages 15 to 64, and the dependent population consists of those under age 15 and those age 65 or older. The ratio of the dependent-age population to the working-age population generally is multiplied by 100 to create the dependency ratio. The higher this ratio is, the more people each individual of working age supports. Countries with high dependency ratios historically are those with high fertility and a large proportion of the population under working age. The higher the dependency ratio, the greater the need for the working-age population to provide economic resources. Dependency ratios of approximately 50 are typical for the United States and Western European countries (Population Reference Bureau, 2007). In this case each dependent is supported by two people of working age. In less developed countries the dependency ratio may be 70 or 80. In those countries each dependent is supported by fewer than 1.5 people of working age.

In young populations the dependency ratio is determined primarily by the relative number of children and youths in the population. As a population ages, the dependency ratio is driven more by the relative size of the elderly population. In the more developed countries the proportion of the population age 65 and older is roughly equal to the proportion under age 15. A more refined measure, the old age dependency ratio, often is used for populations that are aging. Because this index places only those past working age in the numerator, it better captures the dependency needs of aging populations. In the United States this ratio is now close to 20, meaning that there are five people of working age supporting each person over age 65 (Population Reference Bureau, 2007).

## DETERMINANTS OF AGE STRUCTURE

The age structure of a population is determined by the three basic demographic processes: birth, death, and migration. Together those processes shape the age and sex distribution of the population and provide momentum for population growth or decline. Current age structure reflects the past levels and patterns of those processes and the potential for future growth.

Changes in fertility tend to have the most dramatic effect on the age structure of a population. Birthrates determine the number of entrants into a population. Births add new people only to the bottom of the pyramid, but those people stay in the population as they age. For most of history populations had a high proportion of people in the youngest age groups because fertility was very high.

The number of babies born into a population is a function of the number of women of reproductive age (generally 15 to 45 years) and the age-specific fertility rates of those women. If fertility remains constant, large birth cohorts moving into the reproductive ages will create a large number of births. As birthrates fall, the size of the new cohorts decreases. This creates an echo effect in future years as the women in those smaller cohorts reach childbearing age. This smaller group of women, in combination with lower fertility rates, leads to even smaller birth cohorts.

If birthrates temporarily increase, as they did around the 1950s in the United States, an opposite effect—a baby boom—is seen in the age structure. This creates a bulge at the bottom of the age pyramid that travels upward as the cohorts age. The cohorts born before and after the boom are smaller, magnifying the bulge. As the baby boom cohorts reach reproductive age, they create an echo effect as well, this time in the form of a usually smaller baby boom. This boomlet is the artifact of the large number of women in the reproductive ages and occurs even if fertility levels have fallen.

Death rates determine how many people leave the population and at what ages. Because mortality rates are highest among the young and the old, declines in mortality affect those at the youngest and oldest ages to the greatest extent. Mortality declines create population increases at the youngest and oldest ages. In that sense a mortality decline at young ages has an effect on age structure similar to that of an increase in fertility. However, because declines in mortality tend to affect all age groups to some extent, a general decline in mortality without a change in fertility will have only a modest effect on the age structure of the population. In general, declines in mortality create a more rectangular age pyramid.

Unusual patterns of mortality can be detected in the age pyramids of a population. For instance, the effects of war often can be seen in a smaller than expected proportion of older males in a population. Similarly, mortality from HIV creates an unusually high rate of mortality among young men and women in some African populations. This mortality pattern is evident in the population pyramid as a deficit in the expected proportion of the population in the adult ages. Similarly, this type of mortality pattern affects the dependency ratio by decreasing the size of the working-age population.

Migration can both add to and subtract from a population. Migration tends to occur at very specific ages. Most migrants are young adults, and so in-migration adds people to the age structure of the receiving population in a narrow range. In the sending country, conversely, a deficit of young adults is found. These changes have an immediate impact on the age structure, but there is a long-term effect as well because these age groups affect the number of births in the population.

## FEMINIZATION OF OLD AGE

In nearly all countries the relatively longer life expectancy of women compared with men is evident in the larger proportion of females in the older population. This can be seen in the population pyramids of the United States and Italy, where the bars representing females are longer than those representing males, beginning at about age 40. The difference is remarkably evident above age 65. In the United States there were 70 men for every 100 women age 65 and older and 41 men for every 100 women ages 78 or older in 2000 (Hetzel & Smith, 2001). This pattern emerged slowly during the 20th century as mortality improvement was realized faster for women than for men. Men slowly are closing the mortality gap at older ages, and as time goes by, this imbalance in the sex ratio is expected to diminish.

### EFFECTS OF AGE STRUCTURE

These differences in age structure have wide-ranging impacts on a population. As cohorts move through time, their size and characteristics influence the social structure. Younger people in a society have different needs, are treated differently, and have different status compared with those who are older. Those at the upper end of the age spectrum hold a different place in society. As cohorts age, they take with them their characteristics, experiences, and expectations. These differences continue to influence the society throughout the life of the cohort.

Young populations have a large proportion of the population under age 15. A young population can be a resource because its members represent future workers and an anticipated increase in the workforce. At the same time they can stress the economic system. Young members of the population are consumers but not producers. Young populations need services, such as health care and education, that require an economic investment. Those investments can limit investment in industrial development. The social concerns of younger populations are different from those of the adult population as well. In rapidly changing cultures the young may find themselves alienated from traditional cultural ideals and values. This alienation and cultural shift may affect the entire society as those groups age. Some ascribe the major social

changes of the 1960s and 1970s in the United States to the dramatic changes in age structure resulting from the baby boom generation.

Older populations face different sets of problems. As a population ages, the workforce also ages. An aging workforce may be associated with a decline in productivity, although little support has been found for that premise. More significant to a society is the rapid growth of the population over age 65 or, more important, over age 85. The members of this segment of the population have greater needs for health care than do those of other ages, and the stress they place on the health care system can be extreme. In addition, families are often responsible for providing large amounts of informal care to the oldest generation, stressing family resources and having a negative impact on productivity. In the United States and other more developed countries the social services provided for the oldest segment of the population sometimes are seen as competing for investment in younger generations.

Age is only one of the population characteristics that influence society. Sex, race, ethnicity, occupation, and marital status are among the many other factors that can affect the growth of a society, economic productivity, allocation of resources, and culture. Understanding the role of each of these factors and their interaction is important in understanding social change.

# AGEISM/AGE DISCRIMINATION

In 1969, Robert Butler coined the term *ageism*. At that point it joined *racism* and *sexism* as descriptors for irrational biases toward a social group. However, unlike its counterparts, ageism is the only prejudice for which everyone ultimately can become a target. It is a common experience in the later life course that can have a range of negative consequences for its targets.

Ageism is defined as stereotyping, prejudice, and discrimination against people on the basis of age. Stereotyping is the formation of beliefs and expectations about an age group. The age stereotypes underlying ageism generally focus on health, appearance, and cognitive and physical functioning. Although these stereotypes can be both positive and negative, the negative ones tend to be more prevalent in the United States (Palmore, 1999). Prejudice and discrimination, respectively, describe the attitudinal response to and behaviors toward members of that age group that result from the stereotypes. Ageism can be experienced throughout the life span but is most common later in the life course.

## ORIGINS OF AGEISM

Both societal-level and individual-level factors have been said to contribute to the contemporary forms of ageism. On the societal level, modernization, exposure to television, and cultural norms have been found to be associated with ageism. The early contribution of modernization to ageism followed from the invention of the printing press and the Industrial Revolution (Nelson, 2005). The printing press and the related rise in literacy across social classes contributed to the view of elders as less valued in their long-held respected roles as village historians and resources for useful information (Branco & Williamson, 1982). The Industrial Revolution increased the demand for greater mobility of families, frequently eliminating the extended family structure and often leaving elders behind in less developed areas with fewer opportunities to contribute to the growth of society (Stearns, 1986). The growing appreciation of technological skills over experience further displaced elders from their economic roles.

Research suggests that the advent of television also has contributed to ageism. Older characters on television are underrepresented relative to their proportion in the population (Vasil & Wass, 1993). This relative invisibility communicates the idea that older persons are not valuable members of society. Older characters on television are often one-dimensional and serve as comic relief by displaying physical or mental deficits (Kubey, 1980; Montepare & Zebrowitz, 2002). A study found that greater lifetime television exposure is associated with more negative stereotypes (Donlon, Ashman, & Levy, 2005).

It has been suggested that cultural norms underlie ageism. A cross-cultural look at ageism provides support for this societal-level contributor. For instance, modernized countries such as Canada and many Western European countries have experienced historical events and technological developments similar to those that have been suggested to underlie ageism in the United States. Those countries exhibit some of the same cultural norms held in the United States, such as reverence for youth and devaluation of the old (Westerhof & Barrett, 2005).

Consequently, these countries tend to exhibit ageist attitudes and behaviors similar to those found in the United States (McConatha, Schnell, Volkwein, Riley, & Leach, 2003; Palmore, 2004; Westerhof & Barrett, 2005).

Asian countries, in contrast, traditionally have been presented as the antithesis of the United States in terms of their cultural perspectives on aging and expressions of ageism (Levy & Langer, 1994; Palmore, 1999). Asian cultures generally have revered and respected elders because of their age and the experience and wisdom that it represents. This respect has been cultivated over generations through traditions of filial piety (respect and caring for one's parents) and perpetuation of a vertical social structure (Palmore & Maeda, 1985). However, increasing evidence suggests that Asian cultures are becoming less positive toward older adults as they are exposed to European and North American norms and behaviors, in part through television and the Internet, that favor youth and demonstrate prejudice toward older generations (Boduroglu, Yoon, Luo, & Park, 2006).

On an individual level researchers have explored several major antecedents to ageism. First, humans have an innate tendency to categorize the objects, events, and people they encounter (Cuddy & Fiske, 2002). This categorization reduces the amount of information individuals need to process and allows them to make sense of the world more easily. The categories used for groups of people are stereotypes that serve as the basis for initial judgment and interaction with members of specific categories and ultimately lead to the perception of those belonging to categories different from one's own as more similar to one another and thus further removed from oneself. This process can be adaptive by satisfying inherent needs for affiliation and understanding. It also can lead to an us-versus-them mentality, which is suggested to contribute to the development of ageism among the young.

A second individual-level antecedent to ageism consists of implicit processes or automatic cognition without conscious awareness or control (Levy & Banaji, 2002). Theorists suggest that implicit ageism begins early in life in an explicit form, with children observing ageist attitudes and behaviors among adults or in their entertainment sources. Research has shown that children as young as age 6 know the age stereotypes of their culture (Isaacs & Bearison, 1986). Children's continued exposure to and conscious activation of these stereotypes eventually leads to automatic, uncontrolled activation (Levy & Banaji, 2002). The pervasiveness of age stereotypes and the information-processing efficiency achieved through stereotyping trigger and reinforce this implicit ageism throughout adulthood. The strength of the age stereotypes achieved allows the stereotypes to survive both encounters with individuals who contradict them and the transition of individuals to an age at which they become targets of the stereotypes and the stereotypes become self-relevant (Levy, 2003). Put another way, age stereotypes of others can become self-stereotypes.

A third individual-level antecedent to ageism is death anxiety (Greenberg, Schimel, & Mertens, 2002). This fear and the assumed physical and mental decline leading up to death may be one of the fundamental causes of negative ageism. Americans tend to view death as an unnatural part of the life course (Greenberg et al., 2002). Many associate old age with death and consequently fear aging. This may lead to individuals avoiding and belittling older people as a way to circumvent this fear.

## CONSEQUENCES OF AGEISM

The consequences of ageism are numerous and span several domains. Health care is one area in which ageism is particularly prominent. Five key consequences of this ageism are: (a) insufficient geriatrics training for health care professionals, (b) less aggressive preventive care for older patients, (c) less aggressive disease testing and screening of older patients, (d) inappropriate or incomplete treatment of older patients because of failure by clinicians to provide proven medical interventions, and (e) consistent underrepresentation or exclusion of older patients from clinical trials of drugs for which they will be the primary consumers (Alliance for Aging Research, 2003). In addition, older adults frequently are excluded from trials aimed at improving health behaviors (Levy, Kosteas, Slade, & Myers, 2006). They also may experience lower-quality interactions with their clinicians, as there is research suggesting that clinicians are less supportive, patient, and respectful and provide less medical information when interacting with older compared to younger patients (Greene, Adelman, Charon, & Hoffman, 1986).

Ageism is also well documented in the workplace: Its consequences are felt in the form of age discrimination, with older workers less likely to be hired, less likely to be promoted, and more likely to be the earliest victims of company downsizing (McCann & Giles, 2002). Stereotypes of inferior job performance and productivity are thought to lie behind those practices. In fact, research has found that in many settings older individuals are more reliable and productive than their younger coworkers (McCann & Giles, 2002).

The Age Discrimination in Employment Act (ADEA) of 1967, which was amended in 1978 and 1986, has limited overt discrimination in the workplace but has not eliminated age discrimination entirely. In fact, in fiscal year 2006, 16,548 charges of workplace age discrimination were filed with the Equal Employment Opportunity Commission (EEOC), the government agency overseeing the ADEA

(Equal Employment Opportunity Commission, 2007). Of the 14,146 of those charges that reached resolution, the EEOC dismissed more than 60% because of lack of evidence and nearly 20% for administrative reasons. These figures highlight the difficulty of proving discrimination and the lack of effective enforcement of the ADEA.

Ageism also can affect the behaviors of older adults. Stereotypes can become self-stereotypes and ultimately self-fulfilling prophecies, with belief in the stereotypes leading individuals to confirm them (Levy, 2003). For instance, experimental studies have linked negative age stereotypes to cognitive outcomes such as worsened memory performance (Levy, 1996) and physiological measures such as increased cardiac stress (Levy, Hausdorff, Hencke, & Wei, 2000). Stereotypes also have been shown to affect older individuals' reported will to live, with negative stereotypes leading to greater refusal of life-prolonging treatment in hypothetical medical scenarios (Levy, Ashman, & Dror, 1999–2000). Longitudinal studies have corroborated these findings by demonstrating that older persons with more positive self-perceptions of aging reported better functional health status over an 18-year period (Levy, Slade, & Kasl, 2002) as well as extended survival (Levy, Slade, Kunkel, & Kasl, 2002; Uotinen, Rantanen, & Suutama, 2005).

## INTERSECTION OF AGEISM WITH GENDER AND RACE

The experience of ageism can be affected by other social characteristics that affect the life course. Some research suggests a situation of multiple jeopardy in which older adults who belong to another stereotyped group experience a combined effect of the prejudices that is greater than the individual effects (Palmore, 1999). Evidence supports an intersection of ageism with both sexism and racism. The phenomenon among women has been paid particular attention. A clear age-related double standard exists for women so that women are believed to enter middle and old age earlier than men do (Kite & Wagner, 2002). Women thus are stereotyped at a younger age and tend to be the devalued sex when a gender bias is observed. This bias tends to be greatest in reference to physical attractiveness, sexuality, and competence, with older women often thought to be lower on these traits than older men.

The ageism experience of older persons who are part of a racial or ethnic minority group may be particularly challenging (Williams & Wilson, 2001). Older minorities tend to experience greater rates of poverty or near poverty and consequently poorer health and decreased survival. Moreover, the health care consequences of ageism probably are exacerbated among older members of minority groups in light of long-persisting racial differences in access to and quality of medical care. However, older minorities have been found to be higher in certain resources, such as spirituality, that may help them cope with ageism (Taylor, Chatters, & Jackson, 2007).

## FUTURE DIRECTIONS

Research on ageism has evolved over time. The literature, however, is far from complete and has highlighted several issues for future research. More information is needed about how older adults perceive, experience, and report ageism. Questions regarding multiple stigmatized groups also require further exploration. Any future research questions, however, should remain secondary to the ultimate goal of ageism research: reducing ageism or at least ameliorating its effects. The literature suggests several strategies for reaching this goal, including increasing awareness of old age stereotyping, increasing opportunities for high-quality intergenerational interactions, increasing exposure to stereotype-inconsistent information, emphasizing the heterogeneity of older adults, and increasing the involvement of older adults in meaningful social roles such as policy planning (Braithwaite, 2002). The increased awareness of ageism illustrated by the proliferation of research studies and exploration of legislative responses to ageism through the implementation of the ADEA and several hearings of the U.S. Senate regarding ways to address ageism in media, marketing, and health care provides hope of reaching this goal.

# AGING

In 2000, persons age 65 and older comprised about 12.4% of the American population. By 2100 the population of older adults will be about 23% of the total population, nearly one out of every four persons. One reason for the tremendous growth of the older population in the 20th century is the increase in life expectancy among older persons, which is the average number of years an individual can expect to live in old age. As the population continues to age, continued efforts toward a better understanding of aging are essential. Why humans age, how they age, and what happens as age are all important but complex processes related to childhood and early adulthood life. This entry they will outline the fundamental aspects of individual aging, from biological, psychological, and sociological perspectives.

## BIOLOGICAL AGING

Generally, biologists view aging as changes that represent both growth and decline with time. For example, physical development (a sign of growth) occurs from birth to adulthood, while declines in physical functioning are characterized as part of the aging process. *Senescence* refers to the latter of the two processes that marks decline over time and underlies the progressive loss of function with age, which results from an inability to grow and/or repair damages (Williams, 1957). Multiple biological theories attempt to explain aging: why it occurs, how it happens, and who it affects. Programmed theories of aging are synonymous with "why" theories, which denote the driving forces that cause aging to take place. The "how" theories focus on the mechanisms through which we age. Lastly, the "who" theories examine why some individuals or populations age earlier than others.

**Programmed aging** While the importance of biological processes on aging is largely agreed upon, the reason why aging occurs is often debated. Some scientists argue that aging is based on a programmed, molecular clock, whereas others assert that aging is due to random events resulting from an accumulation of physiological insults or damage to the body over time (wear and tear theory). The programmed aging view is supported in the finding of common pathways of aging among various animal models that exhibit similar life trajectories. For instance, the glucose or insulin-like growth factor-1 (IGF-1) pathways are similar among yeast, worms, flies, mice, and humans. These pathways regulate energy and fat accumulation and ultimately affect growth, aging, and mortality. In contrary some researchers argue that aging is due to physiological insults imposed by the environment (e.g., UV-induced damage to DNA) or internal deviations in homeostasis, the maintenance of equilibrium in response to changes in the internal and external environment (e.g., changes in hormone levels or declines in the immune system). Despite this debate, most investigators agree that aging is a result of more than a single cause. Theories of programmed aging suggest that a biological clock drives the process of human development and aging. Proposed explanations of these conserved molecular pathways (e.g., the previously mentioned glucose or IGF-1 pathways found in multiple animal models) include cellular aging and related genetics.

***Cellular aging.*** Cellular aging, an example of programmed aging, is rooted in the discovery that most cellular tissues can divide only a finite number of times. On average, human cells from embryonic tissues stop dividing after fifty cumulative population doublings (CPDs). This phenomenon, introduced by Leonard Hayflick and Paul Moorhead in 1961, is known as Hayflick's limit or replicative senescence (RS) (for further information, see Kirkwood, 1999). Across species, there is an association between the number of CPDs and longevity. For instance, cells from a Galapagos tortoise, which can live more than 100 years, divide approximately 110 times, while cells from mice, which live less than 5 years, divide about 15 times. Moreover, cells from individuals with Werner syndrome (WS), a progeroid syndrome in which individuals undergo accelerated aging, have far fewer CPDs than cells from normal, non-WS individuals. However, exceptions to Hayflick's limit do exist, with some cell lines never reaching RS. These "immortal" cells include embryonic germ cells and cells from tumors.

Biological indicators, or biomarkers, serve as measurements of biological processes that are difficult to observe directly. A potentially universal biomarker of cellular aging (i.e., a marker of cell division cessation), is the enzyme β-galactosidase (SA β-gal) (Campisi, 2003). SA β-gal is a lysosomal hydroblast, an enzyme that aids in the digestion of excess or worn out organelles, that exhibits abnormal behavior in senescent cells and becomes active at a higher pH in senescent cells compared to normal cells (pH 6 compared to pH 4, respectively). Additionally, the percentage of cells undergoing SA β-gal activity (or positive for SA β-gal) increases with CPDs and age; however, immortal cell lines (e.g., HeLa tumor cells) show no association between percentage of cells positive for SA β-gal and CPDs. Using biomarkers, such as SA β-gal, to determine cellular activity could enable the physiologic measurement of cellular aging across species.

***Genetics.*** In addition to cellular aging, genetic influences are another example of programmed aging. The gene that encodes for Apolipoprotein E (ApoE), for example, has been associated with longevity and age-related diseases, such as Alzheimer's Disease (AD) (Vijg and Suh, 2005; Raber, Hugan, and Ashford, 2004). ApoE is a protein involved in cholesterol and lipid transport to neurons. A growing body of research suggests greater associations between AD and specific ApoE isoforms (i.e., a protein with the same function as another protein but encoded by either a different gene or a mutated form of the same gene). For instance, the ApoE ϵ4 isoform has a stronger association with AD compared with the ϵ2 and ϵ3 isoforms. While the precise mechanism behind this remains unknown, it is clear that the ApoE ϵ4 is less effective in binding sterols necessary for neuronal repair, compared to the ϵ2 and ϵ3 isoforms. Further, studies suggest that the ApoE ϵ2 isoform confers a decreased risk of AD. ApoE is only one example of an identified genetic influence on aging and longevity.

A more in-depth review of the genetic influences on aging can be found in a separate entry within this volume.

**How Humans Age** Several mechanisms as to "how" organisms age have been proposed. Most of the theories behind this have come from experimental research that attempts to determine the causes and consequences of aging on physiological systems. In the last two decades, oxidative stress and caloric restriction have garnered substantial attention in the scientific literature.

***Oxidative stress.*** In 1956 Denham Harman first proposed the free radical theory of aging. This theory is based on the idea that oxidative damage, caused by free radicals, accumulates in tissues and cells over time. Free radicals include molecules or atoms with at least one unpaired electron. This unpaired state causes the molecule or atom to be unstable and seek stability by either giving its unpaired electron to another atom/molecule or by taking an electron from another atom/molecule with an unpaired electron. In this sense, free radicals are highly reactive and can cause damage to the important biomolecules, including lipids, proteins, and carbohydrates. Ultimately, this accumulation of oxidative damage (through free radical formation) contributes to declines in physiologic function with age.

In turn, the oxidative stress hypothesis posits that an age-related decline in function is due to the progressive and irreversible accumulation of oxidative damage. Oxidative stress results in molecular damage to living tissues and is found to increase with aging. This vulnerability to damage of DNA, proteins, and lipids, resulted in the evolution of repair systems that protect against these damaging reactive oxygen species (ROS) (i.e., oxygen free radicals). However, these repair systems do not prevent all oxidative damage, giving way to one of the mechanisms of aging.

Mitochondria are membrane-enclosed regions responsible for producing chemicals that cells use for energy. This process occurs through a mechanism called the "electron transport chain," in which electrons are passed between different molecules to produce vital chemical energy. In the final step, oxygen is required, and on occasion, the electron incorrectly interacts with oxygen, thereby producing oxygen free radicals. Hence, mitochondria are likely the link between age-related accumulation of oxidative damage due to ROS and changes in physiologic function related to aging.

***Caloric restriction.*** Calorie restriction (CR) is the practice of limiting dietary energy intake while maintaining nutrition levels. In 1935, Clive M. McCay and colleagues found that CR extended the maximum lifespan (MLS) of laboratory rats and mice by 33%, from three to four years. However, this phenomenon remained relatively under-investigated until the mid-1970s. Since then much research has focused on the biochemical and physiological effects of dietary restriction.

In animal models, when nutrients are readily available, early reproduction, high fecundity, and a shorter life span are exhibited. Conversely, when nutrients are limited and starvation conditions occur, late reproduction, low fecundity, and a longer life span ensue. It is likely that natural selection may play some role in explaining this finding. As a premise, the body requires energy for maintenance and survival. During life, there exists a trade-off between priorities given to self-investment (e.g., during periods of extended starvation or growth and development) and reproduction. Currently, CR is used as a model for understanding the basic mechanisms of aging, due to its robust and reproducible extension of MLS and delay of several age-associated physiological, biochemical, and behavioral changes in a number of non-human species.

It is now known that CR increases the life span across organisms including yeast, rats, worms, mice, and possibly humans. Yeast cells that were grown in nutrient-rich environments lived an average of 6 days; those grown in water or with fewer nutrients lived greater than 17 days; those grown in only 1% potassium acetate, the most restricted environment, lived for years. In comparison to non-CR rodents, CR rodents have also been found to have lower levels of blood glucose, insulin, insulin-like growth factor-1, and inflammation; higher insulin efficiency and resistance to oxidative damage; and lower incidence rates of tumors, kidney disease, vascular calcification, and chronic pneumonia.

While the beneficial effects of CR on non-mammalian taxa are apparent, its effects on humans are still debated. Given the complexity of the mechanisms that affect health and longevity in humans, it is difficult to determine if, and to what extent, the benefits of CR outweigh the energetic and reproductive costs of living in near hibernation. However, some recent studies have attempted to investigate the effects of CR on humans.

Perhaps the most well-known human example of CR is the Biosphere 2 (Poynter, 2006). The Biosphere 2 team lived in a human-made, closed ecosystem in Oracle, Arizona, for 2 years (1991–1992). This eight-member team consisted of individuals who were relatively healthy, with most being young adults. Inhabitants decreased their usual 2,500-calorie intake to 1,800 calories per day. After 6 months, all members had improved levels of physiological state: 15% weight loss, 35% lower blood cholesterol, 18% lower blood glucose, and 18–to 21% (systolic/diastolic) lower blood pressure.

Additionally, favorable changes in biomarkers predictive of human mortality, including dehydroepiandrosterone-sulfate (DHEA-S), body temperature, and insulin levels,

## THIRD AGE

The *third age* refers to the period of life after completing employment and family duties and before the onset of poor health and old age. Given increases in the adult lifespan, reduction in fertility, and, until recently, reductions in age at retirement, this period comprises an increasingly large proportion of the lifespan. The primary proponent of the concept of the third age was Peter Laslett. His seminal work proposed a post-retirement life full of meaning, purpose, and choice (i.e., the third age) that is distinct from the *fourth age,* a stage characterized by decline and decrepitude.

Critics find fault with the subtle implication that attainment of health and happiness depends on engagement in healthy behaviors and those who do not age successfully have not tried hard enough. Furthermore, the popular media have co-opted the concept, conveying the message that buying consumer goods can ensure the attainment of health and happiness in old age. Advocates see the concept as empowering. The concept of the third age may help to promote institutional and normative changes so that newer generations of older persons will have the power to choose a fulfilling lifestyle not tied to meaning found in paid employment.

were found. DHEA-S is a steroid hormone that normally decreases with age. However, in CR-humans, DHEA-S is higher than non-CR humans at the same age. Insulin and body temperature decreased in calorie-restricted individuals as well. Consistent with the beneficial CR effects seen in other animal models, human men with lower temperature, lower insulin, and higher DHEA-S levels had increased survival rates compared to their normal diet counterparts. All in all, CR seems to extend the life span of organisms ranging from yeast to mammals. It may extend longevity in mammals by decreasing both diseases (such as cancers) and inflammation (a response of the body's immune system that protects against infection and foreign bodies, including bacteria and viruses) during aging. However, substantial reductions in caloric intake are difficult to maintain. While the physiologic benefits of CR on yeast and mice are remarkable, it was also found that they lived in states of near hibernation throughout life. Such findings question whether altering metabolic rates in humans via CR is viable and desirable.

**Who Ages** Although aging is inevitable for all, in humans, some populations age more quickly than others. Bio-psycho-social theories attempt to explain who is most vulnerable to adverse changes connected to aging based on person-environment interactions. For example, ethnic minority populations and individuals with low socioeconomic status exhibit both a higher level and earlier onset of age-related disease, including cardiovascular disease and diabetes. To explain this, several theories have been proposed, including the stress theory of aging (Finch and Seeman, 1998). Stress theories of aging suggest that excess stress, due to greater exposure to chronic and acute strains, leads to increased risk for disease and disability. Stress has been involved in disrupting the regulation of several body systems, including the sympathetic nervous system, the immune system, the hypothalamic-pituitary-adrenal axis, and inflammatory responses. Such theories allow researchers to investigate the underlying reasons why health disparities exist across populations and contribute to the overall understanding of aging processes.

### PSYCHOLOGICAL AGING

Some aspects of human psychology undergo changes with age. Psychological aging is not necessarily a series of losses and physiological decrements; rather, aging can also bring improvements in psychological functioning, such as enhanced optimization of positive emotions, or relative stability, as exemplified by personality. Here the authors will describe the relative stability of personality, the positive changes in emotion regulation, and the onset of common psychological disorders with age.

**Personality and Aging** Two different views of personality and aging are presented in trait and growth models of personality development (Staudinger, 2005). Growth models, akin to Erik Erikson's developmental model, suggest that individuals continually adapt to internal and external (i.e., biological and sociocultural) changes in the environment. Such changes allow for personal growth, with the ultimate goal of achieving purpose in life, competence, and wisdom. Conversely, trait models, which are often used in studying personality, focus on individual traits (i.e., dispositional behaviors and attributes) as indicators of personality. These models suggest that personality remains relatively stable after age 30. Studies have shown, however, that a combination of these two models most accurately portrays changes in personality across the lifespan. Simply, both stability and change, or development in personality, occur from adulthood to later life.

Trait models focus on both the structure and content of personality. For instance, personality is measured along the "Big Five" dimensions: extraversion, openness to

experience, neuroticism, conscientiousness, and agreeableness (McCrae and Costa, 1990). While personality generally remains stable with age, some specific changes in each of the "Big Five" dimensions are related to age. Neuroticism, for example, decreases across adulthood but may then increase in late life. With age, there is some decrease in extraversion and openness to experience, while conscientiousness and agreeableness increase slightly. These findings appear to be similar in cross-sectional (studies examining different age groups at one point in time) and longitudinal studies (studies using data at more than one time point, respectively), as well as across countries.

Self-regulation is the set of abilities and skills that an individual uses to monitor experiences and behavior. It is a source of the underlying stability and relatively minor change in personality with age (Staudinger, Kessler, & Dörner, 2006). This view suggests that individuals aim for a relatively constant state across life and utilize self-regulating mechanisms to achieve a state of dynamic homeostasis. Self-evaluation, emotion-regulation, and goal setting are a few examples of methods of self-regulation.

With age, individual may employ compensatory mechanisms of self-evaluation more often, such as reinterpreting reality. Such reinterpretations allow for consistent perceptions of oneself, despite behavioral and experiential changes. Emotion regulation, discussed below, generally does not decline with age, and some increases with age in the balance of positive to negative emotions have been found. Older adults also report greater control of their emotions with age. This may reflect changes in life goals or a shift in priorities from information seeking in younger years to emotion regulation in older adulthood (Carstensen, Isaacowitz, and Charles, 1999). This perspective, known as socioemotional selectivity theory, will be discussed later. Despite experiencing more adverse health events and losses of close friends and family, older adults, on average, maintain their sense of control and agency (Smith & Baltes, 1999). However, this stability cannot be viewed as a moment of standstill, with little growth and learning, but should be seen as an indicator of successful self-regulation.

**Emotions** Compared to younger adults, older adults generally have better emotion regulation and tend to remember negative information less well than positive information (Mather & Carstensen, 2003). Although poorer health conditions are more common among older adults, the shift toward selectively remembering positive instead of negative memories enables them to regulate their emotions and obtain better levels of well-being.

Among older adults, the maintenance of positive levels of affect (the experience of a feeling or emotion) while facing challenging life experiences is a paradox to researchers. This paradox may be explained by three theories of optimization: affective optimization, socioemotional selectivity theory, and differential emotions theory. In 1989 Lawton introduced affective optimization, which states that older adults control their social and environmental surroundings in order to minimize negative contacts and maximize positive situations. As indicated above, socioemotional selectivity theory posits that when the time remaining in one's future is perceived as limited (e.g., in late life and among individuals with terminal medical conditions), there is a reorganization of goals, with a greater emphasis on emotion-regulation as opposed to information-seeking. During this period, close, interpersonal relationships take precedence over educational and career-oriented goals that might have been priorities in earlier life. There is a reduction in peripheral or more distant relationships (e.g., an acquaintance) and a greater focus on core relationships, thereby enhancing and maximizing time spent in positive emotions. This suggests a remarkable adaptive "resiliency" among older adults.

Differential emotions theory suggests that a limited number of primary emotion systems evolved to provide safe, reliable, and automatic ways to deal with states of emergency (Darwin, 1955). These primary emotion systems include negative emotions, such as fear, sadness, anger, and disgust, and positive emotions, such as happiness, interest, and love. The greater positive emotional balance that commonly occurs among older adults reflects the systematic decline in negative emotions over the life course, while positive emotions remain relatively stable or increase slightly. Further, older adults exhibit greater levels of self-control in regulating their emotions, by showing less reactivity when inducted to negative emotions and utilize different defense and adaptation mechanisms. Older adults are more likely to use a defense that gives an abstract meaning to an event or reverses its meaning, while younger adults employ less mature defenses. For example, during times of hardship, older adults are more likely to cognitively reassess the situation toward a more positive light (e.g., view the situation as a valuable learning experience) as opposed to younger adults who more commonly employ escape and avoidance strategies (Diehl, Coyle, & Labouvie-Vief, 1996). Additionally, older adults both recognize and recall fewer negative images compared to positive or neutral images.

**Psychological Disorders** In general, mental health problems, including schizophrenia, anxiety disorders, and major depression, decrease with age. Among adults age 65 and older, only 0.6% have schizophrenia compared to 1.3% of younger adults aged 20. For anxiety disorders, most begin in childhood, adolescence, and early

adulthood, so their onset is much lower among older adults. The average age of onset for major depressive disorder is 25, and it is most common among adults age 25 to 44 and least common among adults age 65 and older. Despite this, older adults are more likely to suffer from mild depression and dementias than younger persons (Woods, 2005). The high prevalence of depressive disorders and dementias in later life have attracted great attention in relation to theory, assessment, and treatment for older adults. The next two sections discuss two major psychological disorders encountered in older adults: dementia and depression.

***Alzheimer's disease.*** Alzheimer's disease (AD), the most common form of dementia, is perhaps the most feared disease of aging, as older adults fear losing their memory and their sense of self while their physical bodies remain intact. AD is the eighth leading cause of death among individuals over age 65 (Alzheimer's Association, 2007). It is a progressive disease involving loss of memory, then of functional ability, and ultimately, loss of life.

Advancing age is the number one risk factor for AD. In 2007, 5.1 million people in the United States were living with AD, and 4.9 million of these individuals were age 65 and older. At age 65, one out of eight people (15%) are estimated to have AD. While the prevalence of AD continues to increase with age, this number dramatically increases for individuals ages 85 and older; such that by age 85, nearly one out of every two people is thought to have AD (Plassman, Langa, Fisher, Heeringa, Weir et al, 2007). Due to declines in death rates after age 65, current and future generations will survive to older ages, where risk of AD is greatest.

The two hallmark abnormalities of AD include beta (B)-amyloid plaques and neurofibrillary tangles (NFTs); however, it is unclear whether these changes cause neuron death or are indicators of a separate, more complex process (DiGiovanna, 2000). Plaques and tangles are present in the brain when the individual is still asymptomatic. As neuron death persists, the individual begins to exhibit declines in short-term memory. Later, declines in verbal and spatial abilities occur, and ultimately, people with AD lose the ability to complete activities of daily living. During the disease progression, brain size decreases, namely in the frontal, temporal, and parietal lobes, in addition to the amygdala, hippocampus, and nucleus basalis.

Common patterns of symptom progression among individuals with AD have been documented and modeled into a progression of "stages." Although staging systems provide a useful frame of reference for understanding how the disease unfolds in the population, it is important to note that not all individuals with AD will experience the same symptoms nor progress at the same rate. Key symptoms characterizing seven stages of AD are indicated below (Reisberg, 2008).

In Stage 1, no impairments in memory are evident during medical interview. The individual appears to have normal cognitive function but plaques and tangles may be detected via other means, such as functional magnetic resonance imaging (fMRI). Individuals in Stage 2, with very mild cognitive decline, may notice some memory lapses, especially in forgetting familiar words, names, or location of keys or eyeglasses. However, these problems are not noticeable to friends, family, co-workers, or upon medical interview. Mild cognitive decline (Stage 3) can be diagnosed in some individuals. Family, friends, and co-workers begin to notice problems in the AD individual, and problems with concentration and memory are now measurable in medical testing. Some common difficulties include: problems recalling words or names of people, retaining little material from recently read passages, losing or misplacing valuable objects, and performance issues in social or work settings.

Medical interviews of people with moderate cognitive decline, also known as mild or early-stage AD (Stage 4) indicate clear deficiencies in: recollection of recent events, ability to perform challenging arithmetic (e.g., serial sevens) and complex tasks, recollection of personal history, and interaction with others in socially or mentally challenging situations. Moderate or mid-stage AD (Stage 5) is indicative of major gaps in memory and deficits in cognitive functioning. During this stage, the individual requires some help with activities of daily living (ADLs). Moderately severe AD (Stage 6) shows a worsening of memory difficulties, significant changes in personality, and extensive help with ADLs. Here, individuals imperfectly recall their personal history, lose most awareness of recent events, exhibit disruptions in their normal sleeping cycle, increasingly exhibit urinary or fecal incontinence, and begin to wander and become lost. Lastly, severe or late-stage AD (Stage 7) marks the time when individuals are unable to respond to the environment, unable to speak, and unable to control their own movement.

***Depression.*** Categories of depression, including major depressive disorder and dysthymia, are characterized in the Diagnostic and Statistical Manual for Mental Disorders (DSM-IV) (American Psychiatric Association, 2000) and the International Classification of Diseases (ICD-10) (World Health Organization, 2004). Major depressive disorder is defined as having both: (a) a depressed mood or loss of interest or pleasure for at least two weeks, (b) at least 5 of 9 other symptoms, including: physical agitation or psychomotor retardation, significant weight loss or appetite changes, feelings of worthlessness or guilt, and difficulty concentrating or making decisions. Dysthymia, by contrast, is defined as having depressive symptoms less severe than

major depression, but lasting for a minimum of 2 years. Major depression disorder and dysthymia may co-occur, known as *double depression*.

Depression is often characterized by different symptoms in younger and older adults (Fiske and Jones, 2005). As such, it is not appropriate to apply the same diagnostic instruments for depression across all age groups and compare rates across age. For example, emotional and cognitive circumstances, including sadness and negative self-attitude, are better indicators of depression in younger adults; however, somatic symptoms (such as fatigue, insomnia, and changes in appetite), feelings of apathy, hopelessness, and thoughts about death are more appropriate indicators of depression among older adults.

Also, older adults more commonly present symptoms that are not characterized by any one diagnostic criterion. This has been referred to in several terms: subsyndromal depression, minor depression (provisionally characterized in DSM-IV), or mild depression (in ICD-10). These differential criteria for older adults reveal the complexity of evaluating depression in this population. This is further illustrated when determining the low and wide-ranging prevalence of depression among older adults. Dysthymia affects about 2% of adults age 65 and older. Major depressive disorder occurs in 12% of older adults, while minor depression is present in 3 13%. To further complicate diagnoses, depression and dementia may coexist, with nearly a quarter of older adults with dementia also having depression.

Late-life depression can be conceptualized as the interplay among biological, psychological, and social influences. For instance, the developmental diathesis-stress model (Gatz, 1996) states that genetic influences on depression onset are more important early in life, while the effects of some biological risk factors (e.g., neuroanatomical changes) and some medical conditions increase with age. Further, susceptibility to depression may decrease with age as adults learn to better adjust expectations and deal with stressors.

On the other hand, having a previous history of depression increases the likelihood of having late-life depression; half of all older adults with depression were depressed earlier in life. Depression onset occurs in conjunction with, and after, certain medical conditions, such as Parkinson's disease, stroke, and general pain. Depression in middle-aged to older adults has also been associated with occurrence of first heart attack, poorer outcomes after a heart attack, mortality post-stroke, and other cardiovascular conditions. Hence, the reciprocal relationship between depression and poor health places other adults at greater risk of comorbidities, or co-existing conditions.

Negative life events and social influences, including bereavement, caregiving, and illness, are associated with depression in older adults. Within the first year of bereavement, depressive symptoms are common among widowed spouses but triggers for depressive symptoms vary for widows and widowers. Concerns about income trigger symptoms in widows, while loss of emotional support triggers depressive symptoms among widowers. Ultimately, depressive disorder is a complex process that often involves consideration of a combination of biological, psychological, and social influences.

## SOCIAL AGING

Social roles and relationships change with age and time. In fact, social scientists view aging as a series of transitions resulting from changing roles connected to sets of rights and responsibilities. Traditionally, transitioning from one social role to the next coincided closely with one's age. In other words, roles in life were traditionally age-segregated. Children and adolescents were students; adult males worked and provided for the family; adult females cared for children; and old age was spent in retirement and caring for oneself.

Over time, however, the links between age and social roles have blurred. For example, as the length of schooling has increased and the idea of retraining has become accepted, "nontraditional age" students now represent nearly 50% of college enrollment. Women, especially women who are mothers, in the work force have increased markedly since the 1960s as women's roles have expanded. More grandparents are providing care and parenting to grandchildren than in earlier decades. It is also true that until recently the age at retirement had been decreasing so that the modal age was 62. This loosening of age structures in work, family, and education is termed the *deinstitutionalization* or *destandardization* of the life course (Sackmann & Wingens, 2003) and represents changes in social aging processes.

The link between social roles and chronological age is not the same in all societies or at all times. As indicated above, the links have been changing in the United States, and such changes have been occurring in much of the world. It is also true that the expected roles and opportunities for older persons are not always those that they desire. For instance, while the age at retirement has been decreasing, there have been many people who were forced to retire when they would prefer to keep working. It is also not always true that the social structure encourages—and in the case of retirement in the past, even legislates—roles that have resulted in the most appropriate fit for the social and economic circumstances of the society. This lack of fit between expected social roles and societal needs has been termed *structural lag*. One can

view the elimination of mandatory retirement in the United States several decades ago as an attempt to achieve a better fit between the desires of individuals, the needs of the society, and the legislated options for working.

**A Quiet Revolution** Biological and psychological aging focus on individuals but social aging examines societal or population-level as well as individual-level change. Population aging has been ongoing in much of the world for more than a century: The proportion of older individuals has been growing and the absolute number of older adults has been increasing. It results not only from improvements in life expectancy at older age, but from increased survival throughout life and the decrease in fertility that results from declining infant mortality. As a result of these forces, there are significant changes in the age structure of societies. In many countries there has been an interest in the implications of aging because of the increase in the number of older dependents to workers. In countries where aging has been taking place for a long time, there has already been a significant increase in the number of older persons supported by each worker. This ratio is closely tracked by national governments because most countries provide living and medical expenses for older persons. What has sometimes not been noted, but is of relevance to the interest in changing age structures, is that at the same time there has been an increase in the number of older dependents, there has been a decrease in the number of younger persons supported by each worker. The expectation is that aging is going to continue in most countries of the world for the foreseeable future and an older age structure will require further adaptation of the link between social roles and age.

**Family Structure** Aging in families has occurred in parallel with population aging. Demographic changes have resulted in a "quiet revolution" that has lead to the transformation of multiple facets of the family (Lowenstein, 2005). Declines in fertility and increases in life expectancy have changed the structure of families and the interactions between generations. In the beginning of the 20th century most family structures, like most populations, resembled a pyramid. They had a large, bottom-heavy base of children, a smaller number of parental age persons, and a small number of grandparents. In many countries both populations and families are changing from a pyramid structure to resemble a beanpole. In this case, over time there may be relatively equal numbers of people at most ages up to the very old and close to equal numbers of family members within each generation. This change in family structure leads to fewer members in each generation but more generations alive at any one time. This will mean fewer younger members available to care for the growing older population.

## MARRIAGE, PARENTHOOD, AND GRANDPARENTHOOD

With the decrease in the number of children and increases in requirements of skilled jobs, more recent generations have been more likely to delay marriage and parenthood in order to devote more time to education and advancing their careers. In 2005 the median age of marriage for men had risen to 27 years and 26 years for women, with a majority (72%) of both men and women having been married at least once by the time they were 30 and 34 years old. There has also been a decline in the traditional family and greater diversity among families, including truncated families, reconstituted families, single-parent families, and alternate families.

Families have traditionally been the source of caregiving for both older and younger members. With reductions in the number of children and increasing variety of family forms, relationships with siblings, extended kin, and non-kin peers (i.e., alternative families) may play increasingly important roles. Caregiving, often provided by children to parents in later life, may be more difficult to obtain in the future as the availability of children is reduced. As the rates of divorce have increased, the number of reconstituted families has also increased. These families, as well as single-parent families and grandparents raising grandchildren, are at greater risk of intergenerational strain and familial disorder.

Despite these changes, intergenerational relationships may not be negatively affected. Parents and children appear to retain relatively close relationships even in societies that have undergone significant familial change. Relatively strong social norms for the provision of intergenerational support appear to have survived even though the family has undergone dramatic change. It is even possible that such changes could have positive benefits. Due to longer years lived, there is more time to share with other generations and this could result in stronger relationships across generations. Despite geographic distance, adult children and parents are able to maintain frequent contact and interaction with improved means of communication. Extended families appear to maintain their intergenerational cohesion.

Research has found that across generations, there are shared values, normative obligations to provide care, and lasting ties between parents and children. Generally, research suggests that parents and children provide needed support to each other and that such support improves emotional states throughout life and contributes to better adjustments to crises, such as widowhood, encountered during later life.

While there have been major changes in expected social roles and their link to age, most people still marry, have children, and become grandparents. Based on current

cohorts of older adults, three-quarters of adults will become grandparents, with a fifth of all women who die after 80 having spent some time in a five-generation family as great-great-grandmothers. Nearly one-third of grandparents will experience great-grandparenthood and will be part of a four-generation family. Not only are families more likely to consist of more generations, but they are also more likely to be grandparents for longer, with some people as grandparents for more than half of their lifetimes. As more people become grandparents for longer periods of their lives, grandparents could occupy an expanding, and increasingly important, role within the family as the opportunity for more and longer interaction across generations increases. Custodial grandparents, or grandparents raising grandkids, have recently garnered increasing attention. The number of grandparent-headed households increased since the late 1990s by more than 50% with 1.3 million children raised solely by a grandparent as of 2005. The increase in grandparents raising grandkids can be attributed to increasing difficulties experienced by the ''middle'' or parent generation, including substance abuse, mental illness, imprisonment, and HIV/AIDS.

## LIFE COURSE PERSPECTIVE

The life course perspective is a theoretical orientation that guides research and contributes to our current understanding of humans' lives (e.g., changing roles and relationships with age and time) within historical and biographical contexts (Elder, 2003). The life course perspective is a framework for studying issues central to social change and developmental trajectories. Development is understood to be a lifelong process of fundamental biological, psychological, and social changes. It is also true that people create their own life course via decisions and actions taken in response to personal, social, and historical circumstances. These choices may affect future trajectories. For instance, a woman's choice to delay marriage and parenthood may then delay her age of grandparenthood. Individuals are shaped by the historical atmosphere and places experienced throughout life. For instance, people who experience devastating events like a war early in life may have their lives forever changed by their experience.

Depending on the time of occurrence during the life course, the same experiences or events affect individuals in varying ways. For instance, early parenthood can have detrimental effects on educational and occupational attainment. It is also true that lives are interdependent and relationships are impacted by social and historical influences. Due to this interdependence, transitions in one individual's life often result in transitions for others as well. For instance, a daughter's early role transition to motherhood results in her mother's early transition to grandparenthood, altering both of their roles and social identities. Interestingly, women who enter parenthood in early life often also enter grandparenthood at an earlier age.

Ultimately, the life course perspective considers individual choice and the process of decision-making. It acknowledges social and historical context, timing of events, role changes, and the interdependency of life. Future generations of researchers will continue to use the life course perspective to expand knowledge of how aging is affected by social influences and how aging, itself, affects social structures and societal roles.

Aging reflects a complex interplay among biological, psychological, and social influences combined. Hence, an interdisciplinary perspective of all three aspects of aging is essential to understanding life from childhood to late adulthood. All make clear that aging is a process that begins early in life and is affected by all one's exposure and experiences, and because the social world changes, aging is not a static experience.

## AGING IN PLACE

As people reach the final stages of their life course, most want to remain as active and independent as possible for as long as possible. They want to age at home surrounded by friends and family, not in institutions such as nursing homes (Marek and Rantz, 2000). According to an American Association of Retired Persons' (AARP) 2005 *State of 50+ American Survey*, 89% of people over age 50 want to remain in their home for as long as possible, and 85% want to stay in their community for as long as possible. Among the reasons for remaining in the community is continuing to be close to friends and family (AARP, 2006). As people age they may be forced to move when characteristics of their home environment, such as stairs, width of doors and hallways, and bathroom and kitchen design, may no longer accommodate changes in health and functional status or when supportive services to accommodate their needs are unavailable. The goal of aging in place is to allow seniors to remain in the

environment of their choice with supportive services as needed (Marek and Rantz, 2000).

Traditionally, older adults have been forced to move as health status deteriorates, needs change, and living environments no longer support successful aging. For older adults who choose to reside in long-term care residential facilities rather than in private homes in the community, state and federal regulations define building safety features, care that can be provided, staffing standards, as well as potential public payment for living in senior housing, residential (assisted living) facilities, or nursing homes. These regulations differ from state to state, but often require an older adult to maintain a certain level of ability to remain in senior housing or residential care. Although relocation has been associated with stress-related illness in older adults, regulations and discharge criteria force older adults to move from senior housing to residential care/assisted living, and finally to a nursing home as health deteriorates (Rantz, Marek, Aud, Johnson, Otto, et al., 2005a). For example, Mr. Jones may be satisfied living in senior housing, having some meals provided. He then experiences pneumonia and a minor stroke. After hospitalization and some rehabilitation in a Medicare skilled nursing facility, he returns to his apartment but has problems with frequent falls and is unable to get up on his own. The housing manager considers him a safety risk and insists he move to the residential care facility nearby so that staff can look after him and help him when he falls. After a few months in residential care, Mr. Jones has another stroke, is hospitalized, and enters a nursing home for rehabilitation in the Medicare unit. Following three weeks of rehabilitation, the physical therapist determines that he will need continuing nursing home care because he cannot walk sufficient distances as required in fire safety drills in his former residential care facility.

*Aging in place* is defined as older adults remaining at home with the services they need for continued residence as they grow older. The key to facilitating aging in place is to separate the type of care provided from the place of the care. In this model, people will not have to move from one level of care delivery to another as their needs change; instead, all the services they need will be delivered in their home. The concept of home includes all residential settings where medical services are not delivered. Home could mean residential care/assisted living, senior housing, an apartment, or private homes (Marek and Rantz, 2000).

The term *aging in place* first emerged in the research literature in the 1980s as researchers were focusing on quality of care and housing needs of older adults. Quality of care was a major issue during the 1980s because of numerous problems in nursing homes that led to U.S. government legislation in 1987 establishing resident rights and standards of care. As one could anticipate with publicity about nursing home problems, people wanted to remain at home as long as possible.

The idea of helping people age at home is not new. Many older individuals age naturally in the environment of their choice with the help of family and friends. Others receive services from a variety of community organizations and businesses. Indeed, many services exist to help older adults age in place. Services are available to help with meals; transportation; housekeeping; shopping for groceries, clothing, or health care items; and help with daily activities like bathing, dressing, or eating. Technologies are also making it easier for people to access health care and communicate with health care professionals. Technologies like such as, the Internet, videophones, and telehealth are helping to make many services more accessible (Demiris, Rantz, Aud, Marek, Tyler, et al., 2004).

Unfortunately, many of these services may not available in rural areas. Rural populations lag behind more populated areas in the variety and amount of services offered, particularly transportation, making aging in place harder. However, many rural people still manage to age in place with the support of family and friends. This option is not always available to older adults; as their children reach young adulthood, many move away from the rural areas to metropolitan areas for employment.

The home itself can affect an individual's ability to age in place. Most homes are not designed with the aging population in mind. The majority of residential housing is tailored to healthy young adults and does not take into account age-related changes such as limited mobility or reduced sensory function (Senior Resources, 2008). Age-related changes may affect one's ability to remain at home, but simple changes can dramatically enhance the home environment. For example, adding grab bars in the bathroom; replacing bathtubs with step-in showers; or moving laundry equipment to the same floor as primary living space will facilitate aging in place.

The term aging in place has been taken over by the senior housing industry to promote a variety of housing options with a range of health care services. The term has been used to market several types of facilities, including assisted living facilities and continuing care retirement communities. However, these settings offer a model of aging in place that differs from the model described here.

Assisted living facilities offer an alternative to nursing home care. Assisted living facilities provide 24-hour care in a residential setting to individuals who need help with some activities of daily living such as bathing, eating, dressing, going to the bathroom, or taking

***Nursing Home.*** *Ebony Martin, 17, and Lilly Maud Walton, 113, in the common area of Ansley Pavilion Nursing Home playing Balloon Volleyball. Many services exist to help older adults age in place.* © MARTIN H. SIMON/CORBIS.

medication, but who do not need the intensive skilled nursing and medical care provided in nursing homes. Assisted living facilities offer the promise of aging in place. However, people move out of assisted living to a higher level of care if health care needs exceed the capacity of the facility to provide care (Chapin and Dobbs-Kepper, 2001; Frank, 2001; Aud, 2004; Ball, Perkins, Whittington, Connell, et al., 2004).

The continuing care retirement community model encompasses different levels of care in one building or on a campus. For example, a community may include independent housing, assisted living, and a nursing home in different buildings within a campus. The continuing care retirement community does allow people to age in place; however the model still requires people to move from place to place within the building or on the campus as their health deteriorates.

In Missouri a demonstration project has been undertaken to evaluate whether aging in place really works. Legislation in 1999 and 2001 enabled the creation of this project within the highly regulated long-term care environment. The purpose of this program was to create innovative approaches to senior housing that incorporate health care services that adjust to the residents' changing needs. One of the four sites chosen for the demonstration, TigerPlace, is a prime example of this new kind of facility.

TigerPlace, a unique senior retirement community, was developed by faculty from the University of Missouri Sinclair School of Nursing and is based on the concept of aging in place. Rather than forcing residents to move as their needs change, TigerPlace offers varied services as needed. TigerPlace not only promotes the independence of its residents (Rantz, 2003) but also helps residents remain healthier and active longer by providing nursing care coordination, direct personal care as needed, ongoing nursing assessment (complete assessment every six months), early illness recognition, health promotion activities, and social activities—all within well-designed housing. TigerPlace is built to nursing home standards, licensed as the state's only aging in place building, and is designed to help residents avoid expensive and debilitating hospitalizations, and for most residents, avoid relocation to a long-term care facility.

The preliminary findings from the demonstration project indicate that this approach positively affects the residents and their families. Satisfaction, overall well-being, social engagement, and maintaining physical function are high while discharges to traditional nursing home care are very infrequent. Several residents died after moving to TigerPlace; most of these deaths were expected, and each resident died with his or her wishes respected, receiving personal care and hospice services as needed, with family and staff close by. These are the truly successful outcomes of aging in place: enjoying life until the end in one's own home with family and friends, getting the required care and services when they are needed.

An important feature of TigerPlace is the interdisciplinary research that takes place there. It is focused on using technology to enhance people's ability age in place and prevent or delay the decline associated with aging (Rantz, Marek, Aud, Tyrer, Skubic, et al., 2005b). Researchers are using sensors to collect physiological data including heart rate, blood pressure, bed restlessness, as well as activity levels (motion sensors). These data are being used to detect changes in health status so health care professionals may intervene to prevent or delay declines in health status (Rantz, Skubic, Burks, Yu, Demiris, et al., 2008).

Others are working on technology that automatically controls room temperature, windows, doors, locks, and other environmental factors (Haigh, Kiff, and Ho, 2006; Plocher, Kiff, and Krichbaum, 2004). Additionally, technology can also provide a safer environment. For example, lights can be automatically switched on when someone enters a room or the stove can automatically turn off if left on too long. All of these technological advances are making it easier for people more safely to age in place.

Aging in place is an idea that is here to stay. People want the independence, privacy, and social support that come with remaining at home. Politicians, researchers, health care providers, and businesses are listening to the wishes of the aging population and are changing to meet their demands.

## ALLOSTATIC LOAD

In recent years, many scholars have used allostatic load to explain how various hardships associated with poor social environments "get under the skin" to affect disease and mortality risks, particularly in later life (Seeman, Singer, Ryff, Love, & Levy-Storms, 2002, p. 395). Allostatic load is based on the concept of *allostasis*, or "the ability

of the body to increase or decrease vital functions to a new steady state on challenge" (McEwen & Stellar, 1993, p. 2093). Broadly speaking, these vital functions include cardiovascular health, body composition, stress hormones, and the immune system (Seeman, Singer, Rowe, Horwitz, & McEwen, 1997; Seplaki, Goldman, Weinstein, & Lin, 2006). The definition of allostasis is reflected in its etymology, which involves the ancient Greek terms *allo* and *stasis*, meaning change and stability, respectively (Szanton, Gill, & Allen, 2005). Indeed, one conception of allostasis is simply physiological "stability through change" (Sterling, 2004, p. 18). Some scholars view allostasis as a complement to the traditional medical concept of homeostasis, which describes the body's ability to maintain internal conditions such as heart rate and body temperature within a normal, well-tolerated set of parameters (McEwen & Wingfield, 2003). Other scholars have argued that because allostasis more accurately describes physiologic processes, it should overthrow homeostasis as the primary model for internal biological maintenance (Sterling, 2004).

Allostasis is vital for short-term adaptation to physical stressors such as caloric imbalance and psychological stressors such as marital distress, but it is not without long-term physiological cost. *Allostatic load* is a concept that attempts to understand the cumulative effect, or "wear and tear" of repeated physiological adjustments to stress (McEwen & Seeman, 1999). It is important to distinguish allostatic load from an *allostatic state*, which "can be defined as a state of chronic deviation of the regulatory systems from their normal state of operation" (Koob & Le Moal, 2001, p. 102). Over time, an allostatic state can result in allostatic load by overwhelming an organism's ability to cope with repeated adaptations to challenging conditions. For example, excessive production of stress hormones such as cortisol (i.e., one form of an allostatic state) over long periods of time may eventually result in elevated blood pressure (Fraser et al, 1999), which has traditionally been viewed as one key marker of allostatic load (Seeman et al., 1997).

## MEASUREMENT

Allostatic load (AL) was initially measured as an index of 10 biomarkers that were believed to measure the level of physiologic dysregulation, which is simply the overall level of bodily duress (Seeman et al., 1997). These biomarkers are defined as follows (MedicineNet.com, 2008; Seeman et al., 1997):

1. Systolic blood pressure: top number in a blood pressure reading that measures the maximum arterial pressure as the heart contracts; included in AL as an indicator of cardiovascular health.
2. Diastolic blood pressure: bottom number in a blood pressure reading that measures the minimum arterial pressure as the heart relaxes; included in AL as an indicator of cardiovascular health.
3. Ratio of (waist circumference / hip circumference): measures adiposity; included in AL to assess calorie imbalance and metabolism.
4. High-density lipoprotein (HDL) cholesterol: good form of cholesterol that protects arteries from plaque accumulation; included in AL to assess risk of developing atherosclerosis (higher values reflect lower risk).
5. Ratio of (total cholesterol / HDL cholesterol): proxy indicator for plaque inducing low-density lipoprotein (LDL) cholesterol; included in AL to assess risk of developing atherosclerosis (higher values reflect higher risk).
6. Glycosylated hemoglobin: blood sugar that has become attached to the hemoglobin molecule in red blood cells; included in AL to measure glucose metabolism and diabetes mellitus (higher values reflect higher risk).
7. Cortisol: a corticosteroid hormone released by the adrenal gland in response to stress; included in AL to measure stress hormones that may weaken the immune system and cause other health issues (e.g., weight gain) at elevated levels.
8. Epinephrine: often referred to as adrenaline, this adrenal hormone causes arterial dilation and increases heart rate; included in AL to assess stress hormone levels.
9. Norepinephrine: an adrenal hormone that causes vasoconstriction and increases blood pressure; included in AL to assess stress hormone levels.
10. Dehydroepiandrosterone sulfate (DHEA-S): an adrenal hormone that is similar to testosterone in its physical effects; included in AL to assess stress hormone levels.

When operationalized in the traditional way, each biomarker is dichotomized into a high-risk quartile (the worst 25% of research participants) with a score of one and a "normal range" category (the remaining 75% of research participants) with a score of 0 and then summed—yielding an index ranging from 0 to 10, with 10 being the maximal score for allostatic load. Since this initial attempt to measure the concept of allostatic load, researchers have developed more complicated and nuanced techniques. This research suggests that some biomarkers may be more important measures of allostatic load than others. For instance, one study (Karlamangla Singer, McEwen, Rowe, & Seeman, 2002) found that

epinephrine and diastolic blood pressure were particularly important measures of allostatic load, whereas other measures such as HDL cholesterol were unnecessary. Similarly, Burton Singer, Carol Ryff, and Teresa Seeman (2004) found that diastolic blood pressure was a particularly important measure of allostatic load. However, unlike Karlamangla et al.'s analysis, Singer and colleagues found that HDL cholesterol was an important contributor to the allostatic load construct.

