Optimum-start control is a feature of some timeclocks that automatically adjusts the equipment start time in response to weather conditions. Some models provide optimum start for both heating and cooling equipment, while others control only for heating equipment. Refer to the Measures that recommend optimum-start control for more details.

Electrical Options

■ Types of Switching Output

Timeclocks have different types of electrical output. Depending on the model, the timeclock may:

- act as a switch, simply opening or closing a circuit. This is called “single-throw” operation. If the timer switches only one wire of a power circuit, the action is called “single-pole, single-throw” (SPST). If the timer switches both wires of the circuit, the action is called “double-pole, single-throw” (DPST).
- act as a switch, transferring from one contact to another. This is called “double-throw” operation. If the timer switches only one wire of a power circuit, the action is called “single-pole, double-throw” (SPDT). If the timer switches both wires of the circuit, the action is called “double-pole, double-throw” (DPDT). Double-throw output can be used for single-throw applications by leaving one of the terminals disconnected.
- connect the equipment to power (“on”) or ground (“off”)
- provide pulses. The duration of pulses may be fixed, or they may be adjustable, typically from one second to one hour. This feature can be used directly for applications such as ringing bells, or the pulses can be used as input signals for relays or digital control systems.

Be sure to select the right kind of output for your application. For example, if you want the timer to close a switch in a low-voltage control circuit, you do not want to discover that your timer applies full line voltage to the circuit.

Some multi-circuit timeclocks can provide pulses on one circuit and switching on another.

■ Current, Power, and Voltage Ratings

Timers are rated by the amperage that they can control. This merely indicates the amperage that the timer can control directly. You can use any timer to control any amount of current by using a suitable relay. A high amperage rating may save the cost and effort of installing a relay.

The amperage rating of a given model may be different for incandescent lighting than for other types of loads. This is because incandescent lamp filaments have much lower resistance when cold than at operating temperature, so they have high starting current.

If the timer is rated by the power that it can control, rather than by amperage, the rating may be lower for

Paragon Electric Company

Fig. 3 Could you program this time control properly? This time control has a good range of features. But, what are they? Where are the instructions? Can you read the buttons easily? Will the letters rub off in a few years? A time control is useless unless everyone involved with it understands it.

motors and fluorescent lighting. This is because motors and magnetic lamp ballasts have low power factor, which requires them to draw extra current for a given amount of power.

The timeclock itself usually operates from normal line voltage. Timeclocks need little power.

■ Backup Against Loss of Power

Most electronic timeclocks avoid the problem of power outages by having a backup power source to protect against loss of external power. Continuous power is needed to keep the clock on time and to preserve the switching schedules.

The backup power source can be a battery or a capacitor. A battery typically can keep the timer in operation for periods up to several months. A capacitor may provide power for periods up to several days.

Some time controls use conventional batteries, and some use rechargeable batteries. The most convenient and economical choice is conventional, non-rechargeable batteries. Rechargeable batteries are desirable only if the facility is subject to frequent power outages, or if equipment operation is critical.

Battery failure from old age is a long-term failure mode. If the battery fails, the unit will probably lose all its programming during a period when external power is lost. Try to find timeclocks that warn of the need to replace the battery. If you cannot find this feature in the type of timeclock you want, put specific dates for replacing the battery on the unit's instruction placard. For example, the placard might say, "Replace the battery in June of each year that ends with a '0' or '5'."

A capacitor power backup almost eliminates this failure mode. Capacitors generally should last for the life of the time control, although electrolytic capacitors do fail more often than other electronic components. The main disadvantage of capacitors is a shorter continuous backup period. However, the capacitor recharges almost immediately if power is restored for a short period. For frequent interruptions of power that last only for a short period, the capacitor is probably a better choice. Look at your application to decide whether a battery or a capacitor provides greater security in your environment.

Important Physical Characteristics

■ Ease of Use

Ease of use is vital to ensure that a timeclock is used properly, and is not abused. Some operators are likely to ignore or abuse a timeclock if it appears to require "programming." The timer should have simple and obvious procedures for setting, for changing settings, and for override. Also, it should easily display the schedules that are currently programmed into the unit. Figure 3 shows the programming panel of a typical time control of medium capability.

Unfortunately, most electronic timeclocks are not yet user-friendly. Find the models that are best in this regard. Ideally, the setting procedures should be almost as easy as using a pushbutton telephone. If you cannot find such a unit, at least try to find models that have large numbers in the displays, large buttons for programming, and large text for the instructions. This is important to middle-aged operators who leave their glasses at home.

Obscure and poorly illustrated instructions are a major failing of present time controls. If you find a unit that has all the control features you want, be prepared to design a good set of instructions to install along with the hardware. See [Reference Note 12](#), Placards, about how to do this.

■ Ruggedness

A weakness of most electronic timeclocks is that they are built more for the environment of a library or a laboratory than for the rugged environment of equipment rooms. Not all people who operate facilities are dainty in their handling of equipment. It takes only one ham-fisted or harried individual to destroy a time control that is too delicate for the environment. Damage becomes almost a certainty if the timer is not easy to use, which incites operators to intemperate behavior.

Many models are available with sturdy steel enclosures. The enclosures are adequate to protect against accidental impact damage, but they do not protect against the greatest hazard, which is the operator in a hurry to get equipment started. In severe environments, the best approach is to make the timeclock itself inaccessible to all but a chosen few, and to install readily accessible overrides, as explained below.

Programmable Thermostats

A programmable thermostat is a combination of a timeclock and a thermostat. The timeclock switches the thermostat from one temperature during the occupied periods to a lower temperature during unoccupied periods. Figure 4 shows the layout and features of a typical programmable thermostat.

In principle, programmable thermostats provide ease and flexibility in controlling heating and cooling equipment. However, most programmable timeclocks are fairly cheap, so they may lack important features. In particular, many models may not be rugged enough for some environments and they may not be easy to program.

When you select a programmable thermostat, consider all the criteria that we have discussed for clock controls. In addition, be sure that the unit has all the thermostatic features needed to provide maximum efficiency for the application. For example, if the space can benefit from deadband temperature control during occupied periods, make sure that the unit includes this capability.

Overrides

The main weakness of clock controls, when used alone, is that they do not provide an easy method of adapting the operation of equipment to irregular times of usage. As a result, clock control is often sabotaged. Figure 5 shows a common example. In many cases, the timeclock is disabled the first time that someone needs the controlled equipment at an unexpected time.

The problem is most severe with time controls that are set remotely, or that are designed to keep people from making changes to them. Figure 6 shows an example.

The solution to this problem is to provide an override feature that allows the equipment to be operated quickly and easily without the need to re-program the timeclock. The override may be part of the clock control itself. Or,

it may be an entirely separate switching device that provides power to the equipment separately from the time control.

Many models of timeclocks have some form of override. These may be satisfactory if the override is easy to find, easy to use, and well marked. Unfortunately, timeclock manufacturers still fail to understand the importance of overrides that are rugged and well marked. Expect that an override feature on the timer may not satisfy the needs of a person who is in a hurry and unfamiliar with the unit.

Fortunately, it is easy to provide an external override. In many applications, the best override is a simple rundown timer (such as a spring-wound dial timer) that is wired in parallel with the timeclock. The rundown timer can be installed where it is most obvious to users

Carrier Corporation

Fig. 4 Programmable thermostat It combines the features of a thermostat with a simple electronic timeclock to change the space temperature settings at different times.

Fig. 5 The fate of any timeclock that lacks an effective override This old timeclock has been sabotaged in the usual way, by removing the “off” trippers, which are lying below the timeclock. An electronic timeclock without an easily accessible override would probably have been put out of commission in a more destructive way.

of the equipment, and the timeclock itself can be kept isolated in a place that is accessible only to persons authorized to program the timeclock.

Overrides that are provided as features of electronic timeclocks typically self-cancel after one on/off cycle. This feature is important. Without it, an override effectively disables the timeclock.

However, even a self-cancelling override can be inefficient. For example, a person working late in an office may use the override to keep a heater running until he leaves, but the override will keep the heater

Paragon Electric Company

Fig. 6 Remote-setting time control This is a handy feature for some applications. However, an override is needed at the point where this control affects people.

running all night. In such cases, it is more efficient to use a separate rundown timer as an override, as this limits the override period.

Installation Issues

Like all control equipment, clock controls should be accessible, well protected, and well explained. The timeclock itself should be installed where it is easily accessible to the people assigned to program it. On the other hand, the override should be installed at a location that is highly visible and accessible to the people who need the controlled equipment. In facilities, such as office buildings, where occupants are not members of the operating staff, expect to install the timeclock in one location, and to install one or more overrides in other locations.

See [Reference Note 12](#) for details of installing the placard, which is an integral part of an effective control installation.

Where to Use Personnel Sensors

Types of Personnel Sensors

- Passive Infrared Sensors

Test Unfamiliar Situations

Monitor Performance

Personnel sensors, also called “motion detectors” and “occupancy sensors,” are devices that sense the presence of people within an area. Originally developed as security devices, personnel sensors have become an efficient method of controlling equipment that is needed only when people are present.

In appropriate applications, personnel sensors match the operation of equipment to space occupancy more accurately than any other method. At the same time, using personnel sensors can be tricky. Inappropriate or careless installation can waste energy, annoy occupants, and create safety hazards. This Note tells you how to select and install personnel sensors successfully.

Where to Use Personnel Sensors

The most common energy conservation application for personnel sensors is controlling lighting. For example, a lighting retrofit program for a large, diverse research hospital found personnel sensors to be the most efficient method of lighting control for a large fraction of the spaces in the hospital, including offices, laboratories, restrooms, etc. Lighting is well suited to control by people sensors because it is needed only when people are present. However, even with lighting, it is sometimes better to control with other methods. For example, sensor control is not appropriate for patient rooms in hospitals.

Personnel sensors can also be used to control other types of equipment that are related to occupancy, such as ventilation fans. Personnel sensors cannot be used to start equipment that needs a warm-up or cool-down period, but they may be an effective means of stopping such equipment in applications where occupancy ends at varying times. For example, timeclocks can be used

to start heating and cooling equipment at the beginning of the day, while personnel sensors are used to control this equipment later in the day.

Do not expect to use one particular model of sensor or one particular mounting method throughout a facility. Typically, you will need three or four different models and many mounting configurations to cover a building of average size and complexity. Expect to tailor each personnel sensor installation to the space that it covers. Expect to spend a lot of time and effort on this.

Personnel sensor control has the potential of annoying people, and even of creating safety hazards. Experience shows that occupants do not object to personnel sensors that are installed with adequate attention to the considerations discussed below. In proper installations, occupants typically are amused by personnel sensors until they no longer notice them.

Types of Personnel Sensors

Various methods have been developed to detect the presence of people in a space. None of them can absolutely distinguish a person from another object, and none can absolutely detect the mode of behavior, such as remaining in a space or just passing through. You have to select the device, or combination of devices, that most reliably detects the person, object, or mode of behavior that is appropriate for your control application. The following are the main types being used to detect people, and objects associated with people.

■ Passive Infrared Sensors

Infrared sensors detect the long-wavelength heat radiation that is emitted by people or other warm objects. The sensor does not emit any radiation itself, so it is

“passive.” For this reason, infrared personnel sensors are commonly called “passive infrared” sensors.

The world is full of warm objects that we do not want to detect, such as heating vents and coffee pots. To avoid being triggered by these objects, infrared personnel sensors exploit the fact that most of these objects are stationary. The device uses a grid and an optical system to sense the motion of people. Only a small amount of motion is needed by a person to trigger the sensor.

Infrared sensors have become the most common type of personnel sensor for energy conservation applications. Figure 1 shows a small ceiling-mounted model that could be used to control lighting, air conditioning, a security system, or other applications.

Infrared sensor models that are designed to replace existing light switches have become popular because of their low cost and ease of installation. Figure 2 shows a good example.