Despite these improvements, Christopher Seplaki and colleagues (2006) have identified a number of limitations of previous efforts to measure allostatic load. For instance, existing measures tend to capture health risks associated with elevated biomarkers (e.g., high blood pressure) but not risks associated with unusually low levels of those same biomarkers (e.g., hypotension). Another limitation is that allostatic load may not operate in the same matter for men and women, suggesting that gender insensitive measures of allostatic load may be inappropriate. Also, most research on allostatic load is based on a single study (the MacArthur Study of Successful Aging), raising serious questions about the generalizability of existing knowledge. Importantly, most research to date has failed to account for immune function, which is a potentially important component of the allostatic load construct.

To account for these shortcomings, Seplaki and colleagues (2006) devised a measure of allostatic load that incorporated a total of 16 biomarkers. In addition to the 10 biomarkers used previously, these scholars included dopamine, body mass index, triglycerides, fasting glucose, insulin-like growth factor-1, and interleukin-6. The latter two biomarkers provided an assessment of immune function, whereas the others offered a more comprehensive picture of stress response, body composition, metabolic function, and cardiovascular health. Using a sample of 972 Taiwanese adults age 70 or older from the 2000 Social Environment and Biomarkers of Aging Study, Seplaki et al. used an advanced statistical technique to create five distinct allostatic load profiles for various sorts of health risk (e.g., low stress hormones but elevated biomarkers for metabolic and cardiovascular function). Analyses showed that this new measure of allostatic load performed better than the traditional 10-count measure in terms of the strength of its associations with health outcomes. In addition to this important finding, the study found only relatively minor gender differences in allostatic load in this sample of older Taiwanese adults, suggesting that previous concerns about gender differences may have been overstated.

## CAUSES OF ALLOSTATIC LOAD

Extant literature suggests that allostatic load is caused by repeated exposures to various stressors across the life course. These stressors have been defined as "external and internal challenges to the body and brain" (Koob & Le Moal, 2001, p. 99) and also as "events that are threatening to an individual and elicit physiological and behavioral responses" (McEwen, 2004, p. 67). These stressors may include (a) physical challenges such as hunger, exhaustion, temperature variations, and infections and (b) emotional and psychological difficulties such as anxiety and depression. (McEwen & Stellar, 1993; Schulkin, 2004). As various body systems—including the autonomic nervous system, the hypothalamo-pituitary-adrenal axis, and the immune system—respond to these challenges, allostasis results; as noted, this is functional for short-term adaptation (McEwen, 2002).

However, overexposure to stressors can provoke allostatic load, which is influenced by "repeated cycles of allostasis as well as the inefficient turning-on or shutting-off of these responses" (p. 32). For instance, depressed individuals are often beset with anxiety about future circumstances, provoking the release and chronic elevation of stress hormones such as cortisol (Schulkin, 2004). This has deleterious consequences, including high metabolic rates in the amygdala (a portion of the brain involved in processing emotions such as fear and anger), which may cause a "biasing of the brain" that further predisposes depressed persons toward negative and fearful affect (p. 9).

Although intuitively appealing, studies on the influence of stressors on allostatic load have produced mixed results. Analyses of data from the Wisconsin Longitudinal Study and the MacArthur Studies of Successful Aging demonstrated that individuals with positive social relationships were significantly less likely than individuals without such bonds to have elevated allostatic load scores (Seeman et al., 2002). To illustrate, women in the Wisconsin Longitudinal Study cohort with positive relationship histories were 78% less likely than women with negative histories to score high on the allostatic load index. Despite these compelling findings, some research has yielded less consistent results. For instance, analyses of 13 different scales of work conditions in a manufacturing plant in southern Germany found that only one of these scales—job demands—was significantly (but only weakly) associated with allostatic load (Schnorpfeil et al., 2003). Contrary to Seeman et al., Schnorpfeil et al. did not find significant associations between allostatic load and social support.

Another study (Glei, Goldman, Chuang, & Weinstein, 2007) found only weak support for the association between chronic stressors and allostatic load in the same sample of older Taiwanese adults examined by Seplaki et al. Similarly, an analysis of 290 Dutch managers failed to find any significant differences in allostatic load between "burned out" and exhausted managers and those with better mental health (Langelaan, Bakker, Schaufeli, van

Rhenen, & van Doornen, 2007). Clearly, further research is needed to sort through these findings and elucidate the causes of allostatic load.

## CONSEQUENCES OF ALLOSTATIC LOAD FOR HEALTH AND WELL-BEING

Research has shown that allostatic load is associated with a number of different health outcomes. In a seminal study documenting the health effects of allostatic load, Seeman et al. (1997) found that higher levels of allostatic load predicted decline in both the cognitive and functional capabilities of research participants in the MacArthur Studies of Successful Aging. These results were supported and extended by Karlamangla et al. (2002), who used canonical correlation analyses to show substantially stronger associations between allostatic load and health outcomes than initially found by Seeman et al. Additional research using the MacArthur Studies of Successful Aging cohort has shown that allostatic load is a strong predictor of mortality risk, independent of baseline health conditions and several other covariates such as sex, age, income, and education (Seeman, McEwen, Rowe, & Singer, 2001). Other research has used sophisticated statistical modeling to demonstrate that allostatic load is significantly associated with self-rated health, physical functioning, and depression in a cohort of older Taiwanese individuals (Seplaki et al., 2006).

In addition to health differences among individuals, Szanton et al. (2005) have suggested that allostatic load may explain health disparities across socioeconomic status groups. As resources such as income and education decline, the risk for exposure to chronic stressors increases (House et al., 1994; Marmot et al., 1991). Consequently, it is not surprising that studies have found higher levels of allostatic load in lower socioeconomic status groups (Seeman et al., 2004; Weinstein, Goldman, Hedley, Lin, & Seeman, 2003). Such findings are potentially important, as the elimination of health disparities is currently a top public health priority in the United States (U.S. Department of Health and Human Services, 2000).

## LIMITATIONS

Allostatic load has provided an innovative and useful way to conceptualize the physiological mechanisms that may mediate physical and psychological stressors and deleterious health outcomes. Prior research has shown that allostatic load predicts a range of health outcomes and, to a lesser extent, is associated with an assortment of stressors. Nevertheless, as Jay Schulkin (2004) pointed out, "There are no knock-down arguments for the concept of allostasis" (p. 12) and important questions remain about the validity of allostatic load.

For instance, studies have shown that some biomarkers used to measure allostatic load are more consequential for health than others and even that some biomarkers have no effect (Karlamangla et al., 2002; Singer et al., 2004). This raises the possibility that allostatic load is simply a new term used to describe previously established threats to health such as high blood pressure and elevated levels of cortisol. Furthermore, although research has shown that stress hormones and biomarkers associated with syndrome X (i.e., high cardiovascular risk) independently predict certain health outcomes, it has yet to show that the subcomponents of allostatic load combine to form a single underlying construct. In fact, preliminary analyses of MacArthur data failed to detect significant associations between latent constructs for stress hormones and syndrome X (Reither & Seeman, 2004). Should further research confirm this finding, would it be fair to say that allostatic load is an overarching construct that describes multiple, co-occurring physiological processes?

Despite these questions, ongoing research is continually refining allostatic load and addressing its limitations. For instance, several studies have adopted sophisticated methodologies to help improve the measurement of allostatic load (Karlamangla et al., 2002; Seplaki et al., 2006; Singer et al., 2004). Also, Seplaki et al. have expanded the number of biomarkers used to measure allostatic load, including two measures of immune function. With additional refinement, allostatic load promises to fulfill its potential as a valid and reliable measure of cumulative, physiological dysregulation. With better measurement comes the promise of superior detection of the preclinical signs of a wide range of diseases that afflict older individuals, which is particularly important given the rapid aging of the world's population.

## ALZHEIMER'S DISEASE

SEE Volume 3: *Cognitive Functioning and Decline; Dementias.*

## ARTHRITIS

Within the past century, scientific and medical advancements have been successful in preserving health and preventing and treating acute, infectious diseases (e.g., polio, tuberculosis) that negatively affect population health. These accomplishments, coupled with the growth of the U.S. population and increased life expectancy, have shifted the attention of medical and public health professionals to the prevalence and incidence of more chronic medical conditions such as hypertension, diabetes, cancer, and arthritis.

Arthritis, a condition characterized by pain, aching, stiffness, and swelling in and around the joint, poses a significant burden on the total U.S. population. It is one of the most common nonfatal chronic diseases (depending on the diagnosis) in the United States and is the leading cause of pain, substantive physical disability, and reduced quality of life, particularly among adults 65 years of age and older. An estimated 21.6% (46.4 million) of the adult U.S. population has been diagnosed

by their doctor with an arthritis condition. Specifically, 29.3% (20.5 million) of those ages 45 to 64 years of age report being doctor-diagnosed with an arthritis condition, with another 50% (17.2 million) among those age 65 and older reporting such a condition. With the increase in life expectancy, the number of diagnosed cases is expected to increase to 67 million adults by 2030.

Derived from the Greek words *arthron* ("joints") and *itis* ("inflammation"), arthritis is a general term used to describe more than 100 different conditions that affect the joint(s) and/or connective tissues. The most common types of arthritis are osteoarthritis (OA), which causes deterioration of the cartilage, and rheumatoid arthritis (RA), an autoimmune disease that causes inflammation of the joint lining and severe and irreversible damage to the heart muscle, lungs, kidneys, liver, and other organs and systems of the body. Other common forms of arthritis include fibromyalgia, gout, and systemic lupus erythematosus, which also have a significant impact on performance of routine tasks, leisure activities, and daily physical activities.

## PHYSICAL AND PSYCHOLOGICAL IMPACT OF ARTHRITIS

Defined as the difficulty, inability, or limitation in performing basic functional activities, an estimated 49 million noninstitutionalized persons report some degree of physical impairment or disability due to chronic illness. Whereas the changes in functional status contribute to lost work productivity, they also increase nursing home admissions, health care use, and expenditures. Approximately 16.9.4 million (7.9%) of the adult U.S. population report arthritis-attributable activity limitation (e.g., walking, bathing, dressing). This is projected to increase to 25 million (9.3%) by 2030. This is of growing concern as 54% of all arthritis-attributable activity limitation cases will be among adults 65 years of age and older by 2030. The physical limitations associated with arthritis involve a process in which muscle weakness leads to unstable joints; the resulting stress that is exerted on unstable joints cause physical disability and pain.

Paradoxically, attempts to avoid the pain associated with normal activities may lead to increased muscle weakness or muscle atrophy, in which the individual may lose muscle tone or experience a wasting or loss of muscle tissue. This may initiate a cycle of activity avoidance, physical disability, and pain.

Pain is the predominant manifestation of arthritis and is a significant predictor of disability, particularly for activities involving transfer, mobility, and other instrumental activities of daily living. Defined as an unpleasant sensory and emotional experience that impacts an individual's physical and psychological health and social well-being, the pain experience is not only a major health concern for individuals with arthritis but is also a significant predictor of current and future medication use, future pain experiences, and subsequent physical disability.

The pain experience varies from patient to patient and is contingent on a myriad of factors, including the history of the illness, duration of the medical condition, type (acute versus chronic) and location of the pain, variability of daily pain, number of painful days, number of joints affected, physiological changes (e.g., changes to the body's tissue structure), and side effects of pharmacologic interventions.

Aside from the physical expression of arthritis, many psychosocial factors are associated with the onset and experience of the disease. Psychosocial factors are defined as psychological, behavioral, and social processes that include beliefs, values, perceptions, culture, coping behaviors, personality indicators, and social resources and networks (e.g.,

social support), all of which influence how the individual detects, interprets, and responds to arthritis.

## CULTURAL DIFFERENCES

Although the biological sensations of pain are universal, the meaning, attitudes, and response to the pain experience differ across race, gender, and age subgroups. For example, some racial and ethnic groups are known to have specific "pain rituals" that shape the expectations and beliefs about pain, as well as strategies to tolerate the pain experience. Factors such as differences in language, ways of understanding and expressing health and disease, preferred modalities of health care management and treatment, the expression and meaning of pain, and the use of identified strategies to cope with pain are among the many factors that define the experience and cultural context of pain. For example, unlike the Western dichotomy of mind and body in explaining the pain experience, pain from a Chinese perspective, is regarded as a complex experience that can be understood only through the understanding of identified Eastern philosophies (e.g., Taoism/Energy Theory, Buddhism, and Confucianism). Social learning is another factor that may explain the contextual patterning and influence lifetime exposure has on how, why, and when this (pain) and other arthritis-related symptoms are experienced.

Race, which comprises ethnicity and culture, is a complex and multidimensional construct that establishes a conceptual framework for how people perceive health, illness, social demands, and environmental changes across the lifespan. To understand the role of race in daily behavior is to understand the extent to which the individual identifies with that particular race (or cultural) group and how experiences throughout the life course influence those experiences.

Social and demographic factors such as age and gender are associated with variability in the arthritis experience. For example, women 65 years of age and older are more likely to experience OA compared to women 35 years of age and younger. Specifically, there is growing evidence of the steady increase in the average age of persons with certain arthritis conditions such as RA, suggesting that RA and related morbidity, mortality, and disability rates are becoming more of an arthritis condition among older adults. Gender also dictates the disease process and its influence on physical health outcomes. Women are more likely to report pain-related chronic conditions such as OA, RA, fibromyalgia, and systemic lupus erythe than their male counterparts. Specifically, arthritis is reported as the most frequent cause of disability among women in general and among those diagnosed with arthritis in particular. National studies corroborate these findings, showing that OA prevalence tends to increase with age and affect woman more frequently than men. Despite the prevalence of these conditions, women are often treated less aggressively for their arthritis-related symptoms. Black women, for example, are at an increased risk for being diagnosed with an arthritis condition that is more severe, physically debilitating, and undertreated when compared to Black men and White men and women. This clearly shows that gender coupled with race has a substantial influence on the arthritis experience.

One's socioeconomic status (SES—e.g., income, education, occupational status), past and current, also influences the experience of arthritis. It is often difficult to determine the effects of SES and race exclusively in reports of arthritis and arthritis-related symptoms. Concatenated data from several national studies show pervasive race differences, with persons from minority populations reporting more severe and debilitating cases of arthritis. Others, however, have found no differences between majority and minority raced populations. Despite these findings, there has been more consistency in documenting the influence of SES on disease onset. Contemporary literature contends that persons with low SES are more likely to report arthritis and experience a decline in functional capacities than those with high SES.

It is important to consider the influence of SES (i.e., social positioning) when examining the etiology, prevalence, and incidence of arthritis, as it may capture lifetime exposure to deprived conditions (social, environmental), which may impact identified health outcomes in general, particularly among persons from more marginalized populations (e.g., minorities, elderly, women, the disabled). This is critical in the attempt to better understand the influence of SES and race on the etiology, progression, and outcome of arthritis among the elderly. For example, it has been shown that, despite equivalent levels of education (i.e., high SES), Whites reported better overall health, whereas Blacks did not enjoy the same health benefits due to higher attained levels of education. Despite these findings, there remains some debate as to whether race and SES function exclusively of one another or as binary constructs. This attests to the difficulty in disentangling the effects of race and SES, as both are cited as being significantly related to one another.

Health reflects a biological, behavioral, and social patterning of differential treatment, rights, and privileges that are defined by the life course, which is embedded in larger historical, geographic, social, cultural, and economic milieus. These constructs become more salient in light the steady increase in the number of older adults. With the increased life expectancy in U.S. society, the focus should extend more to the basic psychological and physical needs of older adults, as many will experience multiple chronic conditions, such as arthritis, within their lifetime. More important, decreasing the impact

of arthritis among the aging population will require proven health policies and applied public health interventions that improve functional abilities, decrease pain, and delay the experience of arthritis-related disabilities. Addressing these issues may ultimately help to identify the social, psychological, physical, and cultural factors that have important implications for policy, advocacy, and long-term needs of our growing population.

# ASSISTED LIVING FACILITIES

With the dramatic increase in the size of the aged population in the United States, Europe, and Asia, people are seeking new ways to approach how to care for and support the elderly. Traditionally, people remained at home (aging in place), and they transitioned into total care institutions (nursing homes) only when infirmity or health conditions became unmanageable. Until quite recently, individuals and families had few, if any, alternatives to these two extremes in their choice for living arrangements. The formal emergence of intermediate forms of housing, often known as assisted living facilities, has made rapid inroads in filling this need. This approach affords older adults the opportunity to maintain autonomy and independence when they find it difficult to manage some aspects of their day-to-day activities but are not in need of skilled nursing care and the restrictions that are associated with a nursing home facility. Often assisted living facilities work with traditional nursing homes systems so the elderly person can transition from limited levels of care, such as with meals and housekeeping, up to and including 24-hour intensive care. If properly managed and administered, this structured series of transitions offer individuals the opportunity to maintain autonomy for as long as reasonable and can offer a greater sense of dignity and control over their lives.

## HISTORICAL PATTERNS OF CARE

Assisted living is a new development in the ongoing evolution of long-term care for the aged. Historically, most individuals did not retire in a formal sense; instead they worked until they died or until they became too impaired to contribute to the household. Prior to the 20th century,

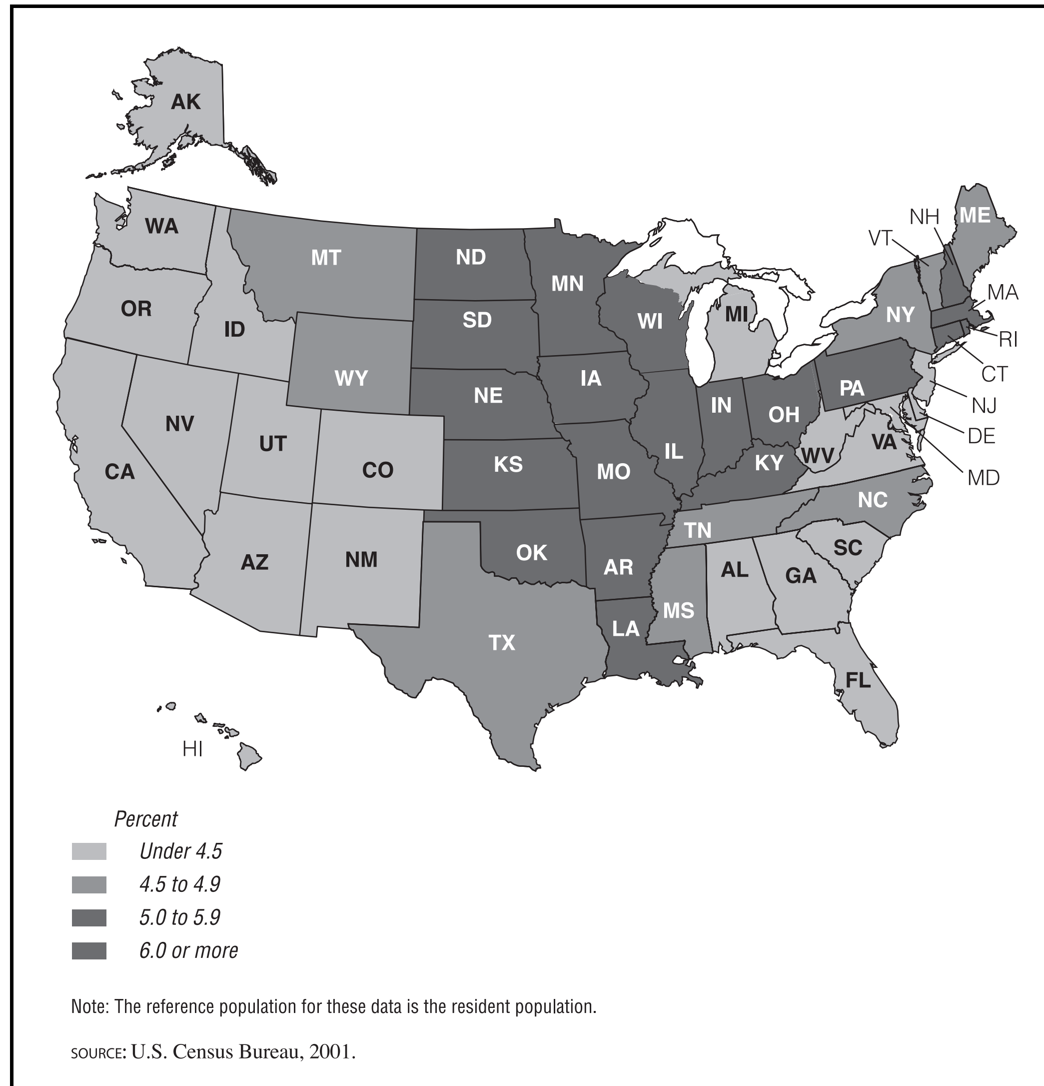

***Figure 1.*** *Percent of the state population aged 65 and over residing in a nursing home, 2000.* CENGAGE LEARNING, GALE.

those people who stopped working in old age normally did so because of physical disability or poor health, although quite often they continued to contribute to the household by performing tasks such as childcare, cooking, and cleaning. With no formal systems of portable economic support (such as pension benefits), the end of work also meant the end of one's income and the capacity to support oneself. Pension systems were rare at that time, and elders who could no longer work and lacked independent resources depended on family, friends, and churches to help them survive. The provision of care was encouraged by social convention and altruism so that most older adults were cared for to some degree—largely by family members. Those who could not depend on family or the community had few alternatives. In the 19th and early 20th centuries, elderly persons who lacked a source of care or support, along with other indigent persons, were frequently required to relocate to state- or locally run homes for the poor. Known under various names, including poorhouses, almshouses, poor farms, infirmaries, and asylums, these residences were often poorly run, overcrowded, and provided only minimal food, shelter, and clothing.

Both home care and state confinement were inadequate sources of care. Home care without an adequate income stream would limit the amount and quality of care a family could provide, and a disabled or infirm elder in the household often represented a strain on family economies. At the other extreme, state confinement in poorhouses was a legislated response to concerns over the destitute population lacking any age-appropriated services or care

consideration. Consequently, the elders in these situations had to accept whatever limited services the poorhouse offered and were unable to receive care that focused on their specific needs. When entering these institutions they became part of a general population undifferentiated by age, health concerns, or mental capacity. This represented a place of last resort for the elderly poor—a situation driven by the lack of systematic programs to provide portable income to the elderly when they ceased working.

Although a number of states in the early 20th century recognized older adults as a vulnerable population and offered old-age assistance, the plans varied widely across states and were difficult to maintain because of their noncontributory structure. As the state allocated and controlled all money being distributed, it was seen as simple charity as opposed to a pension system in which the elderly recovered something they had invested in over a period of years.

The introduction of universal social security in 1935 as part of the New Deal was the mechanism by which this system of poverty and dependence among the aged was addressed at the federal level in the United States. Initially it provided an Old-Age Assistance program that matched 50% of the contribution made at the state level. This was a short-term bridge that allowed the more familiar Old-Age Insurance program to accumulate enough funds for disbursements that would not begin until after 1942. Because Old-Age Assistance funds could not be obtained by older adults living in public institutions, this discouraged and eventually eliminated the presence of poorhouses for the elderly and offered incentives that led to the creation of privately run retirement homes that were the precursors to both the nursing home and the assisted living residential models for the elderly. When Social Security allowed residents of public institutions to receive benefits and required state licensing of nursing homes in the 1950s, the nursing homes industry grew tremendously. It was the addition of Medicare and Medicaid as part of the Social Security Act amendments signed into law by President Lyndon Johnson (1908–1973) on July 30, 1965, that allowed nursing homes to provide a wide array of short- and long-term services to the elderly and marked the true beginning of the total care institutionalized nursing care industry.

## NEW MODELS OF CARE AND THE EMERGENCE OF ASSISTED LIVING RESIDENCES

Although the growth of the licensed nursing home industry immeasurably improved the lives of frail and disabled elders who could no longer live in their homes, it was far from the perfect solution for addressing the needs of a growing elderly population. Licensing helped promote the adequate care and protection of the elderly, but he payment of care remained a contentious issue through the 1970s with Congress debating over the amount of care that Medicare and Medicaid would cover. The 1970s was also a period during which the first severe abuses of the new system of nursing homes came to light. Research by Claire Townsend in 1971 on the quality of life for the aged caused consumer advocate Ralph Nader (b. 1934) to coin the term *eldercide* in describing nursing homes (Kelly, 2007).

New legislation, including the Moss and Miller amendments, attempted to address the issues of competent care and adequate compensation for facilities, but these problems remain a concern today. An equally important issue, however, was that home care and institutional care (nursing homes as opposed to poorhouses) continued to represent the primary choices available to the older population, regardless of their overall health and their various levels of need. Nursing homes, although an important component of overall care strategy, remain *total institutions* in that the lives, movements, and activities of residents are regulated to facilitate the efficiency of an organization providing care to a population whose needs ranged from minimum assistance to 24-hour intensive care. As a consequence, individuals with only mild limitations could find their movements severely restricted, and, in essence, they were required to surrender autonomy in exchange for care despite an ongoing ability to manage many of their daily activities. Similarly, many older adults, although desiring to remain in their homes, reached a point where their physical limitations made this dangerous if not impossible. Yet at the same time, the undesirable loss of independence associated with nursing home residence caused them to remain at home unattended despite an inability to successfully manage the complex tasks associated with unassisted living.

## THE FORMALIZATION OF THE ASSISTED LIVING MODEL

As a response to the limited choices available for care in later life, assisted living facilities have rapidly become a diverse middle ground in formal care systems that target older adults. Unlike the absolutes that tend to define home care and institutionalized care as the polar extremes of care provision, assisted living environments are often presented as a broad system of graduated care whereby providers offer services that are tailored to the specific needs of the older population at different stages in their aging life course. Assisted care facilities have expanded in number rapidly since the late 1980s because they fill a necessary niche in the health care marketplace. As a business model, Michael Keslosky and Glenn Stevens

***Holding Hands.*** *Senior citizens hold hands while sitting on a couch at the assisted living facility where they live. Both also suffer from Alzheimer's disease.* AP IMAGES.

(1999) identified four factors that have encouraged the growth of assisted living facilities: (a) Many seniors need assistance with some aspects of daily life but do not need the intensive care of a nursing home, (b) most seniors prefer to live independently as long as they possibly can, (c) the elderly value the ability to age in place, and (d) the largest market for senior housing is in the lower- to middle-income ranges. A fifth factor, not mentioned by Keslosky and Stevens but important nonetheless, was the increase in discretionary income within the retirement-aged population (Hungerford, Rassette, Iams, & Koenig, 2001–2002).

Because of the long-standing lack of intermediate forms of care, the assisted living industry has grown rapidly. This has had positive impacts as it has increased the number and types of support services available to older adults; however, as both definitions and regulatory control varies widely, this array of alternatives can also make it difficult for the general public to make informed decisions about which provider would be best for their needs. The National Center for Assisted Living (NCAL), an advocacy group for long-term care providers, reflects the positive aspects of assisted living as a resource for the aged by stating that about 1 million Americans live in assisted living facilities, including about 115,000 Medicaid recipients. The NCAL stated that many individuals and their families prefer assisted living housing because of its emphasis on residents' privacy, dignity, and choice (Polzer, 2008). In contrast, the formal definition provided by the National Center for Health Statistics (NCHS) introduced some of the complexities associated with defining assisted living facilities and reported the following:

> [Assisted living facilities] provide some assistance with activities of daily living and instrumental activities of daily living but do not provide round-the-clock skilled nursing services. Assisted living facilities and in-home assisted living care stress independence and generally provide less intensive care than that delivered in nursing homes and other long-term care institutions, but there is no standard definition of these places as they are licensed by individual States, if at all. (Bernstein et al. 2003, p. 213)

The definitions given by the NCHS and the NCAL are accurate representations of assisted living, but they represent very different interpretations of what assisted living is. The U.S. Department of Health and Human Services (2003) offers possibly the most reasonable definition, stating that assisted living facilities are "housing alternatives for older adults who may need help with dressing, bathing, eating, and toileting but do not require the intensive medical and nursing care provided in nursing homes." The variations in these definitions are driven by the contrasting missions of the organizations that create them. Advocacy groups such as NCAL tend to focus on licensed facilities that offer excellent care and represent the quality of care they seek to promote as the standard for their constituency. These groups also can provide invaluable services to the public who seek information to help them navigate though the complexities of planning for long-term care.

The NCAL, for example, has offered an annual report since 2001 that summarizes state regulation and oversight of licensed facilities and represents a valuable tool for the public that is informative and user-friendly. In contrast, the NCHS definition is driven by their role as a government agency with a primary focus on health and information dissemination. In this role the organization represents a valuable resource for the issues related to the risks of poor-quality care. The NCAL's definition, although emphasizing the significant benefits of dignity and needs-based care that makes assisted living such a valuable option, glosses over the payment issues and the very limited role that Medicare and Medicaid play in financing this form of care. Similarly, the NCHS definition fails to recognize the growth in both state licensing and professionalism in the assisted living industry entering the 21st century that have helped reduce some of the major abuses seen in the 1980s and 1990s, particularly in the care of older adults suffering from dementia (Tilly & Reed, 2006).

This wide gulf between advocacy and oversight will remain for the foreseeable future, as the term *assisted living* covers an increasingly wide array of circumstances. Again, referring to the U.S. Department of Health and Human Services (2003) summary, such facilities "may be part of a retirement community, nursing home, senior housing complex, or may stand alone. Licensing requirements for assisted living facilities vary by state and can be known by as many as 26 different names including: residential care, board and care, congregate care, and personal care." With this level of variation, it is difficult, if not impossible, to establish a common standard by which assisted living facilities can be evaluated and compared by either the consumer or the state and federal government.

Similarly, complexities and confusions over the financing of assisted living can make educated choices that much more difficult. As of 2008, Medicare and Medicaid insurance covers very little of the cost of assisted living, generally being applicable to the health care and treatment costs that these programs cover regardless of residence. Even the procedures and costs that are covered within assisted living facilities vary depending on the way individual states administer Medicare and Medicaid. In general, assisted living facilities represent a direct out-of-pocket expense to the individual, and costs can run from as low as $10,000 per year to $50,000 or more, comparable to the costs of many nursing homes. Entering the early 21st century, the growing availability of long-term care insurance that is intended to pay these costs has promise for the future, but at present it is still too new a concept to realistically evaluate.

Because this system is often organized around a mixed model of independent living in private apartments or suites, residents within assisted living facilities face many of the challenges that any normal tenant faces in terms of services, rights, and obligations, and in many cases they also need to meet minimum standards for self-care to remain within the facilities; otherwise, they are required to either transition into nursing care or leave the assisted care environment. The selection and negotiating process required to maximize the value of the assisted living experience can be extremely complex, and, like all late-life decisions, it works best when planned for well in advance.

## CONCLUSIONS

In the scheme of long-term care for older adults, assisted living facilities represent a relatively new and potentially invaluable alternative to home care, which is often stressful and inadequate, and to the total institution that is the nursing home model. Although still unregulated in any systematic manner and with wide variations in the quality of care across states, the assisted living model has grown both in popularity and professionalism in the past decade. Increasingly, older adults with minimal support needs can choose from a wide array of alternatives in terms of housing, services, and opportunities to make smooth transitions into more intensive levels of care as needs change. Still, there is much room for improvement. The industry needs to establish internal standards to better serve the needs of the consumer and to better explain the available choices. Funding models also need to change as the long-term care insurance matures and the costs of this investment begin to be felt by the providers. The level of involvement by the federal government, both in terms of financial assistance and

regulatory oversight, desperately needs to be addressed as the risks for abuse and mistreatment of older adults are a constant concern for the maturing assisted living system.

Overall, however, the current availability of assisted living facility services is an important and necessary improvement over past systems that left older adults, with only mild to moderate support needs, totally dependent on themselves or their families. It also provides an alternative to an early and often inappropriate move into formal nursing care, offering older adults additional years of the autonomy, productivity, and sense of independence that is essential to successful aging.

# ASSISTIVE TECHNOLOGIES

Technology is playing an increasingly important role in the lives of older Americans. By facilitating participation in daily activities and promoting independence, the use of assistive technology can influence life-course transitions related to retirement, living arrangements, and long-term care. About 14–18% of adults ages 65 or older use assistive devices (Cornman, Freedman, & Agree, 2005) and two-thirds of older people who report difficulty with personal care activities use a device to meet daily needs (Agree & Freedman, 2000).

## DEFINING ASSISTIVE TECHNOLOGY

Although there is no single agreed-on definition of assistive technology (also often referred to as assistive devices or special equipment), the Assistive Technology Act of 1998 defines assistive technology broadly as "any item, piece of equipment, or product system, whether acquired commercially, modified, or customized, that is used to increase, maintain, or improve the functional capabilities of individuals with disabilities." This definition includes everyday items (so-called mainstream technologies) such as scissors and microwave ovens as well as specialized devices such as wheelchairs or chair lifts. For research purposes the following narrower definition is often used: items intended for and used by individuals to eliminate, reduce, or assist with impairments in functioning (Committee on Disability in America, 2007). Although medications and medical devices implanted in the body (such as pacemakers or artificial joints) can improve functioning, these items generally fall outside both policy and research definitions.

The Committee on Disability in America (2007) broadly categorized forms of assistive technology into (a) personal (or portable) devices, (b) environmental modifications, and (c) adaptive technologies. Within each category, devices may be used to assist with different impairments (such as lower body limitations, difficulty grasping, sensory impairments, or cognitive decline) or with specific tasks (such as walking, dressing, bathing, or managing medications). Personal assistive devices operate as an extension of a person's own capability, may be used in a variety of settings, and include items such as canes, wheelchairs, hearing and vision aids, medication reminders, and reachers or grabbers. Environmental modifications are items that are put into place to adapt a home or building to accommodate a person's disability and include items such as grab bars, raised toilet seats, ramps, wandering prevention systems, and stair glides.

"Smart homes" also incorporate the use of additional technologies including items such as sensors for detecting falls or devices for monitoring blood pressure (see William Mann's *Smart Technology for Aging,*

*Disability, and Independence* [2005] for further details). More comprehensive structural changes, such as widening doorways to accommodate a wheelchair, may also be considered an environmental modification, although this type of change is often excluded from examinations of assistive technology use. Finally, adaptive technologies can be used to make mainstream objects or devices accessible for individuals with differential functional capacities. For example, computers can be fit with screen readers and voice activation software for individuals with sensory impairments, and fixtures can be placed over appliance dials to make them easier for a person with limited hand strength to use.

Two additional concepts that are distinct from but related to assistive technology are durable medical equipment (DME) and universal design. DME is a coverage-related term used by Medicare, the public insurance program for adults age 65 and over, and Medicaid, the public insurance program for poor, blind, and disabled individuals. DME is a class of technologies that are deemed to be medically necessary, reusable, and prescribed by a physician for use in the home. Assistive technologies that fall outside the scope of this definition are generally not covered through Medicare. For low-income individuals, Medicaid can cover the portions of costs that are not covered by Medicare. In addition, Medicaid's state-administered community-based services waiver programs can provide additional funding for the purchase of some assistive technologies and home modifications, although these programs can vary widely across states (Freiman, Mann, Johnson, Lin, & Locklear, 2006).

Universal design refers to the development of "products and environments to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design" and embraces seven basic principles (Center for Universal Design, 2008). Designs must be equitable for use by people with diverse abilities; be flexible to accommodate different preferences and abilities; be simple and intuitive to use; communicate information efficiently and clearly; minimize hazards and adverse effects of unintended use; be comfortable to use with minimum fatigue; and incorporate the appropriate size and space for use regardless of body size, posture, or mobility. Although it is not likely that an environment or product can accommodate every possible physical or emotional limitation, the spirit behind universal design is to develop products and environments that are accessible to the greatest number of people. Devices that incorporate universal design can be as simple as lever doorknobs or as complex as kitchen sinks that have clear knee space under the sink and adjustable heights so that both users who stand and those who are seated can use them comfortably.

## PEOPLE WHO USE ASSISTIVE TECHNOLOGY

Some individuals are more likely than others to use assistive technology. An individual's underlying capacity (need), various psychosocial factors, the fit between an individual and a device, and selected economic and sociodemographic characteristics all predict whether an individual will use assistive technology. Health and functioning tend to be the most important predictors of whether devices are used, with devices being used more by those with moderate and severe disability and least by those with mild disability (Verbrugge & Sevak, 2002).

Preferences for and attitudes about the use of assistive technology are also related to whether assistive devices are initially adopted and their use sustained. The benefits of device use may include improvements in performing tasks and an increased sense of security and safety. Iezzoni (2003), however, noted that the use of some assistive technologies, particularly those that are highly visible, may be associated with negative psychological consequences such as loss of abilities and independence. Negative feelings toward devices are associated with discontinued use of devices whereas more positive notions (e.g., thinking that devices provide independence and enable individuals to participate in a wider range of activities) are associated with their adoption and continued use (Gitlin, Schemm, Landsberg, & Burgh, 1996).

How well a device fits the needs and lifestyle of an individual also matters. For example, individuals are less likely to use devices that do not do what they were meant to do, do not fully meet the needs of the individual, or do not meet expectations about comfort, safety, and ease of use (Phillips & Zhao, 1993). Discontinuing the use of devices can also result from a lack of adherence to user preferences, inadequate training on the device, or the prescription of devices that are inappropriate or inadequate for the environment in which they are to be used (Iezzoni, 2003; Phillips & Zhao, 1993).

Less clear is the role of economic resources such as income and health insurance and sociodemographic characteristics. Even though more than half the costs of assistive technology are paid for out-of-pocket (Freiman et al., 2006), level of income does not consistently predict the use of assistive technology. For instance, among individuals with a need for assistance, some studies find no relationship between the use of assistive technology and level of income (Agree, Freedman, & Sengupta, 2004; Verbrugge & Sevak, 2002) and another finds that individuals with lower incomes tend to use assistive technology for mobility more often than individuals with the highest levels of income but individuals with incomes that fall in the middle are the most likely to use assistive

technology for bathing (Freedman, Martin, Cornman, Agree, & Schoeni, in press).

Because coverage of assistive technologies is quite limited in many cases, health insurance is also not strongly related to assistive technology use. Although Medicare provides limited coverage of DME to all adults age 65 and over, additional resources for the purchase of assistive technology could come from private insurance that supplements Medicare coverage, Medicaid, Medicaid waivers, benefits for veterans of the armed forces, or cash and counseling demonstration programs that provide a cash benefit to Medicaid recipients (available in about 15 states as of 2007). However, having these supplemental benefits does not translate into greater use of assistive devices (Agree et al., 2004).

Finally, variation in use by sociodemographic factors such as age, sex, race, and education also have been noted. Among individuals who require assistance (e.g., have difficulty with daily tasks), women and those with higher levels of education are more likely to use assistive technology, and rates of its use tend to increase with age (Agree et al., 2004; Freedman et al., in press). Evidence also suggests that ethnic and racial minorities who have a disability are more likely to use assistive technology for mobility difficulty and that non-White Hispanics are more likely to use assistive technology for bathing (Freedman et al., in press). Some of these differences across socioeconomic and demographic groups may be due in part to differences in the types of devices used, the adaptability of the home environment (such as being allowed to or having the resources to instill grab bars in the bathroom), receptivity to and attitudes about the efficacy of using devices, the desire for independence, or difference in expectations, preferences, and opportunities for using specific types of care (e.g., the use and availability of personal care versus devices).

## ASSISTIVE TECHNOLOGY AND LIFE-COURSE TRANSITIONS

Whether used alone or in combination with other accommodations, such as personal help or behavior change (e.g., changes in the way a task is done to compensate for functional difficulties), the use of assistive technology may have a number of positive outcomes, including improved functioning to facilitate independence, prolonged labor force participation, and reduced demand on and need for assistance from personal caregivers.

To live independently, older adults must be able to take care of their daily needs. The use of assistive technology can reduce or even eliminate difficulty with such tasks as dressing, reaching, walking, getting in and out of bed, and going to the toilet (Verbrugge, Rennert, & Maddans, 1997). Use of assistive technology and environmental modifications can also slow the rate of functional decline, potentially prolonging the ability to continue living in the community (Mann, Ottenbacher, Fraas, Tomita, & Granger, 1999).

One report on technology for adaptive aging (Pew & Van Hemel, 2004) noted that the use of assistive technology may also make it possible for adults to continue to work when they otherwise may have left the workforce. A number of changes in physical and cognitive abilities are common as individuals age, which can lead to difficulty in certain work situations. For example, vision loss can make it difficult to read a computer screen, and difficulty with fine motor skills can interfere with the ability to do assembly work or to use common computer input devices such as a mouse or keyboard. However, with assistive technologies such as screen magnifiers, large keyboards, or trackball pointing devices, difficulty with work tasks may be reduced. Although there is little research on the efficacy of assistive technology for enabling people to remain in the labor force, the workforce is getting older (e.g., the proportion of the labor force between 25 and 54 is declining) and employers may need to increasingly adapt the work environment to accommodate functional changes common to the aging process.

Finally, with the high costs associated with formal care and potentially high burden levels for informal caregivers, there is also interest in the potential for assistive technology to substitute for or take the place of personal assistance as well as the potential for assistive technology to reduce the costs of long-term care. In general, the use of assistive devices seems to reduce the amount of care received from another individual, but it rarely replaces human assistance altogether (Agree & Freedman, 2000; Allen, Foster, & Berg, 2001). However, the relationship between personal care and device use may depend on the specific devices used and an individual's underlying functional abilities. For instance, devices such as canes and crutches may reduce the number of hours of informal care needed, but items such as wheelchairs and walkers seem to supplement rather than substitute for the receipt of personal care (Agree & Freedman, 2000; Allen et al., 2001). Similarly, individuals reporting less severe difficulty with tasks are most likely to use equipment alone (potentially substituting devices for human assistance), but those with more severe difficulty are more likely to use equipment in combination with personal care (Agree et al., 2004; Verbrugge & Sevak, 2002). Finally, evidence also suggests that individuals using assistive devices, particularly canes, tend to have lower costs for in-home services and institutional care (Allen et al., 2001; Mann et al., 1999).

## BALTES, MARGRET
***1939–1999***

## BALTES, PAUL
***1939–2006***

Margret Maria Baltes, born in Dillingen, Germany, and Paul B. Baltes, born in Saarlouis, Germany, are two of the world's most prominent lifespan psychologists whose lifework substantially advanced the field of gerontology. They were married in 1963 and had two children—Boris (b. 1965) and Anushka (b. 1971).

Both received their bachelor's and master's degrees from Saarland University in Germany. After also receiving his doctorate in psychology from Saarland University in 1967, Paul Baltes took on his first academic position at West Virginia University, where Margret Baltes completed her doctorate in experimental psychology in 1973. They then both held academic positions in human development at Pennsylvania State University. In 1980 they moved to Berlin, Germany, where he became codirector of the Max Planck Institute (MPI) for Human Development and she became a professor of psychological gerontology at the Free University of Berlin.

Margret and Paul Baltes shared a particular interest in successful aging and the related dynamics between gains and losses. Together they coedited *Successful Aging: Perspectives From the Behavioral Sciences* (1990), an influential book that changed the scope of aging research from focusing on age-related loss of capacity to highlighting older adults' potentials and adaptive competencies. They also introduced one of the most internationally renowned theories of lifespan development: the model of selection, optimization, and compensation (SOC), which proposes three mechanisms thought to promote successful development and aging. In this model *selection* is understood as the principle giving direction to development by focusing a person on particular developmental goal options, *optimization* aims at achieving higher levels of functioning, and *compensation* focuses on using alternative means to maintain functioning in the face of developmental loss. They referred to the pianist Arthur Rubinstein (1887–1982) as a good example for use of SOC processes. Rubinstein once described in a television interview how he dealt with the consequences of aging: He reduced his repertoire to a smaller number of pieces (selection), practiced this smaller repertoire more often (optimization), and slowed down the speed of playing prior to fast passages to produce a contrast that enhanced the impression of speed in fast segments (compensation).

Margret Baltes was a behavioral scientist and gerontologist who enriched the field with valuable and innovative insights into how older persons manage their lives by social means and how it is possible to lead a productive life even with the functional limitations that often accompany old age. Her main contributions include research on dependence in old age, summarized in the book *The Many Faces of Dependency in Old Age* (1996). She conducted groundbreaking observational studies in nursing homes, in which she drew on behavioral concepts such as reinforcement contingencies to explain the direct relationship between professionals' ignoring of patients' independence and enforcement of patients' dependent behavior, resulting in enhanced levels of dependence among patients.

Besides bringing the role of the social environment in caregiving settings to the fore, she also refined the concept of proxy control (exerting control indirectly by enlisting another's help or relying on external means), initiated innovative research on cognitive plasticity in aging by using the testing-the-limits approach as a detection means for early dementia, and developed a model of everyday competence by distinguishing basic (e.g., self-care) and expanded (e.g., leisure and social activities) levels of competence in the Berlin Aging Study (BASE). Marked by her interest in social dynamics, she also proposed a collective perspective for the SOC model to look at how adaptive processes evolve in couples, families or groups, and even societies. Finally, she successfully engaged in translating her research into concrete applications (e.g., training programs for the nursing staff), and she was an important advocate for older adults in policy making throughout her career.

Paul Baltes played a key role in establishing lifespan developmental psychology as an internationally acknowledged discipline, criticizing the predominant focus of developmental psychology on childhood and growth. One key contribution he made to the field was introducing the

***Paul and Margret Baltes.*** PHOTO COURTESY OF BORIS BALTES.

notion that development includes the whole lifespan characterized by gains and losses as well as biological and cultural influences (e.g., he created a metamodel of the incomplete architecture of human ontogeny, stating that because human development was not optimized by evolution, loss becomes predominant in old age, which can be compensated by culture, but that the effectiveness of culture also becomes increasingly limited with advancing age). Another contribution of importance was his advancement of the measurement of developmental change and plasticity (e.g., he provided groundbreaking methodological reflections on the distinction between age, cohort, and period effects and advanced the testing-the-limits paradigm).

His work was characterized by an interdisciplinary orientation, connecting psychological, sociological, and biological perspectives of aging, as manifested in his initiating and chairing of the BASE, a large-scale multidisciplinary study of the old (*third age*) and oldest old (*fourth age*). Furthermore, he developed several paradigms, such as the dual-process model of cognitive development, which distinguishes mechanics and pragmatics of intelligence with differential age-related trajectories (i.e., the decline in mechanics and increase in pragmatics), and the Berlin wisdom paradigm—defining wisdom as expert knowledge about fundamental problems of life meaning and conduct and providing criteria to guide the study of wisdom.

Both Margret and Paul Baltes and were devoted to promoting the careers of young scientists; she founded the graduate program Psychiatry and Psychology of Aging, a joint effort connecting MPI and Berlin universities. Paul Baltes initiated the International Max Planck Research School called The Life Course: Evolutionary and Ontogenetic Dynamics (LIFE) (hosted by the MPI), which involves collaborative graduate study at the University of Michigan, the University of Virginia, the MPI, the Free University of Berlin, and Humboldt University in Berlin.

Their years in Berlin were marked by a stronger realization of the problems evolving in the fourth age. Though findings from the BASE had shown enormous plasticity in the third age, they also indicated a bleaker ontogenetic picture among the oldest old. However, their focus was still more on the rich potential of the third age and the need to find ways of using it more creatively. Their Berlin years were also characterized by very close connections to American academic institutions through their participating in many international collaborations and accepting appointments as visiting professors and scholars at Stanford and the University of Virginia. This time period was tragically altered by Margret Baltes' sudden death in 1999 at age 59. In the following years, Paul Baltes' work was characterized by even more awareness of the last phase of life and its problems and his initiatives to integrate a wider variety of disciplines into the study of aging (e.g., law, art history, and mathematics)—as manifested by his last coedited book *Lifespan Development and the Brain: The Perspective of Biocultural Co-Constructivism* (2006) and in founding and directing the MPI International Research Network on Aging. Paul Baltes passed away in the fall of 2006, at the age of 67.

Margret and Paul Baltes's enormous productivity and contributions are evident in many acclaimed books, hundreds of scholarly papers, accomplishments honored with several international awards, honorary doctorates at many European and American universities, editorial positions for numerous respected publications, as well as by the many young scientists whose lives and careers they influenced and supported, and that they continue to support through the Margret and Paul B. Baltes Foundation, which is dedicated to the advancement of research in lifespan psychology and gerontology.

## BENGTSON, VERN
***1941–***

Vern Bengtson, an American sociologist, social psychologist, and human developmentalist, is known primarily for his contributions to family theory and research on the topic of adult intergenerational relationships. Bengtson developed the *intergenerational solidarity paradigm*—a conceptual model that has become the gold standard in measuring social cohesion between generations. Bengtson also originated and, for 35 years, directed the Longitudinal Study of Generations (LSOG), the project with which he is most closely identified.

An only child of Swedish descent, Bengtson was born in Lindsborg, Kansas, on May 2, and had a peripatetic early childhood. At the age of 2, he and his mother moved to North Carolina where his father was stationed in the Army. Half a year later they moved to Stromsberg, Nebraska, to live on his grandfather's farm while his father was overseas. At the age of 5, after his father came back from World War II (1939–1945), he and his family moved to Denver, Colorado, and 1 year later to Wausa, Nebraska. When Bengtson was 9 his family settled in Hilmar, a small agricultural town in central California, where he graduated from high school in June 1959. He attended North Park College in Chicago and received his B.A. in 1963. As a junior in college, Bengtson met his future wife, Denise, whom he married in 1965. After becoming a widower in 1977, Bengtson married his second wife, Hannah, in 1983.

Bengtson attended graduate school at the University of Chicago where, in 1967, he earned a Ph.D. in human development and social psychology. Under the guidance of Bernice Neugarten (1916–2001), an engaged and intellectually demanding mentor, and Robert Havighurst (1900–1991), Bengtson was inspired by the scholarly fervor he experienced at the University of Chicago's Committee for Human Development at a time when it was building the intellectual architecture for the emergent and interdisciplinary field of adult development and aging.

Bengtson's only academic post was at the University of Southern California (USC). He began in the department of sociology in 1967, eventually splitting his appointment with the fledgling Davis School of Gerontology. In 1989 he was appointed American Association for Retired Persons university professor of gerontology. While at USC Bengtson established a significant research program on families and aging and, for several decades, directed a multidisciplinary training program in aging research.

In 1970 Bengtson's scholarly interest in the *generation gap* spawned one of the most enduring studies in the social sciences: the LSOG, a study of families spanning three generations. The conceptual core of the study was intergenerational solidarity, a construct that described the

***Vern Bengtson.*** **PHOTO COURTESY OF VERN L. BENGTSON.**

emotional, normative, structural, and behavioral factors that bind the generations. In 1985 Bengtson received funding from the National Institute on Aging to make the study longitudinal and to focus on issues pertinent to aging. Drawing from the emerging life course perspective, he added the notion of family time—the metabolism of family life—to that of biographical and historical time in coming to grips with the ways intergenerational relationships develop and change.

As the study progressed through the 1980s and 1990s, families changed in ways that were difficult to predict when the study started: The protest generation moved into careers and family life; women entered the labor force in large numbers; divorce and remarriage became more prevalent; nuclear families became smaller but more complex; and multigenerational families became increasingly common. In 1991 members of the fourth generation—great-grandchildren in the original family lineages—were added to the study. This provided additional leverage in employing a unique research design that could compare family members in the same lineages across historical periods over

which substantial social change had occurred. Most important, each of the linked generations could be assessed at the same chronological age, a feature used in Bengtson's *How Families Still Matter* in 2002.

In developing the LSOG, Bengtson blended a social psychologist's appreciation for the importance of studying multiple perspectives, a sociologist's understanding of social movements, and a developmentalist's appreciation of life course dynamics. His observation that solidarity was persistent over long periods of time (combined with increases in the co-survival of generations) led Bengtson to conclude that adult intergenerational relationships had become increasingly important between the 1970s and the present (the topic of his 1998 Burgess Award lecture). He coined the term *beanpole family* (a name reflecting his rural roots) to describe the vertical extension and horizontal attenuation of family lineages due to increased longevity and reduced fertility.

Bengtson has more than 250 scholarly publications to his credit. He wrote often about the importance of theory to the fields of gerontology and family science, serving as editor of several editions of the *Handbook of the Theories of Aging* and as editor-in-chief of the *Sourcebook of Family Theory and Research*. Bengtson received many honors and awards for his work, including the Ernest W. Burgess Award for outstanding career achievement, the Reuben Hill Award for outstanding contribution to research and theory (both from the National Council on Family Relations), the Distinguished Scholar Award from the American Sociological Association Section on Aging, and two Merit Awards from the National Institute on Aging. He also served as president of the Gerontological Society of America in 1990.

Bengtson retired from his academic position at USC in 2006 and moved with his wife, Hannah, to join their children and grandchildren in Santa Barbara, California. As of 2008, he continues his research with a project funded by the Templeton Foundation that studies the transmission of religion across generations. In attempting to reconcile the dialectic between change and continuity within families, Bengtson's most recent work continues to delve into what remains an enduring paradox in the study of intergenerational relationships.

## CANCER, ADULTHOOD AND LATER LIFE

*Cancer* refers to a group of diseases in which abnormal cells grow and progress through the body. It is the second-leading cause of death in the United States, behind heart disease, and the major cause of death among persons younger than age 85. Cancer's etiology includes both internal (e.g., hormones and inherited genes) and external (e.g., exposures to environmental toxins and infectious organisms) factors, often acting in concert.

### CANCER INCIDENCE ACROSS THE LIFE CYCLE

As a general rule, one's risk of developing cancer increases with each decade of life, with the majority of cancers disproportionately affecting persons aged 55 years and older. This rate is especially pronounced for the four most prominent cancer sites, namely prostate, breast, colon, and lung.

Prostate cancer affects 1 in 39 men between the ages of 40 and 59 years. These odds increase to 1 in 14 men between the ages of 60 and 69 years and 1 in 7 men ages 70 and older. Between 1975, when the National Cancer Institute (NCI) first began to collect data systematically, and 2004, rates of prostate cancer decreased significantly for Black men over the age of 65 years, but remained unchanged for Black men under the age of 65 years, and all White men. Data on incidence rates (the number of new cancer cases in the United States in a given year, usually presented as rate per 100,000) among Asian/Pacific Islanders, Hispanic, and Native American/Alaska Native men were first reported in the mid-1990s. The three ethnic groups have experienced no change in overall incidence rates since that time (Ries, Melbert, Krapcho, Mariotto, Miller, Feuer, et al., 2007)

Cancer of the breast is the most frequently diagnosed cancer among women. Breast cancer affects 1 in 210 females under age 39 years, 1 in 25 females between the ages of 40 and 59 years, 1 in 27 females ages 60 to 69, and 1 in 15 females ages 70 and older. Incidence rates for breast cancer in women increase slightly during menopause, most likely a result of changes in hormone levels. Incidence rates for breast cancer in Black women under 50 years of age, as well as for all White women, have decreased significantly from 1975 to 2004, while incidence rates among Black women over 50 years of age have remained unchanged. Since the mid-1990s, when data were first collected, incidence rates among Hispanic, Asian/Pacific Islander, and Native American/Alaska Native women remained unchanged.

For men, the odds of developing colorectal cancer increase from 1 in 107 for ages 40 to 59 years, to 1 in 60 for ages 60 to 69 years, to 1 in 20 for ages 70 years and older. A similar pattern is observed among women, in which risk increases from 1 in 138 for ages 40 to 59 years, to 1 in 86 for ages 60 to 69 years, to 1 in 22 for ages 70 and older. Between 1975 and 2004, incidence rates for White men and women and Black women decreased significantly, whereas those of Black men remained unchanged. Incidence rates have also remained stable for Native American/Alaskan Native men and women, Hispanic men and women, and Asian/Pacific Islander women since the mid 1990s, when data were first collected. A significant decrease in incidence rates for colorectal cancer is seen only among Asian/Pacific

Islander men. The decrease in this group likely has to do with who immigrated between the mid-1990s and 2004.

The probability of men developing lung cancer increases with age. Between ages 40 to 59 years, 1 in 92 men develop lung cancer. This increases to 1 in 38 among men ages 60 to 69 years, and 1 in 15 in men for those ages 70 and older. The risk of developing lung cancer likewise increases with age among women, from 1 in 117 between the ages of 40 and 59 years, to 1 in 54 for ages 60 to 69 years, and 1 in 22 for ages 70 and older. Over time, however, a decrease in incidence has been observed for Black and White men and women under the ages of 65 years, as well as for both Black and White men over the age of 65 years. Between 1975 and 2004, incidence rates of lung cancer increased only for Black women, ages 65 and older. National Cancer Institute data collected between the years 1995 and 2004 show a significant annual percentage decrease in rates of lung cancer among Hispanic men and women as well as among Asian and Pacific Islander men. For Asian/Pacific Islander women and Native American/ Alaskan Native men and women, incidence rates remained unchanged during that period of time.

## CAUSES AND CORRELATES OF CANCER

While both internal and external factors contribute to cancer incidence and mortality, a small percentage of all cancer cases (i.e., 5–10% for female breast, 10–15% for lung and prostate, and 20% for colorectal) are thought to be caused by hereditary mutations (Gronberg, 2003; Lynch and de la Chapelle, 2003; Olopade, Fackenthal, Dunston, Tainsky, Collins, and Whitfield-Broome, 2003; Schwartz, 2004). The overwhelming majority of cancers, however, result from sporadic or acquired mutations. These mutations occur spontaneously over the life course in response to environmental phenomena and may help to explain the relationship between cancer and age. In addition, changes in physiology occur over time that may sensitize the body to environmental insults, such as exposure to environmental toxins and occupational hazards that disproportionately affect vulnerable populations, and attenuate the effects of health behaviors, such as high-fat diets, sedentary life styles, and smoking.

Living in poverty is also associated with cancer incidence and mortality, in a number of ways. The so-called "food deserts" noted in inner-city neighborhoods, which limit the availability of healthful foods such as fresh produce, are associated with the development of cancer (Wrigley, 2002). Likewise, high-technology cancer treatments that increase odds of survival are less likely to be part of health services in those inner-city neighborhoods.

## CONSEQUENCES OF THE ONSET OF CANCER

The point in the life cycle at which a cancer is diagnosed affects both the course of cancer and response to its

treatment. Although aggressive cancer treatments such as adjuvant chemotherapy (treatment following surgery) improve survival among all persons, older adults are less likely than younger persons to be offered these treatments. They also are more likely to be undertreated (that is, less likely to be offered treatment and less likely to accept proffered treatment) (Bouchardy, Rapiti, Blagojevic, Vlastos, and Vlastos, 2007). It has been proposed that older adults with co-morbidities, physical disabilities, and cognitive and functional impairments respond less well to cancer treatments and are more subject to adverse outcomes, but this view is still under debate (Bouchardy, et al., 2007; Rodin and Mohile, 2007).

Older adults are significantly more likely to be diagnosed with new cancers than other age groups and also more likely to be socially isolated. Thus cancer may come at a time when social networks have been diminished, increasing the burden of some older adults with cancer. This lack of support almost certainly influences medical decision making and ability to cope with the disease and its treatment.

## DIFFERENCES ACROSS RACE AND CLASS

Group differences in the incidence of cancer occur by race, gender, and social class, as do differences in mortality. On the whole, African Americans are more likely to develop prostate, colorectal, and pancreatic cancer; and Whites to develop breast cancer, leukemia, and skin cancer (Ries et al., 2007). Hispanic women have the highest rates of cervical cancer. It is dangerous to generalize, however, because variation occurs even within racial/ethnic groups. Although Asian Americans/Pacific Islanders have the lowest incidence of breast cancer, for example, Native Hawaiians have particularly high incidence.

When cancers develop also varies by race. In West Africa, the geographic area from which African Americans, and their genes, originated, breast cancer appears prior to menopause in 74% of cases, whereas among White women, the odds of developing the disease increase with each year after menopause (Olopade et al., 2003). There is evidence that African-American women disproportionately experience the earlier, more aggressive form of breast cancer seen among women in West Africa. Little is known, however, about breast cancers among other groups.

The reasons that have been given for these racial and ethnic differences combine biological and environmental factors (Gehlert, Sohmer, Sacks, Mininger, McClintock, and Olopade, 2008). Although breast cancers can be classified into the same five identified subtypes (basal-like, erbb2+, "normal," luminal B, luminal A) experienced by women in the general population and White women, the proportion of subtypes varies by race. Basal-like tumors are more common among African-American than White women and are harder to treat. Yet because 70% to 80% of breast cancers are due to sporadic rather than hereditary gene mutations, environmental factors are thought to "get under the skin" to influence the body's natural ability to repair the day-to-day mutations that occur routinely.

Social class, the effects of which are difficult to disentangle from those of race in the United States, is also associated with cancer incidence and mortality. For all races as well as for Black and White adults considered separately, breast cancer survival rates varied by percent of census tracts living below the poverty line (Ries et al., 2007). Cancer incidence is also associated with social class: Individuals from lower social classes have higher rates of all cancers (Ward, Jemal, Cokkinides, Singh, Cardinez et al., 2004). This is, in part, because social class predicts access to education and health insurance coverage and occupational status. Class also predicts exposure to environmental toxins such as industrial waste, social stressors, and access to foods that may protect against cancer.

Health scholars from the biological, behavioral, and social sciences are beginning to understand the myriad factors that influence cancer development, treatment, and outcomes as they relate to adulthood and later life. Medical researchers' approach, however, must become more sophisticated and incorporate the multiple levels of influence on the disease, including biological and societal factors and how the two may interact. Considering both when conducting research will better allow researchers to target interventions.