The number of configurations is growing, especially for lighting control. Passive infrared sensors are now commonly available as an accessory of exterior floodlight fixtures, and they are also installed in other types of light fixtures. For controlling existing lamps, an inexpensive infrared lighting control can be inserted between a light bulb and its socket. Portable infrared sensors are available with a power cord and a male/female plug that allow them to control any appliance.

■ Ultrasonic Sensors

Ultrasonic sensors function by radiating high-frequency sound waves and sensing the frequency shifts (Doppler effect) in the sound that is reflected back to the sensor by moving objects. They cannot distinguish between people and other objects, except by size and location. Ultrasonic sensors are commonly used to open automatic doors, for example. They function well in this application because they open the door for any moving object, whether living or not.

Ultrasonic sensors are used much less commonly than infrared sensors for detecting people inside a space. However, ultrasonic sensors designed for this purpose are available. Figure 3 shows an example.

■ Audible Sound Sensors

Sensitive microphones can be installed to sense the presence of people by the sounds they make. Sound detectors are rarely used for control of energy systems, primarily because there is too much background noise in most applications. They are used most commonly in security systems. However, audible sound detectors may be a good choice for controlling interior security lighting, for controlling lighting in very large spaces, and for other specialized applications.

■ Microwave Sensors

Microwave sensors fill a space with microwave radiation. They detect movement from the distortion of the reflected radiation. They are like the early type of non-directional radar. That is why the radar detector of your car may sound an alarm when you drive past a large building. Microwave sensors are common in security applications, but they are not generally used for control applications.

■ Tread Switches

A tread switch makes or breaks an electrical contact when someone walks on it or rolls equipment over it. For example, tread switches are commonly used to open automatic doors. They are not commonly used for sensing people in a space, because they cannot cover a large area. In principle, you could use a tread switch at the entrance to a space to turn on the lights in the space. However, the switch would not know when the space has been completely vacated. Thus, they are generally not useful for turning equipment off.

Unenco Electronics, Inc.

Fig. 1 Passive infrared sensor for ceiling mounting
This unit sees in all directions. Installing it on the ceiling provides the most reliable coverage of the space. Settings are made with the tiny DIP switches, at the time of installation.

A tread switch may be a good way of conserving energy in a very localized application. For example, a tread pad can be used to turn off a machine tool when the operator is not standing on it.

■ Photoelectric (Light Beam) Switches

A light beam switch senses a person or object interrupting the light beam. A lamp is placed on one side of a path and shines a narrow beam into a photoelectric cell on the other side of the path. For example, light beam switches are commonly used as safety devices to keep automatic doors open when a person or object may be passing through the door.

This device is similar in application to tread switches, and it has similar weaknesses. Light beam switches are reliable and they are fairly inexpensive. In applications involving safety, they have the advantage of failing in a safe mode. For example, if the bulb burns out, the effect is the same as if a person crosses the light beam.

WESINC photo

Fig. 2 Passive infrared sensor for light switch location
This type is inexpensive, easy to install, and easy to use. Its main weakness is the mounting location, which may not provide good coverage and may be easily obstructed. The details of this unit are shown in Figures 6, 7, and 8.

■ Interlocks with Other Controls

Any control that relates to the presence of people can be used as a personnel sensor. For example, the heating of a space may be controlled by the light switch for the space. Or, a contact switch can be installed on a door to turn on lights when the door is opened. Various Measures recommend these techniques where they are appropriate.

How to Select and Install Personnel Sensors

■ Safety

If you use personnel sensors to control lighting, take care to design the lighting layout so that a person will not be trapped in a darkened space if a personnel sensor fails to detect the person. For example, a personnel sensor controlling the light in the restroom may lose sight of a person who enters an enclosed stall. If the

Unenco Electronics, Inc.

Fig. 3 Ultrasonic motion sensor for ceiling mounting
Ultrasound is directional, so this unit has four emitters to provide reasonably complete coverage. It is somewhat larger than a passive infrared unit.

person lingers there, the lights in the restroom may turn off, stranding the person.

The general solution to this problem is to provide enough continuous lighting to allow occupants to find their way safely to an exit. In most commercial buildings, this purpose is served by emergency lighting. If the facility operates only in the daytime, letting in some daylight may suffice.

Safety is also a major consideration where personnel sensors are used to control moving equipment, such as a conveyor belt in a factory. Design the controls to protect both equipment users and maintenance personnel from unexpected starts. The appropriate safeguards depend on the application, and may include warning signs, guards, interlocks, dead man switches, etc.

Ultrasonic sensors may be ineligible for some applications because of concern about their long-term effects on occupants. The fact that ultrasonic sensors remain on the market after years of use for opening doors indicates that no serious problems have been proven. However, it remains questionable whether ultrasonic

controls should be installed where people will be exposed to them for long periods.

Do not use ultrasonic detectors in spaces containing animals that are sensitive to high-frequency sound, unless the animals are unwelcome.

■ Minimize the Perceived Delay in Turning On Lights

Locate sensors where they can immediately see a person entering a space, as when a person abruptly opens the door to a restroom with sensor lighting control. Otherwise, the person will have the unpleasant sensation of walking into a dark space. This problem is especially severe if persons are not familiar with the sensor control, for example, in public restrooms.

If the lighting is fluorescent, the problem is worsened by the starting delay of the lamp. The delay ranges from a fraction of a second for rapid-start lamps, to several seconds for preheat lamps. Most compact fluorescent lamps are preheat types, and many have a noticeable starting interval. Some compact fluorescent lamps take almost a minute to reach full brightness, and these lamps should not be used where instant light is required.

Fig. 4 Coverage pattern of an infrared sensor for corner mounting Infrared sensors use a lens system, so they can be made with any coverage pattern. Coverage can be uniform across the field of view, but sensitivity varies with background temperature.

Unenco Electronics, Inc.

Unenco Electronics, Inc.