# CARDIOVASCULAR DISEASE

Cardiovascular disease (CVD) is common among older adults and is the leading cause of morbidity and mortality in that age group. Some conditions include atherosclerosis, coronary heart disease, heart failure, valvular disease and arrhythmias. A growing number of individuals can expect to live with CVD for a significant portion of the life span. The determinants of CVD include biological, social, psychological, and behavioral factors. Treatment can improve symptoms and promote survival; nonetheless, the impact of CVD can be severe, as can treatment demands and side effects. Effective CVD management, which requires medication adherence and changes in diet and exercise patterns, is influenced by social-cultural and psychological factors.

## PREVALENCE

Approximately 80% of persons in the United States over age 60 have CVD (Rosamund et al., 2008). It is the most common diagnosis in that age group and, as the leading cause of death in the elderly (Centers for Disease Control, 2003), is also costly, with estimated indirect and direct annual costs of $448.5 billion (Rosamund et al., 2008). From 2000 to 2030 the number of older adults in the United States is expected to double (Centers for Disease Control, 2003). Concomitant increases in CVD morbidity, mortality, and costs are likely to occur as well.

## CVD AND AGING

Atherosclerosis, coronary heart disease, heart failure, hypertension, arrhythmias, and valvular diseases are common in older individuals. The increasing risk of such conditions in later life may reflect the increasing lifespan and thus account for the age-related changes in the cardiovascular system, including increases in systolic blood pressure and left ventricular mass, alterations in blood vessels, and reductions in maximal heart rate, cardiac output, and aerobic capacity (Schwartz & Zipes, 2008). These changes may be related to alterations in the autonomic nervous system, oxidative damage, inflammatory responses to stress and cell death (Schwartz & Zipes, 2008). In addition, increases in a high fat and cholesterol diet and a sedentary life style is credited with much of the current cohort-associated diseases that we are discussing.

## ATHEROSCLEROSIS AND CORONARY HEART DISEASE

Coronary heart disease (CHD) is caused by atherosclerotic changes in the inner walls of arteries that supply the heart muscle with blood. Fat deposits within the blood vessels activate macrophage white blood cells, causing inflammation and plaque formation. These narrow the blood vessels and obstruct blood flow. This process may begin early in life and progress asymptomatically for decades. CHD occurs when gradual vessel narrowing becomes severe or when plaque ruptures and initiates a platelet-clotting cascade that culminates in thrombosis that suddenly obstructs blood flow further. This process of blood vessel narrowing is stopped only with medications, diet change, and exercise.

Myocardial ischemia is the result of an inadequate supply of oxygenated blood to the heart and can produce angina pectoris, a syndrome of chest pain and other symptoms. However, myocardial ischemia can be asymptomatic and cause sudden death without warning. Although 50% of men and 64% of women who die suddenly of CHD have no previous symptoms of this disease, some data suggest that 95% of symptomatic respondents accurately recognized chest pain as a myocardial ischemia symptom (Rosamund et al., 2008). Prolonged ischemia can cause a portion of heart muscle to die, leading to myocardial infarction (MI, or"heart attack"). The average age of having a first MI is younger for men (65.8) than for women (70.4; Rosamund et al., 2008), possibly reflecting premenopausal protective effects of estrogen among women.

## HEART FAILURE

In heart failure, a damaged heart is unable to pump adequately. The left side of the heart pumps blood that has been oxygenated in the lungs to the organs (systemic

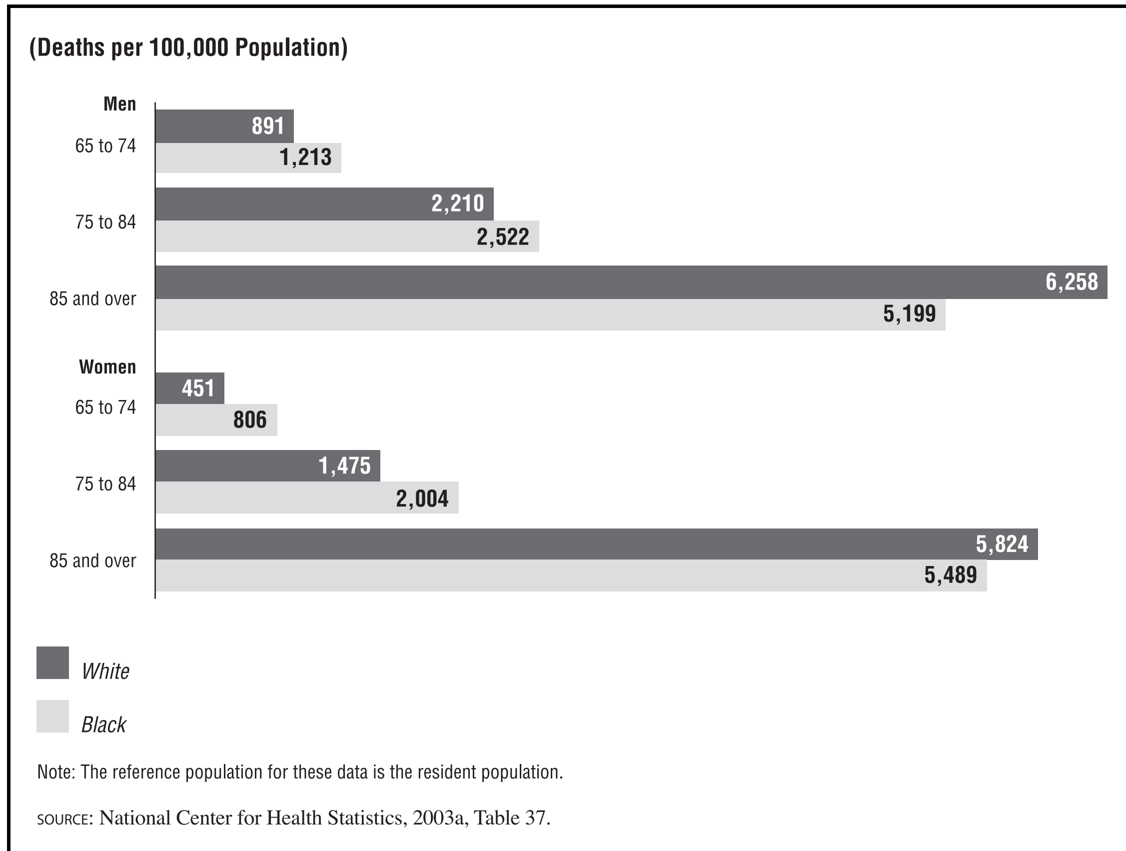

***Figure 1.*** *Death rates for diseases of the heart among people aged 65 and over by age, sex, and race, 2000.* CENGAGE LEARNING, GALE.

circulation), and the right side pumps blood returned from the tissues to the lungs for gas exchange (pulmonary circulation). Impaired systemic circulation can reduce blood supply to organs and cause pulmonary congestion and shortness of breath. Failure of pulmonary circulation can lead to congestion of peripheral tissues and swelling in the lower extremities. The incidence of heart failure is approximately 10 per 1,000 persons among those age 65 and older (Rosamund et al., 2008).

### HYPERTENSION

Hypertension is chronically elevated blood pressure, often as a result of reduced vascular elasticity. Hypertension is a major risk factor for CHD, stroke, heart failure, and kidney disease because it puts an enormous strain on the heart and on blood flow. Approximately 68% of individuals age 65 and older are hypertensive (Rosamund et al., 2008).

### ARRHYTHMIAS

An arrhythmia is any disturbance in electrical activity of the heart that causes an abnormal rhythm. Arrhythmias commonly diagnosed in older persons include atrial tachycardia (rapid heartbeat) and fibrillation (irregular heartbeat). Among the outcomes of arrhythmias are stroke, cardiac arrest, and sudden cardiac death.

### VALVULAR DISEASE

The valves of the heart are made up of leaflets that control the flow of blood with each heart beat. The leaflets become thickened with age and stiffen; they can also be damaged by infections and by bacteria such as streptococcus. When damaged, they become leaky and interfere with flow not only throughout the body but also to the coronary vessels on the heart surface. To prevent strokes and blood clots, medication adherence is critical.

### RISK FACTORS

The traditional risk factors for atherosclerotic CVD are older age, male gender, high total cholesterol levels, hypertension, family history, cigarette smoking, and diabetes. Also implicated are obesity, a sedentary lifestyle, a high fat and carbohydrate diet, low levels of high-density lipoprotein cholesterol, high levels of triglycerides, and

high levels of C-reactive protein and other inflammatory markers. Most risk factors have psychosocial and behavioral influences, and those influences also may promote CVD independently of better-established predictors. Potential psychosocial risk factors for CVD include social isolation, loss of spouse or never-married status, transition to retirement, low socioeconomic status (SES), racial/ethnic minority status, religious involvement, type A behaviors (especially hostility), psychological stressors, depression, and anxiety. It is not necessarily the biology of race and gender that elevates CVD risk. Rather, both traits are associated with a variety of social resources and disadvantages, which may shape one's risk of CVD These characteristics are also thought to promote CVD through direct physiological effects and/or by altering health-related behaviors. Some factors, such as gender, race, and SES, cannot be modified, whereas others may be altered through policy changes in health care and educational systems.

In the United States, CVD disproportionately affects African Americans, Hispanic Americans, and Mexican Americans, persons with low SES, and residents of the Southeast and Appalachia (Mensah, Mokdad, Ford, Greenlund, & Croft, 2005). The independent effects of poverty, minority status, and SES are difficult to disentangle. Individuals from disadvantaged backgrounds may be less educated about warning signs or may have cultural beliefs that clash with Western medicine. Additional challenges include the cost of seeking care, proximity to treatment centers, and racial/ethnic discrimination in treatment seeking. However, health care availability and accessibility do not account fully for the inverse relationship between SES and CVD. Whatever the mechanism, a greater portion of life spent in adverse SES conditions appears to increase the risk for MI (Ljung & Hallqvist, 2006).

CVD incidence among menopausal women approximates that among men of the same age. Biological factors specific to women, including postmenopausal estrogen deficiency and altered arterial structure, may delay the diagnosis and promote complications or poorer recovery. The belief among patients and practitioners that CVD is a "male" disease and sex differences in clinical manifestations may lead to underestimation of treatment urgency (Martin & Lemos, 2002), improper utilization of medical services, and unclear indications for medications or procedures. For example, whereas men with acute MI tend to complain mostly about chest pain, women tend to present with atypical symptoms, including abdominal pain, dyspnea, cold sweat, nausea, back and neck pain, indigestion, palpitations, and unexpected fatigue. It is hypothesized that the vagueness of these symptoms may result in delayed help-seeking behavior and increased disease progression. Other factors that contribute to CVD risk in women include a greater prevalence of emotional distress and mood disorders and lower average SES.

Risk factor potency may change from middle adulthood to late life. The effects of hypertension, cholesterol, smoking, and high body mass index may decline with advancing age, whereas diabetes elevates CHD risk across all age groups (Abbott et al., 2002). Nonetheless, older adults without previous cardiovascular events may have significant subclinical or nonsymptomatic vascular disease. Physicians therefore may need to be more vigilant in identifying (lower the threshold for defining) CVD disease in older individuals, attending to even modest elevations in certain risk factors.

## TREATMENT AND MANAGEMENT

Treatment of CVD has improved significantly over the past few decades with the development of thrombi-dissolving drugs, percutaneous transluminal coronary angioplasty (PTCA), and coronary artery bypass grafting (CABG) surgery. In PTCA a balloon is inserted into the occluded vessel and inflated to compress plaque and restore blood flow. A stent (metal scaffold) usually is inserted to keep the vessel open. In CABG, occluded coronary artery segments are bypassed with grafts taken from healthy vessels elsewhere in the body. Evidence suggests that the more beneficial procedure for patients with advanced CVD is CABG (Hannan et al., 2008), which improves survival, reduces recurrence, relieves angina, and enhances the quality of life.

Postintervention patients typically are prescribed medications to decrease the risk of recurrent CVD and mortality. These medications may include cholesterol-controlling, antihypertensive, antiarrhythmic, and/or antithrombotic agents. Drug effectiveness requires long-term continuous treatment. The benefits for those 65 and older are similar to those for younger individuals. Recommended lifestyle changes for CVD patients include smoking cessation, a low-fat and low-salt diet, and increased physical activity. These are also the secondary prevention tools to control and reverse disease in the coronary vessels to avert obstruction and decrease plaque. Secondary prevention are the treatment regimens that are recommended to control a chronic illness after it has been diagnosed.

Medication nonadherence is prevalent and is linked to increased morbidity and mortality. Adherence (taking medications as prescribed by the physician) is suboptimal both after acute CHD and in the larger population of individuals with poor lipid profiles. Nonadherence increases early and rapidly after the initial prescribing of medication, and approximately 65% of patients are nonadherent after 5 years (Benner et al., 2002). Thus, there is

significant room for improved secondary prevention for CHD in the older segment of the population.

### SOCIAL AND PSYCHOLOGICAL INFLUENCES ON DISEASE MANAGEMENT

Predictors of medication underuse among individuals over 65 include age, social isolation, depression, and dementia. Although older patients can be highly adherent, the oldest-old (over 77 years) have greater difficulty than do young-old adults (60 to 77 years) in comprehending medication information, which may promote nonadherence (Park, Morrell, Frieske, & Kincaid, 1992). Across age groups females tend to engage in less risk reduction behavior than males.

Because most well-established predictors of nonadherence are nonmodifiable, variables that account for their relationships with secondary prevention behaviors and that are modifiable are being sought. Salient among those predictors are patients' beliefs about CVD and its treatment. Secondary prevention may be undermined when patients overemphasize advancing age or stress as a major cause of CHD while failing to recognize the importance of medication, diet, and exercise; this may be especially likely to occur in women (Cameron, Petrie, Ellis, Buick, & Weinman, 2005). The belief that CVD cannot be controlled, failure to acknowledge illness severity, and the notion that PTCA or CABG is a permanent cure also may discourage secondary prevention. Expectations about the positive consequences of cardiac risk-reduction behaviors may explain why some patients are adherent, but false expectations of negative side effects can discourage adherence. Psychosocial factors, beliefs, and behaviors clearly play a significant role in CVD management and provide opportunities for research and intervention.

## CAREGIVING

Caregiving is the provision of regular unpaid help to an individual who, because of limited physical or cognitive abilities, is dependent on others for managing activities of daily life. Caregiving represents a broad range of activities that includes providing personal care, doing household chores, preparing meals, shopping, taking care of finances, providing companionship, regular checkups, arranging and supervising activities and outside services, and coordinating medical care. Because of the voluminous empirical literature on the topic, this entry limits its scope to caregiving that involves older adults, primarily

focusing on care provided in the immediate family and particularly within intergenerational relationships. Intergenerational caregiving can be divided into two general types: older adults as recipients of care from adult children (upstream caregiving), and older adults as providers of care to grandchildren and disabled adult children (downstream caregiving). Although both upstream and downstream caregiving have unique antecedents and target populations—with the former being more normative and based on disability, and the latter being more extraordinary and based on social conditions—both involve older adults and many of the same care activities.

There is no standardized method for identifying caregivers. Some studies define caregivers based on the number of hours they contribute to care. For example, one study identified primary caregivers as those who either lived with a relative with dementia or who provided at least 8 hours of care per week for an older relative living outside their households (Knight, Longmire, Dave, Kim & David, 2007). Other studies rely on a more liberal time threshold, such as the Health and Retirement Study that originally used a 2 hour per week threshold to distinguish higher from lower intensity caregivers to older adults (Soldo & Hill, 1995). More typical are general screening questions, such as that which follows used in the American Association of Retired Person's (AARP) national study in 2004, which prompted respondents to self-identify as a caregiver:

> Do you currently provide or have you provided in the last year unpaid help to a relative or friend who has a disability or chronic disease? This kind of help includes assistance with health or personal needs or household chores. It might be taking care of finances, arranging for outside services, or visiting regularly to see how they are doing.

Identification of an upstream caregiver is typically made irrespective of living arrangements because most caregivers to older adults do not coreside with their care recipients (AARP, 2004). By contrast, grandparent caregivers are most often defined by their household arrangements. A grandparent caregiver is typically so designated when he or she coresides with a dependent grandchild in the absence of a parent. In some instances, grandparent caregivers include those with part-time responsibility for their grandchildren, either as a dominant or subordinate coguardian, or those who provide regular day care assistance to working parents.

Rarely are upstream and downstream caregiving considered together, yet there are parallels between these two types of caregiving that remain unexplored. In this review, caregiving to and by older adults is considered within the context of the life course perspective, specifically in terms of the importance of timing, context, and linked lives. Timing refers to the onset and duration of care and the demographic and historical conditions that give rise to caregiving and guide caregiving careers. Context refers to the cultural and socioeconomic environments that determine the meanings and resources attached to caregiving roles. Linked lives refer to familial structures and interdependencies that shape caregiving decisions and outcomes.

## CAREGIVING TO OLDER PERSONS

With the increase in life expectancy over the last century, informal caregiving to impaired older people has become increasingly common. Family members form the backbone of the support system of frail older adults who live in the community, with adult children serving most often as main care providers. Before focusing on intergenerational caregiving, it is important to mention other forms of informal caregiving that should not be overlooked. Spouses are among the most prolific caregivers to older adults. However, as age peers to their care recipients, spousal caregivers are vulnerable providers in terms of the relatively few psychological and physical resources they bring to the caregiving situation, the heavy burden they confront in performing the caregiving role, and their greater susceptibility to disease and disability (Pinquart & Sörensen, 2003). These very characteristics of spousal caregivers elevate the importance of adult children in the care portfolio of frail married elders. In addition, while about 10% of frail elders receive care from neighbors and friends, research indicates that nonkin have weaker commitment to caregiving when compared to adult children of the recipient (Barker, 2002).

The role of adult children in providing long-term support and care to their aging parents aroused much interest in social gerontology and family studies in the last quarter of the 20th century. Declines in mortality rates and longer periods of chronic illness in later life have increased older adults' need for prolonged periods of care, thus making caregiving to older parents a normative activity in the lives of adult children. Research shows that older parents expect to rely on their adult children for care, support, and attention when confronting old-age dependencies (Blieszner & Mancini, 1987). Christine Himes (1992) estimates that a majority of middle-aged women with a surviving parent can expect to provide parental caregiving at some point in their lives. In the future, caregiving will occur increasingly later in the lives of caregiving children and their parents. The notion of parent care as an unexpected responsibility now has more to do with the unanticipated duration of the care role than with its entry.

According to a 2004 study by the AARP and the National Alliance for Caregiving, 21% of the U.S.

population provided unpaid care to an adult. This percentage translates into 44.4 million caregivers in the United States, a figure that is certain to rise with the aging of the population. According to this study, the typical caregiver to an adult is a 46-year-old female with some college experience, providing 20 hours of care each week to her older mother. Three out of five caregivers are female, and almost half are employed full time. Slightly more than half of caregivers (55%) are providing care for a recipient living in another household. Although informal caregiving labor is unpaid, it represents a significant economic value to society. Estimates of the value of informal caregiving ranges between $196 and $257 billion annually—an amount greater than the costs of formal home care and nursing home care combined (Staton, Shuy, & Byock, 2001).

**The Stress and Coping Paradigm** The most widely used paradigm in caregiving research today is the general stress and coping model of caregiving (Lazarus & Folkman, 1984). In these models, the psychological and physiological well-being of caregivers are linked to their personal characteristics (e.g., health, gender, martial status, economic status, and race or ethnicity), appraisals of the caregiving situation (perceived burden), stress levels (perceived and physiological), external resources (social support, formal services), and coping styles (active, emotion-focused), as well as the demands placed on them by their care recipients' level of impairment. The deleterious consequences of stress and burden are well-documented. Caregivers are at elevated risk for depression, poor self-reported health, low functional capacity, stress-related diseases, cardiovascular reactivity, impaired immunological function, high blood pressure, and elevated cortisol levels. Several meta-analyses of caregiving studies found that caregivers to dementia patients had greater stress and worse physical and mental health than both noncaregivers and caregivers to nondemented recipients (Pinquart & Sörensen, 2003).

There is also strong evidence that coping skills and support resources produce beneficial effects and serve to ameliorate the impact of burden on negative outcomes. Some coping skills, such as reappraising the situation and creative problem-solving, appear to have a positive impact on the well-being of caregivers, whereas coping styles that deny the problem—also known as avoidant coping—may exacerbate the negative consequences of caregiving (Knight, Silverstein, McCallum, & Fox, 2000). Social support that provides emotional and practical assistance to the care provider also serves to reduce burden and its harmful effect on the well-being of caregivers.

One of the more perplexing paradoxes in caregiving research is the relatively low levels of subjectively perceived burden reported by African-American and Hispanic caregivers, despite providing more hours of care and confronting more objective stressors (Knight et al., 2000). Most explanations of this contradiction have centered on the strong cultural values of familism expressed in African-American families that elevate expectations for caregiving and lead to a more positive appraisal of the experience. Other explanations focus on the greater use of religious coping styles and more active informal support networks in African-American families (Aranda & Knight, 1997).

Less investigated are the positive aspects of caregiving. Although often demanding and challenging in time and effort, caregiving can enhance subjective well-being and produce uplifts in mood as an intrinsic reward for helping a loved one. Taking a life span approach to the topic of family elder care, Karen Roberto and Shannon Jarrott (2008) note the emerging literature on caregiver growth that demonstrates the positive aspects of caregiving, including improvement in problem-solving abilities, increased self-understanding, and a growing sense of competence. However, the assumption that caregiving distress is relieved following the death of the care recipient appears to be overstated. One study found that although former caregivers experienced decreases in stress and negative affect, their depressive symptoms and feelings of loneliness did not rebound 3 years after their caregiving activities ceased.

**Allocating Caregiving Roles in the Family** The literature on intergenerational caregiving and support is replete with evidence for structured differentiation of siblings in their parent care activities. Adult children in larger families tend to provide less support per child than those in smaller families (Wolf, Freedman, & Soldo, 1997), suggesting that siblings resolve their division of labor by offsetting each other's efforts in a coordinated response to their parent's needs. The division of labor in caregiving tends to favor children with less discretionary time. For instance, unmarried sons and daughters are more likely to help their frail older parents, and for longer periods of time, compared to their married counterparts.

Caregiving is increasingly viewed as a team effort, with multiple family (and nonfamily) members trading off their care efforts. Although the structure of caregiving is typically hierarchical with a main care provider who coordinates the efforts of subordinate caregivers, research indicates that there is a good degree of turnover in the composition of caregiver networks, as well as in the primary providers over time. In one national study, more than half the personnel of care networks—including more than one-fourth of primary caregivers—changed over a 2-year interval (Szinovacz & Davey, 2007). As dissatisfaction with caregiving appears to accelerate over

time (Walker, Acock, Bowman, & Fuzhong, 1996), the rotation of caregiving networks may help avoid caregiver burnout.

As of 2008, middle-aged children of aging parents—members of the baby boom cohort—have relatively many siblings with whom they can share care duties. However, the next generation of potential caregivers will have fewer siblings than baby boomers, further increasing doubt about the viability of family support to elders. Smaller family size may mean that fewer potential caregivers will be available to support older adults in need. In addition, there have been substantial changes in family structure since the late 1950s, most notably increasing divorce and remarriage rates, and the emergence of stepfamilies as a normative family form. The disruptive effects of divorce and the tenuous nature of stepfamily relations may weaken the responsibility that children feel for their older parents (Silverstein, Bengtson, & Lawton, 1997). Another point of view is that the effects of divorce, remarriage, and family blending may potentially expand the supply of kin available for supporting older family members, and partially compensate for the negative consequences of low fertility and family disruption. However, evidence suggests that caregiving is increasingly focusing on fewer providers. Through the decade of the 1990s, there was a 50% increase in the proportion of primary caregivers who had no secondary partner available to help shoulder the care load, a worrisome trend that may portend greater stress for caregivers and a weaker safety net for care recipients.

One of the most consistent findings in the elder care literature is that women provide more care than men. At the family level of analysis, the presence of daughters appears to suppress the contributions of sons, suggesting that siblings, when they are able, divide caregiving responsibilities along traditional gender lines. Even when sons provide care, they do so with less frequency and intensity. In a review of 223 caregiving studies, Martin Pinquart and Sylvia Sörensen (2006) found that female caregivers provided more hours of care and were more likely to provide personal assistance than male caregivers, and experienced greater burden and depression as a result. Perceived unfairness in the allocation of care duties among siblings may result in feelings of resentment and conflict, particularly if the inequality of effort falls along gender lines.

Scholars using a bargaining framework to better understand family decision-making with respect to parent care explicitly invoke the possibility of intersibling conflict. Adult children negotiate with each other when making decisions about caring for an aged parent based on their own preferences and the anticipation that their siblings will (or will not) provide care or take an aging parent into the household. In such a scenario, adult children may induce their siblings to provide care by bluffing their intention not to provide care.

Finding evidence of systemic familial consequences of caregiving requires examination beyond the caregivers themselves to other family members. Anna Amirkhanyan and Douglas Wolf (2006), for instance, found that noncaregiving sons and daughters of impaired older parents experienced higher rates of depression when compared to their counterparts whose parents were not impaired. Their findings suggest that filial distress in caregiving families may derive from noncaregiving sources, such as concern over unmet need of a frail parent, guilt over not fulfilling an expected role, or intersibling conflict over the allocation of caregiving duties.

**Work-caregiving Stress** One of the most difficult dilemmas facing caregivers who are also working outside the home is the need to balance their labor force participation with their caregiving duties. The number of caregivers who are working at least 30 hours per week has increased between the mid-1980s and mid-1990s, even as the total number of caregivers per recipient has declined (Spillman & Pezzin, 2000). Thus, working caregivers are increasingly common but have fewer colleagues with whom to divide the care load. Not surprisingly, caregivers who are working full time provide lower amounts of care than other caregivers; and while they are also more likely to use supplemental paid providers, their care recipients are at greater risk of having unmet needs (Scharlach, Gustavson, & Dal-Santo, 2007).

Research shows that employed caregivers are at higher risk of health-related problems than nonemployed caregivers. Competing work-family demands adversely affect the physical, mental, social, and economic well-being of workers, elevate their risk of alcohol abuse, and produce stressful home conditions (Bianchi, Casper, & King, 2005). Yet employment also provides income and other work-related benefits that may link the caregiver to ancillary support services, and affords access to coworkers who may serve as an informal support network that lessens the burden and strain associated with caregiving.

Evidence for increasing jeopardy among working caregivers is not gender-neutral. Suzanne Bianchi, Lynne Casper, and Rosalind King (2005) note that women continue to shoulder a disproportionate amount of caregiving even as their responsibilities in the labor market have increased. The continued tilt of caregiving toward adult daughters has raised concerns about the impact of caregiving on their careers. The large time commitment of caregiving appears to reduce working hours more among daughters than among sons, particularly in suppressing full-time employment. Gender imbalances in

care work may be viewed as the product of societal norms and social policies that favor men's participation in the labor force. Nations with welfare state regimes, such as Sweden, provide liberal home care benefits to its older citizens (as well as day care for young children), so that women have more equal access to employment.

**Caregiving and Multiple Family Roles** Discussion of the *sandwich generation* in past decades has centered on the challenges faced by working-age adults who simultaneously care for their parents and their dependent children. Brenda Spillman and Liliana Pezzin (2000) found that the number of sandwich generation caregivers has increased, estimating that approximately 3.5 million individuals were dually responsible for an aging parent and a dependent child. A Canadian study found that almost 3 in 10 of those aged 45 to 64 with unmarried children were also caring for an older relative (Raphael & Schlesinger, 1994), with a higher percentage obtained if care for grandchildren is also considered. While delayed fertility has increased the likelihood that middle-aged individuals will be sandwiched between elderly parents and dependent children, some researchers argue that child care and elder care still occur sequentially more often than they do simultaneously (Ward, Logan, & Spitze, 1992).

Because of increases in life expectancy, the sandwich generation increasingly consists of middle-aged individuals embedded within four-generation families. This generation may be responsible for frail older parents, young adult children experiencing economic and social challenges in the transition to adulthood, and grandchildren in need of care. Some research suggests that there are significant intrafamilial strains in families where adult children are dependent on middle-aged parents who are caring for the oldest generation (Hamill, 1994). However, other research finds few negative outcomes in this type of sandwiched family, with one study finding that living with an adult child relieves caregiving burden in midlife caregivers (Raphael & Schlesinger, 1994).

**Caregiving Norms over Time** Life span developmental theories concerning filial responsibility typically focus on psychosocial adjustments made by individuals to meet family demands at successive life course stages. With regard to parent care responsibility, Margaret Blenkner (1965) invoked the concept of *filial maturity* to describe the transition of adult children from being relatively autonomous from their parents to being dependable sources of support for them. This transition involves a change in perspective that allows middle-aged children to view their parents as vulnerable individuals, thereby strengthening their commitment to provide care in the context of an adult relationship. An alternative developmental framework for conceptualizing filial responsibility is based on caregiving anxiety (Cicirelli, 1988). In this framework, filial responsibility is induced when children worry about how they might successfully manage care duties in advance of the time that care is actually needed by their parents.

Cross-sectional studies have found little empirical evidence of midlife exceptionalism with regard to filial duty to older parents, and, to the contrary, describe a linear decline in elder care responsibility across successive age groups (Peek, Coward, Peek, & Lee, 1998). However, a longitudinal study by Daphna Gans and Merril Silverstein (2006) found that normative commitment to caregiving for older parents peaked in middle age and declined thereafter. Filial anxiety and filial maturity may be mutually reinforcing characteristics, as suggested by Mark Bromley's and Rosemary Blieszner's (1997) finding that adult children who worried about the future dependency needs of their parents also collaboratively discussed possible care options with them.

## CAREGIVING FOR GRANDCHILDREN

As of 2000, more than 2.4 million grandparents claimed primary responsibility for at least one coresident grandchild without a parent in the household, a figure that represents a nearly fourfold increase since 1970 (Simmons & Dye, 2003). Over the same period, the percentage of children living in grandparent-headed households not quite doubled, rising from 3% in 1970 to 5.5% in 1997 (Bryson & Casper, 1999). The number of grandchildren being raised by grandparents has increased in all socioeconomic and ethnic groups but rose most dramatically in African-American families of the inner city starting in the 1980s. When their families were hit particularly hard by the crack cocaine epidemic, HIV and AIDS, lack of employment, and incarceration, African-American grandmothers stepped in to raise their grandchildren in greater numbers, continuing a history of grandparent primacy going back several centuries. Custodial grandparents of all races and backgrounds, but particularly those from poor and minority background, subsequently emerged as an important social policy issue in the late 20th century.

**Well-being of Grandparent Caregivers** Grandparents raising grandchildren represent a high-risk group for illness and disease. They are predisposed to poor physical and mental health outcomes even before their care for a grandchild begins as a result of their generally low socioeconomic status and the difficult family circumstances that precipitated their involvement in care. Evidence also suggests that the high demand of grandchild care itself takes a toll on the physical and mental well-being of

custodial grandparents, particularly the challenge of meeting the needs of children who are facing physical, behavioral, and mental challenges of their own.

Research has shown that grandparents caring for grandchildren, both in skipped and three-generation households, are at elevated risk for many health problems (Minkler & Fuller-Thomson, 1999). Grandparent caregivers tend to have lower levels of functional health, more chronic conditions, greater risk of coronary heart disease, and less satisfaction with their health compared to noncaregiving grandparents. Physical health and mental health are interrelated such that poor physical health and psychological distress mutually influence each other. Thus it is not surprising that this stressed and distressed group of caregivers is at high risk for developing chronic impairments, acute conditions, and mental health problems.

Grandparents raising grandchildren are more likely to suffer from depressive symptoms than grandparents who are not raising their grandchildren. The degree to which elevated levels of distress are related to the caregiving role itself or to the existential social and family conditions that surround and give rise to this nontraditional family arrangement has not been addressed conclusively. The precipitating adverse conditions that triggered entry into the role are at least as stressful as the daily hassles and sacrifices that come with managing the role itself; indeed, they serve to reinforce each other, producing double (and higher order) jeopardies for grandparent caregivers. Pathways into caregiving that involved drug or alcohol abuse in the parental generation produce the most negative psychological outcomes in custodial grandparents, providing evidence of accumulated disadvantages in this group of grandparents over time (Goodman & Silverstein, 2002). The cluster of risk factors involving preexisting social and economic conditions is exacerbated by entry into the caregiving role.

Caring for grandchildren is associated with poor mental and physical outcomes partially because those engaged in this activity tend to have low income, be of minority status, and be unmarried. Grandparents who care full time for their grandchildren are more likely than noncaregivers to live below the poverty line, receive public assistance, and have less than a high school education (Minkler & Fuller-Thomson, 2005). Low socioeconomic status is consistently related to worse health in this population as a result of the disadvantages associated with poverty, such as lack of access to medical care and insufficient support resources. Unmarried grandparent caregivers have worse health than married caregivers for many of the same reasons.

Beyond economic factors, grandparent caregivers are particularly sensitive to their family and household environments. In coparenting situations, grandparents will have contact with their grandchild's parent(s), often to coordinate care or visits. In such instances, it is not unusual for conflict to emerge over child care decisions and childrearing strategies—particularly if the grandparent and parent are living in the same household. Research shows that custodial grandparents have better mental health when they are the sole caregiver and have autonomy in their caretaking role (Goodman, 2003). In such instances, conflict with the child's parent is minimized because parental authority sits squarely with the grandparent. Conversely, grandparent-parent conflict may be particularly acute when parents exert authority over their children, particularly parents who are involved in substance abuse or suffer from serious mental illness.

Grandparent caregiving often arises in response to parental exigencies, deficits, and crises that may have left grandchildren abused or neglected, further raising the challenges faced by custodial grandparents. Children in grandparent-headed households are at heightened risk of hyperactivity, school difficulties, emotional distress, and forming behavioral problems. Given that parenting can be extremely stressful even under optimal conditions, the mental health of grandparents raising grandchildren is of particular concern given their older age, their exposure to poverty, their greater chance of having special-needs grandchildren to supervise, and their (often) problematic adult children. Not surprisingly, grandparent caregivers exhibit even higher levels of stress than parental caregivers (Musil, Youngblut, Ahn, & Curry, 2002), and their parenting stress is associated with higher levels of depressive symptoms.

In a rare comparison of upstream and downstream caregivers, William Strawbridge, Margaret Wallhagen, Sarah Shema, and George Kaplan (1997) found in a longitudinal study (a study of a sample of individuals at multiple points in time) that while all types of caregivers had greater exposure to stress and confronted more social and economic problems than noncaregivers, grandparent caregivers expressed the most distress 20 years prior to caregiving. These results affirm a life course model of caregiver stress and disadvantage. Caregiving grandparents tend to derive from stressful family, economic, and community contexts that carry over into their caregiving lives.

Despite the challenges they face, caregiving grandparents are generally effective caretakers. Compared to day care, after-school programs, babysitters, nannies, and other formal sources of help, grandparents tend to have a less casual interest with the well-being of their grandchildren. Jennifer Solomon and Jonathan Marx (1999), for instance, found that the health and school adjustment of children raised solely by grandparents was nearly equivalent to children raised by one biological parent.

Research indicates that grandmothers who have been raising a grandchild for at least 2 years were more likely than noncaregiving grandmothers to seek preventive medical treatments; ostensibly, these caregivers were motivated to stay healthy for the sake of their grandchildren (Baker & Silverstein, in press).

While most grandparent caregivers are unquestionably committed to the well-being of the grandchildren in their charge, they often have ambivalent feelings about the disruptive effect their unexpected reengagement in the parent role has on their lives. Some caregiving grandparents report disappointment in having to inhibit their leisure activities or postpone their retirement plans. One grandparent summed it up as follows: "I thought this was the time in my life where I could just go off fishing for three days . . . I can't do it now" (Burton 1992, p. 749). Another grandparent said, "I just don't go places . . . it's just easier to stay home . . . that's just the way it has to be . . . this isn't good" (Jendrek 1993, p. 617).

Similar to the literature on caregiving to older adults, caring for grandchildren can enhance feelings of self-efficacy and a sense of satisfaction that comes from filling a valued family role. Engagement in caregiving has been found to provide numerous psychological benefits to grandparents that include the emotional reward of maintaining a strong affective attachment with the grandchild in their care, a renewed sense of purpose in life, and a second chance at parenting. When asked about the stresses and rewards of raising a grandchildren, four out of five caregiving grandparents found the experience extremely rewarding, and more than one-quarter reported that it was more rewarding than it was stressful (Giarrusso, Silverstein, Feng, & Marenco, 2000).

The cultural meaning attached to skipped-generation caregiving has a bearing on whether grandparent caregivers perceive their role as normative or extraordinary. Such meanings are informative regarding grandparents' legitimate claims to intervene on behalf of their grandchildren, and their eventual success in assuming the authority of a parent. Grandparents from cultures with strong expectations to care for at-risk grandchildren adapt more successfully to their custodial role. For example, a study comparing African-American, Latina, and White grandmothers raising their grandchildren found that African-American grandmothers had the best psychological outcomes once the reason for adopting the role was controlled. Better adaptation of African-American grandmothers was explained by a tradition of extended familism and reliance on surrogate caregivers going back to slavery (Goodman & Silverstein, 2002). African-American custodial grandmothers are also more apt to know others raising grandchildren and to have themselves been raised by grandparents, further legitimating this familiar family form.

The increased prevalence of four-generation families in which middle-aged persons have responsibilities to both their older parents and their grandchildren produces opportunities for the middle-aged or penultimate older generation to engage in multiple caregiving. Some research suggests that there are significant intrafamilial strains in families with both older and younger generations in need of care (Hamill, 1994), whereas other research finds few negative outcomes associated with multiple generation caregiving (Loomis & Booth, 1995). Whether additional roles occupied by caregiving grandparents induce or relieve stress has not been conclusively determined. However, one national study found that additional work and family responsibilities did not detract from the psychological well-being of custodial grandparents. In some instances these added roles reduced levels of depression, providing evidence that engaging in outside social spheres may link grandparents to social support, tangible resources, or social capital that could prove to be beneficial (Baker & Silverstein, in press). Research shows that supportive networks have palliative effects on the emotional well-being of caregiving grandparents by buffering the deleterious effects of caregiving stress.

**Part-time Grandparent Caregiving** A more liberal definition of grandparent caregiving includes those grandparents who provide child care in a secondary, supportive capacity. Women's labor force participation has provided grandparents expanded opportunities to care for grandchildren in dual earner and single-mother households. Mary Elizabeth Hughes, Linda Waite, Tracey LaPierre, and Ye Luo (2007) found that part-time caring for grandchildren is quite common in the United States, with 40% of grandparents providing at least 50 hours of care per year for the children of working parents. In the United Kingdom one in five children under 16 years old is looked after by their grandparents during the daytime (Clarke & Cairns, 2001), and a multinational European study found that 40-60% of grandparents reported taking care of grandchildren over a 1-year period (Attias-Donfut, Ogg, & Wolff, 2005).

While part-time caretakers of grandchildren face challenges, they are qualitatively distinct from grandparents who function as surrogate parents. Custodial grandparents are at risk for negative outcomes far in excess to those who provide part-time child care during the day. The evidence is mixed concerning whether providing part-time care to grandchildren is stressful to grandparents. In a national sample, Hughes and colleagues (2007) found that part-time caregiving produced few negative effects on grandparents. The authors are careful to point out that caregiving is just one of many roles that grandparents may occupy, suggesting that it is important to examine the combination of family and these other roles

when assessing the impact of caregiving on the well-being of grandparents.

**Caregiving for a Disabled Grandchild or Child** Providing care for a developmentally or physically disabled grandchild is among the most challenging roles taken on by grandparent caregivers. A review of literature suggests that while these heavily invested grandparents are greatly valued by their families, they are often limited in their capacity to meet the demands of emotionally or physcially challenged grandchildren (Mitchell, 2007). Research by Jennifer Park, Dennis Hogan, and Maryhelen D'Ottavi (2005) reveals that although grandparents are prolific providers of care for special-needs grandchildren, they sometimes face difficulties in bonding with these grandchildren, particularly those exhibiting communication and behavioral problems.

Chronic stressors associated with long-term caregiving interact with aging to produce elevated risk of physical and mental decline among continuing late-life caregivers. Older parents caring for adult children with mental or developmental disabilities report greater health problems due to arthritis, diabetes, heart disease, and depressive symptoms than older parents who were not caregivers (Magana & Smith, 2006). Evidence also shows that older parents who care for adult children with severe mental impairment experience greater economic distress and report lower marital satisfaction compared to their noncaregiving counterparts (Essex & Hong, 2005). Controlled studies of support groups for grandparents caring for grandchildren with developmental delays or disabilities have been shown to reduce depression in these caretakers (McCallion, Janicki, & Kolomer, 2004).

## POLICIES AND PROGRAMS FOR CAREGIVERS

The Family and Medical Leave Act (FMLA), the first U.S. national policy designed to assist working caregivers, mandates the broadest public benefits for family caregivers. The FMLA allows workers in businesses consisting of 50 or more employees to take up to 12 weeks of unpaid leave to care for an ill family member or newborn child; 35 million Americans have taken leave under this law since 1993 (AARP, 2004). Some states have strengthened this coverage by mandating salary replacement rates. Publicly-funded services are also available for family caregivers. In October 2000 Congress established the National Family Caregiver Support Program (NFCSP) to provide support services for family members caring for persons with disabilities and grandparents caring for grandchildren.

According to the Adoption Assistance and Child Welfare Act of 1980, privileged grandparents are now custodians of first choice in the event that parents are not capable guardians of their children; in addition, the Personal Responsibility and Work Opportunity Reconciliation Act of 1996 has allowed public assistance (i.e., grants from the Temporary Assistance for Needy Families [TANF] program) for relative caregivers, even if the caregiver has not adopted the child. Public programs supporting grandparents raising grandchildren are mostly found at the local level. The Departments of Children and Family Services (DCFS) provides formal services such as respite care, public assistance, and legal advice to caregiving grandparents.

However, outside the DCFS foster care system, very few services are specifically targeted at the grandparent caregiver population, as many public benefits depend on whether the grandparent has legal custody of the grandchild. Grandparents who are otherwise eligible to collect public assistance based on their own income do not qualify for full payments for grandchildren if their own children are already covered as eligible dependents. In addition, grandparents raising grandchildren have reported much difficulty obtaining health insurance for their grandchildren; without legal custody, grandparents are usually not able to cover custodial grandchildren under their work-based health insurance. Given that grandparent-headed households are often overcrowded, it is encouraging that special housing specifically designed for grandparents and grandchildren are sprouting up in cities across America, even if there is far more demand than supply as of 2008 (Baker, Silverstein, & Putney, in press).

Programs supporting all types of caregivers include formal therapy sessions, peer-to-peer counseling, and formally organized support groups. Many programs are supported by state and municipal initiatives. Caregivers are taught practical coping skills and relaxation techniques to relieve their stress and are provided with practical information to direct them to appropriate services that could be useful for them. In a meta-analysis of 127 intervention studies with dementia caregivers, Pinquart and Sörensen (2006) found that the best treatments were those therapies and supports that required the most active participation of the caregiver. Informal support groups can be found in all areas of the country, including virtual communities. (Virtual communities are groups of people who interact via letters, telephone, and e-mail for various purposes, rather than face to face.)

Compared to other developed nations, public policy in the United States is not particularly generous with regard to providing relief for long-term chronic caregivers. Because most caregivers are employed, workplace policies and characteristics are arguably more directly important for enhancing the care and support of dependent family members. Several studies have found that positive workplace characteristics—including increased

flexibility in the time and place work occurs, supportive supervisors, and a family-friendly work culture—are associated with fewer work-family conflicts and better health of caregivers and their families.

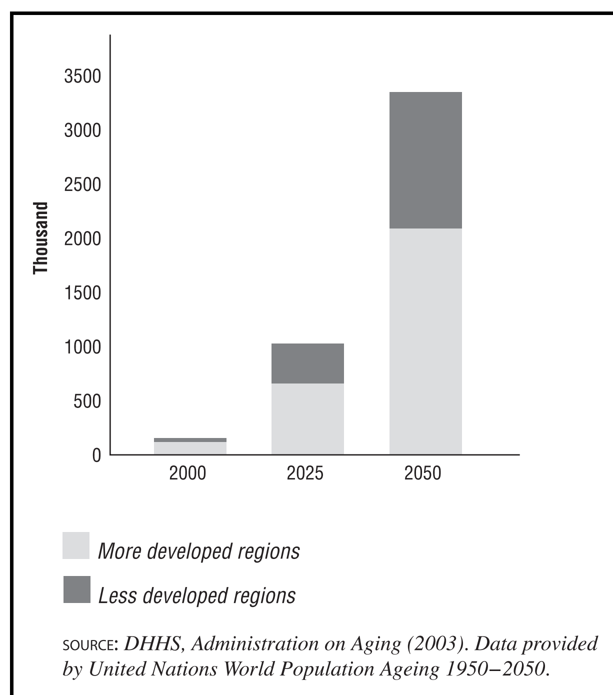
# CENTENARIANS

Centenarians, persons who have reached the age of 100 years or more, are publicly recognized and honored across cultures. Media accounts of a 120-year-old woman bicycling for exercise, a 100-year-old woman and a 101-year-old man in the United Kingdom becoming the oldest married couple in their country, and centenarian veterans of major wars are inspirational, because centenarians symbolize triumph over frailties of the human body and spirit. What are the secrets to their longevity? What can scientists learn from them about the maintenance of physical and psychosocial health? Do centenarians have helpful tips from their life experience that the rest of us could easily adopt? And, perhaps the question most wondered about, does their quality of life make their longevity fulfilling?

## PATTERNS AND TRENDS IN THE CENTENARIAN POPULATION

Approximately one person in 10,000 living in developed countries of the world attains the age of 100. Women are more likely than men to be centenarians. Among centenarians worldwide, the ratio of women to men is about 5:1. James Vaupel (2000) has estimated that half of all girls born in the developed world in the early 21st century will live to age 100.



SOURCE: *DHHS, Administration on Aging (2003). Data provided by United Nations World Population Ageing 1950–2050.*

***Figure 1.*** *Distribution of world centenarians by development region, 2000–2050.* CENGAGE LEARNING, GALE.

Persons who attain the age of 110 or older are termed *supercentenarians*. Approximately 90% of supercentenarians are women, according to L. Stephen Coles (2004). The oldest known surviving person was Jeanne Calment of France, who died in 1997 at age 122. The oldest proven age for a male, 115, is attributed to Christien Mortensen, a Danish-born American who died in 1998. The Japanese island of Tokunoshima claims to have produced the oldest man, Shigechiyo Izumi, who reportedly died in 1986 at the age of 120, but he more likely had inherited the name of an older deceased sibling and was actually 105 when he died.

In 1900 only one in 100,000 Americans was a centenarian, compared to one in 8,000 to 10,000 Americans as of 2000 (Perls & Silver, 1999). In the United States, growth in the centenarian population since 1990 and continuing to 2010 is estimated at about 4% per year. The United Nations has projected that the number of centenarians worldwide will increase about 18-fold between the years 2000 to 2050. Although about two-thirds of this increase will occur in developed countries, an increasing portion will occur in regions that are currently less developed (see Figure 1).

Although marked growth in the number of centenarians is a new phenomenon, human survival approaching 100 years is not. In the 16th century the Italian painter Titian lived to be at least age 90 and may have reached age 99. Several accounts of the life of the ancient philosopher Democritus maintain that he lived more than 100 years, perhaps reaching age 109, and other Greek philosophers are also thought to have lived beyond the age of 90. Thus, it is not the maximum life span obtainable that has changed; what has changed dramatically since 1900 is the number of people who are able to achieve their life expectancy potential.

## PROBLEMS OF AGE MISREPORTING

Several geographic areas (e.g., the Russian Caucasus area and Vilacamba, Ecuador) have claimed to have persons with extreme longevity, but the claims were subsequently found to be exaggerated. Validating the age reported by or on behalf of centenarians and supercentenarians is important in studies of the oldest old (Coles, 2004; Perls, Bochen, Freeman, Alpert, & Silver, 1999). Age exaggeration, rather than minimization, is the primary concern.

Some of the factors contributing to error in centenarian reporting include a tendency among young people to cite an older age at the time of immigration in order to qualify for work, poor record-keeping and updating of vital statistics in some locales, and loss or destruction of birth records. The only recording of birth for some persons born at home in rural areas may consist of a baptismal certificate or a birthdate entered in a family Bible, a pattern especially likely to characterize African American persons born in the southern United States.

## CROSS-NATIONAL COMPARISONS OF CENTENARIANS

As of 2008 the United States had the largest total number of centenarians—more than 55,000 (Hall, 2008)—followed by Japan, China, and England-Wales. The higher number of American centenarians in part reflects the large U.S. population in 1890–1905 compared to other countries with a large number of centenarians. Although the United States reports a larger number of centenarians than does Japan, Japan has a higher ratio of centenarians to the overall population than does the United States. Similarly, China reports a larger number of centenarians than does England-Wales, but England-Wales has a higher ratio of centenarians to the overall population than does China.

Areas characterized by geographic clustering of persons who have reached advanced ages are of particular interest, suggesting that people in those areas share environmental influences and/or genes that enable them to reach extreme ages. A concentration of octogenarian and nonagenarian men living in the Tibetan mountains herd livestock and lead physically strenuous lives. Five times as many people living on the island of Okinawa as

compared to people living in the rest of Japan live to be 100. A *centenarian belt* in North America extending from Minnesota to Nova Scotia may reflect ethnic backgrounds (e.g., Celtic, French/Acadian, and Scotch) that genetically predispose people to extreme longevity. In areas with geographic clustering of centenarians, the sex ratio becomes more equal, suggesting a shared gene pool. For example, in Sardinia, which has an increased prevalence of centenarians, the ratio of women to men centenarians is only 2:1 (MacKnight, 2007).

## UNIQUE CHARACTERISTICS OF EXCEPTIONALLY LONG-LIVED INDIVIDUALS

Centenarians may share genetic factors that facilitate achieving exceptional old age. Jeremiah A. Barondess (2008) noted that more than half of centenarians have first-degree relatives or grandparents who also reached very old ages. Supercentenarians typically have long-lived siblings (Coles, 2004). After age 80 it is likely that genetics play an increasingly important role in determining survival to an advanced age.

Morbidity profiles, which may be genetically based, suggest that centenarians can be broadly classified as *survivors*, *delayers*, and *escapers*, based on their experience with major age-associated disease states such as hypertension, cancer, and dementia. Persons categorized as survivors have an age of onset of less than 80 years for at least one of the major disease states; delayers' age of onset is between ages 80 and 100; and escapers' age of onset is 100 years or not at all (Evert, Lawler, Bogan, & Perls, 2003). Centenarians are more likely to lack variations of *disease genes* that increase the likelihood of developing particular diseases. Compared with other older persons, centenarians seem to markedly delay or escape life-threatening diseases such as cancer and Alzheimer's disease (Hitt, Young-Xu, Silver, & Perls, 1999). A variation of a gene known for its association with Alzheimer's disease becomes markedly less frequent with advancing age (Frisoni, Louhija, Geroldi, & Trabucchi, 2001) as do some genes that are prominent in cardiovascular disease. Centenarians may also have genes that lower their risk for health problems, such as genes that result in a favorable cholesterol profile. *Longevity enabling genes*, which affect rate of aging, are also hypothesized, although not yet identified. Finally, centenarians may be better able to resist the effects of bad genes, avoiding the inflammatory response that characterizes many chronic conditions.

An estimated 30% of centenarians have physical and mental impairments. The remainder function remarkably well, with about 40% having some vision, hearing, or mobility impairment only and 30% showing very few signs of physical or mental impairment. Thus, generally good health characterizes the majority of centenarians, and they have lived most of their lives in good health, experiencing a fairly rapid decline only near the end of their lives (Hitt et al., 1999). Damage to the immune system may lead to an infection that leads to death, or coronary artery disease may worsen and trigger a heart attack.

Do commonalities exist in the lifestyle of centenarians that are evidenced in health behaviors, social connectedness, and reactions to stress? It has been observed that centenarians are rarely obese and that they exercise and eat healthful foods. Substantial smoking rarely characterizes centenarians, although as many as half of centenarians report enjoying alcoholic beverages on a regular basis. Centenarians vary widely in educational and socioeconomic background, religion, and ethnicity, but most describe having close ties with friends and family. Belle Boone Beard (1991), who interviewed 600 centenarians over a 40-year research career, noted that romance should be considered among the possible so-called secrets of longevity.

Mental health characteristics that have been frequently noted among centenarians include a serene or affirmative outlook on life and the capacity to accept what cannot be changed, such as loss of a spouse. Centenarians demonstrate adaptability to age-related losses and may be individuals who are inherently capable throughout life of progressively adjusting their life styles and accepting their conditions (Dello Buono, Urciuoli, & DeLeo, 1998). Centenarians have been described as *stress-shedders*. They also demonstrate a willingness to assert themselves and their individuality (Beard, 1991). Some have been known to laughingly attribute their longevity to having told themselves that they would live to be 100.

Despite diverse social backgrounds and interests and a vast mosaic of life experiences, centenarians for the most part are individuals who have maximized the portion of their lives spent in good health and independent functioning, and they are content. Compressing the onset and duration of illnesses toward the end of life is a widely shared goal. Centenarians in many ways represent the gold standard for aging well (Perls & Silver, 1999), and there is understandably great interest in identifying the genetic and environmental factors that facilitate the model of aging that centenarians provide.

The discovery of genetic variations associated with survival to extreme old age is a promising route toward understanding cellular and biochemical mechanisms of the aging process and susceptibility to age-related diseases. Studies of centenarian populations in North America, Asia, and Europe increasingly point to clusters of clinical characteristics associated with exceptional

longevity that in turn generate genetic investigation. Researchers are also focusing on the significance of non-genetic determinants of long life that are modifiable, including smoking, obesity, and sedentary life style. Registries such as the New England Centenarian Study and the George Centenarian Study facilitate investigation of adaptive mechanisms and functional reserves evident among centenarian survivors. Collectively, centenarian studies not only stimulate the search for new knowledge of the human genome but also have broad potential to improve understanding of how to minimize disability and maximize quality of life in the context of aging.

## CHILDLESSNESS

**SEE** Volume 2: *Childlessness.*

## CHRONIC ILLNESS, ADULTHOOD AND LATER LIFE

A chronic illness is any health condition that results in sickness or activity limitations that last longer than 3 months. In contrast to acute illnesses, chronic conditions often do not have a distinct onset or a single underlying cause. These conditions can have a global impact on a person's life, with social, psychological, and economic consequences. According to the National Center for Health Statistics (2008), the most common chronic illnesses among older adults in the early 21st century are arthritis, diabetes, cancer, heart disease, and respiratory diseases. Chronic illness claims nearly 7 of 10 lives and account, for more than 75% of annual health care costs in the United States.

### DEFINITION

Chronic illness is a broad category that covers a class of diseases with many different causes and patterns of progression. However, these chronic conditions have two commonalities: They are typically not curable, and they are often degenerative, leading to greater limitations in mental and physical function over time. Thus, the goals of medical care typically are to maintain current levels of function; manage the symptoms of the chronic condition, such as pain; and prevent secondary complications (e.g., pneumonia in persons with chronic obstructive pulmonary disease).

### INCIDENCE AND PREVALENCE

The extension of the human life span in developed nations during the 20th century led to a dramatic shift, and chronic illnesses have become the leading causes of death. Medical advances as well as improvements in living conditions (e.g., sanitation) and nutrition have nearly eradicated infectious diseases as primary causes of death at all ages. More persons survive to adulthood and even into the

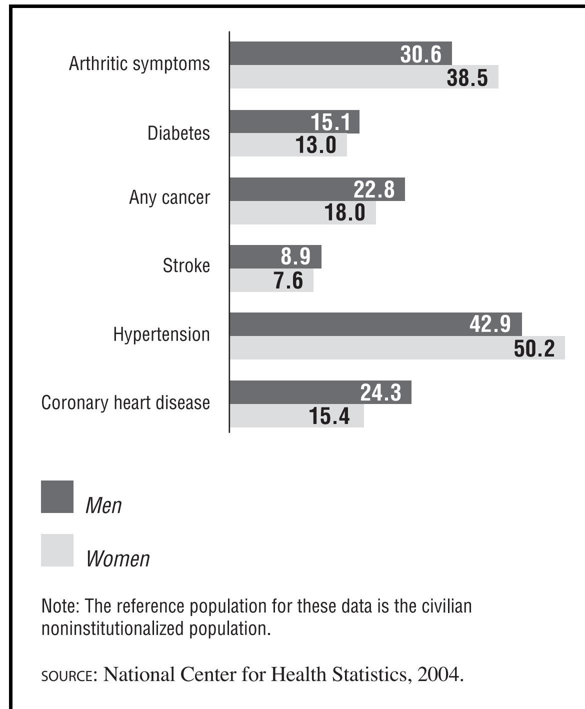

***Figure 1.*** *Prevalence of selected chronic conditions in people aged 65 and over by sex (by percent), 1999–2000.* CENGAGE LEARNING, GALE.

oldest ages than at any other point in history. Five of the six most common causes of death in the United States are chronic illnesses. In 2005 diseases of the heart (27%), cancer (23%), cerebrovascular conditions (6%), respiratory diseases (5%), and diabetes (3%) accounted for 64% of deaths among adults of all ages in the United States.

Considering the population as a whole, nearly 45% of Americans have at least one chronic illness, but there are distinctive patterns of prevalence across age groups. Because the risk of developing most of these conditions accumulates over time, there is a higher concentration of chronic conditions among older adults. 84% of adults age 65 or older report having one or more chronic illnesses. Among people ages 20 to 44, 38% report having at least one chronic condition. Mortality risk from chronic illness peaks from ages 65 to 74, accounting for more than 77% of all deaths in this age group. Although the incidence of chronic illness declines with age, the higher prevalence of these conditions among people of the oldest ages leads to a greater probability of comorbidity and functional limitations. Older Americans are also likely to have chronic conditions that are more disabling, such as arthritis and heart disease. At younger ages, the most prevalent chronic conditions are hypertension and respiratory diseases (asthma and chronic bronchitis).

## CHRONIC ILLNESS OVER THE LIFE COURSE

Even though chronic illness tends to be concentrated among older adults and has a greater influence on functional health in people of advanced age, it is critical to examine chronic illness from a life course perspective. Risk of developing chronic conditions accumulates over a lifetime, influenced by life style factors such as excess body weight, lack of physical activity, poor diet, and tobacco use. These modifiable factors can yield greater gains in long-term health when improved at younger ages. If behavioral interventions and screening are targeted only at older adults, it is likely that there will be only modest gains in the prevention and delay of onset of chronic illnesses.

Over the past decades medical screening procedures have become more specific and sensitive, making it possible to detect chronic diseases at the earliest stages. Early detection can allow early intervention and, for some conditions, treatment. This can have substantial health benefits for individuals, including less disability, a decreased likelihood of secondary complications, and perhaps a slower onset of a condition. Early detection also has increased survivorship, particularly for conditions such as cancer.

Even though a higher proportion of older adults have a chronic illness, the absolute number of persons with chronic conditions is greater among working-age adults. In 2000, 29 million Americans age 65 years and older had one or more chronic conditions, compared to more than 75 million who were age 20 to 64 years. These younger adults are aging with chronic illnesses, which may have significant impact on their social, economic, and mental well-being. Managing a chronic illness can be difficult for working-age adults because many are still employed, raising families, and even perhaps caring for elderly relatives. This directly influences worker productivity, decisions to exit the labor force, ability to fulfill social and familial roles, and long-term functional health. Examining the chronic illness experience from a life course perspective will help researchers and policy makers understand the social, economic, and medical consequences of these conditions not just at advanced ages but over the entire lifetime.

## RISK FACTORS

Although each chronic disease has its own etiology and constellation of risk factors, certain key health behaviors have been linked to nearly every chronic disease: tobacco use, diet, and exercise. According to the Centers for Disease Control, nearly 20% of all premature deaths are due to tobacco use. About 14% of those deaths are caused by a poor diet and lack of exercise. Many of these

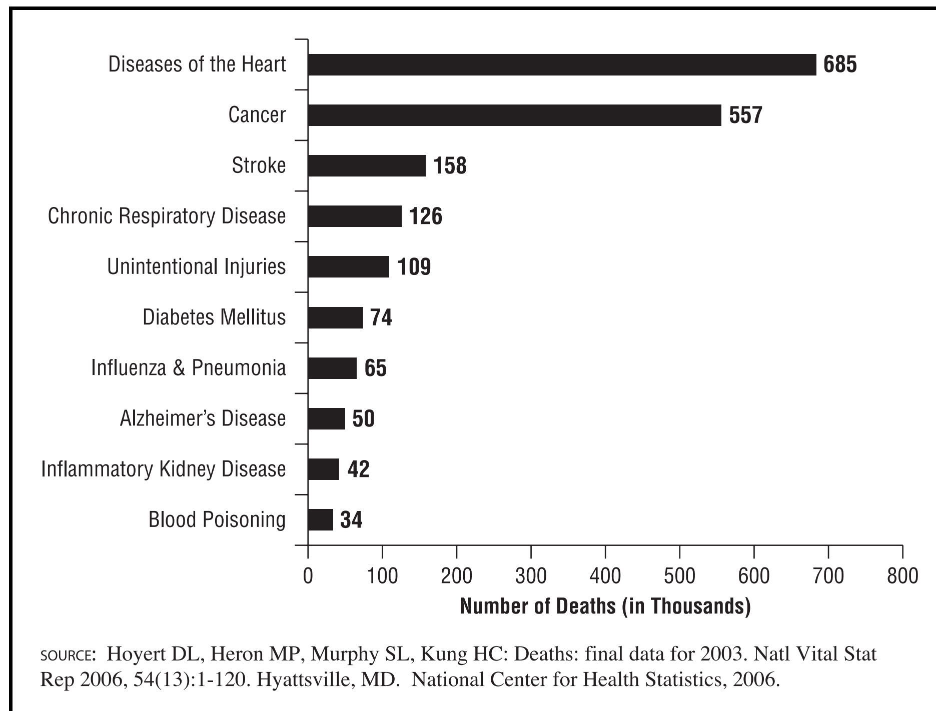

***Figure 2.*** *Leading causes of death in the United States, 2003.* CENGAGE LEARNING, GALE.

risk factors tend to cluster together, so that those who smoke also are more likely to be overweight and have a sedentary life style. Further, these behavioral risk factors can interact with environmental exposures and genetic predispositions to affect the likelihood of developing a chronic condition, the rate of onset, and disease progression over time. The additive and perhaps multiplicative effects of these combined risk factors on the development of chronic illnesses have not been explored sufficiently.

In the last decade of the 20th century and the first decade of the 21st, there were dramatic shifts in mortality risk for specific chronic illnesses among adults age 65 and older. Mortality from diabetes and its complications increased 43% among adults in those two decades. Deaths from chronic lower respiratory diseases increased 62% in the same period (from 185.8 to 300.7 per 100,000 deaths). Largely as a result of advances in lifesaving medical treatments, mortality from diseases of the heart and stroke decreased about 35% in those two decades. Deaths from cancer did not change significantly over that period. Heart diseases remain the primary cause of death for older adults.

Disease etiology and long-term consequences for health and functioning vary substantially with the type of chronic condition. For example, more than 60% of adults age 65 and older have one or more types of arthritis. It is the most prevalent chronic illness and the leading cause of disability in older adults. Although arthritis can be disabling, mortality risk is low. Congestive heart failure, in contrast, affects only 6 to 10% of adults age 65 or older, but the mortality risk is very high. About 40% of those with congestive heart failure die within the first year. This occurs because congestive heart failure is a secondary condition caused by complications from other chronic illnesses, most commonly coronary artery disease, hypertension, and/or diabetes. Type 2 (adult-onset) diabetes accounts for about 90% of diabetes prevalence and generally develops in adults over age 40 as a result of accumulated risk associated with chronic obesity and lack of physical activity. The prevalence rate of diabetes increased rapidly in the last decade of the 20th century and the first decade of the 21st, largely because of growing rates of obesity and sedentary life styles among Americans.

## IMPACT AND CONSEQUENCES

The long-term impact of chronic illness is influenced directly by the nature of the disease, the timing of onset, the rate of progression, and effective management of symptoms. Some conditions can lead to a rapid functional decline, whereas others may take years before impairing one's ability to perform activities. Similarly, some chronic illnesses may affect only a few domains, but others may have a more global impact. Nearly 81.8

million Americans have at least one chronic condition but do not report limitation in any life domains. About 43.2 million Americans have a disability as a result of a chronic condition.

The use of health services is substantially higher among adults with chronic illnesses. Chronic medical care accounts for 72% of physician visits, 76% of hospital admissions, 80% of total hospital days, 88% of prescriptions, and 96% of home care visits. Adults with one or more chronic conditions see a physician on average 7.4 times per year, whereas those without chronic conditions have an average of 1.7 physician visits annually. The use of health services increases substantially with each additional chronic condition.

The social consequences of chronic illness can be as life limiting as mental and physical impairment. Symptoms of the chronic illness, particularly pain, fatigue, and mobility limitations, can hinder participation in social activities. Driving cessation is associated with a rapid decrease in social activities, although this decrease is mediated by marital status and the proximity of grown children. The loss of social roles can accumulate over time as a chronic condition progresses, leading to social isolation, depression, and loneliness.

## MANAGEMENT

Because chronic illnesses are long term and can be degenerative or functionally limiting, individuals must engage in active management of their conditions. Effective disease management can include medications or medical treatments, the use of assistive devices, and healthy behaviors such as exercise. The concept of disease management is associated solely with chronic illness. Unlike the goal of acute medical care, which is to heal or cure the patient, chronic medical care focuses on helping the patient manage the symptoms, maintain independence, and prevent secondary complications. It is a long-term investment to prevent further functional decline and requires a partnership between the patient and the physician (often multiple physicians) as well as permanent life style changes.

Adults with a chronic illness play a crucial role in managing their conditions. They must monitor their symptoms, disease progression, the effectiveness of medication, and the onset of secondary complications. Patient reports of changes or stability in their conditions help the medical team determine the course of treatment. Adults with a chronic illness therefore must be critical consumers of medical care and advocate for treatment or screening that will help maintain their long-term health. Barriers to getting necessary care include the prohibitive cost of care and a lack of assistance in coordinating needed services.

## DEMOGRAPHIC FACTORS

Chronic illness prevalence and the associated risk factors tend to be concentrated among certain demographic groups. Effective interventions to prevent and/or delay chronic illness must address the distinctive risk profiles across gender, race, and ethnic groups and levels of socioeconomic status. Overall, chronic conditions disproportionately affect the poor and racial and ethnic minorities primarily because of a lack of access to preventive health care services and a higher likelihood of having risk factors associated with chronic illness.

For example, non-Hispanic Blacks and Hispanic Americans have the highest proportion of sedentary life styles; 30.3 and 33.3%, respectively, were found not to have participated in any physical activity in the previous month. Among all racial and ethnic groups, Black Americans have the lowest percentage of adults with a body mass index in the normal range (27.7%). There are socioeconomic differences in risk factors as well. Thirty-two percent of persons earning less than $15,000 per year currently smoke, more than double the percentage (14.7%) among those earning more than $50,000 per year. Nearly 40% of adults age 18 to 64 who earn less than $15,000 per year are uninsured, limiting their access to preventive medical care and early disease screening at a time in the life course when intervention can be the most effective.

The number and type of chronic illnesses in the population also have distinctive patterns. Among males, heart disease is one of the five most common chronic conditions in those age 45 years and older; among females it is in the top five only at the oldest ages (75 and older). However, women are substantially more likely than men to have arthritis and report more days in pain. Those with higher incomes are less likely to have multiple chronic conditions than are those with lower incomes. Specific conditions are likely to be concentrated in lower socioeconomic groups as well. Asthma rates are nearly double (13.7) for those earning less than $15,000 per year relative to those earning more than $50,000 per year (7.1). The rate of diabetes is nearly triple among those who have less than a high school education (14.2) compared with those who have a college degree or higher (5.4).

The prevention and treatment of chronic illness require a life course perspective of health and healthy behaviors. Early intervention and screening, particularly among high-risk groups, would reduce both the incidence and the prevalence of chronic illness substantially as well as improve functional outcomes. Although many people live with chronic illness for decades, delaying onset, slowing progression, and preventing secondary conditions would extend life and improve the quality of life at all ages.

# CIVIC ENGAGEMENT, LATER LIFE

**SEE** Volume 3: *Political Behavior and Orientations, Later Life; Time Use, Later Life; Volunteering, Later Life.*

# COGNITIVE FUNCTIONING AND DECLINE

Cognitive skills and abilities, such as reasoning, memory, and problem solving, form the foundation for everyday functioning throughout the life span. Cognitive skills are needed to perform activities of daily living, including tasks such as taking medication, procuring meals, and managing finances. Cognitive ability takes on added importance during later life as selective, typical age-related changes occur. In older adulthood, cognitive abilities are essential to additional important health outcomes, including service utilization, mental health, and mortality. Contrary to aging stereotypes, when considering cognitive functioning in adulthood and later life it is important to keep in mind that (a) as a group, older adults' range of functioning and performance tends to be more heterogeneous than that of younger adults; (b) cognitive changes such as dementia are considered "nonnormative" or atypical and do not constitute the majority of cases; and (c) cognitive prevention, enhancement, and intervention efforts are beneficial. Consistent with sociological and psychological perspectives, individual differences as well as ethnicity, socioeconomic status, gender, cohort, and culture are key to understanding cognitive functioning during adulthood and aging.

## PATTERNS OF COGNITIVE FUNCTIONING ACROSS ADULTHOOD AND LATER LIFE

Investigation and assessment of cognitive functioning in adulthood and later life has typically followed three approaches: (a) a psychometric approach aimed at understanding fundamental cognitive abilities and normative aging; (b) examination of higher order skills needed to function within an individual's day-to-day context; and (c) a clinical or neuropsychological approach, which focuses on mechanisms and outcomes of nonnormative cognitive aging such as occurrence of dementia. From the psychometric perspective, normative age-related changes in cognition are well documented, demonstrating that selected abilities decline with age. Consistent trajectories over time of individual cognitive abilities have been described across samples and cohorts. This body of work also indicates that differential change is evident across various types of cognitive abilities and that abilities need to be considered separately (Christensen, 2001).

Cognitive research typically differentiates two broad classes of cognitive abilities, each composed of several individual skills, and this distinction remains important through very late life. Cognitive abilities that rely on accumulated knowledge and experience, and are highly dependent on an individual's culture, have been described as *crystallized intelligence* (Schaie, 2005). A prime example of such ability is verbal comprehension. In contrast, intellectual skills that are considered more "innate" and biologically driven have been labeled *fluid abilities* (Schaie, 2005). Often fluid abilities focus on the ability to deal with novel situations. One such ability is working memory, in which mental information is manipulated before a response is formulated or information is committed to long-term memory (e.g., backward recital of a presented digit span). Inductive reasoning is another example of a fluid ability, in which individual stimuli are used to decipher a larger pattern (e.g., deciding which letter comes next in a presented series of letters). Crystallized abilities tend to remain stable well into later life, whereas fluid abilities peak in young adulthood (Schaie,

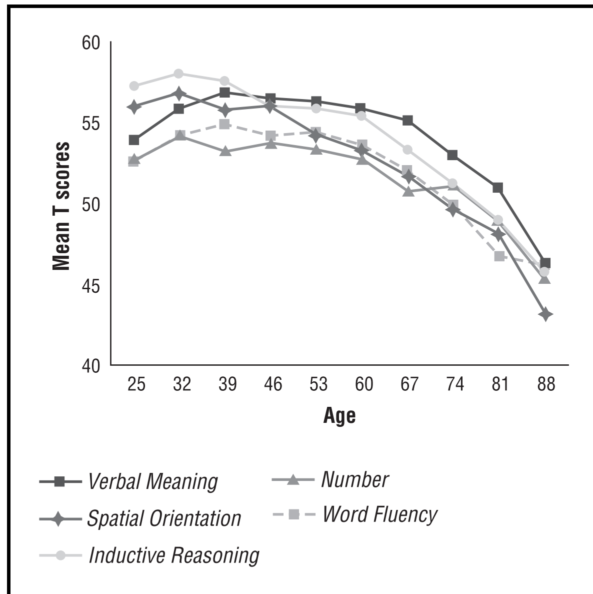

***Figure 1.*** *Estimated age changes from 35-year data for the primary mental abilities.* CENGAGE LEARNING, GALE.

2005). Decreased processing speed (Salthouse, 2000), memory (Christensen, 2001), and attentiveness and inhibition of distracting stimuli/information (e.g., Zacks & Hasher, 1994) in later adulthood have also been observed.

In addition to documenting normative age-related declines, empirical studies have identified two additional developmental phenomena related to cognitive aging. First is the tendency for older adults to demonstrate accelerated cognitive decline close to death. Prior to natural death, some older adults exhibit terminal change (within 3 to 5 years of death) and a drop (within 1 year of death) in their cognitive performance (Bosworth & Siegler, 2002). Second, the very nature and structure of cognitive abilities appears to change throughout older adulthood. Findings suggest that individual cognitive abilities such as memory and verbal knowledge become less differentiated and more similar with increasing age (e.g., deFrias, Lövdén, Lindenberger, & Nilsson, 2007).

Another line of research within the cognitive aging field examines the everyday cognitive and problem-solving skills needed to traverse daily life. In contrast to more narrowly defined individual cognitive skills, problem-solving ability is considered a higher order cognitive skill that depends on the constituent intellectual abilities (Marsiske & Willis, 1995). Within the psychometric approach, there is a reliance on paper-and-pencil measures that are akin to academic tests. However, assessments of problem-solving ability are more contextual and tend to incorporate actual real-life stimuli (e.g., prescription label, transportation schedule). In addition, these assessments are more likely to be experiential and extend beyond paper-and-pencil assessment. For example, participants might be asked to look up a phone number in a telephone book or count out exact change from a lunch bill (e.g., Diehl, Willis, & Schaie, 1995).

Within the cognitive aging literature, everyday problem-solving research has gained momentum as proponents point to the "value added" by using such an approach (see Marsiske & Margrett, 2006). A central issue remains regarding everyday problem solving, namely its relation to everyday functioning and, in part, the difficulty identifying an appropriate standard consistent with actual daily demands by which success can be determined (Marsiske & Margrett, 2006). However, by focusing on what older adults actually do in their day-to-day lives, the primary benefit of examining everyday problem solving is increased ecological validity or relevance, meaning outside of an artificial testing situation. Using this approach, researchers can better approximate how older adults perform in their own real-life settings. These efforts may lead to increased efficiency of assessment using a more concise battery as well as increased participation by older adults and greater self-efficacy when performing the tasks (Marsiske & Margrett, 2006). Additional empirical and theoretical work is needed to explore the nature of everyday problem-solving skills in very late life.

A third approach to understanding cognitive aging stems from a more clinical and neuropsychological perspective aimed at understanding the mechanisms underlying nonnormative cognitive changes such as the occurrence of dementia. From this perspective, global indicators of cognitive functioning and neuropsychological measures are typically employed. For example, a widely used assessment to gauge general cognitive status and distinguish individuals with dementia from those without is the Mini-Mental Status Exam (Folstein, Folstein, & McHugh, 1975). This assessment comprises 11 items that assess orientation to time and place, comprehension and recall of familiar objects, attention and calculation, and language. The maximum score on the Mini-Mental Status Exam is 30, and typically a score of 23 or lower is considered an indication of impairment.

## MEMORY OVERVIEW

Although working memory is often considered an element of fluid abilities, investigation of memory has garnered added attention as this cognitive ability provides a coordinating foundation for higher order cognitive operations with numerous implications for daily functioning. Notably, memory deficiency is linked to mild cognitive impairment and dementia.

Various models have been proposed to describe memory processes. One of the most pervasive models has been the information processing or modal model, which likens memory processes to computer-system processing with input and output. This model focuses on three types of memory: sensory, short-term, and long-term memory (Baddeley, 2007). These three memory constituents vary in capacity and duration. Sensory memory involves very brief retention of sensory input that is either selectively encoded or forgotten. Short-term or working memory involves discrete (limited) tasks such as remembering a telephone number while finding the telephone and waiting to dial. Long-term memory involves more detailed information stored for indefinite periods.

In the process of remembering, people are assumed to engage in three steps. The first step is encoding, in which meaning is ascribed to incoming information. Second, information may then be moved into storage. Third, information may be retrieved via two methods, recognition or recall. Recognition is the easier of the two methods and is conceptually similar to a multiple-choice test. The respondent is presented with several options and asked to identify (remember) which element is the correct answer.

In contrast, recall of information is comparable to an open-ended essay item in which possible responses are not presented. The task is more difficult because respondents must generate (remember) the correct answer. Information may be lost at any stage. For example, the vast majority of received sensory information is not encoded and therefore is not moved into short-term memory. The multicomponent model extends the modal model, particularly in regard to short-term memory and inclusion of an episodic buffer (Baddeley, 2007). In this model, short-term memory is considered very much to be "working," active memory and is distinguished by an attentional (executive) control system with two secondary storage systems that rely on acoustic (auditory) and visuospatial (visual, graphic) representations and processes (Baddeley, 2007). As is discussed later, a link between sensory functioning and processing and cognition is prevalent across differing theories and studies.

As outlined by Bäckman, Small, and Wahlin (2001), long-term memory can be generally classified as episodic (i.e., specific and personal to an individual; memory for events) or nonepisodic (i.e., information related to more general learning and skill building). Age-related differences are evident in storage and retrieval processes across memory type. Generally for nonepisodic memory, younger and older adults' performance is similar; however, differences favoring younger adults may become more pronounced depending on the nature and complexity of the task (Bäckman et al., 2001). In contrast, older adults consistently fare more poorly compared to younger adults on episodic memory tasks, likely reflecting decreased encoding and retrieval abilities by older adults (Bäckman et al., 2001).

## CAUSES AND CORRELATES OF COGNITIVE FUNCTIONING AND DECLINE

The mechanisms underlying both normative or typical cognitive changes, as well as nonnormative (atypical) changes, are debated, and in many ways this work remains in its infancy. Ongoing theoretical and empirical work focuses on factors influencing cognitive functioning and decline, including both individual or micro-level influences (e.g., individual biological factors and sensory functioning) and larger, more macro-level influences occurring within the community or society (e.g., educational system differences between generations). Chronological age alone holds limited predictive value; thus age is usually considered a proxy for other events occurring within and external to the individual. Several theories offer hypotheses related to cognitive change and decline. Neurobiological hypotheses center on cerebral aging, including shrinking of the cortex, impaired neurotransmitter functioning, and development of protein plaques and tangles. Process-oriented explanations focus on individual basic abilities as the foundation for higher order cognitive functioning. From this perspective, older adults' decreased processing speed, attention, and ability to switch tasks and multitask are cited as roots of cognitive decline.

Proponents of a central mechanism theory note that cognitive decline coincides with other declines, including sensory functioning, suggesting a more systemic problem. Related to the latter point is a serious challenge to the investigation of causes and correlates of cognitive functioning. This challenge is the theoretical and practical relationship between cognitive and sensory functioning. Prior work suggests that sensory functioning (particularly hearing and vision) may explain substantial age-related variation in cognitive performance (Li & Lindenberger, 2002). In part these relations could be due to the effect of sensory limitations on cognitive engagement in older adults' daily life, understanding of stimuli in the testing situation, and/or representation of a common mechanism underlying systemic age-related decline.

In a review of studies examining factors related to cognitive change, Christensen (2001) distinguished individual *marker variables* (i.e., fixed characteristics, including early education and genetics) from *risk factors*, which are more dynamic and malleable (e.g., health). Lower education, presence of the APOE ϵ4 allele (a genetic marker linked to Alzheimer's disease), and poorer objective health indicators have been related to negative

cognitive change, although Christensen noted that the relationship may be specific to one or more cognitive abilities. Other individual-level factors have been linked to cognitive performance and change, and these factors vary in duration and malleability. Such factors include nutrition, physical activity, lack of sleep and fatigue, mental health, including depressive symptoms, and prescription and substance use (e.g., Budson & Price, 2005; Poon & Harrington 2006; Starr et al., 2004). Additionally, contextual influences such as the role of significant others, individual and societal attitudes toward aging, changes in emotional regulation, and degree of social and cognitive engagement are important to the development and maintenance of cognitive abilities throughout the life span (e.g., Carstensen, Mikels, & Mather, 2006; Gruber-Baldini, Schaie, & Willis, 1995; Hess, 2006).

In addition to individual, micro-level occurrences, more macro-level factors are also influential in shaping cognition. For instance, differences attributed to cohort or group membership such as generation (e.g., Baby Boomers vs. Generation X), ethnicity, gender, and socioeconomic status impact experiences and access throughout life, which in turn can affect cognitive performance (e.g., Black & Rush, 2002; Orsini et al., 1986; Sloan & Wang, 2005; Willis & Schaie, 1988). In addition to group or cohort affiliation, cognitive ability may also be impacted by historical period. A prime example of cohort and time influence is the generational and period effects related to educational practices and attainment (Schaie, 2005). For instance, Flynn (1987) demonstrated that successive cohorts born in the first half of the 20th century generally evinced superior performance on intelligence (IQ) tests—a phenomenon accounting for several IQ points per generation and one not isolated to the United States. The mechanisms (e.g., nature of intelligence assessment, educational attainment) underlying the observed increase in IQ test performance have been debated as well as how mean-level IQ may or may not correspond with an increase in IQ score variance (Rowe & Rodgers, 2002).

## CONSEQUENCES OF COGNITIVE FUNCTIONING AND DECLINE

Retention of cognitive abilities is linked to critical outcomes in later life, including quality of life and survivorship. Although it is sometimes difficult to distinguish antecedent from consequence, studies and clinical evidence indicate that impaired cognition affects not only cognitive performance but also emotional state, behavior, and day-to-day functioning, including the ability to perform basic and more complex, instrumental activities of daily living (Black & Rush, 2002; Dodge, Du, Saxton, & Ganguli, 2006). The increased heterogeneity observed in older adults' functioning and the increasing prevalence of dementia in very late life provide both challenges as well as the means by which to study successful aging and resiliency in later life.

In contrast to the normative age-related changes described above, dementia and mild cognitive impairment (MCI) are nonnormative and represent significant clinical problems. MCI is usually memory related and a suspected early indicator of dementia (Jorm et al., 2004; Peterson et al., 2001). An individual with MCI experiences subjective memory complaints accompanied by observed impairment; however, activities of daily living are not impaired and the individual is not demented (Peterson et al., 2001). MCI to dementia conversion rates range from 6 to 25% depending on assessment method and study duration (Peterson et al., 2001).

Alzheimer's disease accounts for 50 to 70% of dementia cases, and the characteristic symptom is memory loss for recent events (Alzheimer's Association, 2007). Dementia is linked with an increasing inability to perform activities of daily living. Dementia prevalence rates vary with age. Estimates of the prevalence of early-onset Alzheimer's disease and dementia are 200,000 among persons younger than 65 (Alzheimer's Association, 2007). In contrast, the Alzheimer's Association estimates that 1 in 8 individuals in the United States over the age of 65 have dementia or Alzheimer's disease; this rate dramatically increases among adults 85 and older to 1 in 2 persons. Increased risk associated with greater age raises the question as to the "eventuality" of dementia and the need to delineate risk factors associated with early and late disease contraction or expression. Further research is needed to make clear the transition from normal age-related cognitive changes to cognitive impairment and/or dementia.

A growing area of inquiry within cognitive aging research focuses on cognitive prevention and intervention. To date, intervention approaches have employed a variety of techniques, focusing on specific cognitive abilities (e.g., memory, reasoning), general cognitive processes (e.g., automatic processes), the role of emotions and motivation, as well as incorporation of social partners and everyday life stimuli and activities (Ball et al., 2002; Margrett & Willis, 2006; Park, Gutchess, Meade, & Stine-Morrow, 2007; Rebok, Carlson, & Langbaum, 2007). These interventions hold much promise in the effort to enhance and maintain cognitive acuity throughout adulthood and later life. Providers working both with middle-aged and older adults should be better educated regarding the impact of cognition on adults' day-to-day functioning as well as factors that lead to diminished cognitive abilities. Frequent screening beginning in midlife is essential to ensure early detection of cognitive

impairment and to maximize treatment. From a policy perspective, funds and regulations are needed to support screening, prevention, and intervention efforts.

# COHORT

Perhaps the most fundamental premise of the life course perspective is that individuals are both producers and products of a complex historical and socioeconomic context through which their life experiences are shaped and understood. The concept of *cohort* is essential to this perspective in that it provides a mechanism for identifying and interpreting the potentially distinct collective characteristics of individuals who share a common year of birth. These distinct characteristics are commonly referred to as ‘‘cohort effects,’’ and their empirical identification is a subject of considerable interest.

## DEFINITION AND USAGE

In the most general sense, *cohort* refers to a group of individuals that experiences an event during a common interval of time. For instance, students matriculating at a college in the same year are often referred to as the ‘‘entering cohort.’’ In medicine and epidemiology, the term ‘‘cohort study’’ is used to refer to a study design in which subjects exposed to a treatment or having a particular condition are followed over time and compared to another group not exposed to the condition or treatment. In this example, the cohort is the group of people enrolled in the study at its inception and is defined by the exposure status.

In life course and human development research, the common time interval defining the cohort is often one calendar year, and the shared event is birth. Thus, a birth cohort (often shortened to just ‘‘cohort’’) is the group of people sharing a common year of birth. This is a rather specialized use of the term, and if the subject matter was automobiles or wine rather than people, the analogous term used would be ‘‘vintage.’’ In the former cases, the defining event is production, while in the latter, it is birth. Similar to the way in which knowledge of a wine’s year of production conveys some information about its characteristics, cohort membership is thought to index the unique historical period in which a group’s common experiences are embedded.

Members of a birth cohort have the distinction of potentially experiencing a shared history inasmuch as they are the same age at any given point in time and thus share a common set of political, social, and cultural events at approximately the same point in the life cycle. This confounding of age and birth cohort at any given point in time sometimes leads those unfamiliar with the concepts to refer to an ‘‘age cohort.’’ No expression could be more grating to the life course scholar’s ear, and the term *age cohort* should always be avoided, for it confuses the source of the group’s distinctiveness (i.e., does a particular group characteristic reflect the members’ age or birth cohort?) and denies the significance of historical time in shaping life experiences. For example, in many

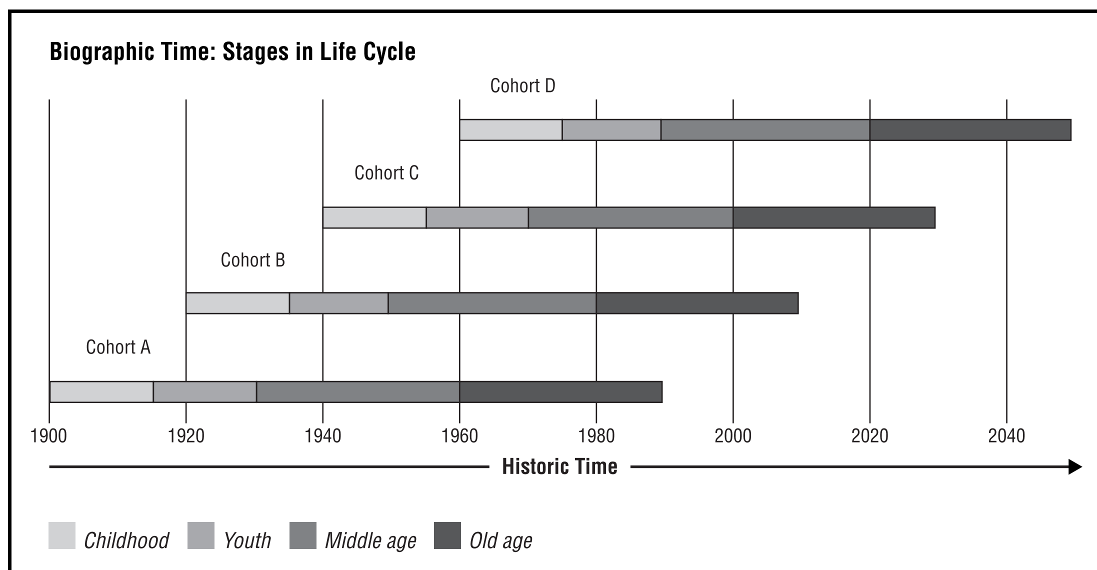

***Figure 1.*** *Interjection of biographic and historic time.* CENGAGE LEARNING, GALE.

areas of interest in the social sciences, 18-year-olds born in 1950 and observed in 1968 are likely much different than 18-year-olds born in 1990 and observed in 2008.

## HISTORICAL DEVELOPMENT: COHORTS AND COHORT EFFECTS

The work of Karl Mannheim (1952) can be credited with bringing the concept of cohort into modern social science and for developing the related idea of *generation* as well as Alwin and McCammon, 2003 for a discussion of the relationship between these concepts). In his work, Mannheim emphasized the role of events experienced early in life in shaping an individual's worldview, stating that "Even if the rest of one's life consisted of one long process of negation and destruction of the natural world view acquired in youth, the determining influence of these early impressions would still be predominant" (1952, p. 298). This idea is central to understanding cohort effects, which are the formative influences of life experiences shared by individuals having the same year of birth.

In his classic 1965 work, Norman Ryder elaborated the role of cohort in shaping social change, emphasizing the demographic procession of cohorts through the life course as a distinct mechanism for social change. Changes in the composition of the population brought on by the succession of early born cohorts by later ones, known as "cohort replacement," is a source of change in society when there are inter-cohort differences in the phenomenon of interest that endure over time. For example, much of the change in racial attitudes in the United States in the late 20th century is attributable to the dying out of earlier-born, more prejudiced cohorts, and their replacement by later-born, less prejudiced ones (Firebaugh & Davis, 1988). Ultimately, the stability of these cohort differences relies on the persistence of individuals' formative characteristics throughout their life spans—a phenomenon known as the *stability of individual differences*. Following from Mannheim, Ryder argues that cohort's place in the study of social change is based on the ideas that "transformations of the social world modify people of different ages in different ways," and that "the effects of these transformations are persistent" (p. 861).

As the works of Mannheim and Ryder reveal, the established view on the origin of cohort effects is that individuals go through a period of impressionable years during youth and young adulthood, and that experiences during these periods shape a variety of socio-individual characteristics: attitudes, beliefs, behaviors, and political orientations, among others. These youthful experiences then become the lens through which the remainder of their lives is experienced and interpreted. While the consequences of the formative experience(s) may differ throughout the life course, the basic idea of cohort effects remains the same, namely that the composition of the population is shaped by persistent birth cohort differences in the experience or interpretation of historical events.

### COHORT VS. GENERATION

Because of its multiple meanings, the term *generation* is frequently a source of confusion. While *generation* may legitimately be used as a kinship term referring to the lineage of individuals in a family, this usage is unrelated to *generations* as a cohort-based phenomenon. A generation is a group of birth cohorts, sometimes overlapping and indistinct with respect to temporal boundaries, that shares a distinctive culture and/or a self-conscious identity by virtue of having experienced the same historical events in the same way at roughly the same time in their lives. Obviously then, there is a common historical referent for cohorts and generations, but unlike *cohort,* a generation "involves more than mere co-presence" in historical and social events (Mannheim, 1952, p. 303). From a more contemporary sociological perspective, a generation is a "joint interpretive construction which insists upon and builds among tangible cohorts in defining a style recognized from outside and from within" (White, 1992, p. 31). As these theorists suggest, a sense of shared identity by its members and recognition of this identity by those outside the group are the essential components of a generation.

## CONTEMPORARY EXAMPLES

The social science literature is replete with examples of cohort effects. As discussed above, these effects commonly arise when a distinctive formative experience which members of a birth cohort (or set of birth cohorts) share shapes their perspectives throughout their lives. Major historical events such as war, economic turmoil, political protest, social upheaval, and technological transformation are frequently identified as sources of cohort effects. For example, people who grew up during the Great Depression of the 1930s have different ideas about money and economic institutions than those who grew up in more prosperous times (Elder, 1974). Other times, cohort differences are of a subtler nature and more diffuse in their origins. For example, it has been

***Greatest Generation.*** *Lines of unemployed people line up in sub-zero weather at a city relief kitchen set up in New York City on January 30, 1934 during the Great Depression. The generation that lived through the Great Depression is often referred to as the Greatest Generation.* AP IMAGES.

suggested that there was a decline in civic involvement in the late 20th century, and that this decline was, in part, attributable to the replacement of earlier-born cohorts of patriotic joiners with later-born and more cynically minded post–World War II cohorts (Putnam, 2000).

Variation in educational experiences and in the quantity and content of formal schooling contributes to cohort differences in a wide range of domains. Knowledge obtained during youth becomes a resource for future intellectual development, and shapes future social and economic opportunities. Given this, it is not surprising that cohort differences in cognitive performance are well documented. Perhaps the best-known example of a systematic cohort effect on cognitive test scores is the so-called "Flynn effect," which is the rise of average IQ test scores over time (Flynn, 1984). While Flynn concludes that a variety of environmental factors contribute to this rise, increases in educational attainment is seen as a substantial contributor. In the area of cognitive aging, significant cohort effects have also been identified. These effects are quite pronounced, and cohort differences may explain a substantial portion of what otherwise might be identified as age-related decline in vocabulary knowledge (Alwin & McCammon, 2001). Similarly, Schaie, Willis, and Pennak, examining longitudinal data (data collected from the same individuals at more than one point in time) from a broad array of cognitive domains, find cohort differences in both absolute levels and rates of change in cognitive performance and that these "cohort differences in intellectual abilities are shaped largely by changes in educational attainment . . . " (p. 64).

While educational, economic, and other social experiences are obviously important in understanding the nature of cohort effects, duration of exposure may also be an important factor in their strength. Examining the

voting behavior of women after the 19th Amendment guaranteed women's suffrage in 1920, Firebaugh and Chen (1995) found an inverse relationship between the duration of women's exposure to political disenfranchisement and their subsequent likelihood of voting relative to their male counterparts. The gender difference in voting behavior was largest in cohorts reaching adulthood prior to the passage of the amendment, and declined to nonexistence in cohorts born after 1925. Many women growing up during the period when women were not permitted to vote retained this norm and remained nonvoters even after the enactment of women's suffrage, whereas later-born women, having never been exposed to gender discrimination in voting rights, were just as likely to vote as men from their same birth cohorts.

Birth cohorts can also be distinctive and exert a unique influence based on their demographic characteristics, such as relative size (i.e., their size relative to other birth cohorts). Easterlin (1987) argues that members of the numerically large birth cohorts making up the post–World War II Baby Boom are at a significant socioeconomic disadvantage relative to members of earlier-born cohorts, because of the effect of their cohort's' size on the opportunity structure. Individuals in large cohorts may experience greater psychological stress in their youth, be less likely to marry, and be more likely to postpone having children (Easterlin, 1987).

### CONCLUSION

Individuals are both cause and consequence of the social context in which their lives are embedded. An individual's year of birth—or *birth cohort*—is the metric used to identify the particular historical context in which they live. In the words of Norman Ryder, "(t)he members of any cohort are entitled to participate in only one slice of life—their unique location in the stream of history" (Ryder, 1965, p. 844). Cohort effects and the phenomenon of cohort replacement demonstrate the reciprocal relationship between individual and society by documenting the role of historically bounded formative experiences in individuals' subsequent interpretation of, and action in, the world around them. Cohort effects are well documented in a variety of domains, and may arise from a number of sources, including economic, political, and educational experiences. Life course scholars are well served to consider birth cohort, and thus, historical context, in their explorations of the interplay between the individual and his environment.

## CONSUMPTION, LATER LIFE

**SEE** Volume 2: *Consumption, Adulthood and Later Life.*

## CREATIVITY, LATER LIFE

Creativity is built into the human species, and it is designed to last throughout the entire life cycle (Andreasen, 2005; Cohen, 2000). Howard Gardiner (1993b) who provided information on *multiple intelligences* also amplified the understanding of creativity presenting in some individuals as *Big C* creativity, and in others as *little c* creativity, but in each case its creative essence is real and

significant. Big C applies to the extraordinary accomplishments of great artists, scientists, and inventors. These forms of creativity typically change fields of thought and the course of progress, as with Albert Einstein's (1879–1955) theory of relativity, Edison's electrical inventions, and Pablo Picasso's (1881–1973) and Georges Braque's (1882–1963) cubism.

Creativity with a little *c* is grounded in the diversity of everyday activities and accomplishments. "Every person has certain areas in which he or she has a special interest," Gardner explains. "It could be something they do at work the way they write memos or their craftsmanship at a factory—or the way they teach a lesson or sell something. After working at it for a while they can get to be pretty good—as good as anybody whom they know in their immediate world."

Sometimes something little *c* can evolve to big *C* creativity, as with Maria Ann Smith (1799–1870) who during her 60s in the 1860s was experimenting in Australia with different fruit seeds. She took great satisfaction in this work, especially when something different grew—something new that she brought into existence that was valued. One of these successes was a hardy French crabapple seedling from which developed the late-ripening Granny Smith apple, bearing her name, which because of its outstanding taste and keeping qualities formed the bulk of Australia's apple exports for many years.

## DEFINITION OF CREATIVITY

Creativity is difficult to define because it is hard to conceptualize. Is it a product or a process? If it is a product, is it tangible, like a painting, or intangible, like an idea? To encompass each of these possibilities and more, the following definition is offered, borrowing on views of Rollo May (1975), Howard Gardiner (1993a), and Mihaly Csikszentmihalyi (1996): *Creativity is bringing something new into existence that is valued* (Cohen, 2000).

## THE CREATIVITY EQUATION

The *creativity equation* ($C = me^2$) represents an attempt to make an elusive concept—creativity—more graspable (Cohen, 2000). The equation states that creativity ($C$) is the result of one's mass ($m$) of knowledge, multiplied by the effects of one's two dimensions of experience ($e^2$). The first dimension is an individual inner world experience reflecting psychological and emotional growth over the years. The second dimension is the outer world experience reflecting accumulating life experience and wisdom in growing older. All these elements interact in a synergy that sets the stage for creativity. The equation also reflects the positive influence of aging where through the passage of time one is enabled to acquire more knowledge along with increased outer world experience and inner world growth. From a lighter perspective, the $me^2$ is what one realizes when looking at the creative side of oneself in the mirror—"Hey, that's *me* to a higher level!"

## CATEGORIES OF CREATIVITY

Keep in mind that creativity applies not just to artists but is also apparent in all aspects of life, including the social realm where over the history of civilization older adults have assumed the creative role of *keepers of the culture,* transmitting accumulated knowledge, traditions, and perspective.

In general discussions of creativity and aging, to the extent its existence was acknowledged, creative expression in later life was often trivialized as being narrow and simple in form. In reality, not only is creativity relevant and prevalent with aging, it shows itself in a depth and breadth of forms. Consider the following four basic patterns of creativity in the second half of life:

- *Continuing Creativity:* This was certainly the case for Herbert Block (1909–2001), better known as Herblock, the *Washington Post* cartoonist, whose nationally syndicated cartoons informed and enriched American culture for more than 70 years. His first cartoon appeared when he was in his 20s; his last was published less than two months before he died at age 91.
- *Changing Creativity* (while changing creativity can be considered a variant of continuing creativity, it is distinguished by the fundamental change in creative direction that the individual takes as he or she ages): The great mathematician and philosopher Bertrand Russell (1872–1970), for instance, focused tightly on mathematics in his youth and middle age. When he was 42 he and Alfred North Whitehead (1861–1947) published the *Principia Mathematica*, which remains a masterpiece of mathematical logic and synthesis. As he grew older his focus shifted to deeper issues, particularly philosophy, and the many social ills of his time. At the age of 73 he published his renowned work, *A History of Western Philosophy* after which he received the Nobel Prize in Literature, and he remained passionately involved in issues of peace and justice until he died at 98.
- *Commencing Creativity:* Some people first significantly tap into their creative potential around age 65; they are often referred to as *late bloomers.* This author's own ideas about creativity with aging and especially about late bloomers blossomed after a visit to a retrospective exhibit of a half-century of folk art at Washington's Corcoran Gallery of Art in Washington, D.C. The works of 20 of the most highly regarded African American folk artists produced from 1930 to 1980

***Grandma Moses.*** *Artist Anna Mary Robertson Moses, known as Grandma Moses, works on one of her paintings at her home in Eagle Bridge, NY, September 1960, the year before she died at age 101. Grandma Moses is one of the most famous examples of someone who found a new creative outlet late in life.* AP IMAGES.

were exhibited. Reading the artists' brief biographies revealed that of the 20 exhibitors, 16—80%—had begun painting or reached a recognizable mature phase as artists after the age of 65; 30% were 80 years of age or older (Livingston & Beardsley, 1982). The folk art story is particularly important because whenever examples are given of important art by older artists such as Pablo Picasso (1881–1973), Titian (born Tiziano Vecelli, lived ca. 1485–1576), or Georgia O'Keeffe (1887–1986), many fire a reflex response that they are "outliers, exceptions from the rule, not typical of aging." But with folk art, older artists are the rule—across the racial and ethnic diversity of our culture (Hartigan, 1990). With their prominence, their work cannot be diminished as uncommon events. Whenever one can find a field, any field, dominated by older people—such as folk art—then one can no longer deny or trivialize creative potential with aging. And what a statement they make with their numbers about it truly being never too late in life to be creative; they make the ultimate case for late blooming. Grandma Moses (1860–1961) who only at 78 turned her serious attention to painting, with her work selected for 15 international exhibits over the next 23 years until she was 101, was but one of a huge crowd of older folk artists with a major impact. William Edmondson (ca. 1882–1951), who had been a janitor until 65 when he lost his job, turned then full-time to sculpture. Louise Dahl-Wolfe, a photographer, captivated by Edmondson's work, sent a portfolio of images of his sculptures to the Museum of Modern Art (MOMA) in New York. The result was that at 67, Edmondson became the first African American artist in the history of the MOMA to have a solo exhibit, opening the doors to generations that followed (Livingston & Beardsley, 1982).

- *Creativity connected with loss:* There is nothing romantic about loss, but the human condition and the human spirit are such that when loss occurs, it is in our nature to try to transcend it by tapping into unknown or underdeveloped other capacities that we possess. Such is captured in the life and work of William Carlos Williams (1883–1963) of Paterson, New Jersey. Carlos Williams was a pediatrician who also wrote poetry. But a stroke in his 60s left him unable to continue practicing medicine and sent him into a depression that required a year of hospitalization. He gradually emerged from that trauma and loss, turning full-time to poetry; the collection was published in his book *Pictures from Brueghel and Other Poems* when he was 79 years old. It was awarded a Pulitzer Prize. In his later-life poetry, William Carlos Williams wrote about "old age that adds as it takes away."

## PSYCHOLOGICAL GROWTH AND DEVELOPMENT WITH AGING

Psychological growth and development sets the stage for creative expression with aging. Psychoanalytic research has found that older adults are more in touch with their inner psychological life than at any point in the life cycle (Maduro, 1974). What an asset in a creative and artistic sense to be more in touch with one's inner world that negotiates access to potential in new ways as we continue to develop with aging.

Four recently described, overlapping developmental phases in the second half of life set the stage for positive change and creative expression (Cohen, 2004, 2005):

**Midlife Reevaluation Phase** The first of four recently described, overlapping developmental phases in the second half of life generally occurs during one's early 40s to late 50s: Plans and actions are shaped by a sense of crisis or quest, although considerably more by quest. Midlife is a powerful time for the expression of human potential because it combines the capacity for insightful reflection with a powerful desire to create meaning in life. This quest is catalyzed in midlife by seriously confronting for the first time one's sense of mortality; on passing the midpoint in the life cycle, one contemplates time left instead of time gone by. This dynamic new inner climate becomes a catalyst for uncovering unrealized creative sides of ourselves, as reflected in Alex Haley's midlife quest that culminated in his publication of *Roots* (1976).

**Liberation Phase** This phase usually emerges from one's mid-50s to mid-70s. Plans and actions are shaped by a new sense of personal freedom to speak one's mind and to do what needs to be done. There are often mounting feelings of "if not now, when," "why not," and "what can they do to me?" that foster a sense of inner liberation. With retirement or partial retirement, common during these years, comes a new experience of external liberation and a feeling of finally having time to experiment with something different.

**Summing-Up Phase** This phase comes most frequently in one's late 60s into one's 80s—or beyond. Plans and actions are shaped by the desire to find larger meaning in the story of one's life as a person looks back, reexamines, and sums up what has happened. This process motivates people to give of the wisdom they have accrued throughout their lives. In the role of keepers-of-the-culture, people who reach this phase begin to share their lessons and fortunes through autobiography and personal story telling, philanthropy, community activism, volunteerism, and other forms of giving back. With Martha Graham (1894–1991), giving back was through choreography from her mid-70s to mid-90s. It is also a time to deal with

### PRAGMATIC CREATIVITY AND AGING

Pragmatic creativity is a form of creativity that researchers describe as increasing with aging (Cohen, 2005). In his mid-70s Howard Miller, the author's father-in-law, illustrated very well the concept of pragmatic creativity with aging. Stuck in a snowstorm with his wife and unable to find a cab to bring them back home, Howard spotted the steamy windows of a pizza parlor and experienced the flash of a creative solution. He took his wife's arm, carefully crossed the slushy road, entered the pizza place, walked up to the counter, and ordered a large cheese pizza for home delivery. He then asserted, "There's one more thing." "What's that?" asked the clerk, to which Howard convincingly replied, "I'd like you to deliver us with it." And they did.

Two key factors explain the greater frequency of pragmatic creativity with aging: (a) the influence of accumulated life experience over time—reflected in the creativity equation, and (b) the influence of the *liberation phase* ("What can they do to me?"), as illustrated by Howard. This is the other part of the $e^2$ in the creativity equation. The flash of a creative solution that Howard experienced reflects "the New Senior Moment" (Cohen, in press).

unresolved conflicts and unfinished business in manners that motivate us to develop creative new strategies.

**Encore Phase** This phase can develop from one's late 70s to the end of one's years. Plans and actions are shaped by the desire to restate and reaffirm major themes in one's life but also to explore novel variations on those themes and to further attend to unfinished business or unresolved conflicts. The desire to live well to the very end has a positive impact on family and community and often influences decisions to have family reunions and other events. The Delany sisters (Sarah [1889–1999] and Bessie [1891–1995]) after a filled century of life, engaged in an encore—a story about themselves with a title that set the stage for an encore: *The Delaney Sisters: The First 100 Years*, which became a best-selling book.

### CONCLUSION

"In the past few years, I have made a thrilling discovery... that until one is over 60, one can never really learn the secret of living. One can then begin to live, not simply with the intense part of oneself, but with one's entire being."

—Pulitzer Prize-winning novelist Ellen Glasgow

# CRIME AND VICTIMIZATION, LATER LIFE

The victimization experiences of older adults, defined as persons age 65 and older who have suffered injury or loss due to a crime, is important to the study of the life course and a pressing social concern. Developmental changes associated with advancing age and changing social circumstances occurring in later life affect key indicators of well-being, including health and financial status as well as personal safety. Research has found that the likelihood of victimization consistently differs by age. It also shows that the form victimization takes varies over the life course, and reflects the interrelationship between victims, offenders, the contexts in which crimes occur, and the degree of physical, psychological, and financial harm. The likelihood of being victimized generally follows an age curve—peaking in late adolescence and declining with older age. A life-course understanding considers an individuals' changing social roles over the life span as well as cohort, historical, and cultural differences that impact the relationships between age and victimization.

Most of what is known about victimization in later life comes from victim surveys including the National Crime Victimization Survey, an annual survey of U.S. households of persons 12 years and older, and the British Crime Survey, a nationally representative household survey of adults 16 and older living in England and Wales. These surveys provide information about victimization experiences among older persons and the households in which they reside. A chief finding is older adults are less likely to become victims of violent crimes than persons under the age of 65—a pattern that holds from 1993 to 2006 in the United States and the United Kingdom (Klaus, 2005; Nichols, Kershaw and Walker 2007; Rand and Catalano, 2007).

Similarly, households headed by an older adult reported lower levels of property victimizations compared to households headed by persons under 65 in both the United States and the United Kingdom. In one offense category older adults in the United States had similar victimization rates as persons under the age of 65—personal larceny which includes purse snatching and pocket picking (Klaus, 2005). In 2006 older adults made up 14% of the U.S. resident population 12 years and older and comprised less than 1% of violent and property victimizations (Rand & Catalano, 2007). Among older adults in the United States, violent and property victimization varied across social categories with higher rates found among males and Blacks ages 65 to 74, and households headed by an older adult with lower family income, city residence, and renting residence (Klaus, 2005).

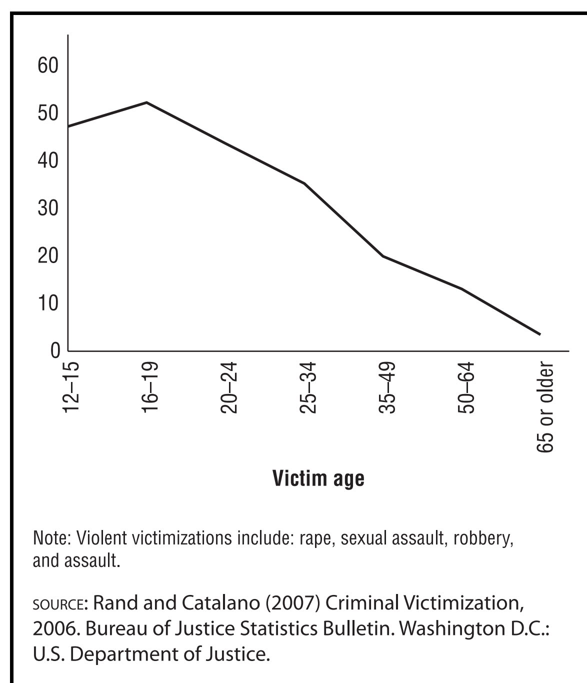

***Figure 1.*** *Violent victimization rate, 2006, per person age 12 years or older.* CENGAGE LEARNING, GALE.

Persons age 65 or older were disproportionately affected by property crimes compared to younger persons. About 9 in 10 victimizations of older adults in the United States were property crimes, including household burglary, motor vehicle theft, and other theft, compared to about 4 in 10 victimizations among younger persons (Rand & Catalano, 2007). Older persons were about as likely as those under age 65 to be victims of personal larceny with contact, including purse snatching (Klaus, 2005). The violent victimization rate of older adults in 2006—including rape, sexual assault, robbery, and aggravated and simple assaults—was about 4 victimizations per 1,000 U.S. residents age 65 and over, compared with 42 victimizations per 1,000 for persons between the ages of 12 and 34 and 17 victimizations per 1,000 for persons between the ages of 35 and 64 (Rand & Catalano, 2007).

Older persons are more likely to be victimized in or near their home and in the daylight hours (Klaus, 2005). In responding to nonfatal violent attacks, older persons in the United States are less likely to resist, about as likely to receive serious injury, and about as likely to be confronted with an armed offender as younger persons (Klaus, 2005). In the United Kingdom, and the United States, older persons are also more likely to report violent incidents of crime than their younger counterparts (Klaus, 2005; Chivite-Matthews & Maggs, 2002). Despite older persons being less likely to experience criminal victimization, fear of crime in the United Kingdom is reported at similar levels among older and younger victims; levels among older women are greater than those reported by older men (Nichols, Kershaw, & Walker, 2007).

Researchers have sought to explain differences in victimization risk by age and other social groupings, including gender, ethnicity, and social class. Lifestyle theory attributes the lower risk of victimization of older persons to differences in lifestyles that decreases exposure to settings associated with greater risk. Examples of settings and lifestyle routines associated with increased risk of victimization include working outside the home, using public transportation, residing in the city, frequenting bars, and going out in public in the evenings. Situational explanations identify contexts that specifically put older persons at higher risk due to the absence of a guardian such as a police officer, or cohabiting family member or roommate. For example, older adults residing alone in crime-prone urban areas less patrolled by police would face greater risks than adults living in more protected contexts.

Importantly, certain contexts are unique to older adults and less understood with respect to victimization occurrence and impact. This includes situations where the older adult is dependent on others—often due to diminishing mental or physical capacities brought on by aging. Unscrupulous caretakers may financially exploit older adults by cashing checks without permission, stealing money and property, and forging and coercing signatures. Older victims may be reticent to report incidents to the police out of concern that it would get a family member in trouble, embarrassment, or out of fear of retaliation from those they depend on for care. Loneliness and isolation of the older adult may also increase susceptibility to being a victim in cases where perpetrators seek out older persons by telephone, mail, and door-to-door solicitation for various types of consumer frauds and identity theft. Further, as health care needs increase, the older person will be more likely to seek care and be subject to charges for unnecessary or unperformed tests, nursing home abuses, misrepresentation of services or quality, and fraudulent medical equipment sales with implications for physical, psychological, and financial harm.

The relatively low property and violent victimization rate of older adults detracts from the potential for serious impact on the aged as well as the alternative contexts unique to older adults where victimizations may go undetected or unreported. A future research agenda on the topic of older adults and crime and victimization includes: improving measurement of victimization by focusing attention on offenses that impact older adults including financial exploitation, neglect, and abuse; extending existing victimization surveys to include

nonhousehold, institutional populations such as nursing homes; design more rigorous panel data collections to more effectively disentangle age, cohort, and period effects on criminal victimization over the life span; and developing age-specific strategies for law enforcement and victim service providers that address the needs of the older population from both health and criminal justice policy perspectives (Lachs, Bachman, & Williams, 2004)

# CULTURAL CAPITAL, LATER LIFE

**SEE** Volume 1: *Cultural Capital.*

# CULTURAL IMAGES, LATER LIFE

In contemporary technological society cultural views of aging are influenced by and reflected in media portrayals, which provide a snapshot of the aging process and provide a cultural perspective on that process. Cultural images are representations of individuals, groups, and society that are captured by a communication event. That event can be a simple picture, a television program, a speech, or a song; essentially any form of communication can serve as a cultural representation.

## NATURE AND EFFECTS OF CULTURAL REPRESENTATIONS

Cultural representations are important because they influence the way people view other social groups, other cultures, and even themselves; media representations serve as socialization mechanisms related to social groups. For example, exposure to television's portrayals of women in traditional roles is associated with children's development of stereotypical sex-role attitudes (Kimball, 1986). The ways in which viewers perceive other social groups is influenced by television portrayals of those groups (Harwood, 1999, Mastro, 2003). Furthermore, portrayals of social groups in the media have consequences for individuals who belong to social groups, who may come to endorse or reject particular ideas about their groups through exposure to the media (Harwood & Roy, 2005).

Additionally, media images influence the specific cognitive schemas people develop to process information about the world around them. Cognitive schemas are mental structures such as stereotypes that help individuals organize how they think about people and situations. When people are exposed to new messages, their schemas are modified (Schneider, 2004). If media images of older adults are negative, a negative stereotype or schema is likely to develop (Robinson, Gustafson, & Popovich, 2008). The activation of negative stereotypes in perceptions of older adults in turn influences communication with older adults and can lead to age-adapted communication strategies such as patronizing or demeaning communication directed at older people (Hummert, 1994, Hummert, Garstka, Ryan, & Bonnesen, 2004). The activation of age-adapted communication that is based on negative stereotypes can occur even in close family relationships such as grandparent-grandchild relationships (Anderson, Harwood, & Hummert, 2005). Thus, the potential impact of cultural images on people's interactions with one another provides a strong reason for examining the representations of older adults in multiple forms of media.

## PORTRAYALS OF AGING IN MEDIA

Research on media portrayals of aging has focused mainly on prime-time television, daytime television, television advertising, and print advertising, primarily in the United States. That research has examined the presence of older adults in media, the role prominence of older adults in media, and images of aging. The most common form of research works by counting older adult characters and comparing their numbers to those in the population.

Older adult characters are defined in a variety of ways in this research (which has been something of a detriment to effective comparisons across studies). Common methods include defining a range of physical features that define old age (e.g., gray hair, noticeably wrinkled skin, use of a walking cane, etc.), defining based on relational roles (e.g., being a grandparent), or simply defining based on chronological age (e.g., cut-offs from 50 to 65 have been used). Coders demonstrate substantial levels of reliability on all these tasks. One goal for this research area should be to standardize a definition of what counts as an older character. We suspect that definitions based on chronological age are least susceptible to bias; we would advocate for work to consider multiple age groups of older adults (e.g., distinguishing 60 to 70 from 70 and above) and to avoid including characters in their 50s from consideration as "older."

In the context of age distribution estimates from census data, older adults consistently are underrepresented in prime-time television programming (Robinson & Skill, 1995, Harwood & Anderson, 2002), television advertising (Hiemstra, Goodman, Middlemiss, Vosco, & Ziegler, 1983, Miller, Leyell, & Mazachek, 2004, Roy & Harwood, 1997), and advertising in national magazines (Gantz, Gartenberg, & Rainbow, 1990). Older adult women are particularly underrepresented relative to older men (Signorielli & Bacue, 1999). Several authors have concluded that this skewed representation of older women reflects a disproportionate value placed on youth for women (Gerbner, Gross, Signorielli, & Morgan, 1980). In contrast, J. Harwood and K. Anderson (2002) found that older adult men and older adult women were equally underrepresented compared with census estimates, although young adult women were found to be overrepresented relative to middle-aged women, again suggesting a bias toward youth for women.

Studies of role prominence examine whether older adults are portrayed as central characters in television shows and advertisements. Researchers have explored major roles, minor roles, and background roles in various forms of television programming. Most older adult characters in television advertisements play minor or background roles (Roy & Harwood, 1997, Swayne & Greco, 1987, Robinson, 1998). For example, A. Roy and Harwood (1997) determined that more than 50% of older adult characters in television advertisements appear in background roles. However, the percentage of older adult characters in major roles increases when the advertised product targets older adults (Robinson, 1998).

Harwood and Anderson (2002) found that the role prominence of older adult characters in prime-time comedies and dramas does not differ significantly across age groups. However, as female characters age, they become less significant to the plot compared with male characters (Gerbner et al., 1980, Vernon, Williams, Phillips, & Wilson, 1990). J. Robinson and T. Skill (1995) noted that peripheral and minor characters may be more revealing of cultural stereotypes in light of the limited ability for development of depth and complexity in those characters and the need for such characters to serve a "quick and dirty" story function. The current television landscape does not offer many older people in lead roles, but examples from the past include *Matlock*'s Andy Griffith and *Murder, She Wrote*'s Angela Lansbury. A character like the grandfather on *The Simpson's* would qualify as a supporting character, while truly peripheral characters typically have one-off background roles (e.g., a store clerk who is only seen once and says a single line).

Studies of the quality of specific images or portrayals focus on personality traits, cognitive abilities, activities and occupations, physical features, and age stereotypes related to older characters. Much of this research has found negative portrayals of older adults (Gerbner et al., 1980, Harris & Feinberg, 1977). For example, S. R. Stern and D. E. Mastro (2004) found that older adults are substantially less likely to be portrayed in occupational roles than are younger characters; their research also showed that female characters suffer particularly on this front, with virtually no older women being shown in productive occupational roles. Of course, these representations might accurately reflect levels of labor force participation among older women; nonetheless, they do also serve as powerful messages about expectations for this group and for future generations as they age.

Other researchers have uncovered more positive portrayals in prime-time television programming (Bell, 1992, Dail, 1988), cartoons (Robinson & Anderson, 2006), and television advertising (Miller et al., 2004, Roy & Harwood, 1997). For example, J. Bell (1992) focused on the prime-time television shows most watched by older adults and found a combination of positive (e.g., powerful, affluent, healthy, active, admired) and negative (e.g., eccentric, foolish, comical) stereotypical portrayals. P. W. Dail (1988) found a similar pattern of positive and negative portrayals in the perceived cognitive ability of older adult characters. Generally, the older adult characters were seen to have positive mental orientation and verbal interaction but had moments of disorientation, confusion, or forgetfulness. This research focused on a very narrow slice of programming rather than the broad areas of programming examined in studies demonstrating negative portrayals.

Research on television advertising has found that older adults generally are portrayed positively but not as positively as other age groups (Miller et al., 2004, Robinson, 1998, Swayne & Greco, 1987). For example, Roy and Harwood (1997) found that older adults were

portrayed as strong, happy, active, and lucid. However, T. E. Robinson (1998) found that the target of the advertisement played a role in the way older adults were portrayed. He examined facial expressions, personal characteristics, and behaviors of older adult characters and found that older adults generally are portrayed as mean, irritable, or grumpy, but are presented as happy when the target of the advertisement is other older adults. Advertisements targeting older adults include products such as medicine, mobility aids, and emergency alerts. Some of these studies reach conclusions about broadly positive portrayals of older adults without doing a relevant comparative examination of younger characters (Harwood, 2007). For instance, T. Robinson and C. Anderson (2006) found predominantly positive portrayals of older characters in cartoons but did not examine younger characters to determine whether those characters are portrayed even more positively. While research has not examined longitudinal trends, reviews of this literature indicate very little in the way of trends towards increasing or more positive portrayals (J. Robinson, Skill, & Turner, 2004).

Most researchers who explore images of aging in media use a quantitative content analysis method. Researchers record a representative sample of programming and analyze the quantity and quality of portrayals through the use of objective coding of characters by independent coders. However, Harwood (2000) took a different methodological approach and provided a textual analysis of one intergenerational interaction in the show *Frasier. Frasier* portrays the interactions between the divorced psychiatrist Dr. Frasier Crane; his psychiatrist brother, Niles; and their father, Martin, a retired police officer. Harwood's analysis demonstrated that this intergenerational interaction included a high level of age salience. The intergenerational bonding that occurred demonstrated a duality of tension between portraying the older adult as counterstereotypical and simultaneously using the stereotype of older adults as forgetful to create humor in the interaction. Thus, although the older adult character generally is portrayed positively, Harwood argues that the lurking incoherence of the portrayal is problematic because it relies on and reinforces the negative stereotypes of aging. Harwood and Giles (1992) reached similar conclusions concerning (counter)-stereotypical portrayals in *The Golden Girls,* which focuses on three retired women who live together in Florida, along with the mother of one of the retirees.