Fig. 5 Coverage pattern of combined infrared and ultrasonic sensor This diagram does not tell the whole story, because each type of sensor is more sensitive in some ways than the other. For example, the IR sensor is most sensitive to motion across the field of view, but the ultrasonic sensor is most sensitive to approaching or departing motion.

Do not use personnel sensors to control high-intensity discharge (HID) lighting. It has a very long delay in starting and restarting, of several minutes or longer.

■ Range, Coverage Pattern, and Sensitivity

Infrared personnel detectors typically have a range from 20 to 70 feet (6 to 20 meters). Detection is strictly line-of-sight. The coverage pattern, or field of view, depends on the geometry of the lenses that focus the heat radiation on the sensor. Ceiling-mounted sensors may have 360° coverage. Infrared sensors that replace existing wall switches may achieve almost 180° coverage against a flat wall. Figure 4 shows the coverage pattern of a model designed to be installed in a corner.

The range of infrared sensors varies with the magnitude of the temperature differential between the person's exposed skin and the background. Infrared sensors can detect remarkably small temperature differences, but it is conceivable that persons could become invisible to the sensors if the background temperature is close to skin temperature.

Infrared detectors sense motion across the sensor's field of view. Hence, the amount of motion required to trigger the unit depends on distance from the sensor. A unit installed close to a desk can sense a person nodding his head or moving his hand across a page, provided that this motion is across the detector's field of view.

WESINC photo

Fig. 6 A good set of features in an infrared sensor
The screw on the right adjusts the daylight level that keeps lights turned off. The screw on the left adjusts the turn-off delay. Both require trial-and-error to set. The slide switch in the middle selects the override mode, explained in Figure 7. The switch plate must be removed to change any of these settings, which is an important safeguard. The little rectangular light amuses occupants by blinking when the sensor detects motion.

Ultrasonic detectors have about the same range as infrared units, or somewhat less. Their range depends on the person's size and direction of motion. Ultrasonic detectors sense motion primarily toward or away from the detector. They are generally less sensitive to motion than infrared detectors. As a result, they are limited to sensing large motions, such as people walking toward a door.

In order to get good sensing reliability, it may be desirable to combine the features of infrared sensing and ultrasonic sensing. Figure 5 shows the coverage pattern of a sensor that uses both types of technology in a single small unit.

Audible sound detectors have unlimited sensitivity potential. Their effective range is limited by the need to avoid false triggering from background noise. Occasional outside noises may be louder than typical human activity inside the space. Furthermore, human activity does not tend to be noisy on a continuous basis. Therefore, audible sound detectors are limited to applications where noise-producing activity is associated with the presence of people.

■ Mounting Location

Sensors must be mounted where they can reliably "see" people in the controlled area.

Infrared radiation is a form of electromagnetic radiation, like visible light. It has about the same penetration. If visible light cannot pass through something, infrared radiation cannot pass through it either. Furthermore, glass and other materials block heat radiation from people.

WESINC photo

Fig. 7 Override options This sticker explains the override modes that are selected by the switch in Figure 6. Option AA is the one to use in most applications. Option MA is efficient, but has few applications. Option MM abolishes the benefit of the sensor. The sticker becomes inaccessible, and hence useless, when the switch is installed.

Infrared sensors that replace wall switches are tempting with their low cost and ease of installation, but make sure that they provide adequate line-of-sight coverage of the space. This may be a problem, because light switches are mounted low on the wall, where the line of sight into the space may be obstructed by partitions, coat racks, etc.

This type of infrared sensor may be difficult to install in place of an existing toggle switch if the present switches are ganged, because the face plate of the sensor unit may be too wide for mounting alongside toggle switches. At least one manufacturer includes a replacement face plate to be used with double switch boxes. With larger numbers of ganged switches, you may need to install a separate junction box for the sensor.

Ultrasonic personnel detectors emit sound at very high frequency, which makes the sound directional. Ultrasound does not bend around objects very much. It does pass through lightweight objects, such as curtains and plants, and it reflects from the surfaces of the space, especially from hard surfaces. Thus, ultrasonic sensors are not limited entirely to line-of-sight detection. However, don't depend on this. Most ultrasonic detectors emit sound in a lobe pattern, with an effective pattern width around 50°. They are usually mounted high on a wall.

Audible sound detectors are non-directional, especially for sounds of lower frequency. This makes them worth considering where the other two methods cannot provide adequate coverage, provided that the environment is fairly quiet. Audible sound detectors can be installed almost anywhere, except that they should be installed away from any sources of noise that are not related to occupancy.

Wall-mounted sensors typically have self-contained override switches, sensitivity and delay adjustments, etc. Ceiling-mounted units either sacrifice these control options or they require separate control panels, which adds wiring cost.

■ Daylight Override

Sensors that are designed to control lighting may have a feature that detects the amount of daylight in the space. It keeps the switch from turning on the electric lights when sufficient daylight is available. This feature requires a setting to adjust the amount of daylight that is needed to deactivate the switch. Figure 6 shows the setting on a typical unit.

■ Turn-Off Delay

Virtually all personnel sensors have delay mechanisms to keep the equipment turned on for a period of time after the last motion or sound is detected. This delay feature compensates for lack of sensitivity. Extending the time delay makes it more probable that a person within the space will move enough to keep the equipment turned on. For example, even a person

reading a book moves enough every few minutes to reactivate an infrared sensor.

The energy penalty of extending the turn-off delay is usually small. For example, if the equipment is kept running for ten minutes after the last person leaves the space, this does not waste much of the energy-saving potential in most applications.

In applications where people frequently enter and leave a space, the turn-off delay minimizes short-cycling of equipment, such as lamps, motors, compressors, etc.

Many delay options are available on different models. Some units have a single fixed delay period. Others have a choice of fixed delay periods. Many units provide a continuous range of delays, as in Figure 6. The latter type can be a nuisance to set, because the setting feature does not accurately indicate the delay. This requires wasting a lot of time with trial and error.