## EFFECTS OF MEDIA IMAGES ON VIEWERS

The effects of media portrayals of aging can be divided into effects on older and younger viewers. A concern in regard to older viewers has been with the effects on their own orientation and attitudes toward aging. M. M. Donlon, O. Ashman, and B. R. Levy (2005), for instance, examined the long-term effects of media consumption by measuring an estimate of life-time television consumption—they multiplied number of years of television viewing by the average number of hours viewed in the current year. They found that older individuals (age 60 to 92) with larger life-span exposure to television have significantly more negative stereotypes of aging than do those with less television exposure (e.g., they were more likely to rate other elders as grumpy or senile). Television exposure accounted for more than 10% of the variance in negative stereotyping, more than did health, depression, education, or age. This research illustrates the potential for television to reinforce self-stereotyping among older adults and ultimately lead to more negative experiences of aging.

Experimental studies have examined whether specific types of portrayals affect different types of older people in different ways. M-L. Mares and J. Cantor (1992) examined whether positive versus negative portrayals of older adults affected depression scores among lonely and non-lonely older viewers. Their findings indicated that older people who are not lonely are made more depressed by seeing negative media images of older people (e.g., images portraying an older person as depressed and socially isolated). In contrast, the same images made lonely older people less depressed. The second finding is explained by the authors in terms of social comparison processes: For individuals who are experiencing problems in their lives, seeing that they are not alone and that others are similarly isolated may serve a comforting function, conveying the message that their distress is not unique to them. This work demonstrates that not all older people respond to portrayals of older adults in the same manner and thus draws attention to the fact that an ideal portrayal of older adults on television will be characterized not by simple positivity but by diversity.

Similar concerns exist in regard to younger people. Gerbner et al. (1980) examined whether overall television consumption is associated with perceptions of the prevalence of older people in the population. As might be expected in light of the data on underrepresentation presented above, teens who viewed a lot of television tended to see older adults as constituting a smaller proportion of the total population compared with those who watched less television. These heavy television viewers also had more negative attitudes about aging. The effect sizes here are small, and there has been discussion about whether they persist when other factors are statistically controlled (Passuth & Cook, 1985).

### THEORETICAL FRAMEWORKS

There are relatively limited theoretical frameworks to utilize in examining the content of media portrayals of older adults. One common option is to base such work on media effects theories. For instance, the content analysis of Gerbner et al. (1980) is grounded in cultivation theory, which says that heavy viewers of television will come to view the television world as the "real world," and so their mental representations of the world will come to resemble television. If that is the case, then there is need to understand the television world in more detail. Similar rationales can be developed that are based on, for instance, social cognitive theory (Bandura, 2002). This theory would suggest that individuals are more likely to model (learn and imitate) behavior that is performed by attractive media characters. That approach would recommend examining interactions between younger and older characters on television in terms of the attractiveness of the younger persons. Younger viewers would be more likely to adopt intergenerational behaviors modeled by attractive peers; therefore, seeing discriminatory or patronizing behavior by a younger person on television would be more potentially damaging if the young person was attractive. No such work has been done, but it presents a productive theoretically driven direction for future research. This perspective also draws attention to the need for more extensive examinations of intergenerational interaction on television. Very little work has considered how older people and younger people talk to one another on television or the effects of those images on the well-being of and interactions among young and old adults.

An alternative to the effects-oriented approach has been described by Harwood and Anderson (2002). They suggest examining media content from an ethnolinguistic vitality perspective (Giles, Bourhis, & Taylor, 1977, Harwood, Giles, & Bourhis, 1994). Vitality theory describes the various facets that contribute to a group's strength in society through a systematic examination of sociostructural features such as demography, social status, and institutional support. For instance, groups in the majority with support from government and with a history of societal prestige will exercise more power in most societies than minority groups with a history of exclusion and oppression. Within the category of institutional support, Giles et al. (1977) define media institutions as important, and other work has corroborated the importance of media in determining group vitality (Abrams, Eveland, & Giles, 2003, Harwood & Roy, 2005). Vitality theory specifies media representation as an important topic independent of effects in light of its role as a component of a theoretically grounded understanding of where groups stand in society. Thus, cultural representations provide a socialization function within groups as well as reflecting a broader perception of how the dominant culture views various social groups.

## CULTURAL VALUES AND CHINESE MEDIA

Media representations of aging have been explored in various cultural contexts outside North America, including India, Germany, Britain, South Korea (Lee, Kim, & Han, 2006), and China (Zhang, Harwood, Williams Ylanne-McEwen, Wadleigh, & Thimm, 2006). Y. B. Zhang and J. Harwood (2004) support the conclusion that a norm of respect for older adults is salient in Chinese television advertisements. Filial piety (*Xiao*) is a cultural norm that is based on the traditional Confucian values of hierarchy and respect for elders; it is clear from their research that advertisers use this value to make their products appeal to consumers. Ads for health-related products, for instance, include tag lines suggesting that the parents' health is the responsibility of the child. Zhang and Harwood's (2004) research explores the extent to which modernization and globalization of Chinese culture is reflected in representations on Chinese television. These authors note the continued presence of traditional themes, but often blended with themes relating to progress, technology, and individual gratification. Themes emphasizing a value of "youth" are also strong in Chinese advertising; Lin (2001) suggested that this is in part a function of the one-child policy, which has resulted in a "little emperor/empress" phenomenon for couples with a single child.

### FUTURE RESEARCH DIRECTIONS

As was noted above, research exploring the intergenerational interactions portrayed on prime-time television could provide additional insight into the role of socialization of media portrayals. Researchers could expand their methodological approach by incorporating mixed methods to explore both the presence and the portrayal of older adults through content analysis and the interactions portrayed through discourse analysis. Furthermore, research that explores the effects of these types of interactions on young adults' perceptions of older adults could provide theoretical support for the media effects approach. That approach often is used as a rationale for doing content analytic work on cultural images of aging

in the media, but the effects of and impact on real-world intergenerational encounters has not been explored.

Particular areas of content are also deserving of more attention than they have received. In particular, considerable research shows that older adults prefer informational and educational programming (news, etc.) to entertainment programming (sitcoms, etc.) (Riggs, 1996, Robinson, Skill, & Turner, 2004). However, relatively little is known about how older people are portrayed in news programming and other news sources (e.g., newspapers, educational programs, C-Span, quiz shows). Examination of such programs would help researchers understand whether the types of media preferred by older people are the types that portray older people in greater numbers or in a more positive or diverse fashion. Additionally, as generational shifts occur the type of program that older people consume are likely to change. Future research should explore whether the influence of the baby boomers on the media preferences of older adults.

### I. GENERAL ISSUES

The term *data* is used to define two distinct products: published literature representing the distillation of research findings and research data, the information underlying those publications. Research data include a growing universe of federal and public tabulations, surveys, and other forms of secondary information. These data allow researchers to examine issues that go beyond the findings presented in published research, and the availability of such data has enhanced understanding of aging and the life course. Sources of data on older adults have increased dramatically as a result of the worldwide growth of the aged population and scholars' and policy makers' need to understand the implications of that growth. The value of these data is enhanced by the development of more detailed survey designs, access to more powerful computers, and more sophisticated models for measuring attitudes, behaviors, and change.

#### EARLY STUDIES OF AGING

Although there has always been interest in aging, many historians consider the 1881 publication of *Clinical Lectures on the Diseases of Old Age* by Jean-Martin Charcot as the formal beginning of gerontology. In the eight decades after that publication, studies of aging episodically appeared in the published literature, but, with the exception of articles such as P. K. Whelpton's 1930 article on the aging transition, there was not a significant social science literature on aging until the 1960s.

At that time researchers such as Agnes Brewster (1961) began examining the potential health care costs of a growing aging population, and George Maddox presented the results from one of the earliest longitudinal studies on the aged in 1963; by the late 1960s researchers began exploring family support relationships between aging parents and their adult children (Rosenmayr, 1968). The 1970s saw a growing body of research as studies addressed topics such as living arrangements (Montgomery, 1972), late-life friendships across sexes (Booth & Hess, 1974), and policy research on alternatives to institutionalization (Abdellah, 1978). That work was informative, but it was also static, as researchers could not replicate or build on those published studies

because they lacked access to the underlying data resources that measured the outcomes. The growing availability of mainframe computers in the late 1970s changed the state of research. The unprecedented growth and declining costs of computing power introduced a tremendous degree of equity into data analysis, and the subsequent flood of secondary data available for research has made good use of this capacity.

## THE EMERGENCE OF DATA RESOURCES FOR THE STUDY OF LATER LIFE

Like the literature on aging, data sources grew slowly, beginning in the late 1960s. An early example of data focusing on the lives of the elderly was the 1968 National Senior Citizens Survey (Schooler, 1979), a national study of persons 65 years of age and older. It was representative of studies that explored the quality of life by measuring life satisfaction, types of social relationships, and access to community services among the elderly. Most early studies of aging had the common weakness of being cross-sectional, providing a snapshot of complex behaviors at a single point in time rather than allowing researchers to study change across time.

The Retirement History Longitudinal Survey conducted by the U.S. Department of Commerce in 1969 (Social Security Administration, 2002) was an early example of the use of longitudinal (or multiwave) data collected by the federal government and then repeated six times over 10 years to document the transition to retirement as a process that occurred over time. Although the six Retirement History Longitudinal Surveys provided insights into the determinants of retirement, more importantly, they showed the value of longitudinal designs, encouraging the application of this framework to a wide array of studies.

Beginning in 1984, the Longitudinal Study of Aging (LSOA) was another landmark study that examined changes in the aging life course (U.S. Department of Health and Human Services, 2007b). The LSOA followed a sample of persons age 70 years and over across four waves, ending in 1990. Not only did this study provide detailed information about health status, living arrangements, social and economic support, and health insurance, along with detailed Medicare records, it also followed the mortality of the respondents and included interviews with persons named by decedents for additional information. The LSOA reflected the standard for aging research data at that time, and its use in more than 1,000 scholarly publications since its release reveals its value.

From those early studies, a clear set of issues emerged that defined studies of aging and the life course. Health and disability issues predominated, but equally important were issues of economic stability and the structure of support networks. Because all these factors changed as a person aged, it was also clear that longitudinal data offered the best opportunities for addressing questions related to successful aging.

## CONTEMPORARY DATA RESOURCES FOR THE STUDY OF LATER LIFE

Since the early 1990s research data have been used to address many issues related to the life course of aging persons. The National Long-Term Care Survey conducted from 1982 to 2004 (Manton, 2007) addressed a major weakness in most studies of the elderly. This survey collected information on the institutionalized elderly, enabling the study of the health and disability status of all the elderly, not just those living in households. Most studies of aging look only at noninstitutionalized populations, and other studies of the institutionalized elderly, such as the National Nursing Home Study (U.S. Department of Health and Human Services, 2007c), tend to be cross-sectional and thus cannot be used to study changes in health.

Specialized studies of the aged also emerged in more recent years. The Changing Lives of Older Couples Study (Nesse, Wortman, House, Kessler, & Lepkowski, 2003) collected data on marriage and the spousal bereavement process for older adults, and the Resources for Enhancing Alzheimer's Caregiver Health study (Schulz, 2006) examined the burden on those caring for someone with dementia or Alzheimer's disease. The breadth of aging studies has ranged from the Religion, Aging, and Health Survey by Neal Krause (2006), which looked at the impact of religion on health and emotional satisfaction, to the National Social Life, Health, and Aging Project (Waite et. al., 2007), which provided a rare examination of late-life sexuality.

Among the resources that emerged after the 1990s, perhaps the most influential has been the Health and Retirement Study (HRS; U.S. Department of Health and Human Services, 2007a). Begun in 1992, this complex study of aging has been repeated every 2 years, and interviews have been conducted with more than 27,000 individuals age 50 and older. Touching on a broad array of topics from economic stability to health, disability, and family support, the HRS represents a highly successful study measuring the major issues of aging and following the lives of the elderly over time. In later years, the HRS model was expanded internationally with studies such as the Survey of Health, Ageing, and Retirement in Europe (Börsch Supan, 2005), the English Longitudinal Study of Ageing (Taylor, 2003), and the Mexican Health and Aging Study (Soldo, Wong, & Palloni, 2002), which incorporated features comparable to the HRS and allowed a broader understanding of aging trends worldwide.

Many of these data sources are made available to the general public through the National Archive of Computerized Data on Aging (NACDA), which is funded by the National Institute on Aging. The NACDA acquires, preserves, and processes data relevant to gerontological research, disseminates the data to researchers, and facilitates the use of the data. By preserving and making available the largest library of electronic data on aging in the United States, the NACDA offers opportunities for data analysis on major issues of scientific and policy relevance.

## II. BERLIN AGING STUDY (BASE)

The Berlin Aging Study (BASE) was established in 1989 to investigate questions about aging and dying in Germany from the collaborative perspectives of four disciplines: psychiatry, psychology, sociology, and internal medicine (Baltes & Mayer, 1999). Two unique features of the study are (a) an extensive face-to-face protocol of standardized interviews, tests, and clinical examinations and (b) a heterogeneous age-by-sex stratified sample of men and women ages 70 to over 100 years (born between 1883 and 1922).

At baseline (1990–1993), demographic information was obtained from the obligatory Berlin city registry for a verified parent sample of 1908. The initial participation rate was 78%. A total of 516 men and women (27% of the parent sample) agreed to complete the BASE extensive protocol of 14 individual 90-min sessions, which

were scheduled over 3 to 5 months. An additional 412 persons (21%) participated at the level of a single 90-min multidisciplinary assessment and 336 (18%) provided a 30-min interview. Information obtained from these subgroups is used to examine the selectivity of the core 516 sample. That means that researchers were able to assess the extent to which the core sample was a positive selection of the original sample. The mean age of the core BASE sample was 85 years at baseline and 14% were living in institutions, such as a nursing home. As of 2007, the study involves seven longitudinal measurement occasions. Subsamples have also been recruited for intensive supplementary studies. Mortality information for the entire sample is obtained regularly from the city registry.

More than 1,000 publications reporting cross-sectional and longitudinal findings from BASE are listed on the project web site (the Internet address is given in the bibliography). These publications deal with a wide range of discipline-specific and multidisciplinary topics regarding the young old (persons ages 70 to 85) and the oldest old (persons 85 and older). Central topics include social inequality, family life, life history and cohort experiences, current life contexts, intergenerational transfer of resources, use of health services, physical health, disability, dental health, dementia, depression, everyday competence, cognitive aging, self and personality, social relationships, social support, and well-being.

## III. ENGLISH LONGITUDINAL STUDY OF AGING (ELSA)

The English Longitudinal Study of Ageing (ELSA) is a large, national panel study of English people aged 50 and older. The ELSA was established to study processes of aging from an interdisciplinary perspective. ELSA sample members were selected from households that had participated in the Health Survey for England (HSE), an annual, nationally representative cross-sectional survey. Participants aged 50 and over at the time of the first wave of data collection in 2002 were eligible to become ELSA sample members. ELSA participants are interviewed every 2 years, with an additional nurse visit to collect biomedical data every 4 years.

Three waves of ELSA data have been collected (in 2002, 2004, and 2006) with 12,100 participants in the first wave, and 9,432 participants in the second wave. Third wave data will become available in early 2008 and the fourth wave fieldwork will begin in Spring 2008. The ELSA is funded by the National Institute on Aging in the United States and by a consortium of government departments in the United Kingdom. The ELSA was designed to be comparable with its U.S. counterpart, the Health and Retirement Study (HRS), as well as the Survey of Health Ageing and Retirement in Europe (SHARE). The content of the ELSA includes demographics; health; physical and cognitive function, including performance tests; psychosocial factors and well-being; social participation; housing; employment; pensions and retirement; income, assets, and consumption; biomedical measures, including blood pressure, lung function, anthropometric measures, and blood analyses; and links to administrative data, including mortality statistics. Key findings from the first two waves of the ELSA highlighted diversity and inequality, with extreme differences in the distribution of wealth in the older population and strong links between wealth, health, and social participation (Marmot et al., 2003).

## IV. HEALTH AND RETIREMENT STUDY (HRS)

The Health and Retirement Study (HRS) is a national longitudinal study of more than 20,000 individuals representing the population over age 50 in the United States. The study began in 1992 with a cohort of then preretirement-age individuals born between 1931 and 1941. New cohorts were added in 1993 and 1998 to round out the sample over age 50, and additional cohorts are enrolled every 6 years (e.g., in 2004, 2010) to refresh

the sample at the younger ages. The study contains oversamples of African Americans and Hispanics. Participants are followed throughout the life course with biennial interviews and supplemental data collections.

The primary focus of the study is on the intersection between health, retirement, and economic status in later life. The survey provides detailed information on these topics, as well as on employment history and pension portfolio, work disability and related benefits, family composition and resource transfers, health insurance coverage, and utilization of health services. Supplemental data collections have focused on special topics such as consumption, prescription drug coverage, diabetes care and management, and dementia. Since 2003 the study has collected periodic measurements of physical performance (e.g., grip strength, walking speed, and so forth), height, weight, waist size, blood pressure, and several biomarkers.

The HRS is the nation's leading resource for data on the health and economic well-being of America's rapidly growing older population. As of early 2008, more than 900 journal articles, books, book chapters, and dissertations have been completed using HRS data. A few selected publications are listed in the bibliography. Key findings from the study are summarized in a recent publication by the National Institute on Aging (2007).

The HRS has been emulated in numerous international studies, including the English Longitudinal Study of Ageing, the Survey of Health, Ageing, and Retirement in Europe, the Mexican Health and Aging Study, the Korean Longitudinal Study on Aging, as well as studies that are underway or will soon be launched in Japan, China, Ireland, and India. This collection of studies provides rich potential for cross-national analysis.

The HRS is conducted by the University of Michigan with primary support from the National Institute on Aging. HRS data products are available without cost to researchers and analysts and may be downloaded from the HRS Web site (see bibliography). The Web site also includes general information about the study, documentation reports, and a searchable bibliography of publications based on HRS data.

## V. LONGITUDINAL STUDY OF AGING (LSOA)

There are two Longitudinal Studies of Aging, known as LSOA-I and LSOA-II. Both are cohort studies conducted collaboratively by the National Center of Health Statistics (NCHS) and the National Institutes of Health (NIH). The baseline for the LSOA-I was the 1984 Supplement on Aging (SOA) of the National Health and Interview Survey (NHIS). The NHIS is a continuous cross-sectional household survey conducted annually by the NCHS to monitor trends in illness and disability in the United States. The baseline for the LSOA-II was the 1994 Supplement on Aging. LSOA-I has three follow-up waves (1986, 1988, and 1990); LSOA-II has only two (1997 and 2000). Study populations are all non-institutionalized individuals age 70 years old or older at baseline, living in the United States. The surveys used stratified multistage probability sampling designs. Face-to-face interviews were conducted only at baseline and relied on self-reported information, except when proxy respondents were needed. Respondents of follow-up waves were interviewed by phone or mail in LSOA-I, and with a Computer-Assisted Telephone Interview (CATI) system in LSOA-II. Baseline sample sizes were 7,527 subjects in 1984 and 9,447 in 1994 (Kovar, Fitti, and Chyba, 1992; NCHS, 2003). Respondents who became institutionalized were interviewed during the follow-up waves, except in 1986, when these respondents were purposefully excluded. Hence, this wave was based on a subsample of 5,151. This wave was the only one with a special tracking of non-interviewed persons.

Some important differences between the two studies are that baseline interviews were held at the same time as the NHIS interviews in LSOA-I, but not in LSOA-II; LSOA-II oversampled African Americans; and attrition at last wave was larger for LSOA-II (27%) than for LSOA-I (14%).

LSOA datasets have been valuable in studying the oldest-old Americans and include topics such as: functional limitations and disability over time (Crimmins, Saito and Reynolds, 1997; Freedman, Crimmins, Schoeni, Spillman, et al, 2004; Speare, Avery, and Lawton, 1991; Worobey and Angel, 1990), institutionalization and living arrangements (Speare, Avery, and Lawton, 1991; Worobey and Angel, 1990), mortality determinants (Allison, Gallagher, Heo, Pi-Sunyer, et al, 1997; Grabowski and Ellis, 2001; Rakowski and Mor, 1992; Steinbach, 1992), and health services utilization (Wolinsky and Johnson, 1991).

## VI. SURVEY OF HEALTH AGEING AND RETIREMENT IN EUROPE (SHARE)

The Survey of Health Ageing and Retirement in Europe (SHARE) is a longitudinal, multidisciplinary, and cross-national database of representative micro data on health, socioeconomic status, and social or family networks of individuals aged 50 and over. Eleven countries contributed to the approximately 30,000 computer-assisted personal interviews conducted during the 2004 SHARE baseline wave. These countries constitute a balanced representation of Continental Europe's regions, ranging from Scandinavia (Denmark and Sweden) through Central Europe (Austria, France, Germany, Switzerland, Belgium, and the Netherlands) to the Mediterranean (Spain, Italy, and Greece). In 2005 and 2006, SHARE data also were collected in Israel. For the second wave of data collection, which was conducted in 2006 and 2007, three additional European Union (EU) member states—the Czech Republic, Ireland, and Poland—joined the SHARE. The survey's third wave, which is scheduled for 2008 and 2009, will focus on the collection of detailed life histories of respondents who participated in previous waves.

The SHARE was modeled after the Health and Retirement Study (HRS) in the United States, and the English Longitudinal Study of Ageing (ELSA). A unique strength of the SHARE is that the data can be used to explore cross-national variations in public policies, cultures, and histories in a variety of European countries. Its measures include health (e.g., self-reported health, physical and cognitive functioning, health behavior, and health care utilization), psychological (e.g., mental health and quality of life), economic (current work situation and job characteristics, sources and composition of current income, wealth, and consumption), and social support (e.g., instrumental help, financial transfers, and volunteer activities) indicators.

The SHARE project is coordinated centrally at the Mannheim Research Institute for the Economics of Aging in Germany. Detailed documentation as well as information on SHARE-based publications is available

on the project's Web site. All researchers may download the SHARE data free of charge.

## VII. WISCONSIN LONGITUDINAL STUDY (WLS)

The Wisconsin Longitudinal Study (WLS) is a long-term study of a random sample of 10,317 men and women who graduated from Wisconsin high schools in 1957 and of their randomly selected brothers and sisters. Survey data were collected from the graduates or their parents in 1957, 1964, 1975, 1992, and 2004; from a selected sibling in 1977, 1994, and 2005; from the spouse of the original respondent in 2004; from the spouse of the selected sibling in 2006; and from widow(er)s of the graduates and siblings in 2006. The data provide information about: family background; youthful aspirations; schooling; military service; occupational histories and job characteristics; income, assets, and interhousehold transfers; health insurance, access to health care; pension coverage; family formation and relationships among family members; mental and physical health; stressful life events; coping behavior; cognitive functioning; social and civic participation; experiences with the early death, severe mental illness, or disability of a child; and medical, legal, religious, and psychological preparation for the end of life. Many of these measures are repeated across time.

Along with survey data, the WLS has a variety of supplemental data such as mental ability tests and measures of school performance; characteristics of communities of residence, schools and colleges, employers, and industries; information from high school yearbooks; and samples of DNA from both the graduate and the sibling. In-home interviews with the original respondents are planned for 2010. All nonidentifying WLS data are publicly available and most restricted data can be made available to researchers on completion of an application. Data, documentation, and publications are available online at www.ssc.wisc.edu/wlsresearch. The WLS has been supported principally by the National Institute on Aging with additional support from the Vilas Estate Trust, the National Science Foundation, the Spencer Foundation, and the Graduate School of the University of Wisconsin-Madison. The WLS data have been used to study important life course issues, such as inter- and intragenerational social mobility, and were the basis for influential "status attainment model" (Sewell & Hauser, 1975).

# DEATH AND DYING

Dying is considered the final stage in the life course, and death is the final life course transition. As such, life course sociologists study the ways that values, beliefs, behaviors, and institutional arrangements concerning death are structured by social environments and contexts. Death is a universal human experience, yet societal responses to death vary according to cultural attitudes toward death, contextual factors including the primary causes of death, and normative age at which death occurs. Although death can occur at any point in the life course, the vast majority of all deaths in the early 21st century occur to older adults. In 2006 nearly three-quarters of the 2.4 million deaths in the United States were deaths to persons ages 65 and older (Centers for Disease Control, 2006).

## HISTORICAL CHANGES IN DEATH PRACTICES

Beliefs and practices surrounding death in the United States have come full circle over the past three centuries. In the 18th century, death was public and visible. Death tended to occur at a relatively young age, at home, and was caused by infectious diseases that could not be cured. The loss of a loved one was expressed by dramatic displays of grief among survivors, and elaborate efforts to memorialize the deceased (Aries, 1981). Throughout the late 19th and most of the 20th century, death became "invisible" (Aries, 1981) and "bureaucratized" (Blauner, 1966). Physicians and hospitals assumed control over dying, death and mourning became private, the handling of dead bodies and funeral rites were transferred from private homes to funeral parlors, and people were encouraged to deny death and believe in medical technologies (Blauner, 1966). Treating dying persons in isolation was believed to help smooth the transition beyond death; reducing the social status of those who were about to die would minimize disruption of ongoing social and economic relationships.

The epidemiology of death also changed dramatically (Omran, 1971). In the 19th and early 20th centuries deaths occurred primarily due to infectious diseases, which were not stratified by social class or gender. Men and women, rich and poor were equally likely to become ill and die, and death often occurred relatively quickly after the initial onset of symptoms. Death during the latter half of the 20th and early 21st centuries, in contrast, occurs overwhelmingly due to chronic diseases, including cancer and heart disease. These diseases tend to strike older rather than younger adults, men more so than women, and persons with fewer rather than richer economic resources. Death typically occurs in late life at the end of a long, often debilitating, and painful illness where the dying patients' final days are spent in a hospital or nursing home, and life-sustaining technologies are used.

In the late 20th and early 21st centuries, death is again becoming visible and managed by the dying and their families. Patients' and care providers' recognition that dying is often a socially isolated, physician-controlled experience has triggered a number of political and social movements with the explicit goal of placing control of the dying process in the hands of patients and their families. The Patient Self-Determination Act, passed by Congress in 1990, requires all government-funded health providers to give patients the opportunity to complete an advance directive (or living will) when they are admitted to a hospital. The hospice movement, which began in the United States in the early 1970s to promote palliative care at the end of life, also has grown in popularity. Hospice care, whether in-hospital or at-home, provides an alternative to the medical, scientific model of dying. Pain management, open communication among family, patient, and care providers, and a peacefully accepted death are core goals (National Hospice and Palliative Care Organization, 2001).

## IMPORTANT SOCIOLOGICAL STUDIES OF DEATH

As the social context of death and dying has changed, the foci of research also have shifted. In the 1950s and early 1960s, research was guided by the assumption that the United States was a death-denying society (Gorer, 1965). Influential works included an examination of the problems associated with transferring death and funeral rites from private homes to professional funeral homes (Mitford, 1963), and explorations of the ways that health care providers, dying patients, and their family members mutually ignore and shield one another from their knowledge that the patient is dying (Glaser & Straus, 1965).

In the late 1960s and 1970s, the *death awareness* movement guided research and theory. Key scholarly works of this era offered important advancements in conceptualizing the dying process. Barney Glaser and Anselm Strauss (1968) proposed that dying tends to follow one of three trajectories: lingering, expected quick, and unexpected quick. The latter was considered most distressing for both health care providers and surviving family members. Elizabeth Kübler-Ross (1969) delineated the emotional and cognitive stages that dying persons pass through, before reaching the final stage of *acceptance*.

In the late 20th and early 21st centuries, research on death and dying has flourished. (For a comprehensive compendium, please see Clifton Bryant's *Handbook of Death and Dying* [2003].) Scholarly and public concern about death reflects two broad social patterns. First,

| All races | White | Black | Asian or Pacific Islander | American Indian | Hispanic |
|---|---|---|---|---|---|
| 1 Diseases of heart | Diseases of heart | Diseases of heart | Diseases of heart | Diseases of heart | Diseases of heart |
| 2 Malignant neoplasms | Malignant neoplasms | Malignant neoplasms | Malignant neoplasms | Malignant neoplasms | Malignant neoplasms |
| 3 Cerebrovascular diseases | Cerebrovascular diseases | Cerebrovascular diseases | Cerebrovascular diseases | Cerebrovascular diseases | Cerebrovascular diseases |
| 4 Chronic lower respiratory diseases | Chronic lower respiratory diseases | Diabetes mellitus | Diabetes mellitus | Diabetes mellitus | Diabetes mellitus |
| 5 Alzheimer's disease | Alzheimer's disease | Nephritis | Influenza and pneumonia | Chronic lower respiratory diseases | Alzheimer's disease |

***Figure 1.*** *Leading causes of death among women age 65 and over, by sex, race, and origin, 2004.* CENGAGE LEARNING, GALE.

increasingly large numbers of older adults are living longer than ever before, with most suffering from at least one chronic and terminal disease at the end of life. At the same time, the expanding population of older adults is experiencing the deaths of spouses, siblings, and friends in large numbers. Second, technological innovations to extend life, including life-support systems, organ transplants, and advances in cancer treatment extend the life span, but also raise important questions about the meaning of life and death.

## CONTROL OVER THE DYING PROCESS

One broad theme of the life course paradigm underlies much current research on death: the importance of personal control and agency, both among dying persons and their survivors. Two specific lines of inquiry, which have developed since the late 1990s, are personal control over practical aspects of the dying process and active *meaning making* among the dying and bereaved.

Mounting research explores how older dying persons and their families make decisions about the type, site, and duration of care they want to receive at the end of life. Sociologists' key contributions have included identifying the cognitive, emotional, and structural factors that may enable or prevent individuals from receiving the type of care they hope to receive. Recent research reveals that patients and their family members seldom have sufficient information about their illness trajectory and future lifespan so that they can make informed decisions. Nicholas Christakis (1999) argues that physicians are extremely poor at prognosis, or projecting how much longer a dying patient has to live, and they often convey an unrealistically optimistic picture of their patient's future.

## MEANING MAKING

A second area of inquiry that has attracted renewed scholarly attention is *meaning making*, both among the dying and their loved ones following loss. This concept was first set forth in *Death and Identity*, where Robert Fulton (1965) argued that preserving, rather than losing, personal identity was a critical aspect of the dying process. Sociologist Victor Marshall (1980) proposed that heightened awareness of one's impending death triggers increased self-reflection, reminiscence, and the conscious construction of a coherent personal history. Similarly, developmental theorist Erik Erikson (1902–1994) proposed that preparation for death is the key developmental challenge for older adults. Older adults must simultaneously balance their fear of death and loss, with a heightened capacity for finding meaning in life. More recently, Edwin Shneidman (1995) proposed that dying persons actively construct a post self, or a lasting image of the self that will persist after one's death.

The ways that bereaved survivors actively find meaning in death was articulated early on by Herman Feifel, who observed that the mourning period following loss provides a time for the bereaved to "redefine and integrate oneself into life" (1990, p. 9). Current research explores the ways that active meaning making among the newly bereaved helps to reestablish predictability and one's sense of security. Other goals for the bereaved include personal growth, an adaptive broadening of philosophical perspectives, and an increased appreciation of other interpersonal relations.

## RESEARCH CHALLENGES

Scholars of death and dying face several important methodological challenges. First, bereavement research focuses nearly exclusively on the loss of a spouse, children, and

parents; few studies investigate personal responses to the deaths of friends, siblings, or unmarried romantic partners (including gay and lesbian partners) in later life. Life course scholars recognize the importance of *linked lives*, underscoring the value of exploring bereavement across multiple relationships. A further limitation is that studies vary widely in their definition of *dying*. Common measures to define it include one's current illness diagnosis, combinations of diagnoses, symptom expression, and functional capacity (George, 2002). Finally, although most conceptual models of the dying process and bereavement are dynamic, such as the stage theory of dying (Kübler-Ross, 1969), most empirical studies still rely on single point-in-time evaluations that retrospectively recall the dying and bereavement process.

## FUTURE DIRECTIONS

In the future, research may focus increasingly on positive aspects of dying, including psychological resilience in the face of loss, and the characteristics of and pathways to a good death. Important research goals include pinpointing modifiable factors of social contexts and relationships that may help ensure a smooth transition to death and bereavement. Early theories of loss proposed that persons who were not depressed following the loss of a loved one were pathological. Researchers now are documenting that the non-depressed bereaved may experience "resilience" rather than pathological "absent grief" (Bonanno, 2004).

Research on the good death also is accumulating. A *good death* is characterized as one where medical treatments minimize avoidable pain and matches patients' and family members' preferences. A good death also encompasses important social, psychological, and philosophical elements, such as accepting one's impending death and not feeling like a burden to loved ones. As norms for a good death are solidified, a fruitful line of inquiry may be the consequences for bereaved family members and health care providers when a death occurs under conditions that fail to meet the widely accepted ideal. Failure to achieve the good death may reflect enduring social and structural obstacles. Family member (or caregiver) involvement is essential to a patient's participation in hospice; few studies have explored the extent to which unmarried or childless older adults rely on hospice. Such inquiries may further reveal the ways that the experience of death reflects persistent social inequalities and diverse sociohistorical contexts.

## DEMENTIAS

*Dementia* is a broad term referring to a syndrome that involves cognitive decline that is sufficiently severe to interfere with an individual's daily functioning. Dementia may encompass a variety of symptoms, including impairment in memory, communication, or personality change, that have a variety of causes (e.g., Alzheimer's disease [AD], cerebrovascular disease, and so forth). Dementia is the behavioral and cognitive expression of an underlying disease process that is causing damage to the brain. For example, AD involves one set of specific brain alterations that lead to a dementia syndrome characterized by severe declines in memory. As AD pathology spreads throughout the brain, additional cognitive, behavioral, and emotional capacities are disrupted. This entry describes several types of dementia including their underlying brain damage, clinical presentation, prevalence, progression, and the extent to which rates of these dementias differ by ethnicity, sex, and geographic region.

Although AD is the most well-known cause of dementia, there are several other pathologies that result in similar symptoms. In general, the dementias are most distinct from one another in the early stages. However, as dementia progresses, the underlying brain damage is more severe and widespread. As a result, more severe dementia involves damage to multiple brain regions and greater impairment in multiple cognitive and behavioral functions. Thus, it is increasingly difficult to find distinctiveness among specific types of dementia as the syndrome progresses over time. An additional source of commonality across types of dementia comes from their overlap in terms of underlying pathology. For example, it is relatively common for individuals to have multiple dementia pathologies, such as both AD and cerebrovascular changes. As a result, some medical experts have advocated a shift in the conceptualization of the various forms of dementia toward the underlying neuropathology rather than the clinical expression of symptoms (Ritchie & Lovestone, 2002). With this distinction in mind, this entry will focus on both the underlying pathology and the expression of symptoms of four types of dementia in their early forms (see Table 1), when their behavioral and cognitive expression is most distinct.

| Symptom | Type of Dementia |
|---|---|
| Memory loss for recent information | AD, VD, LBD, FTD |
| Difficulty performing familiar tasks | AD |
| Difficulties with language and communication | AD, LBD, VD, FTD |
| Disorientation to time and place | AD, LBD, VD |
| Poor or decreased judgment | AD, LBD |
| Misplacing things, especially in unusual places | AD |
| Changes in mood or behavior | AD, LBD, VD, FTD |
| Changes in personality | AD, FTD |
| Difficulty following directions | AD, LBD, VD |
| Recurrent visual hallucinations | LBD |
| Loss of initiative, apathy or unwillingness to talk | AD, VD, FTD |

Note: AD, Alzheimer's disease; VD, vascular dementia; LBD, Lewy body dementia; FTD frontotemporal dementia.

***Table 1.*** *Expression of symptoms of four types of dementia in their early forms.* CENGAGE LEARNING, GALE.

## ALZHEIMER'S DISEASE

AD is the most common and most extensively researched form of dementia, and, as a result, it is treated as the prototypical dementia used to define the broader syndrome itself. Recent estimates suggest that approximately 4.5 million individuals in the United States have AD, and that by the year 2050 this number will grow to more than 13 million with the greatest growth occurring among those over the age of 85 years (Hebert, Beckett, Scherr, & Evans, 2001). The prevalence of AD increases substantially with age. AD is present in roughly 1–1.5% of those in their early 60s (Ritchie & Lovestone, 2002) and in up to 30% among those 80 to 85 years (Blennow, de Leon, & Zetterberg, 2006).

The hallmark neuropathological changes of AD include (a) plaques, which build up between nerve cells and contain deposits of protein fragments; (b) neurofibrillary tangles, which form inside the dying cells and are composed of a protein called tau; and (c) shrinkage of the brain. These changes are initially present in the medial temporal lobes, particularly the hippocampus and related structures, but eventually spread to other regions of the brain, most notably the frontal and parietal lobes. In early AD, these changes are associated with impairment in memory for recent events, names, and locations, but additional changes are observed as the syndrome progresses, including the inability to name common objects, poor judgment, problems with planning and problem-solving, and difficulty with visual-spatial functioning. AD is characterized by a gradual onset and progressive decline. AD can currently only be confirmed by neuropathological evidence (i.e., autopsy); therefore the clinical diagnosis of AD must be considered either possible or probable while the person is still living.

## VASCULAR DEMENTIA

Vascular dementia (VaD) has traditionally been regarded as the second most common form of dementia in late life. Diagnosis requires (a) presence of dementia, or severe cognitive impairment; (b) evidence of cerebrovascular disease such as a stroke; and (c) a temporal connection between the presence of cerebrovascular disease and the onset of dementia. VaD is less homogeneous in its behavioral and cognitive expression than AD because the underlying brain pathology can occur in a variety of locations due to either chronic cerebral ischemia, acute stroke (large or small vessel), or insufficient blood flow to the brain due to hypotensive episodes (O'Brien, 2006; O'Brien et al., 2003). Traditionally, VaD was thought to have a stepwise decline (as opposed to the gradual decline of AD) in which periods of relatively stable functioning were followed by abrupt decrements in function associated with a new vascular event, such as a heart attack or stroke. More recent evidence has suggested that VaD may follow a more progressive course, similar to that of AD (Pedelty & Nyenhuis, 2006). One possible explanation is the considerable overlap between AD and VaD pathology. Many individuals who were clinically diagnosed with VaD demonstrate evidence of both cerebrovascular disease and AD on autopsy, and vascular risk factors appear to place individuals at risk for both VaD and AD. Although the expression of VaD is heterogeneous, it has generally been associated with greater problems with attention, executive functioning that is necessary for tasks such as planning and problem-solving, and slower processing speed in the early stages. VaD is likely to be accompanied by depression and apathy in many cases.

## DEMENTIA WITH LEWY BODIES

Dementia with Lewy bodies (DLB) is becoming increasingly recognized clinically, and some research indicates that DLB may in fact be the second most common type of dementia, representing up to 10–15% of dementia cases (McKeith et al., 1996). DLB is a progressive form of dementia accompanied by the extrapyramidal signs of Parkinson's disease, which are associated with movement (e.g., rigidity, changes in gait, falls, and so forth). Lewy bodies, the underlying pathology, are accumulations of abnormal protein deposits within neurons located in the brain stem, limbic system, and cerebral cortex. Lewy bodies appear to disrupt dopaminergic and cholinergic systems, which play key roles in motor and cognitive functioning (Hou, Carlin, & Miller, 2004). The most prominent clinical symptoms are parkinsonism, fluctuating cognition, and visual hallucinations. Problems with executive functioning and visual-spatial functioning have also been observed in DLB, but memory is relatively spared when compared with AD. DLB has a progression rate similar to that of AD, but may be associated with greater impairment in activities of daily living and greater mortality risk when compared to AD.

## FRONTOTEMPORAL DEMENTIA

Frontotemporal dementia (FTD) is a broad class of dementias characterized by atrophy of the frontal and anterior temporal lobes. These dementias present clinically in several different forms including prominent personality changes or progressive changes in language depending on the region of the brain that is most affected. The frontal variant FTD is characterized by noticeable personality changes, particularly impulsive, disinhibited behavior or apathy and problems with executive functioning. In comparison to AD, memory is relatively preserved. FTD has a gradual and relatively early onset (often younger than 65 years) and is considered to be progressive. Primary progressive aphasia and semantic dementia are related syndromes that fall under

the same general category of dementias associated with frontotemporal lobar degeneration, but which differ in that they primarily affect language and communication skills (Neary et al., 2005; Hou et al., 2004).

## RATES OF DEMENTIA BY ETHNICITY, SEX, AND GEOGRAPHIC REGION

The results from research concerning dementia prevalence rates by ethnicity, sex, and global region has been somewhat mixed and additional research is needed to clarify (a) the extent to which the prevalence of dementia varies as a function of these characteristics, and (b) what factors explain any differences that might exist. Highlighted below are several trends observed in the literature, but the reader is advised to consider these to be provisional findings pending additional research. The vast majority of this research has focused on either dementia in general (not specific to type), AD, and, to a lesser extent, VaD. Very little research has addressed prevalence differences in DLB and FTD along these dimensions.

**Ethnicity and Dementia Prevalence** Research suggests that in the United States, African Americans have higher rates of dementia than European Americans (Froehlich, Bogardus, Jr., & Inouye, 2001) although some studies have not found significant differences (Fillenbaum et al., 1998). In relation to specific dementia types, results have been mixed, but some studies suggest that African Americans have AD incidence rates twice those found for European Americans (Evans et al., 2003; Tang et al., 2001). VaD may be more common than AD among African Americans (Froehlich et al., 2001) and this finding has been attributed to high rates of stroke, diabetes, and hypertension among African Americans. However, although there may be differences between ethnic groups in terms of the prevalence of dementia, it is not yet clear whether these reflect true differences in the prevalence of dementia or whether these differences reflect problems with the methods used to detect and diagnose dementia in minority samples. For example, considerable research has documented a relatively high rate of false positives among minority elders, particularly in Hispanic and African-American populations (Fillenbaum, Heyman, Williams, Prosnitz, & Burchett, 1990). In other words, some of the cognitive tests used to identify cognitive impairment (the core feature of dementia) may misclassify some minority elders, potentially leading to overdiagnosis of dementia in these populations.

**Gender Differences in Dementia** Current research suggests that women have a greater prevalence of dementia in general and AD in particular (Baum, 2005). However, because age is the strongest risk factor for dementia and AD, the greater prevalence of dementia may be partially attributable to well-established differences in survival and longevity between men and women. In fact, one comprehensive review of incident dementia research reported minimal differences between men and women. Women had slightly greater risk for AD in the oldest age groups, but men had greater risk for VaD in younger age groups (Jorm & Jolley, 1998). Still other research has shown that gender is not associated with age of onset in AD, incidence of AD or dementia, or risk for developing dementia (Edland, Rocca, Peterson, Cha, & Kokmen, 2002). These conflicting findings point to the need for more research addressing gender differences in dementia, particularly in relation to incidence, and the genetic and environmental factors that contribute to the development of dementia in men and women.

**Cross-national Comparisons of Dementia Prevalence** In addition to differences by race and gender within countries, additional research has examined differences in the rates of dementia across countries and regions of the world. Over the years dementia research on a global scale has found differences in prevalence by country, region, and ethnicity, but research has not progressed sufficiently to provide stable estimates for all regions of the world. An expert panel convened in 2005 to review all available epidemiological evidence concerning prevalence of dementia on a global scale (Ferri et al., 2005). Using World Health Organization (WHO) regions, they determined that outside of North America, Western Europe, and certain western Pacific countries (especially Japan and Australia), there were not sufficient data to estimate the prevalence of dementia with confidence. Using available data, they estimated that developed nations have higher age-adjusted prevalence rates of dementia than developing nations. The lowest rates of dementia were in African and Southeast Asia. Western Pacific, Latin American, and eastern European countries had higher rates than Africa and Southeast Asia, but lower than Western Europe and North American countries.

Results concerning disparities in prevalence of specific types of dementia throughout the world have been even less clear. Throughout the 1980s and 1990s, most studies showed a preponderance of VaD cases over AD cases in Asian countries (Shibayama, Kasahara, & Kobayashi, 1986; Jorm, Korten, & Henderson, 1987; Larson & Imai, 1996). However, more recent research demonstrates that AD has become the most common dementia-related diagnosis in most countries around the world. In a study conducted in Japan, AD accounted for 55% of all dementia cases, whereas VaD only accounted for 26% (Yamada, Hattori, Miura, Tanabe, & Yamori, 2001). A similar study from China found rates of 55% and 37.5% for AD and VaD, respectively (Li

et al., 2007). The prevalence of AD is even higher in the United States and most of Europe, where it has been reported to account for 76.9–90% of incident dementia cases in people over the age of 65 (Ganguli, Dodge, Chen, Belle, & DeKosky, 2000). Despite the overwhelming prevalence of AD, one study examining Cree Native Americans over the age of 65 found a prevalence rate of 4.2% for all dementias, but only 0.5% for AD (Hendrie et al., 1993). In Africa the demarcations between different types of dementia have been less obvious, though one study examining an elderly Egyptian sample found that AD accounted for 53% of dementia cases (Ineichen, 2000).

Although there is some uncertainty regarding differences in the prevalence of dementia worldwide, there is even less certainty regarding why these apparent differences might occur. These differences may be due to measurement issues (definitions of dementia and the measurement tools designed to detect them) or to sociocultural differences that affect the reporting of dementia. Many of the tests used to screen for dementia may not be equally effective among different cultures, as demonstrated by high false positives found in minority samples (Gurland, Wilder, Cross, Teresi, & Barrett, 1992). Variation could also be due to properties of the screening tests used, the definition of dementia used, lack of standardization of test administration procedures, biases, and differences in literacy of studied populations (Kukull & Ganguli, 2000). Cultural style of education may also affect scores on dementia screening measures. It is nearly impossible to construct a test that is entirely culture-free. Every test that is created will reflect to some extent the culture in which it was constructed, and its questions may have slightly different meanings for people from other cultures.

Prevalence estimates for developing countries may be lower because of underreporting and lower life expectancy. Dementia could be unreported in some countries because of its stigmatization in certain cultures, and the fact that families in some developing countries may tolerate a wider range of behavior considered to be abnormal by Western standards. Moreover, some of these families may seek help from local healers rather than consult Western doctors.

Despite these challenges with cross-cultural dementia research, there is some evidence to suggest that environmental factors may contribute to legitimate differences in the prevalence of dementia. For example, a study examining elderly Japanese Americans living in Hawaii found prevalence estimates of 9.3% for dementia and 5.4% for AD, which more closely resemble those found for European-American samples as opposed to older adults living in Japan (White et al., 1996). A similar study looking at elderly Japanese adults living in Washington state found an AD prevalence of 14% in people between the ages of 85 and 89, a figure that more closely resembles those found for European-American samples than those found in Asia (Graves et al., 1996). A study comparing an elderly sample from Ibadan, Nigeria, with a matched African-American sample from Indianapolis, Indiana, found dementia rates of 2.29% and 8.24% respectively, indicating that people of African decent living in the United States have dementia rates more similar to those found for European Americans than for elders living in Africa (Ogunniyi et al., 2000). Taken together, these findings seem to suggest that environmental characteristics specific to different geographical regions may play a role in the prevalence of AD and other dementias. Collectively these results highlight the need for further research directed toward identifying these factors.

There is also some evidence suggesting that ApoE4 allele may contribute to potential genetic influences on regional dementia differences. ApoE4 is a gene carried by 20–25% of the population and is known to increase risk for developing AD. In the Nigerian study described above, no association was found between possession of the ApoE4 allele and AD, though a significant association was found for the African-American sample (Ogunniyi et al., 2000). A different study comparing American citizens of different ethnicities presents somewhat conflicting results, as authors found that the presence of the ApoE4 allele was a strong risk factor for AD in European Americans, an intermediate risk factor for Hispanic Americans, and not a risk factor for African Americans (Larson & Imai, 1996). Moreover, some have suggested that the lower incidence of AD in Japanese populations may be related to a lower prevalence of the ApoE4 allele (Jorm & Jolley, 1998). The presence of one or more ApoE4 alleles may increase vulnerability to develop AD, but research examining different populations suggests that the extent to which this occurs may function differently between different ethnic and cultural groups. These conflicting, yet intriguing, findings clearly indicate that more research is warranted on the subject of genetic factors that affect the development of AD and dementia. Future research for policy, practice, screening, and interventions should acknowledge differences in the influence of ApoE4 on different populations.

# DEMOGRAPHIC TRANSITION THEORIES

Social scientists have identified two main demographic transitions. The first or "classic" demographic transition refers to the historical declines in mortality and fertility, as witnessed from the 18th century onward in several European populations, and continuing at present in most developing countries. The end point of the first demographic transition (FDT) was supposed to be an older stationary population (i.e., a population that has an even distribution of age groups), with replacement fertility (i.e., just over two children on average), growth rates oscillating around zero (i.e., the total population size is stable), and life expectancies higher than 70 years. At this stage of the demographic transition, there is a balance between deaths and births, and thus populations would not require sustained immigration for their continuation and growth. Moreover, households in all parts of the world would converge toward the nuclear and conjugal types, composed of married couples and their offspring.

The second demographic transition (SDT), by contrast, sees no such equilibrium as the end point. Rather, a shift in values and tastes brings new developments in the form of sustained below-replacement fertility, a multitude of living arrangements other than marriage, the disconnection between marriage and procreation, and no stationary population. Under these conditions, populations would decline in size if not complemented by new migrants (i.e., "replacement migration"), and they will also be much older than envisaged in the FDT model as a result of lower fertility and additional gains in longevity. Migration streams will not be capable of stemming the aging of national populations but will merely stabilize population sizes. On the whole, the SDT brings new social challenges, including those associated with populations that have disproportionately large numbers of older persons, less stability of households, and higher levels of poverty or exclusion among certain household types (e.g., single persons of all ages, single mothers) and that are dealing with the integration of immigrants and other cultures.

## THE FIRST DEMOGRAPHIC TRANSITION

A typical description of the FDT is that it is an irreversible process of change from a demographic regime with high death rates and high birth rates to a stable regime with low birth and death rates. Moreover, such a change is considered typical for societies that move from a preindustrial to an industrialized economy.

**The Origins of the Concept** The concept of the demographic transition has a long history. In 1890 the French demographer Arsène Dumont (1849–1902) explained the onset of the European fertility decline as an indication of "social capillarity"—that is, the process whereby individuals aspire to upward social mobility. As a result, parents project this aspiration onto their children, invest in their education, and thus place a greater emphasis on the "quality" rather than the "quantity" of their offspring. A century later, economists would call this the "quantity–quality shift." The notion of a systemic demographic transition with distinct phases can be traced to two scientists: the American sociologist Warren S. Thompson (1887–1973) and the French demographer and economist Adolphe Landry (1874–1956).

Thompson developed a three-category typology of nations, based on growth rates. The first group includes populations with low growth rates that had made it through the mortality and fertility declines, and these populations would be on the way to a stationary path or even a declining one. This category comprised the northern and western European countries and the nations settled by European immigrants (e.g., the United States, Canada). The second group consisted of populations where the death rates had fallen but where fertility rates were still high—resulting in high population growth rates. This group comprised southern and eastern European populations. The third group was made up of pretransitional or "Malthusian" populations (referring to Thomas Robert Malthus [1766–1834], the influential English demographer who believed population growth would be limited by resource availability). Countries in this third group had not experienced any of these changes in birth and death rates. Thompson was often pessimistic about the final outcome of the demographic transition given the political and economic problems that such an unequal timing of the transition would produce, but he has the merit of presenting the transition as a global ongoing process.

In 1934 Landry published *La Révolution Démographique*, in which he proposed essentially the same ideas as Thompson, although he did so independently. He also predicted a stationary or declining population for those countries that are in the vanguard of the FDT but also theorized that countries that experience the transition at a later point in history would go through the transition much faster than their predecessors. Landry also provided a much more elaborate account of the reasons for the declines in mortality and fertility.

Neither Thompson nor Landry used the term *demographic transition*, however. The American demographers Frank W. Notestein (1902–1983) and Kingsley Davis (1908–1997) coined the term immediately after World War II.

**The FDT and Economic Development** A core assumption of FDT theory is that the transition follows a period

of economic development, marked by specific factors such as urbanization, industrialization, rising real incomes, and increased literacy rates. Another core assumption is that the fertility decline is triggered by a reduction in infant and childhood mortality. Empirical research generated after World War II investigated both of these assumptions by focusing on both industrialized and developing countries. The link between economic development and fertility decline became not only the subject of academic investigation but also the focus of heated political debate. Against the backdrop of a worldwide population explosion in the 1960s and 1970s, "economic developers" and "family planners" debated the primary impetus for fertility declines. The former advocated economic development as the most effective path to fertility reductions, whereas the latter argued that the availability and diffusion of modern contraceptive methods was the answer. To this day, political leaders in developing countries have adopted policies and practices consistent with the family planner model.

During the 1960s and 1970s, tremendous scientific strides were made as well. Among the most notable studies of the FDT were (a) a historical examination of population change in Europe, led by researchers at the Office of Population Research at Princeton University, and (b) the World Fertility Survey, an innovative multination survey of fertility and family formation in developing nations. Both studies amassed large amounts of data and information; analyses of these data played a critical role in reshaping theories about the FDT.

**Institutional and Cultural Factors** In the historical European investigation, or the "Princeton project," researchers reconstructed marriage patterns and marital fertility transitions in all European provinces, from Gibraltar to the Urals. A key finding of the study was that modernization across a broad range of geographic regions only very loosely followed the lines of classic transition theory. Rather, the researchers found a vast number of exceptions, including, for instance, rural areas that experienced the FDT before urban or industrial ones, or areas where fertility declines preceded (rather than resulted from) decreases in childhood mortality. Many areas in France started the control of marital fertility as early as the 18th century, a time when real incomes were declining, mortality rates were not improving, and industrialization had not yet occurred. By contrast, England, the industrial pioneer in Europe, started its marital fertility decline only around 1880—nearly a full century after its initial spell of urban and industrial growth.

Perhaps the most surprising and important finding of the study was that economic factors played a modest and inconsistent role in fertility decline and that a previously overlooked serious series of factors—cultural conditions—were a powerful influence on fertility. For example, language differences emerged as powerful barriers in the widespread acceptance of contraceptive behavior and parity-specific (or rank-specific) fertility control. Put simply, the fertility norms of one region spread or "diffused" most easily to regions that shared a native tongue.

The pace at which demographic modernization occurred also varied widely based on the level of religiosity in a given region, regardless of whether that region was largely Protestant or Catholic. Secular areas that would vote for nonreligious political parties were very often the ones that took the lead in fertility control, and this link proved to be quite robust even when the region's socioeconomic and other demographic characteristics were controlled (e.g., Lesthaeghe & Wilson, 1986). Researchers on the Princeton project also documented the importance of the nuptiality (or marriage) transition for understanding the fertility transition. Specifically, they documented how a pattern of late and nonuniversal marriage in western and northern Europe, also known as the Malthusian marriage pattern, gradually gave way to much younger ages at first marriage and to smaller proportions remaining unmarried (and thus celibate). As a result of this transition in marriage patterns, the overall fertility decline could be broken down into two components referring, respectively, to the modernization of the marriage and marital fertility regimes (see Coale, 1969).

The general conclusion of the Princeton project was that fertility changes were not wholly determined by economic conditions. Rather, a broad array of cultural, religious, and social forces shaped societal-level fertility transitions. The project's findings led the demographer Ansley J. Coale (1973) to reformulate FDT theory. Coale proposed that three preconditions must *all* be satisfied before a fertility transition can occur:

1. *The readiness condition*. The new form of behavior (i.e., adoption of contraception) must have economic advantages for the couple and their already born children.
2. *The willingness condition*. The new form of behavior must be ethically or morally acceptable and not in conflict with one's religious convictions.
3. *The ability condition*. Couples must have access to sufficiently efficient and safe means to accomplish the goal of controlling their number of offspring.

Coale's conditions are commonly referred to as the "ready, willing, and able" model. If any fewer than the three conditions are satisfied simultaneously, then the fertility transition will be delayed. Coale's model adopts a much more holistic approach than the standard FDT, as his model integrates economic and noneconomic factors

associated with readiness and willingness, respectively. He also emphasized the importance of the ability factor, which later became known as the family planning effort dimension in less developed countries (see Robinson & Ross, 2007).

A second major collection of studies sprung up around the World Fertility Surveys (WFS), conducted in the 1970s and 1980s in many developing countries. The surveys measured levels of fertility, infant and childhood mortality, and knowledge and use of contraception across many countries. The WFS went beyond these classic demographic topics and also obtained information about "intermediate fertility variables" (Bongaarts, 1978), or those factors that indirectly affect fertility, such as age at first marriage, length of time one breastfeeds, and incidence of contraceptive failures or nonuse (see the concept of "unmet need," Westoff & Ochoa, 1991). Each of these intermediate variables is related to socioeconomic and cultural indicators such as urbanization, literacy levels, gender relations and female empowerment, media penetration and exposure, religious beliefs, existence of consensual unions or polygyny, local networks, and family planning program organization characteristics.

Studies based on the WFS data revealed that many diverse paths may lead to a fertility transition and that all factors related to the "ready, willing, and able" trio were of significance. Moreover, not only individual characteristics but also those at the village or neighborhood level, along with broader patterns of social organization, mattered as significant factors in shaping the fertility and nuptiality transitions. The WFS led to the creation and implementation of the Demographic and Health Surveys, which also obtained information on health and health practices and access to contraception

Data from the Demographic and Health Surveys reveal that the vast majority of developing countries have either completed or are in the middle of their first demographic transition. As Landry predicted several decades ago, many such countries exhibited this demographic transformation faster and in a more compressed time period than did European nations. As a result, demographers have adjusted downward their projections of the size of the total world population by around the middle of the 21st century. Not all countries, however, have experienced rapid transitions. In many nations—such as Bangladesh, the Dominican Republic, Ghana, Kenya, and Peru—fertility declines stalled in mid-transition, well before reaching replacement-level fertility. Finally, in a handful of countries—mostly in West Africa and the Sahel, a border region along the Sahara Desert—the fertility transition has barely started and life expectancy remains low.

## THE SECOND DEMOGRAPHIC TRANSITION

The idea of a distinct phase in the demographic evolution in Western countries stems directly from Philippe Ariès's (1962) analysis of the history of childhood and his much later article, "Two Successive Motivations for the Declining Birth Rate in the West" (1980). In Ariès's view, the decline in fertility during the FDT was "unleashed by an enormous sentimental and financial investment in the child." Ariès referred to this as the "child-king era," and the fertility transition was carried by an altruistic investment in child quality. Yet this motivation has diminished in modern times. Within the SDT, the motivation for parenthood is adult self-realization; as such, fertility rates have declined to well below replacement rates. Ariès postulated that the altruistic element focusing on offspring has weakened, and the adult dyadic relationship has gained prominence instead. In other words, adults are more focused on themselves and their marital relationships and less focused on producing offspring.

Another major influence on SDT theory is the humanist psychologist Abraham H. Maslow's (1954) theory of changing needs. Maslow argued that as populations become wealthier and more educated, individuals shift their attention away from needs associated with survival, subsistence, security, and solidarity. Instead, they focus on individual self-realization, recognition, grassroots democracy, and expressive work and education values.

Maslow's model carries important implications for the SDT. The SDT is an overarching theory that relies on both economic and sociological reasoning to explain the fertility shifts that occurred in all Western nations beginning in the 1960s. This theory treats ideational changes as exogenous influences that contribute to human behavior—even in periods of economic stability. The SDT links cultural shifts to dynamic processes of cohort succession. That is, sweeping social and ideational change occurs when older, traditional cohorts die off and are replaced by younger cohorts who adhere to a new set of norms and behavioral expectations. Values and behaviors are mutually influential, and these mutual influences unfold over the life course.

Consistent with these broad notions, the SDT predicts that the typical demographic outcomes (such as sustained subreplacement fertility and the growth of alternative living arrangements such as cohabitation) are likely to emerge in non-Western societies when they follow in the direction of capitalist economies, with multilevel democratic institutions and greater emphasis on Maslow's "higher order needs" such as self-actualization.

The original statement of the SDT emphasized the connection between fertility trends and the shift in values

orientations in the political and ethical domains (secularism, "post-materialist" values, anti-authoritarianism, and so on). Initially certain scholars still had some doubts about whether the new values were capable of sustaining a systemic shift in the demographic regime after 1970, but van de Kaa's 1987 article clearly postulated that Europe's SDT is much more than a short-lived accident of history.

## MAJOR CONTRASTS BETWEEN THE FIRST AND THE SECOND DEMOGRAPHIC TRANSITION

Some scholars argue that the SDT is not necessarily a new regime but is instead a mere continuation of the FDT. Such a "single-transition" view obscures major differences of both a demographic and social nature. The contrasts between the FDT and SDT are listed in Table 1. One of the main differences is found in *nuptiality trends*. In the FDT, ages at first marriage declined and the proportions marrying increased. In the SDT, by contrast, marriage occurred later, and nonmarital cohabitation rates increased—especially after 1990 in central and eastern Europe. Out-of-wedlock fertility also follows the Western trend in such nations. Moreover, such patterns are now also emerging in southern Europe (Italy, Malta, Spain, and especially Portugal).

| FDT | SDT |
|---|---|
| **A. Marriage** | |
| • Rise in proportions marrying, declining age at first marriage | • Fall in proportions married, rise in age at first marriage |
| • Low or reduced cohabitation | • Rise in cohabitation (pre- & postmarital) |
| • Low divorce | • Rise in divorce, earlier divorce |
| • High remarriage | • Decline of remarriage following both divorce and widowhood |
| **B. Fertility** | |
| • Decline in marital fertility via reductions at older ages, lowering mean ages at first parenthood | • Further decline in fertility via postponement, increasing mean age at first parenthood, structural subreplacement fertility |
| • Deficient contraception, parity failures | • Efficient contraception (exceptions in specific social groups) |
| • Declining illegitimate fertility | • Rising extra-marital fertility, parenthood within cohabitation |
| • Low definitive childlessness among married couples. | • Rising definitive childlessness in unions |
| **C. Societal background** | |
| • Preoccupations with basic material needs: income, work conditions, housing, health, schooling, social security. Solidarity prime value | • Rise of "higher order" needs: individual autonomy, self-actualisation, expressive work and socialisation values, grass-roots democracy, recognition. Tolerance prime value. |
| • Rising memberships of political, civic and community oriented networks. Strengthening of social cohesion | • Disengagement from civic and community oriented networks, social capital shifts to expressive and affective types. Weakening of social cohesion. |
| • Strong normative regulation by State and Churches. First secularisation wave, political and social "pillarisation" | • Retreat of the State, second secularisation wave, sexual revolution, refusal of authority, political "depillarisation". |
| • Segregated gender roles, familistic policies, embourgeoisement. | • Rising symmetry in gender roles, female economic autonomy. |
| • Ordered life course transitions, prudent marriage and dominance of one single family model. | • Flexible life course organisation, multiple lifestyles, open future. |

***Table 1.*** *Overview of demographic and societal characteristics respectively related to the FDT and SDT (Western Europe).* CENGAGE LEARNING, GALE.

Another important contrast between the FDT and the SDT involves the background of particular societies. With the exception of the very early fertility decline in France and a few other small European regions, much of the FDT was an integral part of a development phase during which economic growth fostered material aspirations and improvements in material living conditions. The SDT, by contrast, is founded on the rise of the higher order needs. Once the basic material preoccupations are satisfied, further income growth and educational expansion jointly lead to the articulation of more existential and expressive needs. These are centered on a triad: *self-actualization* in formulating goals, *individual autonomy* in choosing means, and claiming *recognition* for their realization. These issues emerge in a variety of domains, and this is why the SDT is related to such a broad array of indicators of ideational or cultural shift.

## RECENT SDT DEVELOPMENTS

Questions about the future development of the SDT mainly pertain to its potential spread to non-Western cultures and to the sequencing of the SDT characteristics in such contexts. In the West, either all SDT traits emerged fairly simultaneously or followed a typical sequence:

1. Postponement of marriage and parenthood, leading to subreplacement fertility.
2. Rise of premarital and postmarital cohabitation.
3. The addition as well of procreation among cohabitors.

Most cross-national differences observed to date reflect differences in the sequencing of the three above patterns. Several non-Western populations have by now experienced the first pattern: Japan, South Korea, Taiwan, Hong Kong, and Singapore all have experienced postponement of marriage and parenthood and have fertility levels well below replacement as a consequence. Demographers speculate that urban China should be added to that list. In addition, premarital cohabitation has emerged in Japan. Furthermore, fertility has dipped below replacement in a number of other settings, several of them Islamic (e.g., Iran, Tunisia, Kazakhstan), others Caribbean (e.g., Puerto Rico, Cuba, Jamaica, Trinidad and Tobago, Surinam) or part of the Indian subcontinent (e.g., the state of Kerala

and several large urban areas in India). Studies have not yet documented, however, whether fertility dips in these parts of the world are associated with postponement of marriage and parenthood.

Finally, Scandinavian and western European countries that were in the vanguard of the SDT now have fertility levels that are *higher* than those in countries that transitioned later (Sobotka, in press). In the former countries, parenthood continues to be delayed until later in life, yet many couples quickly proceed to having a second child—a process scholars refer to as the "catching-up" effect. In contrast, other countries with total fertility rates that dipped below 1.5 children generally do not exhibit this same trend. Hence, researchers have observed a major bifurcation within the SDT context between populations that do and do not exhibit a catching-up effect. It is possible that cultural differences regarding gender roles, public policies aimed at establishing gender equity, and greater compatibility between domestic duties and work have helped to facilitate couples' ability to "catch up" in terms of their childbearing. Such policies are much more pronounced in the countries that were the initial SDT trendsetters, such as those in Scandinavia and western Europe. Conversely, the persistence of traditional gender roles and/or the lack of policies facilitating the work and family combination would curtail the catching-up effect and lead to much lower fertility (e.g., McDonald, 2000; Micheli, 2000; Reher, 1998; Tsuya, Bumpass, & Choe, 2000). Such questions will be at the forefront of demographers' and life course scholars' research agendas in the coming decades.

# DIABETES, ADULTHOOD AND LATER LIFE

Diabetes is a significant and growing chronic health problem in the United States (Mokdad et al., 2000, 2003) and around the world (Wild, Roglic, Green, Sicree, & King, 2004). For persons with diabetes, the body cannot make or properly use insulin, the hormone that converts foods (particularly sugars and starches) into the fuel that is needed for daily energy. There are three classifications diabetes diagnoses: Type 1, in which the body cannot make insulin, affects 5 to 10% of Americans diagnosed with diabetes (usually at younger ages); type 2, in which the body does not properly use insulin, affects 90 to 95% of Americans diagnosed with diabetes (usually in midlife and older ages); and gestational diabetes, which occurs during pregnancy, affects about 4% of allpregnant women in the United States (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2007). More recently, doctors have begun to diagnose a condition known as prediabetes in which the body is at high risk for not properly using insulin. This condition affects more than double the number of people already diagnosed with type 2 diabetes.

The cause of diabetes is unknown, although most experts agree that many factors are involved. That is, although the reason why some people develop diabetes and others do not is unclear, scientists have made great strides in recent years in identifying both biological and environmental factors that are associated with diabetes. For example, middle-age and older adults, women who had gestational diabetes, and members of certain race and ethnic groups are disproportionately represented among those diagnosed with diabetes, particularly type 2 diabetes. Similarly, diabetes rates are higher in people who are overweight, who do not exercise regularly, or who have high blood pressure or high cholesterol (Centers for Disease Control and Prevention [CDC], 2007; NIDDK, 2007). The following sections discuss trends in the prevalence and incidence of diabetes; identify causes and correlates of diabetes; describe the consequences of diabetes; and explain the differences in the onset and management of diabetes by gender, race/ethnicity, and social status.

## TRENDS IN PREVALENCE AND INCIDENCE OF DIABETES

According to researchers at the CDC (Mokdad et al., 2000, 2003), the prevalence (or total number at any point in time) of all types of diabetes in the United States has increased sharply in recent decades—from 4.9% in 1990 to 7.9% in 2001 (or more than 60% since 1990). The increases in the prevalence of diabetes have been observed in both men and women, across all age groups, in all race/ethnicity groups, and in all but five states. Reports of diabetes in men grew from 4.1% in 1990 to 6.8% in 2001 (a 66% increase), and in women from 5.6% in 1990 to 8.9% in 2001 (a 59% increase). The age groups with the greatest changes in reports of diabetes between 1990 and 2001 were adults ages 30 to 39 (from 2.1% to 4.1%, a 95% increase), 40 to 49 (from 3.6% to 6.6%, a 83% increase), and 50 to 59 (from 7.5% to 11.2%, a 49% increase). Although type 2 diabetes has been diagnosed in younger age groups, and more so in recent years, it is still most commonly diagnosed in middle-age and older adults. In fact, about 1 in 10 adults ages 40 to 59 and 1 in 5 adults ages 60 and older have diabetes, comprising the majority of all people with diabetes (NIDDK, 2007). Unfortunately, what is known about diabetes in age groups younger than 20 is currently hampered by a lack of nationally representative data needed to track changes in the risk and onset of diabetes.

The incidence (or number of new cases) of diabetes has increased in recent years as well. Using nationally representative survey data, about 603,000 cases of diabetes were newly diagnosed in 1990, more than doubling (to 1.2 million) by 2001 (NIDDK, 2007). Some 1.5 million cases of diabetes were newly diagnosed in 2005, nearly 9 in 10 (1.3 million) of those in middle-age and older adults. Despite the fact that some of the dramatic increases in the prevalence and incidence of diabetes may be due to greater awareness of the risks for diabetes from public health campaigns and, in turn, more doctor visits resulting in diagnoses, the increases in prevalence and incidence are troubling due to the serious individual and societal consequences of the disease. Government mandates, such as those described in the federal *Healthy People* reports, aim to reverse those trends and related consequences by focusing on the known causes and correlates of diabetes.

## CAUSES AND CORRELATES

As noted earlier, if a person cannot make or properly use insulin to provide needed daily energy, it is likely that the person has higher than normal levels of blood glucose, which may lead to a diagnosis of diabetes. Symptoms common to people with diabetes include increased thirst and urination, extreme tiredness, unexplained weight loss

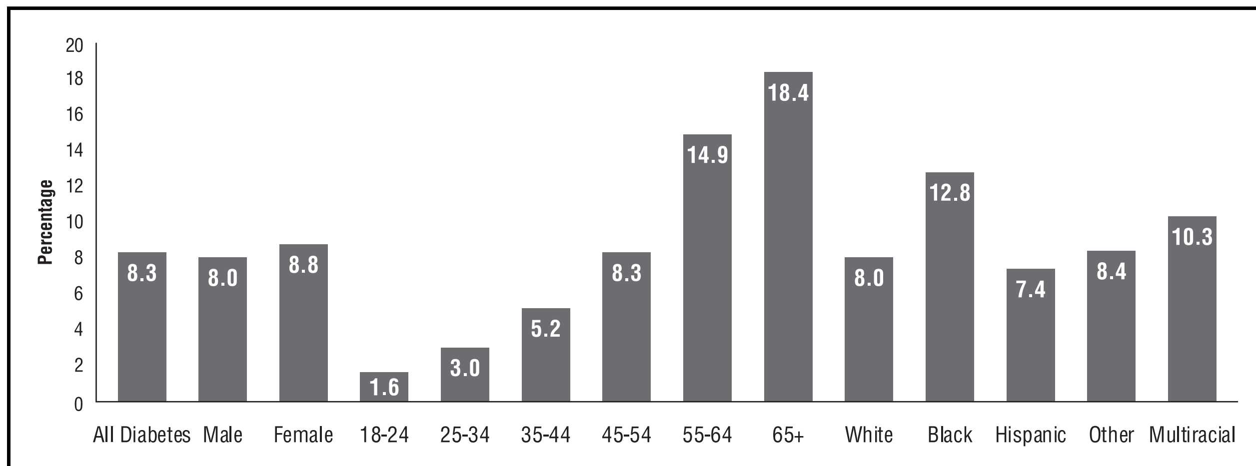

***Figure 1.*** *Diabetes prevalence in the U.S., by sex, age, and race/ethnicity, BRFSS 2006.* CENGAGE LEARNING, GALE.

or weight gain, blurred vision, frequent infections, and slow-healing wounds (NIDDK, 2007). Although the specific causes of diabetes remain a mystery, several biological and environmental factors are associated with the risk for or onset of diabetes, some nonmodifiable and some modifiable. For example, in addition to insulin problems, people with diabetes often have other clinical indicators such as higher than normal levels of blood pressure, LDL (or "bad") cholesterol, and triglycerides, as well as higher than normal waist-to-hip ratios, all indicators with both nonmodifiable and modifiable causes. The risk for diabetes also escalates with increasing age and membership in minority or non-White race/ethnic groups, both nonmodifiable factors.

Excess weight—and particularly obesity—is the modifiable risk factor most often identified with the onset and complications of diabetes. Just as the prevalence of diabetes has risen markedly in recent decades, the prevalence of obesity has also increased by more than 77% since 1990, from 11.8% in 1990 to 20.9% in 2001 (Mokdad et al., 2000, 2003). Many health care providers consider diabetes and obesity to be rising in tandem to epidemic proportions, leading to public health campaigns aimed at reversing the trends in both health problems (American Diabetes Association, 2007; CDC, 2007). Obesity, like diabetes, is disproportionately prevalent in midlife and in ethnic minority groups (Mokdad et al., 2001, 2003).

Because most of the management and consequences of diabetes are in the hands of the person living with diabetes, protective health behaviors such as weight loss and increased physical activity may be critical to good management as well as to fewer and less serious consequences. Despite the recommendations for weight loss, however, obesity is much more prevalent in people with diabetes than in those without (Mokdad et al., 2001; Wray, Blaum, Ofstedal, & Herzog, 2004). Nonetheless, a recent study documented that overweight middle-aged adults were at least 50% more likely to report they had lost 10 pounds of excess body weight if they had been diagnosed with diabetes than if they had not, suggesting that adults with diabetes understand their need to lose weight (Wray et al., 2004). In contrast, adults with diabetes continue to report lower levels of physical activity than do adults without diabetes, perhaps in part due to their higher numbers of health conditions. However, participation in other protective health behaviors may be increasing in recent years. For example, studies have shown that diabetes-related health behaviors such as daily monitoring of blood glucose, as well as getting annual appropriate physical exams, have increased between 1995 and 2001 (Okoro et al., 2004). Similarly, other general practices such as quitting smoking and getting flu and pneumonia vaccines have also increased.

## CONSEQUENCES OF DIABETES

According to NIDDK (2007), adults with diabetes are more likely than those without diabetes to have high blood pressure and other diseases and conditions associated with vascular disease, such as stroke, heart diseases, foot amputations, and vision impairments. High blood pressure is twice as common in persons with diabetes compared to persons without the disease; and up to 75% of cardiovascular disease is attributable to high blood pressure. It is not surprising then that in 2000 one in three people with diabetes reported they had also been diagnosed with cardiovascular disease. Diabetes confers a two-fold to four-fold increased risk of heart attacks and strokes in men and up to a ten-fold increased risk in premenopausal women (Engelgau et al., 2004).

***Insulin.*** *A diabetic person prepares an insulin shot.* NATIONAL GEOGRAPHIC/GETTY IMAGES.

Diabetes is also associated with limitations in physical functioning and disabilities in older adults, lower active life expectancy, and premature mortality (Wray, Alwin, McCammon, Manning, & Best, 2006). For example, age-adjusted mortality in adults with diabetes is about twice that of adults without the disease. Older adults with diabetes are also more likely to have arthritis and geriatric conditions such as incontinence, falls, and poor cognitive performance.

Diabetes killed 73,249 people in the United States in 2002, making it the sixth leading cause of death in the United States. However, that ranking may be an underestimate because diabetes is often left off death certificates as an underlying cause of death, particularly in cases in which there may be multiple causes of death (NIDDK, 2007). For instance, roughly two out of three deaths to people with diabetes are attributed to heart disease and stroke, currently the first and third leading causes of death in the United States (Miniño, Heron, Murphy, & Kochanek, 2007). An estimate of the total costs of diabetes to the United States in 2002 is $132 billion (American Diabetes Association, 2003), including both direct medical costs ($92 billion) and indirect costs from disability, work loss, and premature mortality ($40 billion), accounting for one-tenth of all health care costs in the United States.

Despite these troubling statistics, adults with diabetes can reduce their risk for serious complications by controlling their blood glucose, blood pressure, and cholesterol, as well as participating in the protective diabetes-related health behaviors such as monitoring their blood glucose and having regular foot and eye exams (American Diabetes Association, 2007). According to NIDDK (2007), good glucose control reduces the risk of eye, kidney, and nerve complications; good blood pressure control reduces risks for both heart disease and stroke, as well as eye, kidney, and nerve complications; and good cholesterol control reduces the risk of heart disease and stroke.

## DIFFERENCES BY GENDER, RACE, AND SOCIAL STATUS

The onset of diabetes differs markedly by gender, race, and social status for reasons that are not yet clear. For example, studies using nationally representative data show diabetes and its complications are found disproportionately in women as well as in African American and Hispanic American adults (Mokdad et al., 2000, 2003; Wray et al., 2006). One in every three people born in the United States in 2000—and one in every two African American, American Indian, Hispanic American, and Asian American individuals born in 2000—are projected to develop diabetes in their lifetime (CDC, 2007). Analyses of census and other population-based survey data indicate that the prevalence of diabetes will increase 225% across all ages between 2000 and 2050, a rise from 12 to 39 million, and disproportionately in members of ethnic minority groups (CDC, 2007). Reasons for that projected increase include the overall aging and ethnic diversity of the U.S. population, as well as rising rates of obesity across all ages.

Because there is currently little or no evidence that sex- or race-linked biological differences underlie differences in the prevalence of most diseases, disability, and mortality (Wray & Blaum, 2001), other factors on which males and females differ may be responsible—for example, participation in risky health behaviors (e.g., smoking, drinking, and substance abuse), personality characteristics (e.g., hostility, anger), levels of and responses to stressful situation, and social support. Many of the risky behaviors associated with diabetes and its comorbid conditions (e.g., obesity, physical inactivity, smoking) are disproportionately prevalent in older adults with diabetes, compared to their older and younger counterparts without diabetes, as well as in African American and Hispanic American adults (Wray et al., 2006).

Similarly, middle-aged and older adults with diagnosed diabetes report lower education, income, net worth, and labor force participation than do those without diabetes (Wray, Ofstedal, Langa, & Blaum, 2005; Wray et al., 2006). Many of the risk factors described above also vary widely by social status such that lower levels of schooling, income, or wealth are associated with increasing numbers of risky health behaviors (Wray, Alwin, & McCammon, 2005). Although many existing studies have indicated that these more traditional health risks explain few health and mortality inequalities in general, research on their link to disparities in diabetes in particular is sparse. Wray and colleagues (2006) documented the persistent disproportionate prevalence and incidence of diabetes in African American and Hispanic American adults in midlife and older age, even after accounting for differences in education, income, and net worth. These troubling disparities need further exploration and understanding.

The dramatically increasing rates of diabetes and its serious complications across the United States are raising major concerns with health care providers, health educators, and policy makers, as well as those who have or at risk of getting the disease. Fortunately, studies and public health campaigns stress that people can play a major role in preventing the disease or reducing its complications by adopting a lifestyle that includes eating a healthy diet, maintaining a normal weight, being physically active, not smoking, and seeing a doctor regularly.

# DISABILITY AND FUNCTIONAL LIMITATION, LATER LIFE

At some point in their lifetimes, many people living in the United States experience brief periods of difficulty

carrying out everyday activities. For a small minority, having a functional limitation or disability is a lifelong challenge. In old age, when the likelihood of disability is greatest, people follow a variety of trajectories over time, including full functioning until death, onset of limitation followed rapidly by recovery, and steadily increasing limitation.

Many measures and sources of information on disability and functional limitation exist, but analysis of data from the U.S. Census indicates that in 2000, 19.3% of the population aged 5 years and older or almost 50 million people had a limitation or disability. The figures for population aged 65 and older were 41.9% and 14 million (Freedman, Martin, & Schoeni, 2004, Table 1). The definition used was broad and included physical, sensory, and cognitive limitations; self-care and going-outside-the-home disability; and for those aged 21 to 64, disability that affected employment.

Disability and functional limitation may negatively affect individual quality of life and productivity; they are also associated with increased medical expenditures. As the members of the U.S. Baby Boom generation (those born 1946 to 1964) approach old age, policymakers are especially interested in tracking trends in disability over time at the population level and in understanding better who is at greatest risk of having disabilities and how onset can be delayed and recovery facilitated.

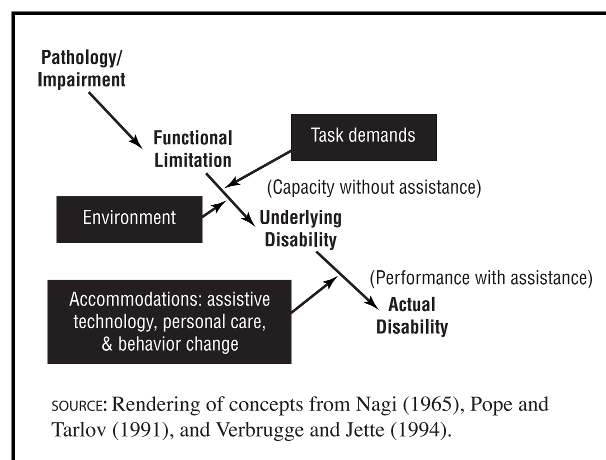

***Figure 1.*** *The disablement process.* CENGAGE LEARNING, GALE.

## INCONSISTENTLY USED CONCEPTS AND TERMS

The terms *disability* and *functional limitations* are not used consistently by researchers or policymakers in the United States or in other countries around the world. Many employ no conceptual framework at all when considering these constructs, but indeed two widely recognized models exist. The most commonly used in the United States is the so-called *Disablement Process* that draws from the work of Nagi (1965), the Institute of Medicine (Pope & Tarlov, 1991), and Verbrugge and Jette (1994). As indicated in Figure 1, the basic stages of the process are: pathology/impairment, functional limitation, and disability carrying out socially defined roles or activities in a particular environment. Although it is sometimes difficult to distinguish between pathology and impairment, theoretically the former occurs at the cellular level, and the latter at the level of an organ or systems of organs. Functional limitations, which may be physical, sensory, or cognitive, refer to the level of the organism, and disability to how the person interacts with the greater world. For example, arthritis (pathology) may make it difficult to bend the knee (impairment), thus limiting the ability of the person to stoop (functional limitation). Whether such a limitation will in turn lead to a disability regarding, say, bathing may depend on whether a person uses a shower or a bathtub. Similarly, whether arthritis of the fingers leads to a work disability may depend on the demands of the tasks involved in the job. A computer operator or piano player might have a disability, but a night watchman might not have such disability.

Note that it is not the person who is disabled or not. That is, disability is not an inherent attribute of an individual. Rather a disability arises when a person's capacity is not sufficient to meet the demands of a particular task in a specific environment. This conceptualization of disability moves beyond a simple medical perspective that conceives of disability as solely reflecting the health of an individual to a view in which the individual, the task, and the environment are all factors. Moreover, besides built environment, the term *environment* includes the social environment. For example, social role expectations may influence self-assessments of ability to carry out some routine household tasks, such as cooking and cleaning. In the past, at least, women had greater experience with such activities and perceived them as part of their roles. Expected social roles also vary by age, as indicated by the 2000 Census's limiting questioning about work disability to those aged 21 to 64.

As shown in Figure 1, besides task demands and the environment, the use of various accommodations may influence whether a person of a given health status experiences a disability. Accommodations include changes in how the task is carried out, use of assistive technology, and receipt of help or supervision from another person. For example, if one's arthritis is worsening, a person may limit trips up and down stairs each day, use a cane, or take the arm of another person. Verbrugge and Jette (1994) and a few surveys distinguish between an intrinsic

or underlying disability—an inability on one's own—and actual or residual disability—an inability even with behavior change, aids, and help.

Internationally, the World Health Organization has been at the forefront of efforts to conceptualize and measure disability since 1980. In the late 1990s, it undertook a consultative process that led to the 2002 publication of its International Classification of Functioning, Disabilities, and Health (known as ICF; World Health Organization, 2002). The ICF emphasizes positive language, focuses on participation in life situations as its ultimate outcome, and, like the Disablement Process, emphasizes the role of the environment, including physical, social, and attitudinal factors. A report by a committee of the U.S. Institute of Medicine (Field & Jette, 2007) encouraged the ICF's further refinement and operationalization with particular attention to developing a clearer distinction between specific activities of life and broader domains of participation. Nevertheless, the report called on various U.S. government statistical agencies to go ahead and adopt the ICF. In the meantime, the language of the Disablement Process framework is more commonly, although not universally or precisely, used in research and data collection in the United States.

## MEASURES

Multiple national-level surveys and the Census in the United States collect information from older people on functional limitations and disability. Typically these data take the form of self-reports, and response categories include difficulty, severity of difficulty, or inability. Some questions are phrased in terms of intrinsic disability, but others in terms of residual disability. Some surveys follow up questions about intrinsic disability with questions about use of assistive technology or personal help. One notable survey, the National Long Term Care Survey (NLTCS), imposes a requirement of chronicity, that is, it asks about disability lasting at least three months. For those who are unable to answer for themselves, proxy responses are sought by most surveys, although such responses in some cases may differ from self-reports if they were possible. Finally, whether the survey includes the institutionalized population as well as those living in the community may influence estimates. Thus, no universal method is used for seeking information about functional limitations and disability (Freedman, Martin, & Schoeni, 2004), although the core concepts are similar, as indicated in the following discussion.

**Functional Limitations** The most commonly used survey indicators of physical functional limitations in old age are the so-called Nagi (1965) measures, which were designed to assess Social Security disability applicants. Although originally used by medical personnel, today population surveys elicit self-reports of difficulty with such functions as standing for two hours, sitting for two hours, walking several blocks, lifting and carrying 10 pounds, stooping, climbing a flight of stairs, reaching over one's head, and grasping a small object. For example, since 1997 the annual National Health Interview Survey (NHIS) has asked one adult per household about nine such functions. Sometimes these measures are analyzed individually, but at other times researchers combine all the measures into a single indicator of ability or difficulty, or into indices of lower-body and upper-body functioning.

Tests in laboratory and clinical settings have indicated that some simple measures of physical performance also are predictive of the onset of disability and mortality (e.g., Guralnik, Simonsick, Ferrucci, Glynn, Berkman, Blazer et al., 1994; Onder, Penninx, Ferrucci, Fried, Guralnik, & Pahor, 2005; Rantanen, Volpato, Ferrucci, Heikkinen, Fried, & Guralnik, 2003). Accordingly, interest is growing in conducting such tests of physical functioning, rather than relying solely on self-reports, during in-person survey data collection efforts. For example, the 2002 wave of the Health and Retirement Study (HRS) included tests of lung function, grip strength, and walking speed. In the 2006 wave, tests of standing balance were added.

Regarding sensory functioning, questions about vision are often phrased in terms of difficulty reading a newspaper even when using glasses or contacts, but sometimes concentrate on blindness. Questions about hearing also range from difficulty hearing a conversation or the television to deafness. For example, the 2000 U.S. Census asked about blindness, deafness, and severe vision or hearing impairment.

A battery of questions are typically used to assess cognitive limitations, which may include difficulty with short- and long-term memory, deterioration of language function, apraxia (impaired ability to execute motor activities), agnosia (inability to recognize objects), and disturbances in executive functioning (inability to think abstractly and process information). The Mini-Mental State Examination (Folstein, Folstein, & McHugh, 1975), which was designed for clinical settings, forms the basis for the Telephone Interview Cognitive Screen (Brandt, Spencer, & Folstein, 1988), which in turn has been modified and adapted by various surveys. For example, the Asset and Health Dynamics of the Oldest Old study (AHEAD) and the HRS focus on memory and executive functioning. In particular, they use an immediate recall test involving 10 words (10 points); a delayed recall test of the same words (10 points); naming the day of the week and date (4 points); naming the object that people usually use to cut paper, the kind of prickly plant

that grows in the desert, and the U.S. president and vice president (4 points); a serial 7s test that requires subtracting 7 from 100 five times (5 points); and counting backwards from 20 for 10 consecutive numbers (2 points). Different researchers use different summary measures, but Herzog and Wallace (1997) have suggested that those scoring eight or less (out of 35) are likely severely cognitively impaired.

**Disability** Disability is the most commonly used measure of the "health" of the older population. For members of this group, being able to care for themselves and live independently in the community are typically viewed as extremely desirable. Thus, assessment of disability in U.S. surveys of the older population is most often based on questions about activities of daily living (ADLs) and instrumental activities of daily living (IADL). The ADL battery of questions was originally proposed by Katz and colleagues (Katz, Ford, Moskowitz, Jackson, & Jaffee, 1963; Katz, Downs, Cash, & Grotz, 1970) to gauge the potential for rehabilitation of older hospital patients and involves asking about and observing such personal self-care activities as bathing, dressing, using the toilet, eating, transferring from bed to chair, continence, and grooming. The IADL questions were developed by Lawton and Brody (1969) to assist health care providers and others in assessing competence in taking care of such more routine needs as using the telephone, shopping, preparing meals, housekeeping, doing laundry, taking public transportation, taking medication, and handling finances. In the case of both ADLs and IADLs, some surveys ask about any difficulty or degree of difficulty doing these activities, with some including a response of inability as the most severe category. Some questions are formulated in terms of underlying disability, but others about residual disability, that is, even with help from another person or use of assistive technology. Yet another model is provided by the NHIS, which asks about need for help with these activities.

U.S. government programs to assist those with disability use a variety of definitions of disability (Freedman, Martin, & Schoeni, 2004). The largest program, that of the Social Security Administration, focuses on those under age 65 and on work disability by which it means the "inability to engage in any substantial gainful activity by reason of a medically determinable physical or mental impairment which can be expected to result in death or can be expected to last for a continuous period of not less than 12 months." This definition focuses on the health of the individual and does not take into consideration the environmental considerations of the conceptual frameworks presented earlier. Moreover, it does not focus on a specific job and the task demands of it, but on gainful activity in general. Nor, given the purpose of determining benefit eligibility, does it address the possibility that people who are working might still have limitations associated with work (Jette & Badley, 2000).

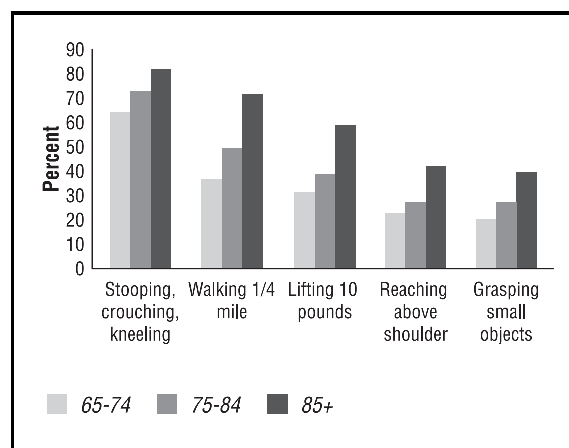

***Figure 2.*** *Percentage of community-dwelling population 65 and over with difficulty with physical functions by age group, 2004.* CENGAGE LEARNING, GALE.

Unlike the census, some surveys, such as the Current Population Survey (CPS), do ask older people about work disability. The CPS uses a definition similar to, although not exactly the same as, that of the Social Security Administration. However, as acknowledged by the survey designers, concern exists that answers to questions about work disability may represent rationalization of retirement decisions after the fact (Kreider, 1999) and, in the preretirement years, may be influenced by the availability of disability benefits (Duggan & Ingerman, 2008). Thus, for purposes of understanding the relation between health and work, such questions should be used with care.

## LEVELS OF FUNCTIONAL LIMITATIONS AND DISABILITIES

Figure 2 presents data from the 2004 Medicare Current Beneficiary Survey (MCBS) for five physical functional limitations for the 65 and older population by broad age groups. Clearly limitations increase with age, and such lower-body functions as walking one quarter mile present more difficulty than such upper-body functions as grasping small objects. Overall, almost 70% of the 65 and older population (all age groups combined) reported difficulty with stooping, crouching, and kneeling. However, as noted earlier, the way questions are worded may make a big difference in how people assess their functioning. The National Center for Health Statistics (NCHS) points out that a similar question on the NHIS that substitutes *bending* for *crouching* results in fewer than 50% reporting difficulty (NCHS, 2007a).

| | 65+ | 65–74 | 75–84 | 85+ |
|---|---|---|---|---|
| **IADLs** | | | | |
| Doing heavy housework | 30.59 | 23.12 | 33.46 | 52.95 |
| Shopping | 13.39 | 7.96 | 14.41 | 32.96 |
| Doing light housework | 11.39 | 7.43 | 12.10 | 25.78 |
| Preparing meals | 8.84 | 5.09 | 9.01 | 24.01 |
| Managing money | 6.93 | 3.52 | 7.43 | 21.16 |
| Using the telephone | 6.83 | 3.15 | 7.42 | 18.83 |
| **ADLs** | | | | |
| Walking | 23.37 | 16.53 | 26.18 | 43.20 |
| Getting in/out of bed/chairs | 11.69 | 8.12 | 13.11 | 24.66 |

***Table 1.*** *Percentage with difficulty with instrumental activities of daily living and activities of daily living by age, community-dwelling population ages 65 and over, Medicare Current Beneficiary Survey, 2004.* CENGAGE LEARNING, GALE.

Sensory and cognitive limitations also increase with age. In 2004, according to NHIS data for the community-dwelling population, 14% of those aged 65 to 74 reported trouble seeing, even with glasses or contacts, compared with 20% of those ages 75 and older (NCHS, 2007b). The proportions reporting deafness or trouble hearing without a hearing aid were 7% and 15%, respectively. Data from the HRS from the mid-1990s indicate that about 6% of the 70 and older community-dwelling population is cognitively impaired, with percentages ranging from 3% for those aged 70 to 74, to 24% for those 90 and older (Suthers, Kim, & Crimmins, 2003). The proportions for the population in institutions are much higher, roughly 50%, but do not vary much by age. Overall, about 10% of the U.S. population 70 and older is cognitively impaired.

All of these functional limitations—physical, sensory, and cognitive—may contribute to difficulties with IADLs and ADLs. Table 1, which is based on data from the 2004 MCBS, shows the proportions of the older population with specific IADL and ADL disabilities. Reports of IADL difficulty among the 65 and older group range from 7% for using the telephone to almost a third for doing heavy housework.

Less common is difficulty with ADLs, which typically identifies the older population with the greatest needs. Only about 2% of the 65 and older population report difficulty eating, but 10% report difficulty bathing or showering, and mobility within the house is a problem for almost a quarter.

The figures presented in Table 1 are for the noninstitutionalized population. Not surprisingly, a much greater proportion of the older population living in long-term care facilities report difficulties. (In the MCBS, facilities are defined as institutions having three or more beds and providing long-term care, such as nursing homes, assisted care homes, and mental health institutions.) For example, more than 90% of the 65 and older population in facilities report difficulty with bathing or showering, which some consider a sentinel ADL.

The variation by age in functional limitation and disability has been highlighted, but significant disparities by other demographic and socioeconomic characteristics also exist. Generally, women are more likely than men to experience limitations and disabilities, as are the unmarried, members of racial and ethnic minorities, the least educated, and the poorest (Freedman, Martin, & Schoeni, 2004). An exception to these patterns is hearing limitation, which is more common among men than women, perhaps reflecting occupational exposure to loud noise.

## POPULATION TRENDS OVER TIME

A central question in the study of aging is whether the extra years of life that result from improvements in survival are spent in good or bad health. Some have argued that there will be an epidemic of disease as older people are kept alive in increasingly frail states (Gruenberg, 1977), whereas others have suggested that there will be a compression of morbidity to a short period before death (Fries, 1980). A third, intermediate, perspective hypothesizes an increase in chronic disease but whose progression is slowed (Manton, 1982).

Although disability is not a pure measure of health, it has been the measure related to late-life health that has been most commonly assessed over time at the population level in the United States. So when studies based on data from the 1970s suggested increasing disability (Waidmann, Bound, & Schoenbaum, 1995), prospects for health in old age were thought to be gloomy.

Subsequently, the research and policy communities were surprised and somewhat cautious in response to the initial report of decline in late-life disability in the 1980s, which was based on NLTCS data (Freedman & Soldo, 1994; Manton, Corder, & Stallard, 1993). But an additional decade of data from the NLTCS and data from other surveys have shown a similar trend (Freedman, Martin, & Schoeni, 2002). In addition, a collaborative effort by the top researchers in the field to understand differences in survey designs and other technical issues has led to the consensus that late-life disability has indeed declined since the late 1980s (Freedman, Crimmins, Schoeni, Spillman, Aykan, Kramarow et al., 2004).

Data from the 1984 to 2006 NHIS, which of all the national surveys provides the longest time series of consistently measured annual observations, indicate that for

much of the period decline in needing help with IADLs appears to drive the decline in overall disability. Detecting changes in ADL-type disability has been more challenging, in part because of the smaller numbers involved. One group of experts, however, using all the available data sets and taking into consideration the differences in question wording, concluded that although evidence was mixed for the 1980s, there indeed was a decline in ADL-type disability for the 70 and older population beginning in the mid- to late-1990s (Freedman, Crimmins, Schoeni, Spillman, Aykan, Kramarow et al., 2004).

Among the IADLs, Spillman (2004) has found using NLTCS data that the biggest declines in disability were for managing money, shopping for groceries, and doing laundry. She suggests that the improvement in the first may be less about physical and cognitive functioning and more about the shift of the Social Security Administration to direct deposit of checks in 1987.

Time trends in functional limitations, whether physical, cognitive, or sensory, have been studied less than trends in disability (see Freedman, Martin, & Schoeni, 2002, for a review of work until that date). Data from the Survey on Income and Program Participation show declines in physical and vision limitations from 1984 to 1999 (Cutler, 2001; Freedman & Martin, 1998). Other datasets show little change in hearing limitations over the period. Analysis of more recent data suggest increases in physical functional limitations for the older population (Kramarow, Lubitz, Lentzner, & Gorina, 2007), but clearly more research is needed on these health measures.

There is some controversy about trends in late-life cognitive functioning. Freedman, Aykan, & Martin (2001) analyzed 1993 and 1998 data from the HRS (and its companion AHEAD study) and found a decline in severe cognitive impairment in the 70 and older population, but Rodgers, Ofstedal, & Herzog (2003) found no improvement after they added data from the 2000 wave to the analysis and controlled for the possibility of panel respondents retaining knowledge of the test from one wave to the next. However, analysis of NLTCS data suggests a decline in severe cognitive impairment from 1982 to 1999 (Manton, Gu, & Ukraintseva, 2005).

This discussion of trends in functional limitation and disability has focused on recent decades. However, some research on change in disability from early in the 20th century until recent years compares data on Union Army veterans of the Civil War era with contemporary data. Such comparisons are challenging given differences in sampling, measurements, and so on, but indicate declines in prevalence of physical and sensory limitations over the course of the century (Costa, 2002).

This discussion also has focused on *average* trends in functioning and disability. Only limited research has been done on demographic and socioeconomic disparities in trends. Schoeni, Freedman, & Martin (2008) have found using NHIS data that all major demographic and socioeconomic groups experienced declining disability (ADL and IADL combined) in old-age from 1982 to 2002, but the magnitude of the decrease was larger for those who had higher income, had more years of education, were married, and were younger. For ADL-type disability, there were actual increases in the prevalence of disability for those with the lowest income and those with 8 or fewer years of education (Schoeni, Martin, Andreski, & Freedman, 2005).

## EXPLANATIONS FOR THE DECLINE IN LATE-LIFE DISABILITY

Understanding why late-life disability has declined in recent decades may be helpful in extending the decline into the future and expanding it to subgroups of the population that have not yet benefited. Identifying the reasons, as well as any health costs associated with them, also may inform projections of future Medicare spending (Chernew, Goldman, Pan, & Shang, 2005). Given the plethora of possible explanations (e.g., demographic, socioeconomic, medical, and environmental), however, no single data set allows simultaneous examination of all these influences.

One socioeconomic change that has undoubtedly played a role is the dramatic increase in the educational attainment of older people in the United States over the last few decades of the 20th century (Freedman & Martin, 1999). Data from the Current Population Survey indicate that the proportion of the 65 and older population with eight or fewer years of education declined from 35% in 1985 to 13% in 2005. Over the same period the proportion with more than a high school education doubled from 19% to 38%. Freedman and Martin concluded that, depending on the specific function, from 25% to 75% of the decline in functional limitations among the 65 and older population from 1984 to 1993 could be attributed to increased education attainment. They could not specify the particular mechanisms by which more education reduces limitations but mentioned multiple possibilities, including greater access to health care throughout life, healthier behaviors, less risky occupations, and greater use of assistive devices.

Through a thorough literature review and several new analyses, Schoeni, Freedman, and Martin (2008) eliminated several possible explanations for the disability decline and highlighted several others as promising. Data from the NHIS indicate that from 1997 to 2005, respondents ages 70 and older have become less likely to report some conditions as causing their disability, namely, heart and circulatory conditions, musculoskeletal conditions, and vision problems. This pattern is

confirmed by Schoeni and colleagues' analysis of data from 1982 to 2005, as well as by Freedman and colleagues' analysis (Freedman, Schoeni, Martin, & Cornman, 2007) for the period from 1997 to 2004 for the 65 and older population. At the same time, these studies suggest that cancer, diabetes, ear conditions, lung disease, mental conditions, and conditions of the nervous system have not played a significant role in the decline in rates of disability. Although detailed time series data on medical interventions over the same period are not available, the authors note the concurrent increases in the pharmacological treatment of and surgical procedures for heart disease (e.g., beta blockers, balloon angioplasty), musculoskeletal conditions (e.g., nonsteroidal anti-inflammatories, joint replacement surgery), and vision problems (e.g., cataract surgery), which may in part explain the decline in disability.

Schoeni, Freedman, and Martin (2008) also find that increases in the use of assistive technologies, declines in poverty, declines in widowhood, as well as increases in the educational attainment of the older population have likely played a role in the disability decline. They rule out roles for changes in smoking behavior (which thus far have been small, as reported by the surviving population in old age) and changes in some aspects of population composition, namely, race/ethnicity and foreign birth. Overall, Freedman and colleagues (Freedman, Schoeni, Martin, & Cornman, 2007) find that changes in sociodemographic risk factors account for about one third and changes in chronic conditions about two thirds of the decline from 1997 to 2004.

## INDIVIDUAL DISABILITY DYNAMICS AND LIFE-COURSE PERSPECTIVES

The preceding discussion of late-life disability trends was focused on time series of the prevalence of disability, namely, the proportion of the population at any one time reporting having a disability. However, underlying these cross-sectional snapshots are many individual experiences of disability onset, progression, and recovery. Studying dynamic aspects of individual disability requires longitudinal survey data that track respondents' experiences over time. The frequency of observations is critical. Even with one-and two-year intervals between survey waves (which is typical of the best of nationally representative surveys for this purpose, such as the Longitudinal Study on Aging [LSOA] and the HRS), many transitions in disability may be missed. Based on monthly data from a small study in the New Haven, Connecticut, area (sample size: 754 people), Gill and colleagues (Gill, Hardy, & Williams, 2002) found that such intervals often underestimate recovery, as well as disability onset among those who die or who are lost to follow-up during the survey interval. That substantial recovery from disability occurs has been known for some time (e.g., Crimmins & Saito, 1993), but analysis of such monthly data indicates that it is even more common than previously thought. Hardy & Gill (2004) found using the New Haven data that more than 80% of people experiencing onset of disability in at least one of four ADLs recovered within 12 months, most of the recovery took place in the first six months, and more than half of those who recovered maintained independence for at least six months.

In addition to data demands, investigating disability dynamics involves methodological challenges, especially as one moves beyond models of just two periods. As the number of observations, starting states (disabled or not), and outcomes (disabled, not disabled, dead, lost to follow-up) grows, the possible number of trajectories multiplies. Simply summarizing these trajectories, let alone identifying common characteristics of people with similar trajectories, is daunting (Wolinsky, Armbrecht, & Wyrwich, 2000).

In their two-period models of LSOA data on physical functional limitations, ADLs, and IADLs, Crimmins and Saito (1993) found that among the community-dwelling population ages 70 and over, between 1984 and 1986, higher age and being non-White were associated with onset of limitation or disability, but generally not with recovery. Being female was associated with greater risk of onset of functional limitation, but smaller risk of developing a disability among those starting the observation period without one. It could be that those women who experienced disability were more likely to move into institutions and thus not be included in the survey. Generally, having arthritis, vision or hearing problems, or a stroke had the strongest relations with onset.

Evidence is growing that the factors associated with onset indeed are different from those associated with recovery. For example, focusing on functional limitations and using data for the 25 and over population from the Americans' Changing Lives Survey for 1986 and 1994, Zimmer and House (2003) found that income is associated with both onset and recovery, but education is related only to onset, suggesting a relatively greater role for it in the prevention of the development of functional limitation. Similarly, Melzer, Izmirlian, Leveille, and Guralnik (2001) have found, using data for a subnational sample of people aged 65 to 84 who were observed for seven years in the 1980s, that education is associated with the onset of, but not recovery from, inability to climb a flight of stairs or walk half a mile.

These results and the broader literature on the enduring influences of early-life experiences on late-life health (see, for example, Kuh & Ben-Shlomo, 2004) argue for a life-course perspective in research on late-life functioning and disability. Unfortunately, the necessary

data for such analyses are rare. The HRS has asked respondents to assess retrospectively their childhood health and socioeconomic status (SES). Using these data, Freedman and colleagues (Freedman, Martin, Schoeni, & Cornman, 2008) found that among the 75 and older population from 1995 to 2004, even after controlling for late-life factors (such as SES and health), being born in the southern United States, reporting less than excellent health as a child, and having eight or fewer years of education are associated with having a disability in late life. The influences of other early-life factors, such as disadvantaged childhood SES and mother's education level being low, are reduced after late-life factors are controlled for, suggesting that they affect late-life disability only indirectly.

Of course, as mentioned at the outset, for some small group, disability is a life-long experience. Using data from a special disability supplement to the 1994 NHIS, Verbrugge and Yang (2002) found that 9% of adults who had a disability reported onset before age 20. Moreover, a recent Institute of Medicine report (Field & Jette, 2007) noted that the survival of children and young adults from previously fatal conditions is increasing the number of people at risk for midlife disability, the development of secondary conditions (i.e., conditions that result from the disability), negative consequences of earlier treatment (e.g., for childhood cancer), and premature aging.

## FUTURE TRENDS AND RESEARCH

Will the declines in late-life disability continue? Most projections have involved either linear extrapolations of past disability trends or have focused on trends in a particular factor associated with disability in the cross-section. For example, much media attention has been given to the growth of obesity in the United States, and some researchers have modeled how a continuation of that trend might affect disability prevalence, assuming that the relation between obesity and disability is stable (Sturm, Ringel, & Andreyeva, 2004). Although this connection warrants close monitoring and obesity is indeed associated with disability, relatively few older people report that obesity causes their disabilities, in comparison with those attributing disabilities to other health conditions such as arthritis and cardiovascular disease (Freedman et al., 2007).

Educational attainment of older people, a very important covariate of late-life disability in the cross-section, can be predicted with much greater certainty, because most people complete their education relatively early in life. Although more education played an important role in the 1984 to 1993 decline in functional limitations mentioned earlier and although the increase in the educational attainment will continue into the future, Freedman and Martin (1999) have cautioned that the rate of increase will be slower. In analyses of disability decline from 1997 to 2004 (Freedman et al., 2007), education did not on balance play a role. The overall increase in educational attainment was offset by the growing disability disadvantage of those with relatively low education, perhaps a more negatively selected group over time.

Given the many influences on the disablement process and without a better overall understanding of the reasons for the recent declines in late-life disability, it is difficult to predict the future. New data collection efforts ideally will track all the elements of the Disablement Process and will obtain frequent observations of disability status for improved analysis of individual onset and recovery. Such information also may facilitate the development and evaluation of interventions to prevent the onset of disability and to enhance the chances of recovery.

Also essential is refinement of the measures used to assess disability in population-based surveys. More than 40 years have passed since the design of the ADL and IADL questions still commonly used in the early 21st century. Daily activities of older people have certainly changed, especially with the revolution in information and communication technologies. Moreover, as labor force participation in late life has grown, greater attention to barriers to and facilitators of work is warranted. More generally, given their relatively low prevalence in the community-dwelling population, alternative measures to ADLs and IADLs that incorporate all levels of functioning are needed to understand and possibly prevent downward transitions. Wider use of self-reports of physical functional limitations and performance-based measures, which provide complementary information, could be helpful.

The subjective nature of self-reports of disability and functional limitations has been the focus of recent innovative research attempting to benchmark responses across different subgroups and periods. The use of so-called *anchoring vignettes* appears promising (Salomon, Tandon, & Murray, 2004). Besides being asked about their own health, respondents are presented with vignettes describing hypothetical persons and asked to rate their health or disability. Responses to the vignettes allows recalibration of own responses and thus more accurate interpersonal comparisons.

Another new approach to understanding late-life disability is the collection of time-use data. Although not measuring disability per se, such data may help identify how behavior changes to accommodate mismatches between underlying capacity, task demands, and the environment. This technique also may provide information on how the onset of or recovery from disability affects time devoted to other tasks, as well as insight into how to enhance fuller participation of older people and those who help them in activities that they enjoy and value.

## ELDER ABUSE AND NEGLECT

Elder abuse and neglect is controversial. Everyone seems to agree that it is a national, even global, problem with serious consequences for victims. There is little consensus, however, on anything else. Controversy exists on how to define elder abuse and neglect, what forms it takes, how frequently it occurs, and what characterizes victims and perpetrators.

The crux of the controversies rests in scholars' and practitioners' inability to come up with a universally accepted definition of elder abuse and neglect. Since the late 1970s this has challenged researchers and policy makers alike. The areas of contention include whether or not actions against older adults must be intentional (as opposed to passive behaviors), reflect repeated patterns of conduct (versus single incidents), involve only older adults who are vulnerable because of mental or physical impairments (as opposed to including those who are cognitively intact and able-bodied), and be perpetrated by persons who have a close or special relationship with the victim (versus strangers or casual acquaintances).

Lack of consensus has resulted in a proliferation of different elder abuse and neglect definitions in empirical studies and state laws, thus limiting the comparability of research findings and reporting statistics. The National Research Council (2003) convened a panel of experts to evaluate research on elder abuse and neglect and develop recommendations for future directions. In doing so, it proposed a standardized definition that considers the problem in relatively narrow terms. "Elder mistreatment" represents:

> (a) intentional actions that cause harm or create a serious risk of harm, whether or not harm is intended, to a vulnerable elder by caregiver or other person who stands in a trust relationship to the elder, or (b) failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm. (p. 39).

Definitions lend themselves to classifying elder abuse and neglect into forms. Again, there is no universally accepted set, although those suggested by the National Center on Elder Abuse are commonly used: physical abuse, sexual abuse, emotional abuse, financial/material exploitation, neglect, abandonment, and self-neglect. Missing from the list but frequently found in international descriptions of the problem are violation of rights, abduction, and systemic abuse (in which the failure to adequately or appropriately implement policy or services contributes to abuse occurrences).

### PROBLEM SCOPE AND REPORTING

Although it is uncertain how frequently elder abuse and neglect occurs, there is evidence that the problem is far from rare, with certain forms experienced by older adults more than other forms. Unlike the areas of child mistreatment and partner violence, no national prevalence study of elder abuse and neglect has been conducted in the United States. As a result, knowledge in this area is based on a number of geographically and often methodologically limited investigations. Together these investigations suggest a prevalence rate between 1% and 10% among surveyed older adults (Anetzberger, 2005).

A random sample study of elderly households in the metropolitan Boston area revealed physical abuse to be twice as common as verbal aggression and four times as frequent as neglect. Other forms were not considered (Pillemer & Finkelhor, 1988). These findings contrast with those from the National Elder Abuse Incidence Study (National Center on Elder Abuse, 1998) and compilations of state reports on elder abuse and neglect.

The National Incidence Study's aim was to uncover new domestic cases seen by adult protective services (APS) or community agencies serving older adults during 1996. Using a representative sample drawn from 20 counties in 15 states, researchers suggested an annual elder abuse and neglect incidence rate of 551,011. They also found that only 21% of the cases had been reported to APS, despite the existence of mandatory reporting laws in nearly every state. The largest number of cases (over one-third) represented self-neglect, that is, situations in which an older adult is unable to perform self-care tasks, such as obtaining food and shelter or managing finances, because of impairment or incapacity. Among the remainder of the cases, the most common forms (in order of frequency) were neglect, psychological abuse, exploitation, and physical abuse.

The National Center on Elder Abuse commissioned a nationwide collection of state-level APS data on elder abuse and neglect for 2004 (Teaster et al., 2006). The results revealed that APS received a total of 565,747 reports that year affecting both older and vulnerable younger adults, a nearly 20% increase from 2000. Among reports in which elder abuse was confirmed, the most common form was self-neglect (39.3%), followed by caregiver neglect (21.6%), financial exploitation (13.8%), emotional/psychological/verbal abuse (12.8%), and physical abuse (10.1%). Sexual abuse represented just 1.1% of substantiated reports.

Outside of the United States, elder abuse and neglect prevalence rates seem to fall into the 1% to 10% range as well. This is true for such countries as Canada, Great Britain, Germany, Finland, Australia, and Korea. Rates appear to be higher in only a very few locales, such as Hong Kong at 23.5% (Yan & Tang, 2001); this may result, however, from using a broader definition of elder abuse for research purposes. Moreover, for several of these countries, and in contrast to the situation in the United States, financial exploitation and verbal abuse appear to be more common than other forms.

## HISTORY OF ELDER ABUSE AND NEGLECT RECOGNITION

Elder abuse and neglect has likely existed throughout human history. Examples of it date back centuries in both historical records and literature. Much seems to reflect a perception by younger family members that older relatives are burdens. This is evident in ethnographic accounts of the Fulani of West Africa and the Inuit of North America along with documents on the treatment of elderly widows in 16th- and 17th-century Europe and colonial America, for instance. In literature, elder abuse and neglect is found in such early writings as Greek mythology, old English fairy tales, and even Shakespearean plays such as *King Lear*. Prior to the 20th century, however, nowhere is the phenomenon viewed as a social problem, public health issue, or notable criminal activity.

Recognition of elder abuse and neglect as a societal concern had antecedents in the United States during the 1950s and early 1960s. At that time attention in urban communities, such as Cleveland and Chicago, began focusing on the growing number of adults living to old age and believed to be at risk of neglect and exploitation because they were mentally impaired, lived alone, and lacked nearby or adequate family support. APS evolved from this and then expanded across the country with an infusion of funding from Title XX of the Social Security Act into social welfare agencies during the mid-1970s.

Concurrently, physicians in the United States and Great Britain began recognizing physical abuse and self-neglect among some of their elderly patients, describing the syndromes in medical journals and other publications. By the late 1970s, exploratory studies of elder abuse and neglect were underway, Congressional hearings on the problem were beginning, and states started enacting laws to provide appropriate responses.

Most experts agree that the 1980s represented the watershed decade for elder abuse and neglect recognition. By its end, media portrayals of the problem were fairly common, most states had passed elder abuse reporting laws, research had begun unraveling the dimensions and dynamics of elder abuse and neglect, the first quarterly academic journal devoted to the subject was launched—Haworth Press's *Journal of Elder Abuse & Neglect*—and many relevant national and local advocacy organizations and clearinghouses had been formed, including the National Committee for the Prevention of Elder Abuse and the Clearinghouse on Abuse and Neglect of the Elderly.

Since 1990 research on elder abuse and neglect has advanced, largely as a result of scholarly forums establishing agendas for empirical study and expanded funding opportunities, especially from the National Institute on Aging and the National Institute of Justice. These advancements have generated interest in the topic among investigators new to the field and supported research into aspects of elder abuse and neglect insufficiently studied in the past. Similarly, evaluation of programs and approaches

to detect, prevent, and treat the problem have become more common. The effort to learn what works and what does not mirrors broader movements in medicine and criminal justice for evidence-based interventions, as the field of elder abuse and neglect itself has become more medicalized and criminalized.

## THEORETICAL EXPLANATIONS AND RISK FACTORS

Various theories have been proposed to explain elder abuse and neglect. Some have been used to understand other mistreated populations. Conflict theory and feminist theory are good illustrations. Applied to an elderly population, conflict theory suggests that given imbalances in scarce resources, such as available time or money, the potential exists for someone to take advantage of an older adult. Feminist theory sees violence against women, including elderly ones, originating in structural inequities in society that foster gender disadvantage.

Only a few theories have been supported through empirical investigation, most notably psychopathology theory and symbolic interactionism. Psychopathology theory suggests that problems in psychosocial functioning of the perpetrator can promote or provoke elder abuse and neglect. With symbolic interactionism, elder abuse and neglect occurs in social relations with discrepancies between behaviors and role expectations. Caregiving can be such a relationship. Research indicates that mistreatment may result when the caregiver finds the behaviors of the elderly care recipient disturbing or disruptive, particularly when the behaviors also are regarded as deliberate or controllable. If the care recipient is noncompliant, complaining, criticizing, or aggressive, this can represent disturbing behavior for abusive caregivers.

Finally, some theories have been combined into overarching perspectives on the problem. Edward Ansello's (1996) environmental press model also provides operational protocols for interventions to address elder abuse and neglect. The model incorporates various theories to diagnose the origins of inadequate care or neglect of an impaired older adult and to recommend courses of treatment. Accordingly, inadequate care or neglect can result when the demands of the environment are either too strong or too weak for the individual to exercise his or her competence.

A complex problem such as elder abuse and neglect is unlikely to be explained by any single theory, and no theory, alone or in combination with other theories, has been rigorously tested. Instead, empirical study has focused on identifying risk factors for the problem. Risk factors may encompass characteristics of the perpetrator, victim, or environment that tend to predict the occurrence of elder abuse and neglect. Although many risk factors are suggested in the literature, only a handful have been substantiated through research (Lachs & Pillemer, 1995; National Research Council, 2003).

The most important risk factors relate to the perpetrator, and chief among them are pathology and dependency. Perpetrators, more than nonperpetrators, have been found to be alcoholic, to have a diagnosed mental illness, to have spent time in a psychiatric hospital, or to suffer emotional distress (Anetzberger, Korbin, & Austin, 1994; Reis & Nahmiash, 1998; Wolf & Pillemer, 1989). Moreover, they are more likely to be dependent on the victim with respect to finances or housing. Other suggested perpetrator risk factors have less support through research, including caregiver stress and transgenerational violence.

Important victim risk factors are functional incapacity and problem behaviors. Incapacity can be due to physical, cognitive, or mental impairment. It can render the victim dependent on the perpetrator for care, which may be inadequate or inappropriate. Functional declines also can reduce the victim's awareness of elder abuse and neglect or inhibit his or her ability to stop or escape from it. Although problem behavior was discussed previously, one source deserves special mention. Studies suggest that those who care for persons with dementia are two to three times more likely to mistreat care recipients than those caring for persons without dementia (Paveza et al., 1992). Other proposed victim risk factors, such as gender and age, have not been validated.

Shared living arrangements and social isolation are the most salient environmental risk factors. Usually the perpetrator and victim reside together, a situation that can produce tension, conflict, and even mistreatment. The typical perpetrator is either the spouse (Pillemer & Finkelhor, 1988) or adult child (National Center on Elder Abuse, 1998; Teaster et al., 2006). Furthermore, there is evidence that perpetrators and victims tend to be either socially isolated or perceive themselves that way. This can mean there are few, if any, persons around to provide support, monitor the situation, or alert authorities when things go wrong. Other proposed environmental risk factors, such as family disharmony or crowded conditions, lack substantiation.

## PROBLEM RESPONSE AND FUTURE CHALLENGES

The potential effect of elder abuse and neglect on victims can have five dimensions: physical (such as injury and pain), behavioral (including helplessness and reduced coping), psychological (such as fear and anxiety), social (including dependence and withdrawal), and financial (such as loss of property and income). Research suggests that victims are more likely than nonvictims to

experience depression, distress, and suicidal thoughts. There is evidence, too, that they tend to die younger (Lachs, Williams, O'Brien, Pillemer, & Charlson, 1998).

The serious and complex nature of the problem means that elder abuse and neglect requires intervention across disciplines, systems, and approaches (Nerenberg, 2008). It is not surprising, therefore, that many organizations and communities establish multidisciplinary teams (Anetzberger, Dayton, Miller, McGreevey, & Schimer, 2005). Although their purposes vary, most seek to resolve difficult cases, identify service gaps or system problems, and advocate for legislation and new programs. Some teams have special foci, such as financial exploitation or fatality review. Most include representation from law enforcement, APS, mental health services, aging service providers, public guardians, and domestic violence advocates.

The need for case coordination and community collaboration also stems from the large number of organizations responsible for responding to elder abuse and neglect (Brandl et al., 2007). Those with federal or state authority include APS, civil and criminal justice, long-term care ombudsman, and public health. Others with useful services for victims or perpetrators include domestic violence and sexual assault programs, health care providers, the Aging Network, humane societies, mental health and substance abuse service providers, and caregiver advocates.

There is a race underway to better understand the dynamics of elder abuse and neglect and to identify effective strategies for preventing and resolving it. The aging of the baby boomers compels action on both fronts, because there is reason to believe that the problem will explode as this generation swells the ranks of older adults. Reasons for concern reflect characteristics of the baby boomers and changes in the larger society. For example, boomer tendencies to have fewer children, higher rates of divorce, and greater geographic mobility relative to earlier cohorts of older adults may translate into fewer available family caregivers and more neglect and self-neglect. Related societal changes may exasperate the situation. These changes include declining numbers of health care providers, particularly in long-term care, and dwindling public revenues to offer economic, medical, and social service support for an extended old age.

## END OF LIFE DECISION-MAKING

Increased longevity and the aging of the baby boom generation are posing substantial challenges to society. The percent of the population aged 65 to 84 years is

projected to increase from 10.9% to 15.7% by 2050, an absolute increase of over 35 million people. Those 85 and older will increase from 1.5% (approximately 4 million) to 5% of the population, or nearly 20 million people (President's Council on Bioethics, 2005). However, while average life expectancy at age 65 has increased to over 20 years, only 11.9 of those years are expected to be healthy. After age 85, only one person in 20 is still fully mobile (Sharma, Chan, Liu, & Ginsberg, 2001).

Chronic illnesses, that is, conditions that tend to be long-lasting, persistent in their symptoms, and generally incurable, and including some cancers, organ system failure (primarily heart, lung, liver, or kidney failure), dementia, and stroke, are now the leading causes of death for Americans. Nearly all of the burden of illness and utilization of health care is now concentrated in the last few years of life when people generally live with established, serious chronic diseases and increasing disability that will eventually result in death.