■ Minimize False Triggering

Personnel sensors can be triggered by stimuli other than people, or by the wrong people. False triggering wastes energy and wears out equipment. To determine whether false triggering is occurring, observe the operation of the equipment during unoccupied periods. You can temporarily connect an inexpensive data logger to the controlled equipment for this purpose.

Infrared detectors may be triggered by equipment that turns on and off while the space is vacant. Examples are heating and cooling equipment, refrigerator motors and thermostatically controlled coffee pots. Infrared sensors are not triggered by the air from the conditioning units, but by surfaces that are heated or cooled rapidly by the air, including the surfaces of the conditioning units themselves. The same problem can be created by sunlight that enters through windows and skylights. Fortunately, window glass is opaque to heat radiation, which minimizes (but does not eliminate) false triggering caused by moving heat sources seen through windows.

Experience will teach you where to expect false triggering. Infrared control is line-of-sight, so you can usually prevent false triggering by installing shutters or blinders to keep the sensor from seeing the heated areas. Some infrared units include adjustable shutters to limit their field of view. Some infrared sensors have sensitivity controls that may avoid false triggering.

Ultrasonic personnel sensors may be triggered by moving objects within vacant spaces, such as machinery, exposed fans, blowing curtains, kinetic artworks, etc. They may also be triggered by transient sounds, such as thunder or an air conditioner turning on. Ultrasonic sensors may have sensitivity controls to limit unwanted triggering.

With audible sound detectors, it is virtually impossible to prevent some false triggering by sounds from outside the controlled space. Also, false triggering may be caused by equipment sounds that occur within

the space while it is vacant. Selecting the best mounting location and adjusting the sensitivity control are the ways to minimize false triggering.

■ How to Confine the Area of Control

Arrange the control layout so that people located in one area do not trigger sensors in other areas. You can do this by limiting the sensitive area of each sensor. For example, to provide individual lighting for a number of indoor tennis courts, install a sensor for each court and aim it at the center of its court. This may require adjusting shutters or installing blinders on the sensors.

The weakness of this technique is that people who are near the edges of controlled areas may not trigger sensors reliably. You can solve this problem, at increased cost, by installing a larger number of short-range sensors. For example, the lighting for each desk in an open office bay can be controlled by its own sensor.

Another approach is to install partitions. This may not be as expensive as it sounds. With infrared sensors, only lightweight visual screens are needed.

■ How to Control Large Areas with Few Sensors

Use clever sensor layout to minimize the number and cost of the sensors needed to provide coverage of a large area. For example, you may provide adequate control for lighting a basketball court by installing sensors near the basket, at the entrances, and at the front of the seating area.

If you use this “sampling” technique to control lighting, it is especially important to design the lighting so that safe egress is possible under all conditions.

Consider audible sound detectors for large areas that are sparsely or irregularly occupied, provided that the background noise is not too high. Audible detectors provide the advantage of complete coverage, avoiding the uncertainties of control on a sampling basis.

■ Accommodate Diverse Control Requirements

It may be desirable for equipment to respond differently to different types of occupancy. For example, the air conditioning unit in a room should start when the first occupant enters, but not when a security guard looks inside. One way to make this distinction is to mask out the portion of the space where unwanted triggering can occur. If this is not practical, consider subdividing the space into smaller controlled areas by using a number of sensors of limited range.

Cleaning crews deserve special attention because they go almost everywhere and they work at hours when the regular occupants are gone. For control of lighting, personnel sensors respond almost perfectly to cleaning crews. However, for control of conditioning equipment, they have just the wrong response. You may need to combine personnel sensors with other controls to keep equipment from starting as a result of the transient presence of people in an area.

(Permit a small sermon. Designers fail to account for operational factors like cleaning crews, window washing, light bulb changing, and equipment maintenance because they do not acquire experience in facility operations during the years they are in training. This is a glaring defect in our present way of training architects and engineers.)

■ Anticipate Changes in Space Configurations

Try to anticipate future changes in space configuration that may interfere with the operation of personnel sensors, such as relocation of furniture, addition of privacy screens, etc. Even small changes may mask the coverage of a sensor, such as placing a coat rack next to a wall sensor. Retrofit sensors that replace toggle switches are most vulnerable to changes because they are installed at a low height.

■ On and Off Override Switches

Personnel sensors cannot respond to all the conditions that may occur, so they may include a manual “off” switch, a manual “on” switch, or both. Figures 6 and 7 show an interesting combination of choices for selecting manual or automatic operation.

It is usually desirable to provide a manual “off” override, either on the sensor itself or separately. For example, in lighting applications, there is usually an occasional need to darken a space while it is occupied, e.g., to show slides in a conference room. Make the override switch easily accessible.

On the other hand, avoid sensors that include an “on” override. If the sensor has this feature, it is likely that someone will leave the switch in the “on” position, disabling its ability to turn equipment off. There should be no circumstances that require an “on” override. If a personnel sensor fails to turn on equipment automatically

Fig. 8 Critical electrical information This infrared switch can control different kinds of electrical equipment, including motors, but the capacity ratings are different for each kind.

when it is needed, it is either installed improperly or it is not appropriate for the application.

■ Sensors with Three-Way Switches

Some wall-mounted sensors can act as a 3-way switch. These units are intended as replacements for existing 3-way toggle switches. These can be used in two ways. If all the manual switches are replaced with sensor switches, sensors in different parts of the space can control a single set of equipment. Or, if a single sensor switch is used in combination with manual switches, the manual switches can act as overrides to force the controlled equipment off.

■ Maximum Amperage or Wattage

The cost of electronic devices is related to the current they handle, so many personnel sensors are not designed to handle full circuit capacity. Be sure to check that the amperage or wattage rating of the sensor is adequate for the controlled load.

The amperage rating may be lower for incandescent lighting than for other types of loads. This is because incandescent lamp filaments have lower resistance when cold than at operating temperature, so they have high starting current.

If the sensor is rated by power, rather than by amperage, the rating may be lower for motors and fluorescent lighting. This is because motors and magnetic lamp ballasts have low power factor, which requires them to draw extra current for a given amount of power.