The extension of the life course into very late old age, along with the increasing use of an array of high technology interventions, such as ventilators, cardiopulmonary resuscitation (CPR), and percutaneous endoscopic gastrostomy (PEG) tube for artificial nutrition, that can sustain life in many compromised states, presents individuals, families, and health care professionals with very difficult decisions about the timing and course of the dying process. For example, most people, when asked, would prefer to die at home. However, more than 80% of deaths in the United States occur in hospitals or nursing homes and often with aggressive high technology treatment (Lunney, Lynn, & Hogan, 2002). It is not always clear that these interventions are useful, wanted, or that their application always contributes to quality care or quality of life. An extensive number of end of life care studies indicate that the end of life is associated with a substantial burden of suffering among dying individuals and that there are important negative health and financial consequences that extend to family members and society (Steinhauser et al., 2000).

Traditionally, all medical treatment decisions were made by the physician, who was considered to have the necessary technical knowledge to make decisions regarding patient care. Decisions were based on the physician's assessment of the likely prognosis, risks and benefits of each option, and the physician's belief about the needs of the patient. However, underlying this paternalistic model of decision-making is the assumption that the patient may need to be protected from the facts or may not be capable of understanding the complexities involved in making medical care decisions. With the rise of consumer movements in the 1970s, this traditional model became outdated and the medical community moved toward a more patient-centered model of care focusing on shared decision-making.

## PATIENT AUTONOMY AND PATIENT-CENTERED CARE

Patient autonomy and individual choice are core values in European bioethics and important components of patient and family-centered end of life decision-making (President's Council on Bioethics, 2005). Patient-centered care focuses on the patient's right to participate in making decisions about his or her medical care, and views the physician-patient relationship as a partnership (Gillespie, Florin, & Gillam, 2004). In this shared decision-making model, each participant brings a unique experience and expertise. The patient brings important values, beliefs, personal experience, culture, concerns, and desires, which are central to the decision-making process. The physician brings clinical knowledge, information about disease, treatment, outcomes, effects, risks, and benefits. Where there is an ongoing therapeutic relationship between a patient and a physician, a space for gradually exploring and sharing information, clarifying values, and developing consensus is possible. This process has benefits for both parties, with the patient becoming more empowered and the physician being able to provide the kind of care the patient wants. Where the patient can no longer speak for themselves, the family becomes the surrogate or substitute decision-maker.

## ADVANCE DIRECTIVES AND ADVANCE CARE PLANNING

Advance directives, and more recently, a more comprehensive approach to advance directives called advance care planning (ACP), have been promoted as the most practical means of ensuring patient autonomy and shared decision-making to assist the medical care system in providing quality end of life care (Lorenz et al., 2008). Advance directives are defined as a written instructional health care directive or appointment of an agent, or a written refusal to appoint an agent or execute a directive. In some, but not all, definitions, an advance directive also includes verbal instructions. A health care agent or surrogate is defined as an individual designated in a legal document, known as a durable power of attorney for health care (DPOAHC), who is designated to make a health care decision for the individual granting them power in the event of incapacity (e.g., coma, dementia, and so forth).

Advance directives began as simple requests to avoid medical treatments that would prolong life in undesirable conditions. They have evolved into increasingly complicated, detailed, and specific legal documents containing statements of patient preferences for an assortment of

medical treatments under hypothetical medical scenarios. In the early 21st century, all 50 states and the District of Columbia have addressed end of life issues, either by legalizing some form of advance directives, do not resuscitate (DNR) orders, checklists with yes-or-no treatment decisions by the individual regarding the use of life-sustaining medical technology (e.g., ventilators), do not hospitalize (DNH) orders, or by enacting alternative provisions for end of life decisions in the form of family consent, surrogacy, or succession laws that do not require a document to be signed prior to a loss of competency. In addition, the U.S. Congress passed the Patient Self-Determination Act (PSDA) in 1990, which gives legal force to living wills, establishes the legality of the appointment of substitute (e.g., surrogate) health care decision-makers, and allows the possibility of the withdrawal of life support (Brown, 2003).

Since their inception, advance directives have been the focus of intense academic research and broad societal discussion as providers, medical ethicists, policy makers, legislators, and the public have debated important questions concerning patient autonomy, quality of life at the end of life, and the withholding or withdrawal of life-sustaining treatments. In the best case scenario, the patient, family, and physician have held ongoing, comprehensive discussions about treatment options and preferences throughout the course of advanced illness and the individual's wishes have been documented in their medical record. In the absence of such discussions, health care providers or families are left having to choose what they think their loved one would have wanted concerning treatment without guidance from the individual.

However, contrary to widely accepted assumptions about the utility of advance directives, the research conducted to date on the impact of advance directives has generally shown that, despite two decades of legislation and advocacy, advance directive completion rates (that is, the number of people who fill out an advance directive form) remain low (ranging from 15% to 25%) and that advance directives have not been very effective in reducing unwanted aggressive medical treatments or costs at the end of life (Lorenz et al., 2008). End of life care often does not involve explicit, rational decision-making but rather is influenced by a variety of external factors, including the existing medical professional standards and guidelines for care, state and federal laws and regulations, and the financing systems of the health care systems the patient is being treated in; interpersonal factors, such as the patients' age, the nature of the patient's illness, the social, religious, and cultural value systems of participants, including health care providers; and medical care factors, such as the uncertainty of prognosis and the potential benefits and risks associated with various aggressive medical interventions.

Research has shown that few patients have end of life treatment discussions, either with their physician or with their family, and that if these discussions take place, they are often not documented in the medical record. Even when advance directives are executed, physicians are frequently unaware of them, they are not easily available to providers when needed, or they are invoked late in the dying process when the patient is hopelessly ill and actively dying. Advance directives are often too general or are inapplicable to the current clinical circumstances of the patient, or they are overridden by providers and family members. Complicating this situation is the instability of patient preferences; they change over time as the patient's circumstances change and participants, including health care professionals, are often uncomfortable using the rational, analytical decision approach inherent in the legal basis of advance directive documents, particularly amidst the complex and emotion-laden end of life situations. Finally, many patients, families, and providers do not want to face these hard decisions or are not prepared to give up on therapies aimed at cure and life-prolongation in order to focus totally on comfort and the relief of suffering (Lorenz et al., 2008; Street & Ottmann, 2006).

Clinicians, researchers, and advocates have developed new comprehensive, system and community-wide models of end of life planning that build on the original goals of autonomy and self-determination, while addressing the identified shortcomings of advance directives, to better meet the needs of patients and families. Advance care planning (ACP) is defined as a comprehensive and longitudinal process of communication and shared decision-making as circumstances change between the patient, family, and health care providers to determine the patient's goals of care (e.g., from prevention to attempts at cure, or from life prolonging interventions to the use of comfort measures and a focus on the relief of suffering). Many of these ACP models have demonstrated reductions in unnecessary hospitalizations and aggressive care at the end of life, an increase in care that is more consistent with patient goals, and the reduction of caregivers' anxiety, depression, and burden in both hospital and nursing home settings (Lorenz et al., 2008).

### DIRECTIONS FOR THE FUTURE

Though encouraging, these programs have yet to be rigorously evaluated and, while highly successful in terms of completion rates for ACP documents and compliance of end of life care to documented wishes, it is not clear from the methodologically weak and limited research conducted to date which program or contextual variables are the salient features of these program's success. There are a number of ethical, programmatic, conceptual, policy, research, and methodological issues concerning advance care planning and shared decision-making that have yet to be resolved and require continued research—including why advance care planning works when it does, what components of successful programs contribute most to its success, and why it often fails.

In addition, further research is needed on the applicability and utility of advance care planning in various patient populations (such as the elderly, younger and disabled people, ethnically and culturally diverse populations, and so forth); settings (e.g., intensive care units, nursing homes, residential care facilities, or hospitals); and circumstances (of healthy individuals, those with advanced illness, and those facing the end of life). Efforts to date suggest that advance care planning holds great promise, but future efforts should be based on the most successful models. These approaches should integrate change at the community level (e.g., provider practice patterns, institutional protocols, and consumer involvement) with structures and mechanisms at the state and federal level (e.g., legal and health care facility regulations and the financing of care promoting ACP) to facilitate shared decision-making and continuity of care. More flexible legal instruments, the naming of a proxy/surrogate, an emphasis on patient/family/provider communication, and advance care planning educational and skills training tools that support the end of life decision-making process can best inform care in a clinically relevant way.

## EPIDEMIOLOGIC TRANSITION

Relatively recent historical changes in patterns of death and disability have made fundamental changes in the trajectory of the life course. During the 19th and 20th centuries, most countries experienced a substantial decline in mortality from infectious disease, with a resulting increase in deaths from chronic conditions. One theory of the historical processes of change that describes these shifts in patterns of morbidity and mortality is known as the epidemiologic transition. This theory is relevant to life-course research because of its implications for the aging process and the timing of important

life-course transitions related to schooling, marriage, reproduction, and retirement.

## CLASSICAL THEORY OF THE EPIDEMIOLOGIC TRANSITION

The epidemiologic transition as it originally was conceptualized by A. R. Omran (1971) describes recent rapid declines in mortality as a process by which pandemics of infectious diseases (such as influenza) gradually were replaced by degenerative diseases (such as arthritis) and human-made diseases (such as some cancers and heart disease) as the primary causes of morbidity and mortality. According to Omran, the theory of the epidemiologic transition is focused on "the complex change in patterns of health and disease *and* on the interactions between these patterns and their demographic, economic and sociologic determinants and consequences" (Omran, 1971, p. 510).

Omran divided the epidemiologic transition into three historical stages, which he labeled the age of pestilence and famine, the age of receding pandemics, and the age of degenerative and human-made diseases. During the age of pestilence and famine, mortality rates were high and average life expectancy at birth was 20 to 40 years. That stage lasted until the late 17th century for most Western nations and was characterized by death rates that fluctuated greatly in response to periodic occurrences of epidemics of infectious diseases. The leading causes of death included pneumonia, influenza, smallpox, tuberculosis, and other infectious diseases.

The age of receding pandemics was characterized by a sudden rapid and then steady decline in mortality caused by a decrease in epidemics of infectious disease. As those epidemics receded, death rates began to show less fluctuation and average life expectancy increased to around 50 years. The risk of death from infectious diseases was highest among infants, children, and women of reproductive age, because these groups tended to have weaker immune response and because women and infants often died during childbirth. Thus the epidemiologic transition favors the young over the old and women over men in terms of survivorship. In Western nations the mortality decline began during the late 1700s and continued until the early 19th century. Mortality declines in other countries began at various points in the 18th and 19th centuries.

During the age of degenerative and human-made diseases, mortality continued to decline, though less rapidly than it had in the prior stages, and eventually stabilized at relatively low levels toward the end of the transition. With a decrease in mortality at younger ages, more of the population survived to contract diseases associated with middle age and old age. Thus during that period the leading causes of death shifted to the chronic degenerative diseases that characterize the middle and older ages, such as heart disease, stroke, and cancer. As a result of these improvements in survivorship, life expectancy reached 70 years, with little expectation of further improvement.

## VARIATION IN TRANSITION EXPERIENCE

Although dramatic declines in mortality have occurred globally, the specific experience of the epidemiologic transition varies across nations. Omran (1982) proposed four models of epidemiologic transition to account for variations in the pattern, determinants, and consequences of the transition: the Classical (Western), Accelerated, Delayed, and Transitional Variant of Delayed models.

The Classical (Western) model describes the experience of industrialized countries such as the United States, Great Britain, and most other Western European countries. This model is characterized by a gradual transition from high to low mortality rates that accompanied the process of modernization and began as early as the 1750s. In this model, declines in mortality are attributed primarily to economic development, improvements in food supply and nutrition, and advances in sanitation and hygiene. Medical advances are thought to have played a minor role in the initial transition to low mortality, though, as noted by J. B. McKinlay and S. M. McKinlay (1977), the stabilization of mortality at low levels during the third phase is probably attributable to the development of medical technology.

In the Accelerated model, the transition to low mortality occurs in a shorter period and does not begin until the 1850s. Accordingly, the shift to degenerative and human-made diseases also occurs much more swiftly. In addition, the increases in the survival rates of children and young women that are typical of the Classical model occur over shorter periods. As in the Classical model, the primary determinants of the transition are socioeconomic improvements, along with technological and medical advances. This model describes the transition experience in Japan, Eastern Europe, and the former Soviet Union, where the process of modernization occurred in a relatively short period.

The Delayed model describes the relatively recent and incomplete transition experienced by most developing countries. In these countries substantial declines in mortality did not begin until after World War II. Mortality rates among infants, young children, and women of reproductive age did not decline as dramatically as in the Classical and Accelerated models. In fact, mortality declines have begun to recede in most countries, with life expectancy reaching only about 55 years. The

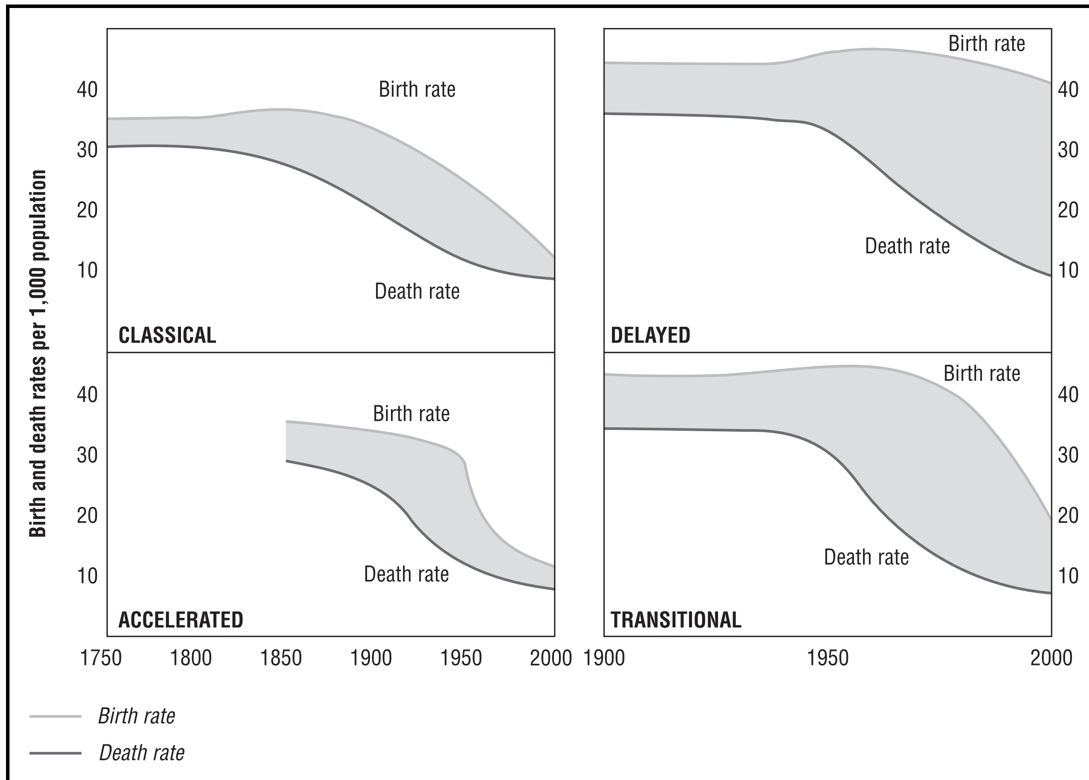

*Figure 1. Models of the epidemiologic transition.* CENGAGE LEARNING, GALE.

decreases in mortality that have occurred are due primarily to medical interventions such as vaccines and public health measures aimed at disease control. Further declines in mortality are not expected to occur until economic and social infrastructures are improved. This model typifies the experience of India and most countries in Africa and Latin America.

The Transitional Variant of the Delayed model has been proposed to describe the experience of countries that have had a delayed transition but where the mortality decline did not lessen to the same extent as in the delayed model with consistent declines in mortality. These countries have the necessary infrastructure, in terms of health-care delivery, to experience sustained declines in mortality. Countries with this transition experience include South Korea, China, and Jamaica.

## CONSEQUENCES FOR POPULATION DYNAMICS

A central proposition of epidemiologic transition theory is that mortality is the main driver of population dynamics. The dramatic decline in mortality from infectious diseases has had a significant impact on population dynamics. A fundamental characteristic of the epidemiologic transition is the shift in the age pattern of mortality. The decrease in infectious disease mortality primarily benefited children and young women, increasing their chances of surviving to middle and older ages. This shift in the age pattern of mortality has had implications for population growth, population aging, and sex differences in survival.

Before the epidemiologic transition both mortality and fertility rates were high, resulting in minimal increases in population sizes. For some time after mortality began to decline, fertility rates remained high, producing an explosion in population growth. During that period, as A. J. Coale (1974) notes, populations grew much faster than they had in earlier human history. In countries that have completed the epidemiologic transition, the declines in mortality eventually were followed by similar declines in fertility. For some countries, such as Italy and other Western European countries, fertility rates eventually fell to below replacement levels. (Women must have, on average, 2.1 children over the course of their childbearing years to maintain population levels.) This phenomenon, which is referred to as the second demographic transition, has resulted in negative population growth in those countries except when immigration has offset the effect of low fertility, as has been the case in the United States. In contrast, in countries experiencing a delayed transition, the decline in fertility has not

matched declines in mortality. These countries have experienced sustained population growth, with countries such as India and China experiencing overpopulation.

In addition to overall population growth there have been increases in the population of specific age groups. As a result of the epidemiologic transition, for the first time the human population as a whole has been growing older, as S. J. Olshansky, B. A. Carnes, and A. Désesquelles observe (2001). As mortality from epidemics of infection declined, the leading causes of death shifted to chronic diseases that emerge in middle and later adulthood. Initially, declines in infant, child, and maternal mortality make the population younger, but this improved survival ultimately leads to a drop in births rates and the beginning of population aging. For some countries, such as the United States and Japan, the population has aged dramatically in a relatively short period.

Shifts in the pattern of mortality also have resulted in changes in the sex composition of the population. Changes in cause-specific death rates that accompanied the epidemiologic transition favored women over men. Decreases in maternal mortality resulted in improved survival among women. Men, in contrast, are slightly more susceptible to cardiovascular disease and cancer, two of the leading causes of death that have emerged in the age of human-made degenerative diseases. The male mortality disadvantage is primarily a product of the less healthy life styles of males in terms of diet, risk-taking behavior, health-care utilization, and so on. Thus improvements in life expectancy that result from the epidemiologic transition benefit women more than men.

## SIGNIFICANCE FOR LIFE COURSE TRANSITIONS

The increased life span resulting from the epidemiologic transition has had significant implications for life-course transitions related to schooling, marriage, reproduction, and retirement. The timing of life events depends partly on the average number of years people can expect to live. Increased life expectancy allows individuals to delay life events and increases the chances that individuals will experience certain life events. For instance, the increase in longevity among women and children enabled women to delay childbearing and marriage and spend more of their lives obtaining an education and participating in the labor force. The increased survival of infants and children meant that women could have fewer children than in the past and be assured that most, if not all, of their children would survive to adulthood. When this was combined with increases in their own survival rates, women were able to postpone childbearing and have fewer children.

A longer life span has allowed both men and women to devote more years of their lives to schooling, which in turn may increase life expectancy, and has resulted in more time spent in the workforce. Whereas most of the population did not survive to middle and old age before the epidemiologic transition, the increased longevity that followed the transition has resulted in more of the population experiencing a relatively recent but important life-course transition: retirement. Before the epidemiologic transition, life course transitions related to older age were not experienced by most of the population. Because life expectancy has increased throughout the population, transitions related to older age, such as retirement, have come to be recognized as important stages in the life course.

## RECONCEPTUALIZING CLASSICAL EPIDEMIOLOGIC TRANSITION THEORY

In its original conceptualization, the theory of epidemiologic transition assumes that populations that have completed the transition have achieved a lower limit to mortality (i.e., the risk of death is as low as it can be) and an upper limit to longevity (i.e., the average life expectancy is as long as it can be). This is the case because traditional epidemiologic theory focuses on mortality declines that benefit the young. Because mortality rates among infants and children probably cannot be lowered further, additional increases in life expectancy necessarily will come from mortality declines at older ages. Indeed, after completing the classical epidemiologic transition, many countries experienced further declines in mortality at middle and old ages. To explain continued declines in mortality and increases in longevity, classical epidemiologic transition theory has been reconceptualized to include a fourth stage, the age of delayed degenerative disease, as described by Olshansky and A. B. Ault (1986), and a fifth stage, the age of slowing of senescence, as described by S. Horiuchi (1999).

The age of delayed degenerative diseases describes more recent developments in the epidemiologic experience of populations considered to have completed the classical epidemiologic transition. From the 1950s to the 1970s many countries experienced a decline in cardiovascular and cancer mortality. Classical epidemiologic transition theory emphasizes gains in life expectancy that result from reductions in mortality at younger ages. However, reductions in cardiovascular and cancer mortality occurred primarily among those of middle and older ages, and those declines pushed the upper limit of life expectancy.

A recent development in mortality transition, the age of slowing of senescence, describes reductions in mortality at older ages. Declines in mortality from cardiovascular disease and cancer result in more of the population

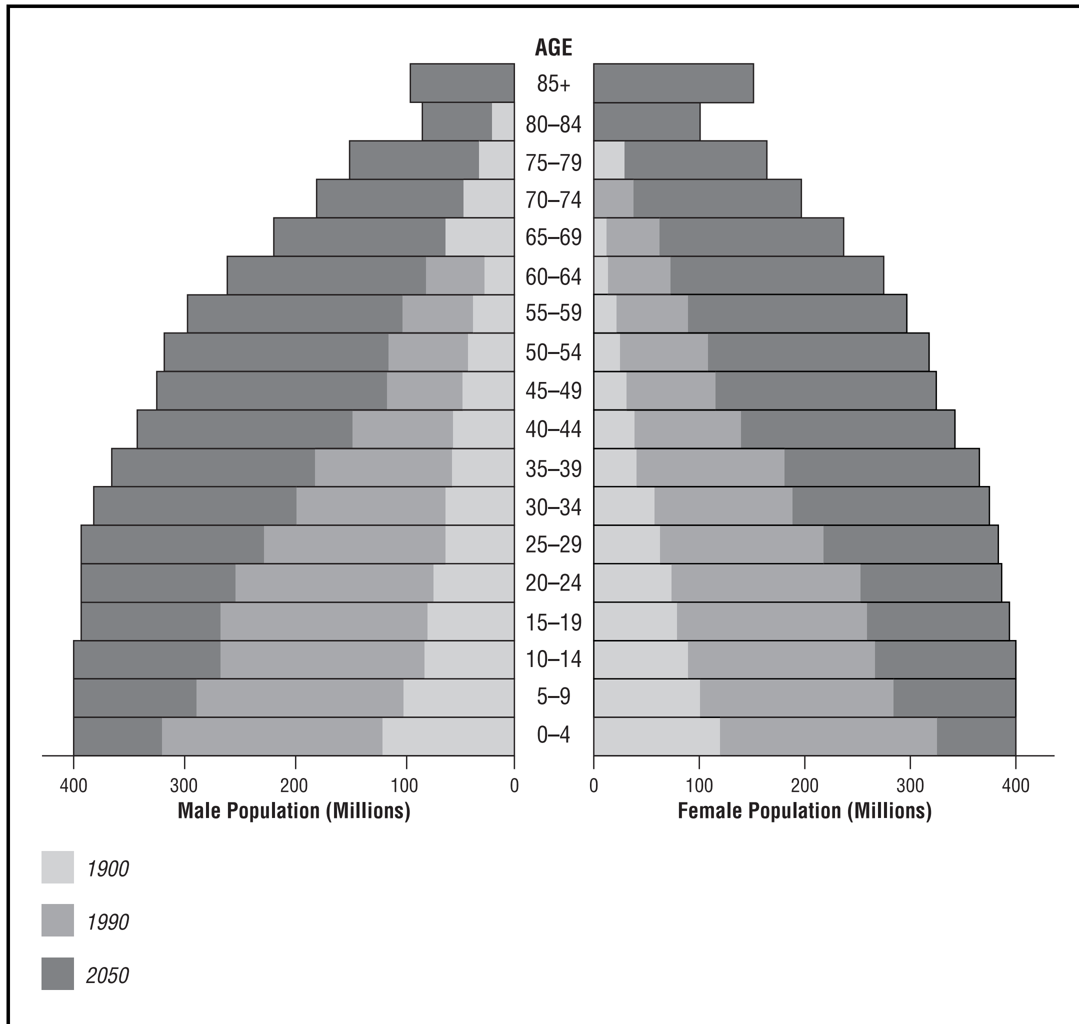

***Figure 2.*** *Since 1990 age structure has become wider and more rectilinear because relatively larger numbers of people in the growing population are surviving to older ages. By the middle of the 21st century it will be very nearly rectangular.* CENGAGE LEARNING, GALE.

surviving to an advanced age. Thus further increases in life expectancy can occur if mortality declines among the elderly. For mortality to decline among the elderly, deaths from old-age physiological frailties would have to be delayed until even later years of the life course. Although there is debate about the biological limits to human longevity, it is clear that a slowing of senescence would push the limits of longevity further, as the work of J. F. Fries (1980); V. Kannisto, J. Lauitsen, A. R. Thatcher, and J. W. Vaupel (1994); J. Oeppen and J. W. Vaupel (2002); and Olshansky et al. (2001) demonstrates.

## THE FUTURE OF THE EPIDEMIOLOGIC TRANSITION

Trends in morbidity and mortality have prompted researchers to address two major limitations of the classical epidemiologic transition theory. First, the theory assumes a unidirectional experience of declining mortality with no attention to the possibility of reversals in the transition to low mortality, as occurred in the former Soviet Union following an economic transition and the resulting health-care finance crisis. Second, the theory was formulated to describe population-level trends in morbidity and mortality. Thus substantial between-group variation in the transition experience within countries has not been explained fully.

Several trends in disease and mortality are not accounted for in classical epidemiologic transition theory. For instance, as noted by R. Barret, C. W. Kuzawa, T. McDade, and G. J. Armelagos (1998), there has been a reemergence of pandemics of infectious disease. HIV/AIDS has increased age-specific mortality in parts of Asia

and Africa as well as in some industrialized countries, such as the United States. Furthermore, there is evidence of a global reemergence of infectious diseases, such as tuberculosis, that were thought to be under control. In addition to increases in epidemics of infectious disease, epidemics of noncommunicable disease have emerged. For instance, a significant number of premature deaths in both developed and developing countries can be attributed to smoking-related mortality, as M. Ezatti and A. D. Lopez (2003) note. In addition, there is growing evidence, as B. M. Popkin and C. M. Doak (1998) observe, of the emergence of a global epidemic of obesity that has implications for population health.

These reverse transitions or countertransitions do not fit within the traditional theory because of an implicit assumption of unidirectional transition experience. Furthermore, many developing countries are experiencing a double burden of disease. In these countries mortality rates are high for both communicable and noncommunicable diseases. This burden makes it difficult for those countries to continue to develop in ways that ultimately would improve the health of their populations.

Because the epidemiologic transition focuses on population-level trends in morbidity and mortality, variation within populations tends to be overlooked. The rate of change and the underlying causes of the transition differ among subgroups of the population. For instance, although there has been a rapid and general decline in adult mortality, socioeconomic and racial inequalities have been maintained if not widened, according to R. G. Rogers (1992) and J. Vallin (1980). In addition, the long-term downward trend in U.S. infant mortality has not benefited Blacks and Whites equally. Not only has the disparity persisted, it has increased and is not expected to diminish, as noted by G. K. Singh and S. M. Yu (1995) and I. W. Eberstein and J. R. Parker (1984). Differences in transition experiences among subgroups within populations have produced significant inequalities in health and mortality. Further research is needed to understand the origins of these inequalities.

The epidemiologic transition describes the global historical transition from very high and fluctuating mortality to low and stable mortality. However, populations continue to experience changes related to morbidity and mortality. Thus, the classical epidemiologic transition theory needs to be updated continually in response to changing trends in diseases and death.

## FAMILY AND HOUSEHOLD STRUCTURE, LATER LIFE

Throughout the life course, individuals commonly turn to family members for help when faced with instrumental, emotional, financial, or other types of needs. Although many exchanges of support occur between family members who do not live together, intensive support is facilitated by family members choosing to live in the same household. The ways in which families and households are structured can provide insights into the multidimensional layering of exchanges and attachments that bind family members to one another.

At every stage of the life course, family and household structure evolves in response to changes in family membership and roles, economic resources, and needs for support and assistance. Life course events experienced by an individual, such as changes in marital status or having children, frequently result in changes in the composition of one's household. Events and experiences occurring to others, however, can also impact an individual's household composition. Because individual life trajectories are interconnected with the trajectories of others in one's network, the life course events experienced by close family members may trigger a reconfiguration of living arrangements. For example, an older woman living with her adult daughter may be thrust into a three-generation household if the daughter has a child. Similarly, a frail married woman living with her husband may become widowed and move in with her single "young-old" daughter, transforming her daughter's living situation into a two-person household. The cascading sequences of demographic, social, and economic events experienced by individuals, as well as by others who are close to them, shape family and household structure.

### THE SIGNIFICANCE OF FAMILY AND HOUSEHOLD STRUCTURE

A *household* is defined as the group of individuals who collectively occupy a housing unit (that is, the people who live together in the same home or apartment). The concepts of family and household are closely linked because the vast majority of households are composed of family groups. Only a relatively few people share living quarters with nonrelatives, especially in later life. For example, in 2000 only 3% of individuals aged 65 and over lived exclusively with nonrelatives, a category that includes boarders, roommates, and cohabiting partners. A far larger share of older people—28% in 2000—live alone in a single-person home. Aside from the 6% of older people who live in group quarters such as nursing homes, the rest of the older population, totaling 63% or roughly 22 million people aged 65 and over, share a household with family members (figures calculated based on the Public Use Microdata Sample of the 2000 U.S. Census). This entry focuses on family relationships as they overlap with household relationships among older people. Other entries in this volume report on key family relationships in later life that transcend household boundaries, including relationships with adult children, grandchildren, and siblings.

Household composition has been described as "one of the most basic and essential determinants of the well-being

of older adults" (Zimmer, 2003, p. 248), with implications for their economic, physical, and psychosocial well-being. At a minimum, households are economic units, sharing shelter as well as many other resources. Household members, especially those who are related to one another, often pool finances for food and other expenses. The economies of scale realized through sharing living quarters can result in an improved quality of life for older adults, as well as for those with whom they live.

Members of the same household support one another in a variety of noneconomic ways as well. Those who are disabled may receive assistance with activities of daily living (e.g., bathing, dressing) or instrumental activities of daily living (e.g., managing finances, taking medications), effectively forestalling the need for nursing home care. Older individuals in a multigenerational household may support younger family members by providing child care or other services. Indeed, living arrangements may be considered the most visible, though not the only, social indicator of familial embeddedness, support, and solidarity across generations.

## CONCEPTUAL ISSUES UNDERLYING HOUSEHOLD AND FAMILY STRUCTURE

One conceptual theme informing the understanding of household and family structure in later life involves the tension between independence and familial interdependence or mutual support. Just as leaving the parental home and establishing a home of one's own signals adult independence among young adults, relinquishing one's own home by moving in with family members, moving to assisted living, or entering a nursing home may be experienced by many older individuals as a signal of dependency. One of the tasks of the intergenerational family is to facilitate the efforts of different generations to achieve a balance between independence and mutual support, as played out in residential choices. Strong family solidarity may result in the obligation to support dependent family members through coresidence, even when the pull toward independence is strong.

A related theme relevant to any discussion of family and household structure is that of reciprocation, or the give and take of family relationships. Family members are in need of different types of help and support at various stages of the life course, and may experience high levels of dependency at some points but not at others. With the provision of assistance to a family member comes the expectation that help will be reciprocated—if not immediately, then in the future, and if not from the family member who was helped, then from another participant in the family "support bank" (Antonucci, 1990). These interdependencies, and the associated norm of reciprocation, imply that aging family members will make residential choices taking into account both the network members on whom they can rely for help and those members who are counting on them for support.

Perhaps the most enduring theoretical approach to conceptualizing household structure in later life assumes a rational evaluation of living arrangement options in light of preferences, resources, and the availability of alternative opportunities (Burr & Mutchler, 1992; Wolf & Soldo, 1988). Rational choice theory assumes that older people engage in an ongoing evaluation of their living circumstances with respect to their preferred goals. Alternative living arrangement opportunities are assessed in light of the resources that affect one's ability to maintain or alter one's residential setting. In practice, this evaluation likely occurs primarily at key life course transition points. Events most likely to prompt a reevaluation of household structure include a change in family circumstances such as the death of a spouse, or a change in personal resources such as the onset of disability.

Greatly complicating decisions about household structure is the fact that any given household is the result not only of the choices made by a single individual but also potentially of multiple individuals' opportunities, preferences, and constraints. Those who are married or partnered evaluate and respond not to a single set of conditions but to both partners' sets of constraints and preferences. Household decisions may reflect intergenerational decision making as well. An older couple may be capable of living as a pair and satisfied doing so, but their adult daughter may need to live with them because she is unable to make ends meet in an independent household. An older widow may prefer to live alone, but her children may feel strongly that she lacks the physical capability to do so and pressure her to live with them. Acknowledging the linked decision making that occurs throughout the family system and that shapes household composition is a challenging but critical part of understanding living arrangement patterns in later life.

**Preferences** The choices that people make about where to live and whom to live with are typically described as partially a function of preferences or "tastes" for various living arrangements (i.e., what living arrangements would provide the greatest satisfaction?). Social scientists acknowledge a general preference for independence in living arrangements. All else being equal, older people in the United States prefer to live alone or exclusively with a spouse or partner, once their children are grown. Living with adult children or other relatives, or moving to a nursing home, is considered less preferable (Shanas, 1979; Wister & Burch, 1987). Given the growing cultural diversity of the older population, this assumed preference for living alone or with a spouse only has been

called into question. Indeed, research has demonstrated considerable variability in living arrangement preferences and in perceptions of obligation to share living quarters across generations (Burr & Mutchler, 1999; Lee, Peek, & Coward, 1998). Attributes such as race, ethnicity, immigration history, and level of acculturation appear to shape these preferences and predispositions (Angel, Angel, & Himes, 1992; Burr & Mutchler, 1993b). Moreover, research in Asian and Latin American countries suggests that the cultural underpinnings of preferences for intergenerational coresidence may be breaking down. For instance, increasing numbers of seniors in Japan and China express a preference for living independently (Logan, Bian, and Bian, 1998; Takagi, Silverstein, and Crimmins, 2007).

**Availability of Alternatives** Household composition choices also reflect the availability of others with whom to live (i.e., are there family members or others with whom a shared residence could be established?). Life course trajectories and events are critical in shaping these choices. Older individuals who do not live alone most typically live with their spouses, with their adult children, or with both. As such, demographic events occurring throughout the life course, such as marriage and union formation, union dissolution, and childbearing, largely determine the availability of others with whom one could live. Individuals who never married or who divorced and did not remarry do not have a spouse with whom to live in old age, and are far more likely to live with other relatives or alone. Individuals who have several children are more likely to have at least one with whom they could live compatibly.

Availability of alternatives is also a function of processes of geographic dispersion within the family system. Adult children move away from the communities in which they grew up, leaving their aging parents behind. Many retirees relocate to the Sun Belt or other "amenity" destinations, leaving the communities in which extended family members and support networks are established. Geographic mobility results in aging adults and their extended family members often being geographically separated. When older individuals who are geographically distant from family care networks become frail, widowed, or in need of more assistance, they may move to be closer to (or live with) support networks such as adult children (Litwak & Longino, 1987). Together, the life course processes associated with marriage, marital dissolution, having children, dying, and geographic mobility that occur in the lives of older individuals and in the lives of their close family members combine to define the living arrangement options available to an individual at any given time.

**Resources** Household composition decisions are based also on the financial and other resources available to the older individual. Sufficient economic resources are necessary to live independently; these resources are strongly shaped by life course trajectories earlier in life. The accumulation of assets, such as an owned home and a private pension, is shaped by decisions made earlier in life about educational attainment, employment, and consumption. Individuals who obtain higher levels of education and who develop a stable and well-compensated work career are more likely to reach old age with resources that facilitate realizing their living arrangement preferences. In contrast, those with unstable or poorly compensated lifetime work careers may have even fewer resources in later life. Those with low levels of economic security may be unable to maintain an independent household and may have no choice other than to live with extended family members or others.

Health and disability levels also represent resources that factor into living arrangement decisions. Nominal needs for assistance associated with health declines may be readily met through services provided in an older individual's home by family members living nearby, or by paid or volunteer service organizations. Should the needs of the elderly individual be so extensive that he or she cannot be left alone or if needs for assistance occur routinely throughout the day and night, a reconfiguration of the household may be required. The highest level of disease and disability burden is likely to precipitate a move to a nursing home, especially if family members are unable or unwilling to facilitate support within the community.

**Environment** Features of the environmental context may also shape household and family structure in later life. A home that adequately met the needs of a couple for many years may no longer be suitable when they are unable to manage stairs, for example. Evolving challenges in the environment may be countered by making changes to the physical environment, such as renovations that allow a person to live on a single level. Environmental challenges may be met instead through moving to a more suitable environment, where suitability is judged both by the physical features of the living situation and by the social support available. The process of adjusting one's living circumstances to one's current physical capacity, or optimizing "person–environment fit" (Lawton, 1982), can increase independence and allow the aging individual to avoid the exacerbation of disabilities. Indeed, the biopsychosocial model of disability, one example of which is the International Classification of Functioning, Disability, and Health (ICF) put forth by the World Health Organization (WHO, 2002), points out that health conditions and functioning need not result in

limits on participation or activity if the environment is adequately supportive. Paradoxically, making social support available within the household environment is one vehicle through which participation and independence may be facilitated.

An additional line of research suggests that features of the community may enter into decisions about household composition. A shortage of housing, high housing costs, and other features of the housing environment may limit the range of housing choices available to older adults as well as to their families. If housing costs—including not only rent or mortgage but also taxes, utilities, and other related costs—are excessively high in a community, then older adults may view opportunities to live with extended family members more favorably. Indeed, younger relatives in the same high-cost community may have few alternatives to living with older relatives. One study established empirically that older individuals and couples who live in high-cost housing markets are more likely to live with other adults; the same study suggests that older single persons who live in communities with lower median rental costs for small apartments are more likely to avoid institutionalization (Mutchler and Burr, 2003). Thus environmental and cost-of-living factors that are beyond the control of families may also shape household structure in later life.

**Mutual Exchange** The formation of extended family households, especially coresidence between aging parents and their adult children, is an important alternative to living alone or solely with a spouse. The extent to which grown children can serve as resources for frail older parents, including contemplating sharing living quarters, depends not only on the needs and resources of the parents but also on the characteristics and life stage of the adult children. Some literature points specifically to the ambiguity in establishing who is being helped in intergenerational households (Choi, 2003; Speare and Avery, 1993), with most empirical literature suggesting that adult children are often the recipients of support in these households rather than the providers of care, except when the parent is very old or suffers from severe functional limitation.

Yet the exchanges occurring within the household involve many different currencies, including not only financial support but also instrumental assistance and other forms of care. For example, an older man may be able to afford living alone, yet he might not be able to keep his home in good repair unless his son lives with him. An older widow may be financially supported by her son and his wife, with whom she lives. Yet her days may be spent caring for the home and for her grandchildren, allowing her son and his wife to work long hours. The reciprocity embedded in such exchanges occurring within the intergenerational household makes it difficult to determine why the household was formed, who is benefiting the most, and how enduring the arrangement will be.

The well-being of older adults is affected in both tangible and symbolic ways by the composition of the families and households within which they are embedded. Coresident family members such as a spouse, adult children, or other relatives can be important sources of social support, instrumental help, and economic assistance. As well, the help and support that older people provide to the people with whom they live—for instance, providing child care within a three-generation household or caring for a disabled loved one—can bring satisfaction and purpose to their lives. Yet the values of independence and privacy are strong in many segments of American society, and these values tend to support the goal of smaller, more individualistic households. Ultimately, the implications of family and household structure for well-being reflect the balance of these disparate practical and symbolic elements that together shape the formation and maintenance of different kinds of households.

## TRENDS AND PATTERNS IN HOUSEHOLD AND FAMILY STRUCTURE

Perhaps the most notable trend in household and family structure in later life is the rising prevalence of living alone. Throughout the last half of the 19th century, and several decades into the 20th, fewer than 10% of all individuals aged 65 and over lived alone (see Figure 1a). By 1950, 10% of older men and 17% of older women were living in one-person households; rates rose decade by decade until 1990, when 16% of older men and more than 40% of older women were living alone. (These calculations are based on individuals living in households and exclude those living in group quarters such as nursing homes, prisons, and the like.) Historians and others debate the relative significance of demographic factors, preferences, and economic resources in shaping this increase, although it is clear that all three sets of factors contributed to this trend. The concurrent timing of the upturn in rates of living alone in the mid-20th century, and the expansion of the Social Security system, supports the contention of some that the rising ability to "purchase privacy" accounts for part of the upswing (Burch and Matthews, 1987; Kobrin, 1976). Demographic changes in marriage and childbearing, along with the well-established gap in expectation of life between men and women, are also significant (Kramarow, 1995). Indeed, among older men and women who are not currently married (most of whom are widows or widowers), the propensity to live alone is quite similar albeit at higher levels throughout the time period considered, rising to approximately 65% by 1990 (see Figure 1b).

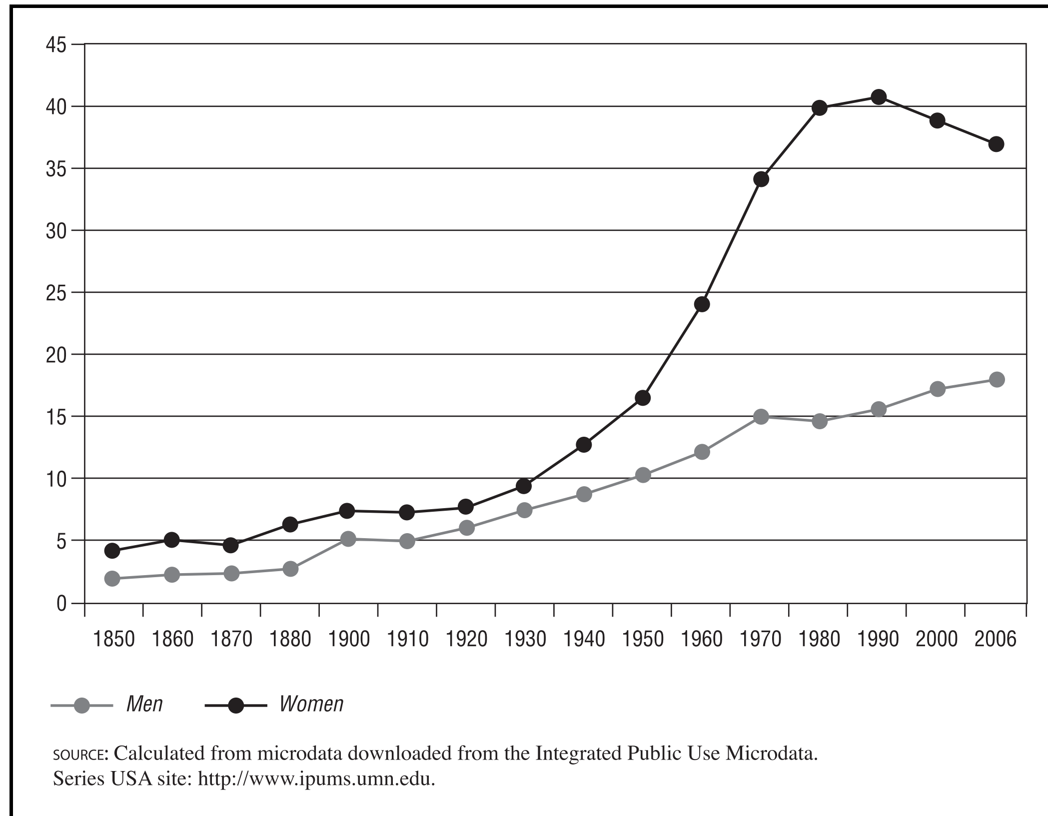

***Figure 1a.*** *Percentage living alone by year and gender, age 65+ only, living in the community.* CENGAGE LEARNING, GALE.

The sizable gender gap between rates of living alone between men and women shown in Figure 1a, a gap that is especially pronounced during the latter decades of the 20th century, is almost entirely the result of the far higher likelihood of older women to have outlived their spouses.

Some investigations by historians have suggested that intergenerational living—that is, three or more generations coresiding under the same roof—was considered desirable in the preindustrial United States, even though it was not commonly observed because demographic conditions made it unlikely that three or more generations in the same family were alive at the same time (Ruggles, 1987). Although demographic conditions in the early 21st century support a situation where three, four, and even five generations are alive at the same time in many families (Matthews and Sun, 2006), intergenerational coresidence occurs at relatively low levels in the United States. The empirical finding that most seniors do live alone or exclusively with a spouse suggests that independent living in later life is indeed viewed favorably by many seniors.

Figures presented in Table 1 show the living arrangements experienced by the population of older individuals in the United States in 2000, as well as within demographic segments of the older population. These tabulations are based on microdata from the U.S. Census of Population and Housing and reflect both composition of the household and whether or not the older individual is the household head. Household headship is assigned to the individual in whose name the home is rented or owned. In these tabulations, both the person listed as the householder and his or her spouse are considered to be ''heads of household.''

For the entire population aged 65 and over, 70% live in so-called independent households—the older person alone or with his or her spouse only. (Note that these percentages include a small number of seniors—less than one-half of 1%—who also live with their own child under the age of 18.) Another 16% is head of a household that includes other people, most typically the older person's adult child(ren) and/or grandchild(ren). Fewer than 10% are living in the household of someone else (that is, not head of household), and just 6% live in group quarters such as nursing homes, prisons, or mental institutions. Older persons not living alone or exclusively with a spouse will most typically be living with an adult child either in their own home or in the home of the child. For the sample as a whole, fewer than 2% of the seniors live in a household that

***Figure 1b.*** *Percentage living alone by year and gender, age 65+ only, not married only, living in the community.* CENGAGE LEARNING, GALE.

includes one or more siblings, and fewer than 3% live in a household including another relative, such as a cousin, a niece, or a parent (data not shown).

The pattern of household structure presented here suggests that for the older population as a whole, household headship and independent living are typical. Preferences for independent living, supported by relatively good health and adequate economic resources, commonly result in older persons living on their own in an independent household. "Pseudo-coresidence," or having children live geographically close by but not actually in the same housing unit, can facilitate independent living arrangements even when needs for assistance are high (Zimmer, 2003), as can the use of high-quality and affordable formal in-home services such as homemaker care and visiting nurse care. However, comparisons of household structure patterns across gender, age, and race and ethnic groups suggest that these experiences are not universally shared.

**Gender Differences in Household Structure** As shown in Table 1, older women are considerably more likely to live alone than are older men (36% versus 17%), whereas older men are far more likely to live with a spouse only (57% versus 32%). These patterns largely reflect longer survivorship on the part of women—that is, the greater probability for men that a spouse is available with whom to live—but support the conclusion that both men and women typically live in independent residential situations in later life. Men and women are similarly distributed across most other living arrangements, although women are considerably more likely to live in someone else's household or to live in group quarters. This higher propensity is partly reflective of greater needs for assistance on the part of older women. Older single women also typically have far fewer economic resources than do their male counterparts; indeed, widowhood can trigger a substantial drop in income even for those women who had been part of an economically secure marital unit (Holden, Burkhauser, and Feaster, 1988).

**Age Differences in Household Structure** Table 1 also shows that even among the oldest seniors, residential independence is typical. While 73% of individuals aged 65 to 79 live alone or with a spouse only, even among those aged 80 and over, more than half—64%—live independently. Individuals who are 80 and over are somewhat more likely than their younger counterparts to live in a child's household, and are less likely to head a multigenerational household. Although the oldest individuals are considerably more likely to live in group quarters than are those under age 80, even among these oldest seniors fewer than one out of six lives in a group quarters residence such as a nursing home.

[1]In the 2000 Census, individuals may report more than one race although the vast majority (98%) of the population aged 65 and over reports a single race. Race and Hispanic ethnicity are reported separately in the Census; a person reporting Hispanic ethnicity may also report any race.
[2]A small share of these households (less than one-half of one percent) include children under age 18.

SOURCE: Created by the author from the Public Use Microdata Sample (PUMS) from the 2000 U.S. Census of Population and Housing.

***Table 1.*** *Living arrangements of U.S. population aged 65 and over, by gender, age group, and race/ethnicity, 2000.* CENGAGE LEARNING, GALE.

**Race and Ethnic Differences in Household Structure** In addition to reflecting differences in resources, including financial, social, and health-based resources, comparisons by race and ethnicity reflect preferences for living arrangements that may be culturally or normatively defined. Members of some groups, such as African Americans, enter old age having experienced socially structured inequality that shape the ways in which family resources are conceptualized and drawn upon. Members of other groups, such as Asian Americans and Latinos, frequently have also experienced discrimination and reduced opportunities throughout their life course. In addition, these groups are heavily composed of first- and second-generation immigrants. Immigrants may use their family networks in distinctive ways throughout the life course (Van Hook and Glick, 2007) to facilitate adaptation to a new culture and environment. Moreover, some older immigrants migrate to the United States for the express purpose of helping and participating in the lives of their adult children and grandchildren, goals that foster intergenerational living arrangements.

Statistics reported in Table 1 support the conclusion that family and household structure take different forms in later life for members of different racial and ethnic groups. For example, living alone is experienced by 29% of non-Hispanic White seniors and 30% of non-Hispanic Black seniors, but only 13% of Asians and 19% of Latinos. Living with a spouse only is most common among Whites, both because they are more likely to have a surviving spouse (as compared to Blacks, for instance) and because they are less likely to live in multigenerational family households. Heading a multigenerational household is most common among African Americans (26%) and Latinos (24%), but least common among Whites (10%). Living in someone else's household is most common among Asians (36%). Living in group quarters is not common for any of the groups but is especially unlikely for Asians and Latinos.

Although not shown separately here, one aspect of family and household composition that is important for many seniors is providing care for a grandchild who lives with them. A considerable amount of scholarly literature has addressed the phenomenon of "skipped-generation" households—that is, households that include grandparents and grandchildren, but not the grandchild's parent(s). These types of households most frequently occur when a child's parents are unavailable or unable to care for them because of institutionalization, imprisonment, substance abuse, or death (Burton and Bengtson, 1985). As many as 2 million grandparents care for grandchildren in skipped-generation households (Simmons and Dye, 2003), and many more provide substantial levels of support and care to their grandchildren in three-generation settings. Grandparents most likely to care for a coresident grandchild are under age 65, female, and a member of a racial or ethnic minority group (especially African Americans).

## LIFE COURSE TRANSITIONS AND HOUSEHOLD COMPOSITION

The aging process frequently involves changes in resources, family networks, and other circumstances that may promote a transition in household structure. A decline in

economic resources, or the onset of frailty and emergence of new needs for assistance, may trigger a household adjustment. Some homes can be structurally modified to better align with age-related onset of disability—installing ramps so outside stairs can be avoided, for instance, or remodeling a home so all the living space is on a single floor. Homes that cannot be modified structurally, or disabilities that cannot be accommodated through structural accommodation, need not force a residential move if appropriate personal assistance is secured, in some cases. The modification of household structure—by including a familial caregiver in one's own household, for instance—is one way by which living environments may be modified to accommodate changing abilities in later life.

Adjustments in household structure may also occur based on transitions of others in the network—spouses, children, and grandchildren in particular. One of the most common life course transitions having implications for household structure is the loss of a spouse through death. The older individual whose husband or wife dies often experiences an abrupt transition into living alone. If the surviving widow or widower has the economic and health resources to live alone successfully, this living arrangement may persist for the rest of his or her life. Many older individuals, however, are not prepared to live alone upon the loss of a spouse. Some individuals experience substantial financial strain when a spouse dies and may no longer be able to afford to live alone. Disabled widow(er)s may have been reliant on the deceased spouse for assistance with activities of daily living or instrumental activities of daily living, and may need to identify a substitute source of help. If the new financial, emotional, and assistance-related challenges cannot be met within the household as it is configured following the spouse's death, residential adjustment may need to occur.

Many life course transitions having implications for household structure in later life occur not in the life of the older person, but rather in the lives of close members of his or her family network. Established support networks may be fragmented as close others die, move away, or become frail themselves. Most notably, changes in the resources or life circumstances of adult children are relevant in shaping transitions in household composition of older individuals. Observers note that many adult children continue to live at home with their parents for a prolonged period of time, reflecting both the high cost of establishing an independent household as a young adult and delayed patterns of marriage and family formation (Furstenberg, Kennedy, McLoyd, Rumbaut & Settersten, 2004). As a result, some children may still be living at home as adults move into later life. Others may return home following the breakup of a marriage, when experiencing financial difficulties, or as other challenges to independence occur. The "empty nest" commonly associated with middle age, therefore, extends for some individuals well into later life and may have a recurring quality as adult children come and go. These movements of children and grandchildren in and out of the older household may be experienced as a destabilizing influence; for some families, however, such occurrences give older individuals an important productive role, can provide some financial assistance as resources are shared, and can provide opportunities for reciprocal intergenerational exchange of support.

## IMPACTS ON WELL-BEING

Household structure may shape economic well-being in later life either positively or negatively. Through the pooling of resources and the economies of scale facilitated by a shared residence, older persons may experience a more economically secure lifestyle by living with others than they could achieve on their own. Economic benefits may not necessarily occur, however. As noted previously, many intergenerational households are formed because of economic needs for assistance on the part of the younger generation. Older parents who have the resources to support themselves adequately while living alone may experience economic challenges when sharing a home with other family members, if those household additions do not contribute substantially to the household economy. One example in which this situation may be especially challenging is when grandparents take on responsibility for a grandchild in a skipped-generation household. A grandparent who was getting by economically on his or her own may be unable to cover the many financial costs associated with caring for a dependent child.

Emotional well-being may be affected by household structure as well. Some transitions—for example, transitioning to a one-person household or relinquishing one's own home to move in with a grown child—may be experienced as stressful and require a period of adjustment. Loss of a spouse is widely acknowledged to be a stressful event, often requiring significant role adjustment and potentially leading to short- or long-term depression (Carr et al., 2000); the associated household transition corresponding to the death of a spouse may be a contributing factor in this response.

Household composition may also be related to health outcomes in some cases. For example, researchers determined in a prospective study that older women who live alone are less likely to experience functional decline (Sarwari, Fredman, Langenberg, and Magaziner, 1998). The authors speculate that drawing on the social and emotional resources needed to live alone successfully may promote longevity. Other research has suggested that women who live alone may have greater longevity than those who live with someone other than a spouse

(Davis, Moritz, Newhaus, Barclay, & Gee, 1997). Definitive conclusions regarding health implications of household structure are elusive, given the reciprocal causal pathways linking health outcomes and living arrangement decisions.

## FAMILY AND HOUSEHOLD STRUCTURE IN COMING DECADES

Family and household structures among older adults are likely to be shaped in the future by processes similar to those that have been significant in the past. Demographic influences relating to marriage, childbearing, and other close family relationships will continue to determine the availability of family members who may be sources of support and coresidence opportunities for older individuals, and who, in turn, may require assistance and support from the older individual. Financial and health-related resources will continue to shape evaluations of when it is no longer possible to live independently. Preferences will continue to drive the way that older individuals and their families evaluate options for household structure that will be most appropriate at each stage of life. Because the composition of the older population continues to change, however, the resources, family relationships, and preferences of younger cohorts are different from those characterizing the elderly population of the early 21st century. As one elderly cohort is replaced by another, past patterns of aging are frequently inaccurate predictors of behaviors that may be typical in the future. Changed outlines of family and household structure are likely to result from this process of cohort succession.

Compared to the cohorts of those 65-plus, the middle-aged cohorts of the early 21st century will enter later life having experienced later marriage, more marital disruption, fewer children, and greater acceptance of nonmarital sexual relationships, including cohabitation. While fewer may be living with a spouse as a result of these marital patterns, more may share a household with a cohabiting partner if past living arrangement patterns are carried into later life. More of the older population in coming years will have remained childless, and most will have had smaller families than did their parents. As a result, more may live alone, and fewer will share a household with a child. At the beginning of the 21st century, other relatives, such as siblings, shared households only rarely. However, because many members of the baby boom cohort have more siblings than children, the possibility that conventional forms of household composition may adapt to accommodate changing demographic realities cannot be ruled out.

The resources of the cohorts who will be entering later life in the first few decades of the 21st century are also likely to be distinctive. Estimates suggest that baby boomers, on average, are healthier and better prepared financially for retirement than their parents were (Greenblatt, 2007). Better health and lower levels of disability may result in fewer needs for assistance on the part of incoming cohorts of seniors; if so, residential independence will be more likely for many. Moreover, if they reach later life with better financial security, they may be better able than the older cohorts of the early 21st century to realize their household structure goals. Some evidence suggests, however, that baby boomers are less likely to own a home at midlife than were same-age people a generation earlier. Inasmuch as an owned home is the most significant asset held by most older people, this may reflect a gap in economic security among seniors in the future that could have implications for household structure.

Emerging options for receiving assistance and securing independence may reshape household composition in coming years. It is likely that in the future a wider range of in-home services will be available; if these services are provided at acceptable cost and in a convenient way, then even elders with substantial needs for assistance may be able to live independently. Housing options such as assisted-living and continuing-care communities are likely to be increasingly available. For members of the new cohorts of seniors who prefer independent living arrangements and can afford these options, and especially for those with few familial resources on which to draw, these options are likely to be heavily used and will result in more seniors living in "quasi-independent" households.

An additional factor that will contribute to the reshaping of household and family structure among older people in the future is the growing racial and ethnic diversity of the population. The baby boom includes far more Asians and Latinos than earlier cohorts, and almost one in six boomers is an immigrant, mostly from Latin America or Asia. These diverse populations bring unique life course experiences shaping family composition, the accumulation of resources, and the health and disability trajectories that determine needs for assistance. As well, most of these rapidly growing groups are considered to hold "familistic" values that support intergenerational caregiving and coresidence. Household composition among older Americans in coming years could be modified to include more intergenerational families as a result of these growing ethnic populations. However, to the extent that patterns of higher intergenerational coresidence are primarily a reflection of recent immigration to the United States (Van Hook & Glick, 2007) or of socioeconomic status (Burr & Mutchler, 1993a), household structure differences among race and ethnic groups may not persist assuming high levels of assimilation and acculturation.

## FONER, ANNE

***1921–***

Anne Foner illustrates in her own life a key principle she and her colleagues have emphasized in the sociological analysis of aging and society: that the process of aging from birth to death is not immutable but changes as society itself undergoes transformation. She was part of the first wave of adult married women in the United States who returned to school and the workforce when they were in their 30s and 40s, helping to establish a new life course pattern for women in the United States.

Foner received her B.A. in 1941 from Queens College, now part of the City University of New York, as a member of the first graduating class. She did not go on to graduate study until 1960, having spent the intervening years in domestic, volunteer, and part-time work activities. She received a Ph.D. in sociology from New York University in 1969 and went on to teach in the sociology department at Rutgers University. She officially retired in 1991 but continued professional activity well into her 80s.

It was at New York University that she first met Matilda White Riley (b. 1911), with whom she later collaborated on what was Foner's first major published work: a multivolume series on aging and society. The first volume, *Aging and Society I: An Inventory of Research Findings*, was more than a catalog of research on aging. It selected from a voluminous literature and condensed and organized social science findings on people in their middle and later years. It began to suggest broad generalizations about human aging. At the same time, it pointed to limitations in the available studies and called attention to commonly accepted beliefs about aging that did not hold up to careful scrutiny. The third volume, *Aging and Society III: A Sociology of Age Stratification*, coauthored with Riley and Marilyn Johnson, explored the implications of research on aging for understanding age as built into social institutions and affecting individual attitudes and behavior.

In subsequent publications she explored age as an element in social structures and social change and highlighted that it—like sex and race—is a basis of social

***Anne Foner.*** **PHOTO BY PEGGY FONER. COURTESY OF ANNE FONER.**

differentiation and inequality. Like other forms of social stratification, she noted that age-based inequalities in power and privilege are found in all societies, but age systems of inequality are unique. Because aging is inevitable, as people grow up and grow older they confront different opportunities or constraints over the life course—and this can affect how they react to disadvantages or advantages experienced at any given time.

Age-based inequalities, Foner observed, are also the basis of age conflicts. The young may perceive themselves as relatively disadvantaged and may challenge the middle-aged and older adults who seek to protect their privileges. Age conflicts can also stem from differences in worldviews and values arising from the social, political, and economic context of the period in which successive cohorts live out their lives. Generally, age conflicts are played out in institutional spheres such as the family, the workplace, and religious associations, but occasionally they spill out across the whole society—typically over moral issues that do not lend themselves to compromise. Societal-wide age conflicts can lead to change in age systems in the society, a major theme in Foner's work.

According to Foner, change in age systems can affect different elements of these systems. For example, there may be changes in the number of socially recognized age divisions such as the discovery in earlier times of adolescence as a distinct life stage, changes in the relative sizes of different age strata such as the increase in the number of older people and decrease in the proportion of children and adolescents in recent times, or changes in age norms governing attitudes and behavior deemed appropriate for people of given ages. These changes often come about as societies and individuals deal with societal events such as wars and depressions and technological and political transformations.

Sometimes the push for change comes about from coordinated actions of many individuals in organized social movements. At other times the push for change comes about from the uncoordinated actions of many people of a given age reacting to new circumstances in the society. A case in point is the move by many individual married adult women into the paid workforce in the 20th century. In changing their own lives, they also changed societal norms of appropriate behavior for adult women.

Beyond these macro-level issues, Foner focused on individual-level processes, including retirement, intergenerational relationships in the family, transitions over the life course, and age-related political attitudes and behavior. In studying aging from birth to death and recognizing age as a key element in social structure and social change, Foner has helped broaden the understanding of age as a social phenomenon and strengthen its connection to the entire sociological tradition.

# FRAILTY AND ROBUSTNESS

Generally speaking, scientists have used the term *frailty* to describe a state of health in which a person is more susceptible to negative health outcomes, such as serious illness or death, than a person termed *robust*. Different scientific disciplines offer competing yet complementary perspectives on frailty, its causes, and its consequences. However, a consequence recognized by all is that such differences across people imply that everyone can expect their own, unique experience of health across their lifetime and particularly in late life. Some people may "age well" and maintain the ability to perform their day-to-day tasks efficiently, leading active and fulfilling lives through advanced ages. Others may be less fortunate, perhaps losing the ability to perform some activities that they would otherwise like or need to do, and less able to endure the daily challenges that those living independently encounter on a regular basis. Examples of such challenges include the physical task of walking up and down stairs or to the corner store, recovery from an illness or fall, or distressing events such as the death of a spouse. Failure to successfully meet these and other related challenges may serve as important markers for elevated risks of subsequent health declines in late life, including serious disease or death.

Robust older adults are more likely than others to successfully meet these challenges and avoid long-term, negative impacts on their health; frail elders are less fortunate and more likely to suffer greater frequency and severity of illness, adverse events, and, potentially, a shorter life span. Several of the studies reviewed here, particularly those in the medical sciences, consider this susceptibility as a relative inability to recover from common stressors, examples of which might include illness, surgery, a fall, negative psychosocial experiences, or traumatic events. A person who is not frail is thought to be relatively robust to the health risks that could accompany such exposures.

Although such notions of frailty and robustness (in related contexts sometimes called *resilience*) could be characterized in other age groups, the discussion in this entry focuses on the concepts of frailty and robustness in late life. However, even among older adults only, the prevalence of frailty might differ widely, depending on the perceptions of elders, their families, and their health care providers. As a result, researchers and health care providers have worked to specify exactly what these terms mean, what they imply for the clinical care of elders, and the clinical and public health opportunities for development of interventions to enhance health in late life. In addition, the concept of frailty has implications for the study of population health: If the most frail die youngest, then one must be careful when interpreting data characterizing the older population because it would naturally reflect the less frail survivors (Vaupel & Yashin, 1985).

The concepts of frailty and robustness can be illustrated using the following two fictitious case histories. Mr. X is a 75-year-old man who volunteers each week teaching children to read, walks his dog with his wife every day, and controls his high blood pressure with exercise, a low-salt diet, and medication. He interacts regularly with a wide circle of friends and neighbors and is considering joining a bridge club at his church. A month ago, Mr. X had surgery to remove a cataract, recovered well, and is now completely back to his prior level of function. In contrast, Mr. Y is a 75-year-old man who used to walk outside regularly, but he now feels uncertain on the sidewalks and largely restricts his movement to inside his house. He says that he rarely has

the energy to socialize with friends and, although he still enjoys tending to his garden, he is worried that he might fall and so keeps only a window-box garden. Mr. Y recently had a small stroke following cataract surgery, which has affected his balance and coordination, and both he and Mrs. Y are concerned about his safety and whether he should continue to live with his wife in their home. Mr. X would be regarded as nonfrail or robust, whereas Mr. Y would be regarded as frail.

Researchers from a variety of scientific disciplines have sought to define frailty and understand the reasons that people vary in their ability to avoid the long-term health risks associated with negative physical or emotional experiences (e.g., the minor surgery in the preceding case histories) and recover to their original level of health. The fact that older adults with similar health vary in their ability to withstand such exposures and either maintain function or falter has led researchers and health care providers to seek an explanation for such differences, and this entry reviews several important studies. Some of this work examines large numbers of older adults to try to improve researchers' ability to predict mortality rates across populations or time, primarily through tailoring statistical methods to account for unseen differences in people, such as frailty, that affects their risk of death. Other studies highlighted here focus on the individual and seek to unravel, at the biological level, the mechanisms that define how resilient a person may be to the numerous negative physical and social incidents that accumulate throughout late life.

Among social scientists, demographers have developed a notion of frailty in their quest to understand differences in mortality across populations or population subgroups. For example, James Vaupel, Kenneth Manton, and Eric Stallard (1979) wanted to improve the way in which demographers calculate mortality rates for a population. Building on prior work, they modified typical calculations for mortality to account for potential differences in the risk of death across people in a population. In particular, they assumed that being frail meant that a person's risk of death was relatively higher than another member of the population who is not frail. Defining frailty in this way is consistent with the core notion outlined previously (i.e., that frailty comprises elevated risk of subsequent poor health but is distinctive in that it is generally not focused on understanding the biological sources and detailed individual mechanisms that produce elevated health risks for individuals). However, some subsequent work has moved in this direction; for example, work by Anatoli Yashin and Ivan Iachine (1997) developed a method to use data on twins to study the relative effect of genes and environment on longevity, and a review that includes twin studies (Christensen, Johnson, & Vaupel, 2006) suggested that life span may, to some degree, be affected by genetic factors.

Many researchers in demography and other social science disciplines have expanded on the preceding work and related ideas. Researchers have also adapted the earlier notion of frailty to study important life-course events that are unrelated to health—these include, for example, childbirth, marriage, or employment. This work uses particular kinds of statistical models that estimate the risk of death or each of these other important life-course events and applies the term *unmeasured* (or unobserved) *heterogeneity* to describe the unspecified individual differences in the probability of such outcomes (Wooldridge 2002, p. 703), which is consistent with the theme underlying earlier use of the term *frailty* in demographic literature.

In the medical sciences, research on frailty is led by gerontologists and geriatricians and can be seen as complementing work in the social sciences by focusing on the identification of specific biological mechanisms and a clinical, diagnosable syndrome that could lead to a range of health outcomes, including death and other clinically significant end points. Several conceptualizations of the geriatric syndrome of frailty have been developed but, although the specifics of each vary somewhat, Howard Bergman et al. (2007) found, "general agreement that the core feature of frailty is increased vulnerability to stressors due to impairments in multiple, inter-related systems" (pp. 731–732). Stressors might include, for example, an episode of illness or distressing events such as the death of a spouse. However, because of the differences in which frailty is theorized to operate, a variety of methods have been proposed to measure frailty. In the following we review several distinct theoretical conceptualizations for the geriatric syndrome of frailty that extend from this core conceptualization of "vulnerability to stressors" and impaired function of multiple biological systems and the empirical measurement approaches that have been suggested to accompany each. Each measurement approach has been associated with a variety of negative health outcomes associated with aging.

Linda Fried et al. (2001) theorized that frailty is a clinically observable syndrome that follows a specific, cyclical pattern. Specifically, they suggested that processes of aging and existing disease can induce loss of muscle mass, followed by declines in strength and endurance, then reduced activity and metabolic function, lower energy use, and, finally, nutritional deficiencies. Closing the cycle, nutritional deficiencies are hypothesized to induce further muscle loss and so on (see p. M147 and Figure 1). Researchers have operationalized this conceptualization in studies by defining as frail a study participant who has at least three of five measured characteristics, including weak grip strength, slow walking speed, exhaustion, low energy expenditure, and weight loss (Bandeen-Roche et al., 2006).

Other researchers have adopted this approach but measured a larger variety of characteristics in defining frail (Puts, Lips, & Deeg, 2005). A contrasting view is provided by Kenneth Rockwood and Arnold Mitnitski (2007), who defined the geriatric syndrome of frailty more broadly as being manifest in the total number of deficits (e.g., diseases, clinical diagnostics, disability measures, and so on) that a person has. That is, they suggested that "The more things individuals have wrong with them, the higher the likelihood that they will be frail" (p. 722). This approach is operationalized by calculating a continuous frailty index equal to the proportion of deficits present. A recent comparison of these two conceptualizations of geriatric frailty and their measurement (Rockwood, Andrew, & Mitnitski, 2007) found that the measures are related (using a variety of statistical tests). However, their discussion points out that the different perspective (i.e., specific cyclical pattern vs. global assessment of deficits) and empirical operationalizations (i.e., a discrete count variable from 1 to 5 vs. a continuous index between zero and 1) mean that each approach has strengths and weaknesses for the study of biological mechanisms and clinical translation of frailty.

Frailty is a concept that is potentially important to a variety of events in later life. First, as suggested by the literature reviewed previously, it is a risk factor for a range of significant health outcomes in late life, which in turn play an important role in decisions that govern numerous events in the later life course. For example, frailty is associated with disability, which could affect decisions about work, the decision of a spouse to provide informal support, the decision by an elder to coreside with children or other family and receive informal support from them, the ability of elders to "age in place" or move to new surroundings, and the degree of social engagement that can be maintained. These are major changes that affect older adults, members of their family, and their social networks. In addition, because they can be associated with health, these changes also affect every taxpayer, because public programs such as Medicare and Medicaid spend many taxpayer dollars on health care for older adults. Conversely, the life-course perspective can also bring numerous insights and stimulate advances in the study of frailty (Kuh, 2007).

This entry closes by revisiting Mr. X and Mr. Y and reconsidering their experiences of health change, both in light of the preceding discussion of frailty and robustness and to illustrate the wide range of factors that determine health in late life. Mr. X was identified as nonfrail because he has maintained the capacity to actively engage with his environment; by volunteering, walking, and effectively managing his health conditions, he demonstrates the ability to respond successfully to a multitude of physical and cognitive challenges. He seeks out additional interaction and challenges in the form of his social activities. Finally, in the face of an acute stressor (his surgery), he regained his prior level of function with no lasting adverse effects. Conversely, Mr. Y exemplifies a frail older adult. He has reduced his level of activity because of his perceived inability to navigate safely outside and his lack of energy. In addition, the surgery experience was followed by a stroke, which (although not necessarily causally related) left him with a markedly reduced level of physical function. At present, frailty research offers the physician and family of each man an integrated perspective on their respective experiences and proposes a rationale for why each man achieved, or suffered, his respective outcome. In the future, as research on frailty progresses, perhaps one day a frailty diagnosis may offer physicians, their patients, and their families an opportunity for treatment. Ultimately, the objective of research on frailty and robustness is to design interventions to increase robustness and prevent frailty.

# FRIENDSHIP, LATER LIFE

Friendships contribute to health and well-being throughout the life course, including later adulthood. Older adults with close friendships have been found to be healthier, happier, and more socially active than those without close friendships (Rawlins, 2004).

## AGE SIMILARITIES AND DIFFERENCES IN FRIENDSHIP

Friendships in later life are similar to friendships in earlier life stages in some ways. For example, later life friendships continue to provide someone to spend time with, talk to, help with practical tasks, and provide emotional support and companionship. Throughout life, then, friends are people with whom individual share mutual trust and respect, interests and values, and affection and support (Blieszner & Roberto, 2004).

Later life friendships also differ in some ways from earlier friendships. Friendships in childhood, limited by children's cognitive abilities, tend to be rather self-serving, focusing primarily on companionship and enjoyment (Blieszner & Roberto, 2004). Maturing cognitive processes in adolescence increase the importance of mutuality and reciprocity in relationships, and friends come to be seen not only as companions, but as intimate confidants (Berndt, 1996). In young adulthood, friendship networks expand, as new lives and social ties are forged away from home. In later adulthood, in contrast, new friendships are less likely to be formed, although some older adults do attempt to form new ties and many are successful, especially following the death of a spouse (Lamme, Dykstra, & Broese van Groenou, 1996).

In general, social networks tend to shrink rather than expand in later life. Yet this generally does not increase older adults' susceptibility to loneliness because the number of close friends changes little over time; declines in social networks, instead, result from reduced contact with peripheral social ties (Carstensen, Fung, & Charles, 2003). Thus, with increasing age, the number of friends in people's social networks tends to decline, but the remaining friendships tend to be deeper and more fulfilling.

## QUALITATIVE ASPECTS OF FRIENDSHIPS IN LATER LIFE

Qualitative aspects of friendships often influence whether a friendship will withstand the test of time. As people age, friendships based primarily on shared interests may diminish as a result of declining health or transportation difficulties. In contrast, close friendships based on a long history of shared experiences and intimate exchanges are more likely to endure. These long-term friendships provide older adults with a sense of continuity in their lives and, as a result, are highly valued. In fact, older adults' close friendships are less likely to end as a result of increasing distance or decreasing contact, whereas these factors often lead to the dissolution of friendships in younger age groups (Nussbaum, 1994).

Evidence that the quality, rather than the quantity, of social ties is particularly important also can be found in studies that have examined the contributions of contact with friends versus family members toward older adults' well-being. For many older adults, life satisfaction appears to be more strongly related to contacts with friends than with family (Lawton, Winter, Kleban, & Ruckdeschel, 1999). Friendships are voluntary in nature, making interactions with friends enjoyable (Rawlins, 2004). Family relationships, in contrast, are more obligatory in nature, and interactions with family members may be enjoyable at times but routinized or perfunctory at other times. In fact, a study of older adults' daily activities and well-being found that their interactions with friends frequently involved stimulating leisure activities, whereas their interactions with family members frequently involved maintenance tasks (e.g., housework) or passive forms of leisure (e.g., watching television; Larson, Mannell, & Zuzanek, l986). Not surprisingly, interactions with friends are more strongly related to well-being (Pruchno & Rosenbaum, 2003).

However, family members are most often called on when older adults fall ill to provide sustained aid and care that might strain a friendship (Rawlins, 2004). Friends and family members, therefore, can be regarded as making

***Old Friends.*** *For five decades, this group of eight women has gathered once a month to play cards, enjoy good food, and savor lasting friendships. In January 2006, they celebrated their golden anniversary in Salt Lake City at the same place where they played their first hand of canasta in November 1955.* AP IMAGES.

complementary contributions to older adults' health and well-being by serving as sources of companionship and care (Rook & Ituarte, 1999).

## DEMOGRAPHIC CHARACTERISTICS AND INDIVIDUAL DIFFERENCES THAT INFLUENCE FRIENDSHIPS IN LATER LIFE

Demographic and individual differences influence later life friendships. As is true throughout life, women's friendships are characterized by more intimate self-disclosure, whereas men's friendships typically involve shared activities (Beals & Rook, 2006). As a result, women tend to have closer same-sex friendships than men, and this is particularly true for married people. Most married women have close confidants beyond their spouses, but men typically do not (Phillipson, 1997). Social class also continues to play a role in later life friendships, with middle-class people having more friends than working class older adults (Phillipson, 1997), most likely due to their greater financial resources. Personality factors also affect friendship formation and maintenance in later life. Not surprisingly, extroverts and those who are more open to experience have been found to have larger social networks than introverts and those less open to experience, even among the oldest old (80 years and older; Lang, Staudinger, & Carstensen, 1998).

Other factors (e.g., poor health and mobility, financial problems, residential relocation, transportation difficulties) can impede the formation or maintenance of later life friendships. Although these problems can contribute to or exacerbate relationship tensions (August, Rook, & Newsom, 2007), many older adults report great satisfaction with their social relationships despite these obstacles (Carstensen et al., 2003).

## THEORETICAL PERSPECTIVES ON AGE AND FRIENDSHIP INVOLVEMENT

A strikingly robust finding in social gerontology is an age-related reduction in social network involvement. According to Disengagement Theory (Cumming & Henry, 1961), this decline is a natural aspect of aging that allows older adults to turn inward and reflect on their lives as they prepare for the approaching end of life. According to Activity Theory (Maddox, 1963), in contrast, this decline reflects societal rejection of the elderly, driven by ageist attitudes. The key to successful aging according to this theory is to maintain social activity, replacing lost social roles (e.g., worker) with new ones (e.g., volunteer) if necessary. Neither of these theories, however, fully captures the complex relationship between social involvement and well-being in later life. Whereas some older adults strive for extensive social involvement, many are content with a reduced level of social activity.

Socioemotional Selectivity Theory (Carstensen et al., 2003) contends that the age-related decline in social network involvement is due to people's growing awareness as they age that time left to live is limited, creating a preference to spend one's time with the most meaningful, emotionally rewarding interaction partners. Thus, the reduction in network size reflects the shedding of superficial relationships while the closest and most important relationships remain intact.

Another theoretical perspective on friendships, Social Exchange Theory (Thibaut & Kelley, 1959), posits that healthy friendships are those that have an equitable "give and take," and this remains true in later life. Reciprocity, being able to give back an amount of support equivalent to what was received, may be even more important to relationship satisfaction in friendships than in family relationships (Rook, 1987). However, declines that accompany aging, such as diminishing health or resources, may keep older people from seeking support from friends if they feel unable to reciprocate (Rawlins, 2004).

## CURRENT TRENDS AND FUTURE DIRECTIONS

Losses are increasingly common as one ages, and friendship loss is no exception. In one study of adults over age 65, 25% reported the death of a friend in the preceding year (Aldwin, 1990). Another study found that for those older than age 85, the numbers increase to 59% for men and 42% for women (Johnson & Troll, 1992). But despite the high rates of loss, friendships in later life likely will increase in importance in the future because demographic trends suggest that more older adults will be single, childless, and/or living far from relatives. Friendships are a particularly important source of support and companionship for single people and are especially important when family members are not available (Cantor, 1979; Lang et al., 1998). In one study, neighbors and friends of frail elders assisted with instrumental support tasks such as providing transportation and helping with daily tasks (Barker, 2002). Highly personal forms of care for incapacitated elders, such as bathing or feeding, are, however, typically performed by family members or formal caregivers. More research is needed to determine whether friends can comfortably and effectively perform such support tasks over time (Rook, Sorkin, & Zettel, 2002).

More research examining the diverse forms and functions of friendship in later life is also needed. For example, future research should investigate the patterns of friendships throughout life for sexual minorities (i.e., gay, lesbian, bisexual, and transgendered people; Galupo, 2007) as well as for various ethnic minority groups. Researchers also should investigate the role that intergenerational friendships can play in the social networks of older adults. Although same-age friends are most typical throughout the lifespan, having some friends who are younger may be beneficial for older adults given the increased probability of illness or death among friends who are closer in age. Moreover, as greater numbers of older adults become comfortable accessing the Internet, alternative modes of communication (e.g., e-mail, online chat rooms) may enhance later life friendships when relocation or limited mobility hinder in-person interactions. Finally, some intervention studies have shown promise in terms of helping lonely older adults form friendships (e.g., Stevens, Martina, & Westerhof, 2006); researchers should continue to pursue interventions that have the potential to enhance friendships in later life.

## GAYS AND LESBIANS, LATER LIFE

The study of lesbian, gay, bisexual, and transgender (LGBT) older persons has much to contribute to the understanding of aging in minority communities and under stigmatized conditions. As such, it has much to offer an analysis of aging more generally (de Vries and Blando, 2004), fostering a more holistic and inclusive view of the diverse experiences of older persons and the life course.

### PARAMETERS OF THE POPULATION

In some contexts and situations, the term *LGBT* has been expanded to include: Q, for *queer*, and another *Q* for *questioning*; *I* for *intersex*; another *T* for *two-spirit*. As de Vries (2007) has pointed out, these additions are motivated by a variety of social forces including age and cohort, an increased attention to process, advances in theory and the body of knowledge, and an explicit recognition of the role of culture, as respectively revealed below. For instance, *queer* is a term more commonly endorsed by younger rather than older gay men and lesbians, perhaps in the service of empowerment and neutralizing and/or claiming a pejorative label (Adelman, Gurevitch, de Vries & Blando, 2006). *Questioning* reflects a more fluid appreciation of sexual experiences. *Intersex* derives from the reframing and deeper understanding of those born with genitalia that are neither exclusively male nor female. *Two-spirit* is a term rooted in Native American and Canadian first nations cultures characterizing the presence of both a masculine and feminine spirit within the same body.

Among older adults, the majority of research has focused on gay men and, to a somewhat lesser extent, lesbians. Much is missed by this relatively restricted focus. Miller, Andre, Ebin, and Bessonova (2007) remind readers that bisexuals are not identified by the gender of their partner(s); that is, a bisexual woman whose partner is a woman remains a bisexual rather than lesbian; a bisexual woman whose partner is a man remains a bisexual rather than a heterosexual. Such invisibility dramatically adds to the challenges of the bisexual experience. Intersex persons of the later years have also been neglected in research and analyses; similarly, transgendered persons are rightly critical of the largely superficial and often dismissing ways in which their experiences have been incorporated. As is true to varying degrees for those who identify as lesbian, gay, bisexual, or intersex, a great diversity is meant to be contained within the single *T* category. For example, transgender persons include heterosexual, homosexual, and bisexual persons. They include persons who present as male and/or female in varying situations. They include persons who may be postoperative, preoperative (e.g., transitioning), or nonoperative male-to-female (MTF) or female-to-male (FTM) (Cook-Daniels, 2006).

Within the above constraints and considerations, estimates of the prevalence of LGBT persons in general, and older LGBT persons in particular, vary widely: The

legacy of stigma (and hence the reticence to identify as LGBT) and the malleability of sexuality and identity render the validity of such estimates questionable. Cahill, South, and Spade (2000) suggest that the current LGBT population in the United States over the age of 65 may be as large as 3 million people—perhaps expanding to as many as 4 million by the year 2030. These estimates are likely under-representative of this population—a statement of increasing significance with the aging of subsequent cohorts who are known for their questioning of authority and pushing of boundaries.

## STUDYING THE LGBT POPULATION

Perspectives on sexuality and the elderly have been framed by myths declaring older persons are sexually unattractive, neither desirous nor capable of sexual expression. In contrast, the very notion of an LGBT gerontology raises the issue of sexuality directly (de Vries and Blando, 2004). The literature on LGBT aging and older persons has developed in both size and complexity since the early 1980s. Early publications were largely anecdotal and/or clinical, descriptive accounts often depicting older homosexual men and women as socially isolated, depressed, sexually frustrated, unhappy, among a host of other such characteristics (Berger, 1996). As the field grew, the publications became increasingly empirical in nature, although typically still based on small samples of openly disclosing women and men recruited from public and urban centers who were willing to participate in research. Still, the extent to which there can be a representative sample of men and women manifesting characteristics (or representing a variety of terms and constructs) that are stigmatized and in flux remains problematic.

The literature on gay and lesbian older adults frequently comments on the marked cohort effects in communities of LGBT persons and how their lives have been shaped by historical period. The LGBT cohort now in later life are individuals whose expressions of love were "diagnosed" as a psychiatric disorder in the *Diagnostic and Statistical Manual* (the psychiatric diagnosis "bible") until it was changed in 1973. Even in the early 21st century, their committed relationships are the subject of intense debate with threats of constitutional exclusion in the United States. These are individuals who, through the course of their lives, have been labeled as anti-family and immoral by religious groups, and as a security risk or morale threat by military leaders (Kochman, 1997). These are women and men who endured and have seen AIDS decimate their social networks and destroy their communities.

A common and significant reference point defining this cohort is the Stonewall Rebellion or Riot. On the evening of June 27, 1969, a contingent from the New York City Police Department (NYPD) raided the Stonewall Inn, a gay dance bar in Greenwich Village, New York City. These raids were part of a routine pattern of harassment endured by the occupants of this and most other gay and lesbian bars. On this evening, however, the police raid escalated into several nights of street fights and clashes between outraged gay men and a NYPD that was not accustomed to homosexuals fighting back. The events of these evenings were widely reported in and sensationalized by the media; it became known as the Stonewall Rebellion and what many identify as the turning point in the struggle for gay rights in the United States.

## THEMES AND PROMINENT ISSUES IN THE STUDY OF LGBT AGING

The developing research into the lives of older LGBT persons suggests a population both challenged and bolstered by its demography and experiences. de Vries (2006) reported that LGBT older adults are significantly less likely than heterosexual women and men of comparable age to be in partnered relationships and to have children, two of the groups most frequently called upon in the provision of care for an elder in need. For example, a large community survey, including more than 700 participants at least 50 years of age, found that about three-quarters of gay men and about one-half of the lesbians reported their relationship status as single and only one-quarter of gay men and one-half of lesbians had children (Adelman et al., 2006), the majority of whom were born into the previous heterosexual marriages of these individuals. A national survey of LGBT baby boomers found that many reported concerns about where and how their future care might be addressed (MetLife Survey, 2007). At the same time, the literature reveals significant discussions of "chosen families," the strong bonds forged by the inner circle of friends and those on whom an individual might call in a time of need, often in response to alienation from biological kin (Weston, 1991).

Interestingly, income levels appear similar across LGBT and heterosexual aging populations, despite persistent myths of relative LGBT affluence (Badget, 1998). LGBT adults tend to be more highly educated (also supported by census-level data, see Black, Gates, Sanders, and Taylor, 2000), providing a point of contrast to the frequently noted association between income and education. Relatedly, several authors have proposed that LGBT older adults have fashioned a sense of hardiness/competence out of a lifetime of surviving as a sexual minority in an often-hostile heterosexual environment—a strategy of engaging their environment that may bode well for success in the challenges of later life. For example, Friend

***Gay Pride.*** *A man is helped by a transsexual as he marches in the streets of Paris carrying a placard reading "Gay pensioners don't want to retire" during the gay and lesbian parade themed "March of proud gays, lesbians, and transsexuals."* PIERRE ANDRIEU/AFP/GETTY IMAGES.

(1991) has offered a theory of successful aging as applied to older lesbians and gay men, primarily based on such "crisis competence" (Kimmel, 1979) and confronting rigid gender roles and ageist assumptions. Friend suggests that being freed (or excluded) from the relative bounds of traditional gender role definitions have afforded gay men and lesbians the opportunity to engage in behaviors throughout their lives that heterosexuals rarely confront, perhaps until the death of a spouse. A popular example of this may be found in Harvey Fierstein's *Torch Song Trilogy* (1983) in which Arnold, the main character, a gay man in his early middle years, says that he can cook a meal, sew a shirt, hammer a nail—whatever it takes to get through—he can do it himself as has been required of him throughout his life.

There is some suggestion that later life may bring with it some unique physical and mental health issues for this population. Although not unique to LGBT communities, several authors have commented that ageism is particularly

strong within gay male communities (e.g., Bergling, 2004). Palmore (1990) proposes that persons subjected to prejudice and discrimination tend to adopt the dominant group's negative image and to behave in ways that conform to that negative image with associated potentially deleterious consequences on mental health and well-being. Herdt and Kertzner (2006) reported evidence of higher levels of depression and psychological distress among midlife and older lesbians and gay men, which they attribute to the accumulation of a lifetime of stigma. Adelman and colleagues (2006), in their large community-based empirical study, found higher rates of chronic disease and disability, not the least of which was HIV/AIDS, among older gay men. Rather than a difference in the constellation of disorders, Barker (2004) notes that older lesbian and bisexual women may suffer an exacerbation of prevalence, earlier onset, and manifestation of common disorders. Health issues for transgender persons are similarly made more complicated by the interaction of the aging body with the introduction of hormones for those who have transitioned from one biological gender to another.

## FUTURE DIRECTIONS

In the early 21st century, the first cohort of openly lesbian, gay, bisexual and transgender persons is approaching the later years, creating their own way with little historical reference to serve as a guide. Dozens of efforts are afoot by LGBT communities to provide and care for the aging pioneers of a population. There are parallels in these efforts to the dramatic and inspiring ways in which the LGBT communities (comprising many of these same, now older adults) rose to the challenge of caring for those dying of AIDS in the early years of the pandemic—a time when families, medical facilities, and governments shamefully retreated from their responsibilities.

As de Vries (2007) has noted, it is the interaction of these historical, demographic, and bio-psycho-social factors that make more complex the issues faced by older LGBT persons and the delivery of services that meet their needs. The discriminatory experiences LGBT adults have experienced in North American health care settings (e.g., Brotman, Ryan, and Cormier, 2003) have led to an unfortunate and understandable reluctance to seek out health care services and to evaluate the delivery of such services negatively. When gay and lesbian support and services are available, still rare and certainly an urban phenomenon, they tend to be more frequently used in comparison with the use of generic, heteronormative senior services (see Quam and Whtiford, 1992) and are evaluated more positively. Moreover, the norms and presumptions of heterosexuality and the "family-centrism" that pervade societal institutions often serve to exclude (or at least not invite) the LGBT elder. For example, non-registered domestic partners have been denied entry to the hospital room in which their loved one was dying. Sadly, older LGBT persons who have struggled to come out and live openly in a frequently hostile environment "often find themselves having to [go] back into hiding when they begin to require health care services" (Brotman, et al, 2003, p. 193). The families that LGBT persons create, either in lieu of or in addition to their biological families, are often not recognized and honored by those outside of these intimate circles (de Vries and Hoctel, 2007).

In some ways, the study of LGBT aging and concerns about the services needed and delivered do not differ from that of other groups bounded by culture or relationship status or some other social construct. Studying the particular context within which members of such groups age, their experiences and the source and type of care they receive and need is a necessary prerequisite to the development and offering of services appropriately tailored and to a full and complete appreciation of the life course.

## GENERATION

**SEE** *Cohort.*

## GENETIC INFLUENCES, LATER LIFE

Genetic influences are the influences that can be attributed to heredity (family likeness). Heredity is the passing of characteristics (traits) from parents to offspring. Genetic influences in later life are attributed to traits related to aging such as life span and longevity, age at menopause, age at onset of specific diseases in late life (Alzheimer's disease, heart disease, and so on), physical health and cognitive functioning in later life, rate of aging (estimated through tests for biological age), rate-of-change traits, and biomarkers of aging (Finch, 2007).

Genetic influences are also related to effects of the fundamental chemical units of heredity called genes. A gene is a segment of deoxyribonucleic acid (DNA) carrying coded hereditary information. The number of gerontogenes (genes involved in the aging process) remains to be established, but there are no doubts of their existence. For example, in humans one of the forms of a gene coding apolipoprotein E (APOE2) is associated with exceptional longevity (more prevalent among centenarians) and decreased susceptibility to Alzheimer's disease (Finch, 2007; Martin, Bergman, & Barzilai, 2007).

Genetic influences operate through the mechanism of gene action—the way in which genes produce their effect on an organism by influencing biochemical processes during development and aging. Many of the genes within a given cell are inactive much or even all the time (repressed). Different genes can be switched on or off depending on cell specialization (differentiation)—a phenomenon called differential gene expression. Gene expression may change over time within a given cell during development and aging. Changes in differential gene expression are vitally important for cell differentiation during early child development, but they may persist further in later life and become the driving force of the aging process.

Although genes determine the features an organism may develop (genotype), the features that actually develop (phenotype) depend upon the complex interaction between genes and their environment, called gene–environment interaction. Gene–environment interactions are important because genes produce their effects in an indirect way (through proteins), and, therefore, the ultimate outcome of gene action may be different in different circumstances (Ryff & Singer, 2005). Although genes do not change over the life course (creating the impression of causal links), many traits in later life demonstrate very high environmental plasticity; that is, they can be modified in response to an environmental change (Ryff & Singer, 2005). Older adults on average experience poorer health compared to younger adults, so genetic contribution to health, functional status, and cognition are among the most thoroughly studied traits in later life.

### STUDY METHODS AND DESIGNS

Most studies of genetic influences use quantitative genetics (or ACE) models to separate the sources of phenotypic or observed variability into an *additive* genetic

component (A), a *common* or shared environment component (C), and a nonshared *environment* element (E). Shared environmental influences are shared nongenetic factors that are transmitted from parents to offspring or are shared by the members of the same family (such as lifestyle or diet). Nonshared environmental influences are nongenetic factors that are different among family members. The genetic contribution to phenotypic variability of trait is measured using heritability estimates. Heritability estimates represent the proportion of phenotypic variation of trait that can be explained by genetic effects. A heritability value of 1.0 (or 100%) means that the trait is fully genetically determined, whereas a value of 0 means that the trait is fully environmentally determined.

Quantitative genetics uses a number of designs in the study of genetic influences, including family design, twin design, and the adoption method. Family design compares the incidence of disease (or other trait) among biological and nonbiological relatives of an affected individual (called proband). The famous statistician Karl Pearson (1857–1936) and Alexander Graham Bell (1847–1922), the inventor of the telephone, were among the first researchers to try to estimate the contribution of genetic factors into the human life span at the beginning of the 20th century (see review in Gavrilov, Gavrilova, Olshansky, & Carnes, 2002). The first comprehensive studies of familial resemblance and longevity go back to the 1930s when the American biostatistician Raymond Pearl published his seminal book, *The Ancestry of the Long-Lived*, which showed that close relatives of nonagenarians (persons in their 90s) live longer than relatives of shorter lived persons (Pearl & Pearl, 1934). This initial finding was later replicated by numerous studies of persons with exceptional longevity, including early 21st century studies of centenarians (Martin et al., 2007).

The twin design is based on the comparison of identical (monozygotic) twins and fraternal (dizygotic) twins. Monozygotic twins are assumed to be genetically identical to each other because they developed from the same fertilized egg. Dizygotic twins are formed from two different fertilized eggs and have only half of their genes in common. If a trait is genetically influenced, then monozygotic twins should show a closer resemblance to each other in regard to that trait compared to dizygotic twins. Franz J. Kallmann was the first researcher to apply twin design to the study of late-life traits and to conduct a survey of old twin pairs (Kallmann & Sander, 1948).

The adoption method is a quasi-experimental design based on cases in which children are adopted away from their biological parents early in life. This gives researchers the opportunity to separate the effects of nature and nurture. The Swedish Adoption/Twin Study of Aging is probably the largest repository of data on adopted twins (Pedersen & Svedberg, 2000).

In addition to the methods of quantitative genetics, molecular genetic methods are used to identify specific genes responsible for genetic influence. In molecular genetic studies of human aging traits, the gene association studies remain the most common research approach (De Benedictis et al., 2001). In these studies the effect of candidate genes on longevity is analyzed by comparing gene frequencies between affected individuals (cases) and unaffected control individuals. The comparison of candidate gene frequencies among centenarians and younger controls is a typical example of such studies. Another molecular genetics approach—the genome-wide linkage scan of genes—is a relatively new direction of research. Linkage analysis is a mapping of genetic loci using observations of related individuals (pairs of affected and nonaffected siblings, for example). This direction of research has a potential for obtaining interesting results, although the success of genome-wide scans of complex human diseases requires large sample sizes and considerable effort and expense.

In addition to common phenotypic traits (such as the presence or absence of disease), the genetic epidemiology of aging incorporates age in the specification of traits under study. The traits that are specific for later life are survival traits and rate-of-change traits (Hadley et al., 2000). A survival trait is defined in terms of the specific age interval over which an individual is at risk for a specific outcome. For example, early-onset and late-onset variants of Alzheimer's disease are associated with different genes and modes of action. Rate-of-change traits are defined as changes in physiological, cognitive, or behavioral traits over a period of time. The study of genetic influences on rate-of-change traits is a rapidly developing area of research in the early 21st century (Pedersen & Svedberg, 2000).

## MAJOR RESEARCH FINDINGS

Longevity is one of the most widely studied broad survival traits. It was shown that siblings and parents of persons with exceptional longevity have significantly lower mortality compared to population-based controls and that the offspring of long-lived parents live longer than the offspring of short-lived parents (Gavrilov, Gavrilova, Olshansky, & Carnes, 2002; Martin et al., 2007). Genetic influences on longevity found in family studies were confirmed in twin and adoption studies (see Gavrilov et al., 2002). Although a strong familial clustering of longevity is now a well-established fact, heritability estimates for life span using standard methods of quantitative genetics are moderate—20% to 30% (Cournil & Kirkwood, 2001).

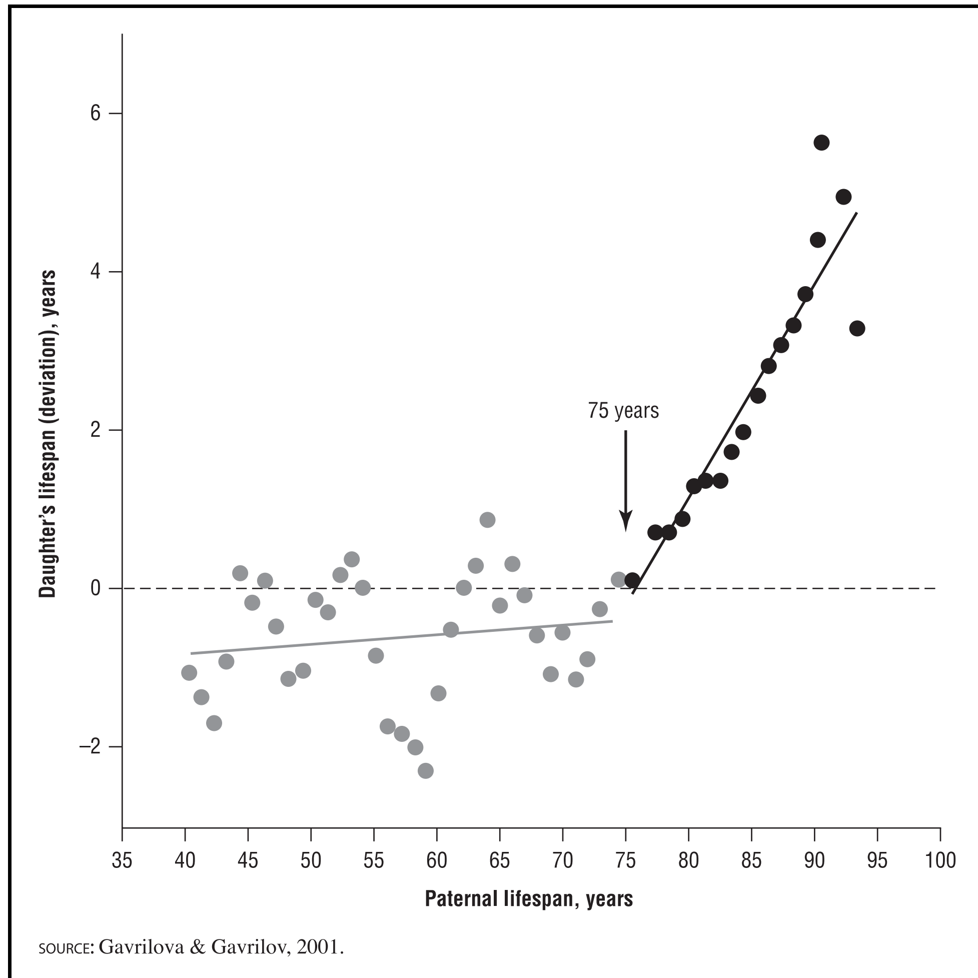

***Figure 1.*** *Daughter's life span (deviation from the cohort mean) as a function of paternal life span. Based on the data for 5,779 daughters from European aristocratic families born between 1800 and 1880 who survived to age 30. Data are smoothed by a 5–year moving average.* CENGAGE LEARNING, GALE.

Heritability estimation by standard methods of quantitative genetics is based on the assumption of linear dependence between offspring and parental traits. A study of more than 10,000 adult men and women from the European aristocracy, however, demonstrated that familial resemblance in life span between parents and children is essentially nonlinear (see Figure 1): very small when parents live shorter lives (30 to 70 years) and very strong in the case of longer lived parents (80+ years), suggesting an unusual nonlinear pattern of life-span inheritance (Gavrilov et al., 2002). These findings may explain the existing longevity paradox: Although the heritability estimates for life span were reported to be rather low (Cournil & Kirkwood, 2001), it is well known that longevity runs in families (Martin et al., 2007). A 2006 study of Danish and Finnish twin cohorts confirmed that genetic influences on human life span are minimal before age 60 but increase thereafter (Hjelmborg et al., 2006).

A review of gene–longevity association studies revealed that different studies often produced inconsistent and even contradictory results (De Benedictis et al., 2001). Most studies of gene–longevity association are based on case-control studies of centenarians, in which the proportion of a certain genotype among long-lived individuals is compared to the same proportion in a presumably shorter lived control group (usually persons of middle age). If the proportion of a particular genotype is higher among long-lived individuals compared to the control group, then it is assumed that this genotype may be associated with longevity. The association of a genotype with longevity in case-control studies is usually measured using odds ratio, which is a measure comparing whether the probability of longevity is the same between two groups. An odds ratio higher than unity means that carriers of a particular genotype have a higher chance of living to 100 compared to non-carriers; alternatively, an odds ratio less

than unity means that carriers of a particular genotype have a smaller chance of living to 100 compared to non-carriers.

The APOE gene is the only one that demonstrated consistency in different case-control gene–longevity studies (Finch, 2007). Apolipoprotein E (APOE) is a protein involved in cholesterol transport that binds to LDL receptors and is crucial to blood cholesterol levels (Finch, 2007). The APOE4 gene variant (allele) was found to be associated with heart disease, Alzheimer's disease, and longevity. APOE3 is the most prevalent allele in human populations, whereas APOE4 may vary and is higher than 15% in northern Europe and among aboriginal populations of New Guinea and Australia (Finch, 2007).

A combined analysis of eight APOE findings showed a net odds ratio for extreme longevity of 0.51 for the E3/E4 genotype compared to the common E3/E3 genotype, implying that the E3/E4 genotype reduces by roughly 50% the chances of survival to extreme ages compared to E3/E3 (Melzer, Hurst, & Frayling, 2007). The prevalence of APOE4 decreases with age because of differential survival—the mortality of E4 carriers is 10% to 14% higher and the mortality of E2 carriers 4% to 12% lower compared to E3/E3 and E4/E2 genotypes. It was estimated that individuals with the E4/E4 genotype may have a life expectancy at age 65 that is 5 years shorter than that of individuals with the E2/E2 and E2/E3 genotypes (Ewbank, 2004). Linkage studies of longevity genes are less common compared to association studies. One genome-wide linkage study of U.S. centenarians found a suggestive locus at chromosome 4, although this finding was not replicated in other populations (Melzer et al., 2007).

Parental age is another genetically linked factor affecting longevity. Children conceived by fathers at older ages have more inborn mutations (Vogel & Motulsky, 1997) and may be at higher risk of Alzheimer's disease and prostate cancer in later life. Daughters conceived by fathers age 45 and older live shorter lives (on average), whereas sons seems to be unaffected, suggesting the possible role of mutations on the paternal X chromosome (inherited by daughters only) in the aging process (Gavrilov et al., 2002).

Most chronic diseases in later life are complex multifactorial disorders. Multifactorial disorders are influenced by multiple genes, often coupled with the effects of environmental factors. Many diseases common to old age, such as late-onset Alzheimer's disease, heart disease, and diabetes, are considered to fall into this category. Most genes associated with multifactorial disorders have low penetrance, meaning that genotype carriers' likelihood of developing the disease is low. Thus, the individuals with disease-related genes do not necessarily succumb to the disease (Ryff & Singer, 2005). With a favorable lifestyle and environment, there is an opportunity for an individual with genetic risk factors to delay and even avoid the disease. For example, in the 1960s and 1970s the population of North Karelia in Finland had very high levels of heart disease and a significant proportion of people carrying mutations predisposing them to familial hypercholesterolemia (high blood cholesterol). However, an intensive community-based intervention program directed at lifestyle improvement significantly percent reduced (by 60% to 70%) heart disease and cancer rates over the span of 25 years (Ryff & Singer, 2005). Thus, the genetic risks of diseases in later life can be substantially reduced by proper behavioral, social, and economic measures.

Alzheimer's disease is the most common cause of severe memory loss at older ages. For late-life forms of dementia, the APOE4 allele was found to be strongly associated with both late-onset Alzheimer's disease and accelerated cognitive decline after age 65 (Finch, 2007). The highest cognitive decline was observed in APOE4 carriers with diabetes, carotid atherosclerosis, and peripheral vascular disease. APOE4 carriers with mild cognitive impairment were two to five times more likely to develop Alzheimer's disease compared to carriers of the most common APOE3 genotype. Another APOE allele, the APOE2, was found to be protective against Alzheimer's disease (Finch, 2007).

Many biomarkers of physiological or functional status including handgrip strength, walk speed, systolic blood pressure, pulmonary function, fasting glucose level, and bone degeneration demonstrate a high heritability at older ages (Melzer et al., 2007). Integral estimates of biological age have also been shown to have a strong genetic component, with heritability estimates ranging from 27% to 57%. Age at natural menopause was found to be highly heritable: Data from the two generations of the Framingham Heart Study showed that the crude and multivariable-adjusted heritability estimates for age at natural menopause were 0.49 and 0.52 (Murabito, Yang, Fox, Wilson, & Cupples, 2005). Sex hormone levels play an important role in health and survival at older ages. Studies of male twins ages 59 to 70 found that plasma testosterone levels have substantial genetic variation, whereas estrogen concentrations were largely influenced by environmental factors.

Cognitive functioning also shows a significant genetic component. Most studies of cognitive abilities in later life were conducted using studies of older twins, which showed that the overall cognitive functioning in older age is highly heritable with estimates of heritability equal to 76% in Danish twins 70 and older and 62% in Swedish twins 80 and older (Melzer et al., 2007).

Researchers have also started to collect information on genetic influences at different ages as well as on rate-of-change traits (Pedersen & Svedberg, 2000). Studies show that phenotypic variability has a tendency to increase with age for the majority of traits because of nonshared environmental effects. Genetic contribution to variability in cognitive abilities shows stability until ages 65 to 70 and declines thereafter. A similar pattern was found for self-rated health. Rate-of-change traits usually demonstrate a lower heritability compared to the absolute levels of studied traits. This was found to be the case for such traits as cognitive performance, body mass index, and lipid and lipoprotein levels. Thus, the rate-of-change traits apparently are not significantly affected by genetic factors.

Gene–environment interactions represent one of the most important and promising areas for the studies of the life course. Gene–environment interactions refer to differential genetic sensitivity to specific environmental factors. Genetic factors often act as effect modifiers (or moderators) when effects of socioeconomic or behavioral factors are analyzed. For example, there is no increase in risk for Alzheimer's disease among persons with head injury if they do not carry the APOE4 gene. For carriers of APOE4, however, head injury results in a tenfold increase in the risk of Alzheimer's disease. Similarly, APOE4 was found to be a risk factor for ischemic heart disease, but this applied mainly to smokers (Ryff & Singer, 2005).

It should be noted that heritability estimates for late-life traits may vary significantly across populations and that populations living in less favorable environments generally demonstrate smaller effects of genetic factors on variability of late-life traits. For example, the heritability of forced respiratory volume in Russian twins was found to be much smaller compared to Swedish twins most likely because of differences in environmental influences between Russian and Swedish samples (Whitfield, Brandon, & Wiggins, 2002).

## RESEARCH CHALLENGES AND FUTURE DIRECTIONS

Studies of genetic influences in later life face many methodological challenges. The main problem is that many individuals do not survive to late ages, and this survival is affected by both environmental and genetic factors. Twin studies often suffer from the limitations of cross-sectional design when it is impossible to distinguish selection effects (genetically determined differential survival) from true aging changes (Pedersen & Svedberg, 2000). Studies on exceptional longevity often suffer from the lack of data on living relatives, including parents (Hadley et al., 2000). Inconsistency in the findings of many gene–longevity association studies may be due to the lack of proper control groups in these case-control studies, because cases (centenarians) and controls (young adults) belong to different birth cohorts with different past histories. Thus, a comparison of centenarians and young adults is susceptible to artifacts resulting from differences in genetic makeup between different age cohorts unrelated to differential survival. The collection of longitudinal data (data from the same individuals over time) for twins and adoptees will alleviate the problems posed by cross-sectional designs and help to discriminate between selection processes and true aging changes. The collection of biomarkers (including genetic markers) that is underway in many population surveys and longitudinal studies in the early 21st century will fill the gap in knowledge about the association between specific genetic markers and later life traits. The most promising areas of research—gene–environment interactions in later life and early life genetic influences on late-life traits—are at the beginning of their development and will shape future life-course research on genetic influences in later life (Pedersen & Svedberg, 2000; Ryff & Singer, 2005).

## POLICY ISSUES

The rapid development of molecular genetics and the prospect of individual genome scans raise serious ethical concerns about the proper use of individual genetic information. Should individuals be informed about genetic risks for chronic diseases in later life if this information may result in unnecessary stress? Older persons having genes predisposing them to the risk of certain diseases (such as the APO4 gene) may be unfairly treated by insurance companies. These problems require both the protecting sensitive genetic information and educating the public that having genes predisposing a person to late-onset diseases is not a destiny and that individuals with unfavorable genotypes may never develop the specific disease (Ryff & Singer, 2005). At the same time, knowledge about genetic markers predisposing to late-life diseases may lead to the development of intervention measures specific to individual genetic makeups. Such a personalized approach may eventually become a fixture in medical care.

## GLOBAL AGING

Global aging broadly refers to the process by which the populations of the world's nations are growing increasingly older; indicators of population aging include the proportion of a nation's population that is age 65 or older, as well as trend data showing that the average and median ages of a nation's population have increased over time. Population aging processes throughout the world will have critically important social and economic consequences, including a potential shortage of working-age individuals, heightened demand for costly health care services, adequate housing accommodations and pensions for older adults, and a growing number of older adults relying on their children and grandchildren for social and economic support.

The rapid increase in population aging across the globe signals one of the most important demographic changes in recent history. In the latter half of the 20th century, the world's developed nations completed the demographic transition (Phillipson, 1998). The demographic transition refers to a societal-level shift from high mortality rates and high fertility rates (thus, short life spans and large families) to low mortality rates and low fertility rates (thus longer life expectancies, and smaller families). Countries that proceed through this transition ultimately have relatively high proportions of older persons and low proportions of younger persons (Powell, 2005). This transformation has taken many years to unfold, and is influenced by multiple factors. For example, in Europe and North America, the process of population aging is driven by factors including basic public health measures that steadily reduced the risk of contagious disease and modern medicine that has prolonged lives. In developing nations, by contrast, the demographic transition is still underway. These countries vary widely in how far along they are in the demographic transition; although most developing nations have much younger populations than developed nations, their numbers of older adults are increasing rapidly.

Researchers use a variety of methodological tools to document trends in population aging, and to predict the societal consequences of these demographic changes. Data on population aging processes come from multiple sources. Vital statistics registries, maintained by local governments, track all births and deaths as well as changes in an individual's legal status such as marriage, divorce, and migration (registration of one's place of residence) (Phillipson, 1998). In developed countries with good registration systems (such as the United States and much of Europe), registry statistics are the best data source for enumerating the number of births and deaths in populations (Bengtson and Lowenstein, 2004).

Researchers also use data obtained from population censuses. Censuses are usually conducted by national governments and attempt to enumerate every person in a country (Gavrilov & Gavrilova, 1991). Censuses also gather basic social and demographic information about a

nation's population. However, in contrast to vital statistics data that are typically collected continuously and summarized on an annual basis, censuses occur at longer intervals, typically every 10 years. For example, the decennial U. S. Census takes place only once every ten years (Phillipson, 1998). However, the Census Bureau also collects information annually through the American Community Survey. In nations where the vital registration system is incomplete, censuses may be used as an alternative source of information about fertility and mortality. For example, the Chinese census gathers information on births and deaths that occurred in the 18 months immediately preceding the start of the data collection period (Cook & Powell, 2007).

Drawing on these two types of data sources, researchers use a diverse range of measures to study global aging patterns. Demographers typically rely on statistics such as national birth rates (the number of live births for every 100,000 persons in a population), life expectancy projections (average expected length of life at birth), and dependency ratios (the proportion of the population who is of non-working age relative to those who are of working age) to compare and contrast the aging processes of diverse societies.

One important indicator of population aging is the percentage of persons age 65 and older in a population. In the United States, persons ages 65 and older accounted for 13% of the national population in 2000, yet this figure is expected to increase to 20% by 2030 (Estes, 2001). While the proportions of older people in a population are typically highest in developed countries, very steep growth of elderly populations is projected in developing nations (Cook & Powell, 2007). For example, between 2006 and 2030, the number of older people in less developed countries is projected to increase by 140%, compared to an increase of 51% in more developed countries (Krug, 2002).

Population aging not only reflects the proportion of a population that is age 65 and older; demographers also are interested in heterogeneity within the older population. Demographers often count and contrast the "old" (65+) with the "oldest old" (85 and older). The oldest old population is growing at an even more rapid pace than the overall older adult population. Around the world, the 85 and older population is projected to increase 151% between 2005 and 2030, compared to a 104% increase for the overall population age 65 and over, and a 21% increase for the population under age 65 (Bengtson & Lowenstein, 2004). This rapid growth partly reflects the fact that very small numbers of persons were ages 85 and older in prior decades; thus the small number is growing at a proportionally large pace.

The most striking increase will occur in Japan: By 2030 nearly 24% of all older (age 65 and older) Japanese are expected to be at least 85 years old (Kim & Lee, 2007). As will be discussed below, the rise in the oldest old population has important consequences for family relations. For example, the number of four-generation families (that is, families with living children, parents, grandparents and great-grandparents) may become more common as the oldest generation enjoys increasingly long life.

When the proportion of older persons in a population increases, the proportion of younger persons necessarily decreases. This ratio of older persons to younger persons is an important indicator calculated by demographers, as it is often viewed as a potential indication of a society's economic vitality. Demographers often calculate *dependency ratios*, which refer to the number of "dependents" (that is, persons under age 15 and over age 64), relative to those of working age (15 to 64). Interestingly, absolute dependency ratios have changed little over time, but the composition of the dependent population has shifted drastically.

Throughout most of human history, dependent populations had large numbers of young persons (due to high birth rates) and small numbers of older persons, yet in the early 21st century older persons account for a large and growing share of the dependent population. This shift has sweeping implications for policy and culture. For example, a society with a large youthful population would need to invest its national resources in education or job training programs to prepare the young people for the work force. A society with a large older population, by contrast, would need to invest its resources in health care and public pension programs.

## THE SIZE AND GROWTH OF THE WORLD'S OLDER POPULATION

In nearly every nation there is concern about population aging and its consequences for individuals, families, economies, and the state. On one hand, global aging is a triumph of modern times—a desirable consequence of improved public health, sanitation, and social and economic development. On the other hand, long life spans and population that is old often create fiscal strains for societies and families. Although a large proportion of older adults are physically, emotionally, and financially well off, many live with physical disability, cognitive impairment, and financial strain. This disparity creates challenges for governments and families worldwide. These challenges are expected to be most acute for the governments of developing nations because they are experiencing the most rapid growth in the older population.

Population aging can be put into perspective by reviewing a number of statistics that reveal the magnitude of changes that have occurred over the past century. The

United Nations (UN) estimates that the global population of those over 60 years will double, from 542 million in 1995 to around 1.2 billion people by the year 2025 (Krug, 2002, p. 125). Between 2003 and 2004 alone, the world's older adult population grew by 10.3 million persons. Projections suggest that the annual net gain will continue to exceed 10 million over the next decade.

In 1990 only 26 nations worldwide had 2 million or more older persons. By 2000, 31 countries had reached the 2 million older person mark (Cook & Powell, 2007). By 2030 more than 60 countries will have at least 2 million people age 65 or older, according to UN projections. The world is likely to have one billion older people by 2030 (Krug, 2002).

Not only is the total size of the older adult population growing worldwide, but so is the proportion. By 2045, for the first time in history, the global population of persons ages 60 years and over will likely surpass the number of children under age 15 (Powell, 2005). In every region of the world, the rate of population increase for the 65-and-over age group is higher than for the under-14 age group and the 15–64 age group (Bengston & Lowenstein, 2004). As noted earlier, this transformation of the world's dependent population reflects reduced fertility and increased life expectancy. Total fertility rates are expected to decline from 2.82 children per woman worldwide in 1995–2000 to 2.15 children in 2045–2050. Life expectancy worldwide is expected to increase by 11 years, from 65 in 1995–2000 to 76 in 2045–2050—although increases will be more moderate in nations suffering from high rates of HIV/AIDS mortality (Phillipson, 1998).

When absolute numbers are considered, the majority of the world's older adult population lives in developing countries. Even in the world's poorest countries—many of which are plagued by epidemics, AIDS, natural disasters, starvation, and warfare—life expectancy is increasing and the number of older people is growing. By 2015 an estimated two-thirds of the world's elderly population (or roughly 597 million older people) will reside in developing countries (Bengtson & Lowenstein, 2004). In 2005, 1 in 12 people in developing countries were over 60. By 2015, 1 in 10 persons in developing countries will be over 60, and by 2050, 1 in 5 people in developing countries will be over 60.

Throughout most of the globe, older persons are more likely than younger persons to be female. In 2006 there were 82 men for every 100 women over age 60 worldwide (Powell, 2005). In developing countries, the gap is less wide: There are 85 men for every 100 women over 60. However, as age increases, the sex ratio grows even more imbalanced. For persons over age 80, there are only 73 men for every 100 women (Bengston & Lowenstein, 2004). This pattern reflects the fact that men die younger than women, and has important implications for the daily lives of older adults and their families.

## THE CAUSES AND CONSEQUENCES OF GLOBAL AGING

Scholars are not only interested in documenting the pace and level of population aging. They are also concerned with documenting the causes and consequences of such important patterns. As noted earlier, population aging is caused by the relative increase in the older population relative to the younger population. The rise in the number of older persons largely reflects the fact that life expectancy is increasing. Increases in life expectancy are a consequence of changes in how individuals die in the early 21st century. Infant mortality rates have dropped considerably over the past three centuries, and infectious diseases that kill infants, children, and persons of working age have largely been eradicated (or can be treated). Thus, more people are surviving through the difficult early-life years and are living through later life. In later life, the leading causes of disease are conditions that are chronic, meaning older persons can live with diseases such as heart disease or cancer for relatively long time periods. However, these years of survivorship are often marked by physical discomfort, difficult treatment regimens, and expensive health care costs.

These processes have important implications for families, as well as individuals. As people live longer and have fewer children, family structures are transformed, leaving older people with fewer options for care. This erosion of family support has increased demand for federally funded social insurance systems. As social insurance expenditures escalate, countries are carefully evaluating the sustainability of these systems.

Population aging also will have dramatic effects on social entitlement programs, labor supply, trade, and savings around the globe, and may require new fiscal approaches to accommodate a changing world. For example, shrinking ratios of workers to pensioners and people spending a larger portion of their lives in retirement increasingly challenge existing health and pension systems (Bengtson & Lowenstein, 2004; Krug, 2002; Estes, 2001). The expansion of social programs targeted toward the elderly may have the unintended consequence of increasing stigma and perpetuating negative stereotypes of older adults. Younger working adults may perceive that they are funding public programs for the large and growing number of older adults, and may grow to resent their elders (Estes, Biggs, & Phillipson, 2003).

Although many of the challenges of aging are addressed at the national level (as will be elaborated below), population aging can no longer be viewed as a national

problem but as one that affects transnational agencies and communities. Local approaches to addressing the challenges of global aging had some meaning in a world where states were in control of their own destinies, and when *citizenship* and *national boundaries* were clear-cut and readily defined concepts. However, through processes of globalization, nations are increasingly interdependent and the aging of one society may have important implications (and require policy shifts) from other nations. For example, an aged population in one nation (such as Germany) may create the need for the importing of labor from other distant countries, such as Turkey. This is just one example of how globalization shapes nations' individual responses to population aging. To illustrate the diverse ways that global aging is unfolding in three non-U.S. contexts, this entry next briefly highlight key trends across the world: Europe, Asia, and Africa.

**Europe** The population structure of western European countries has changed dramatically since the turn of the 20th century. In 1901 just over 6% of the population was age 65+; this figure increased to 18% by 2001 (Powell, 2005). During the same time period, the population of persons under age 16 fell from 35% to 20%. As a result of these changes, dependency rates shifted—with important consequences for the European labor force. For example, in 1950 there were 12 people aged 15 to 64 to support each one of retirement age. It will be only 4-to-1 by 2050 (Powell, 2005). Some economists fear this will lead to bankrupt pensions, lower living standards, and a labor shortage. Nations including France, Germany, Greece, Italy, Russia, and the Ukraine have already seen an absolute decline in the size of their workforces throughout the 20th century. In the United Kingdom, for example, the percentage of people of working age is projected to drop from 64% in 1994 to 58% in 2031 (Powell, 2005).

These population trends have important implications for the European political climate. For example, Germany has the largest total population in Europe and the third oldest population in the world. As such, the German government faces challenging questions about funding public pensions and health care. Aging issues have started to figure prominently in political discussions prior to 2009 elections, as political parties vie for the elderly vote. The Angela Merkel administration (beginning 2007) has been criticized for increasing pensions while opponents talk about a "war of generations" requiring young people to pay for taxation for elder care.

Germany is not alone in its concerns. As the number of workers per pensioner decreases throughout Europe, there will be pressure on pension provision. This is evident in 2008, in such areas as pensions and long-term care, the retreat of the state made evident in the erosion of State Earnings Related Pay, forcing people to devise their own strategies for economic survival in old age (Phillipson, 1998). In the British context that also impinges on global societies in general: Private pensions are slowly being introduced in order to prevent the burden of an aging population. These are ways in which the state continues to rely on apocalyptic projections, the "demographic time bomb," about aging populations in order to justify cuts in public expenditure (Powell, 2005). Despite these worries, there is also widespread understanding of the unique contributions older persons make to society; older people take much of the responsibility for our social and civic life and for the care of children, the sick and the very old in the community.