Figure 8 illustrates how a single sensor may have a number of different wattage and volt-amp ratings for different types of loads.

If you need to control a large amount of amperage or power, consider using a power relay instead of a more expensive sensor. Using multiple relays allows a single sensor to control as many circuits as desired. A relay also allows any sensor to control equipment of any voltage.

■ Minimum Wattage

An odd feature of some personnel sensors is that they require the controlled equipment to have a minimum wattage. For example, some lighting sensors cannot control lamps smaller than 40 watts. This is related to the switching characteristics of semiconductors.

■ Lamp Flicker

Some personnel sensors cause fluorescent lamps to flicker. This appears to be a problem associated with aged lamps. Also, high-efficiency fluorescent tubes are more susceptible to flicker than conventional tubes. The problem is most serious immediately after the lights are turned on. These problems suggest that the personnel sensors are lowering the peak voltage to the lamps.

For fluorescent lighting and other applications where the voltage and waveform of the power are critical, test candidate units to ensure that they do not cause problems.

Some electronic fluorescent lighting ballasts compensate for variations in input voltage, including variations caused by personnel detectors.

■ Grounding

Good grounding is especially important for reliable operation of semiconductor switching equipment, as well as for safety. It is good practice to ground the sensor units using separate ground wires attached to the boxes, rather than relying on the mounting screws for grounding. Trouble is likely to occur if the existing electrical system is not well grounded.

■ Placards

Even though personnel sensors are fully automatic, expect to install placards to inform occupants about them. Incomprehensible control operation is annoying, and people may respond in a manner that is wasteful or unsafe. See [Reference Note 12](#), Placards, for details of effective placard design, materials, and installation. Placards about personnel sensors should explain the following:

- which equipment is controlled
- that the equipment responds to the presence of people in the space
- that the control will delay turning off the equipment for a short period after it ceases to sense people in the space
- how to operate the manual features of the control (if any)
- that the user should set the switch back to “automatic” after using any manual settings
- whom to contact in the event of malfunction.

Test Unfamiliar Situations

It is difficult to anticipate exactly how particular models of personnel sensors will work in any particular environment. In case of doubt, test a few candidate sensors in some typical spaces before purchasing large numbers.

Monitor Performance

For a period of several days after a sensor is installed, check with the occupants of the space to see whether the controls are causing any problems. Make any appropriate corrections.

Don't forget this step. If a dangerous or inconvenient situation is created by the sensor control, you want to know about it before trouble occurs.

Placard Materials

How to Attach Placards
Make Them Attractive
Update Them
Coordinate Your Placard Installations
Coordinate with Other Communications Methods

A large fraction of the energy consumption of a facility is under the control of people. These people include managers, operating staff, employees, occupants, tenants, guests, etc. Where people control energy consumption, much energy waste is caused by failing to effectively tell those people how to conserve energy.

In many environments, placards are potentially the best method of communicating with people about the energy conservation actions that they should take. Placards themselves are cheap, but designing and installing them properly requires perception, effort, and a certain gift for communications. This Note will guide you in using these powerful energy saving tools.

Why Placards are Important

When deciding where to use placards and how to design them, put yourself in the position of the people you are trying to reach. The common communication problems that lead to missed conservation opportunities are:

- people are not aware that particular equipment, such as lighting or air conditioning or machinery, is using energy, or how much
- people are not aware of energy-conserving actions that they can take
- even if they are aware, they are not sure about what to do, or when to do it
- the purpose of controls is not clear
- controls are inaccessible, inconvenient, or out of sight
- people are concerned that taking action will offend others, draw criticism, or be ridiculed
- people lack motivation to act
- people lack the skill required.

Placards attack each of these problems. Placards do more than provide information. They have important psychological functions. They request action, and equally important, they grant permission to act. They assure the person that actions taken to conserve energy are appropriate.

Placards can be a powerful means of overcoming social inhibition that deters energy conservation. It is

not generally true that “people don’t care” about energy conservation, or that people are irresponsible. Instead, people are hesitant to act if doing so may offend others, or if they may be subjected to ridicule for taking unusual initiative. By the same token, people will take appropriate action if two conditions are satisfied: (1) the desired action is stated clearly, and (2) the desired action appears to be appropriate and expected. Design your placards to satisfy both of these requirements.

The presence of an official-looking placard says, in effect, “It is polite and conscientious to conserve energy.” This is especially important for persons who are not employed in the operation of the facility.

Expect to break new ground and invest effort. In the past, people responsible for energy efficiency failed to recognize the potential benefit of placards. When they have used placards, they failed to understand the amount of effort needed to produce good ones. Most placards have been overly general, poorly presented, and impermanent. For example, a sign scrawled on a piece of cardboard with pencil is illegible, it lacks authority, and it will not survive.

Generic “conserve energy” stickers and posters are almost worthless. To be effective, each placard must be customized to its application and environment.

Where Placards are Most Effective

Placards are an economical way of motivating efficient operation of almost any kind of equipment. However, the potential effectiveness of placards varies considerably in different situations. Placards are most effective if they are related to individual responsibilities. For example, a placard on a chilled water temperature reset control is most effective if specific persons are assigned to operate the chiller plant.

If responsibility cannot be assigned to a specific individual, placards work best in single-occupant spaces where there is low personnel turnover and a high level of personal responsibility. If there is more than one occupant, each occupant is reluctant to act for fear of annoying other occupants. In such situations, you can improve the effectiveness of placards with additional publicity, as discussed below.

By the same token, you can enhance energy conservation by making designated individuals responsible for specific energy conservation activities. When you do this, the placard acts as a “homing device,” guiding the designated individual to the activity.

Where to Install Placards

Install placards on all devices affecting energy consumption that require some human action. This includes windows, light fixtures, thermostats, fan control switches, heat/cool selector switches, timeclocks, manual radiator valves, etc.

Also, install placards to inform people of the operation of automatic controls that have overt effects. For example, if lighting is controlled with motion sensors, install a placard at the entrance to the space that states this fact. This prevents unpleasant surprise, avoids safety problems, and limits resentment toward energy conservation in general.

The location of placards is critical. Locate placards where they are conspicuous, where they will be noticed at the time they are needed, and where their relationship to the equipment is obvious. The best location depends on the information that is being conveyed. For example, if the purpose of the placard is to encourage efficient temperature setting, install the placard at the thermostat. If the purpose of the placard is to get people to turn off their equipment at the end of the day, you might install the placard at the switch controlling the equipment, or at the exit.

Do not be reluctant to install more than one placard if there is no single best location. For example, you might install one placard at the thermostat for temperature control, and another at the exit to suggest turning off the conditioning unit when the last occupant leaves the space.

What Placards Should Say

In order for a placard to be effective, it should state clearly:

- the purpose or identity of the item
- what to do (or avoid doing)
- when to do it
- how to do it
- what response to expect
- how to get help, if needed,

Some of these items can be omitted if they are obvious.

When designing a placard, put yourself in the position of the intended user. Do not assume any prior knowledge, and do not ignore any steps.

Current technology lets you make durable placards that include diagrams and photographs. Use illustrations where they can communicate more effectively than words alone.

Examples

■ Thermostat Placard

In an office that is conditioned by several four-pipe fan-coil units, install a placard at the room thermostat that says:

THIS THERMOSTAT CONTROLS THE THREE HEATING AND COOLING UNITS IN THIS ROOM.

To conserve energy, please adjust the temperature setting on this control unit as follows:

- Select HEAT or COOL on the top selector switch.
 - If HEAT is selected, set the HEAT lever to the lowest comfortable temperature.
 - If COOL is selected, set the COOL lever to the highest comfortable temperature.
 - Set the FAN switch to AUTOMATIC.
-
- If you leave the room for several hours or longer, please turn the FAN switch to OFF.
 - Call Extension 89 if there is a problem with heating or cooling.

■ Local Control of Heating and Cooling

In a conference room where conditioning is controlled by rundown timer, install a placard at the timer that says:

THIS TIME SWITCH CONTROLS THE HEATING AND COOLING IN THIS ROOM.

The room temperature will become comfortable within a few minutes.

- Please set the timer for the minimum length of time that you will be using the room. You can add more time as needed.
- Call Extension 89 if there is a problem with heating or cooling.

■ Kitchen Range Hood

On the range hood in the kitchen of a hotel located in a cold climate, install a placard that says:

PLEASE TURN OFF THE HOOD FAN WHEN THE COOKING EQUIPMENT IS TURNED OFF.

The fan draws a large amount of heat out of the building when it is running. The fan switch is located inside the door of the dry storage room.

■ Openable Windows

In a room that has user-controlled heating and cooling, and openable windows, install a placard at a visible location near the windows that says:

PLEASE CONSERVE ENERGY.
Close the windows
when heating or cooling.

■ Lighting Controlled by Motion Sensors

In a small room that has lights controlled by a motion sensor, install a placard at the entrance that says:

THE LIGHTS IN THIS ROOM ARE CONTROLLED BY AN AUTOMATIC SWITCH THAT SENSES MOTION.

- The lights will turn on as soon as you enter the room.
- To turn the lights off while you are in the room, use the "lights off" switch beside the door.
- Call Extension 89 if there is a problem with the lights.

■ Marking Delamped Light Fixtures

To mark fluorescent fixtures that have been delamped, attach stickers to the outside of the fixtures that say:

- Use only (wattage), (color) lamps in this fixture.
- (number) lamps have been removed from this fixture for energy conservation.

■ System Diagram

In the central monitoring station of the heating and cooling plant, install a large diagram that indicates the location of all the controls that should be adjusted to optimize energy efficiency, with inset photographs of each control.

■ Some Real Examples

Figures 1 through 4 illustrate the present state of placard usage. These actual examples range from fairly good to useless. Clearly, there is a long way to go. You may find it useful to score each of these examples in terms of how well it satisfies the criteria that we stated previously.

Placard Materials

Make placards out of materials that are durable enough to survive as long as the equipment to which they relate. Consider these materials:

- **photographically etched metal.** Virtually any kind of text or graphics can be imprinted on aluminum placards with a photographic etching process. At present, this process is limited to a single color, and is somewhat limited in contrast. This product is available from trophy shops, some sign companies, and miscellaneous specialty companies.
- **painted metal.** Text and bold graphics can be made on painted metal signs. Several colors may be used, and silk screening can be used to reproduce virtually any type of copy. Aluminum or enameled steel signs can survive harsher environments. Simple signs with bold lettering are produced by sign shops. More complex signs are produced by specialty silk screening shops.

- **engraved laminated plastic.** Engraved plastic signs are bold, but limited to plain text and single colors. Laminated plastic cannot survive mechanical stress, strong sunlight, or outdoor conditions. Engraved plastic signs are available from office supply stores and specialty marking companies.
- **printed plastic.** Placards can be printed on many types of plastic materials, including the reverse sides of transparent plastic. Any type of text or graphics can be produced using silk screening. Plastic cannot survive mechanical stress or strong sunlight. Printed plastic signs are produced by specialty silk screening shops, and by specialty sign shops.
- **plain paper.** Plain paper is rarely durable enough for placards. Its merit is cheapness and the ability to be printed with any type of material. Paper may be the only choice in highly protected applications where low cost is important, as in marking delamped light fixtures. Self-adhesive stickers are produced in large quantities at low cost by label manufacturing companies. Also, you can make them yourself using a desktop computer.
- **plastic-coated paper.** Anything that can be printed on paper can be protected with a plastic film. The film greatly increases the durability of the placard. Still, plastic-covered paper is suitable only for dry indoor environments. Many printing shops can produce placards on plastic-coated paper. If you make paper placards yourself, you can easily laminate them by using self-adhesive laminating sheets or an inexpensive laminating machine.

WESINC

Fig. 1 Not pretty, but pretty good This placard is on the door of a motel room. It is big, and easy to read. It spells out what is wanted, and when. Guests see it at the proper time. It will last a long time. It could be presented more elegantly in an upscale setting.

How to Attach Placards

Make the method of attachment as durable as the placard itself. In most cases, install placards with screws or bolts having ample grip in the material to which the placard is attached.

Adhesives are usually unsatisfactory because they dry out and lose their stickiness within a few years. Adhesives may be the only practical choice for some applications, such as light fixture delamping stickers. However, expect that any placards attached with adhesives will need periodic replacement, which is unlikely to occur when it is needed.

Select the attachment method to survive the environment and future actions to the related equipment. For example, if you need a placard to tell how to set a manual valve in a machinery room, make the placard out of non-corroding metal and attach it to the adjacent pipe with metal straps. Don't bolt the placard to a flange on the valve itself, because the placard is likely to be lost when the valve is removed for maintenance.

Make Them Attractive

Facility managers may resist installing placards in visible locations because they feel that placards are unsightly. The solution is to design the placards to fit the decor. Generic "conserve energy" stickers, such as the ones given away by utility companies and government agencies, typically clash with a well planned decor.

For example, when designing placards for the guest rooms of a luxury hotel, select a complementary color scheme and attractive lettering, and perhaps the logo of

WESINC

Fig. 2 Much better than nothing This sign is probably well attuned to the staff. It identifies the switch, and spells out the essential action. It should be more specific about time. It will survive until the next paint job.

the hotel. Invite the hotel's interior decorator to participate in the design.

Update Them

Any sign becomes invisible to a person who sees it repeatedly. That is why Coca-Cola keeps changing its advertisements. The same is true of placards. In particular, placards that request people to take optional action, such as turning off lights, tend to fade from consciousness. The first way to reduce this effect is to be specific about the action requested, as previously discussed.

Another way is to periodically redesign and replace the placard. Present the same information in a different style. This gives you a chance to discover your hidden artistic talents. You can improve the information provided by the placards using experience gained from the response to the earlier placards.

When you design a placard, decide whether to make it permanent or to replace it periodically. This affects the selection of materials and installation methods. For example, if you plan to replace an indoor placard every year, you may print it on plastic-coated paper instead of more expensive material. Install replaceable placards with screws, clips, or other easily detachable methods, rather than with adhesive.

Placards that provide needed information generally do not have to be refreshed. For example, people do not need novelty in a placard that indicates where a timeclock is located. The main guideline for such placards is to install them where they are conspicuous.

Keep an updated list of all placards. Use it periodically to survey your facility. Check to see if placards need to be replaced or modified. Find new opportunities for exploiting placards. The list also serves as a guide to all your energy conservation activities that need action by people.

WESINC

Fig. 3 Useless placard This sticker on a light fixture is just visual clutter. It gives no guidance about what is expected, if anything. It numbs people toward conserving energy.

Coordinate Your Placard Installations

You will be amazed at how many places you can improve efficiency and occupant satisfaction with effective placards. Save time, effort, and money by planning and producing all your placards as a batch. You will learn a lot about your facility in the process.

Where it is more effective to do so, use a single placard for several energy conserving actions. For example, use one placard to request turning off the lights and turning off the conditioning equipment at the end of the day.

The material cost of placards drops dramatically with quantity, which can save money with placards used on common items, such as thermostats and light switches. However, do not allow this to lure you into using general instructions where more customized instructions are appropriate.

Coordinate with Other Communications Methods

Placards are a means of communication. They are usually not fully effective by themselves. Make each placard part of an overall program of communicating

with each intended audience. For example, coordinate placards for maintenance personnel with maintenance training programs. Publicize your use of placards in company newsletters, posters, incentive programs, etc.

WESINC

Fig. 4 Ridiculous placard The tiny sticker on this thermostat cover tells people what temperatures to set. The cover is locked, so they can't reach the thermostat. Anyway, the print is too small to read.

Energy Management Control Systems**An Alternative to Specialized Controls
Unique or Advantageous EMCS Capabilities**

- Monitoring
- Reports

- Coordinated Control
- Complex Control Functions

**Inappropriate Applications
System Configurations****True System Cost****Continuing Problems**

- Management Failure to Use the System
- Operator Confusion
- Staffing
- Inadequate Software
- Inadequate Programming Support
- Hardware Defects
- Rapid Obsolescence
- Lack of Standardization

An energy management control system (EMCS) is a centralized control system intended to operate a facility's equipment efficiently. These systems are also known by a variety of other names, including "energy management systems" (EMS), "smart building controls," etc. A system typically has a central computer, distributed programmable controllers, and a digital communication system. The communication system may carry signals directly between the computer and the controlled equipment, or there may be tiers of communications.

These systems are still evolving rapidly, and they are controversial. This Note explains the basic elements of an EMCS, the major alternative configurations, and the advantages and disadvantages of EMCS's.

An Alternative to Specialized Controls

As a method of control, an EMCS is an alternative to using specialized controllers for individual items of equipment. In general, any control function that can be performed with an EMCS can also be performed with a less expensive single-purpose controller.

An EMCS has two inherent advantages over local controllers. One is two-way communication with the equipment, which makes it possible to monitor conditions as well as to exercise control. The other advantage is the versatility provided by the general-purpose computer, which in principle can be programmed at any time to perform any function.

On the other hand, dedicated controllers are more reliable and easier to maintain. In most facilities, the total cost of individual controllers would be much less than the cost of an EMCS. Install an EMCS only if its unique advantages outweigh its inherent disadvantages.

Unique or Advantageous EMCS Capabilities

In deciding whether to install an EMCS, be clear about what you expect it to do. Some of the following are functions that only an EMCS can accomplish. Others

are functions that an EMCS may be able to accomplish better than local controls.

■ Monitoring

A computer has input as well as output, so it can monitor equipment as well as control it. Part of the original EMCS concept was the ideal of having perfect knowledge of the facility's status from the splendid isolation of the air conditioned office. As a real example, an operator can call up the supply air temperature of a particular air handling unit at the keyboard, and the temperature may be presented on a multi-color diagram of the system that appears on the computer screen. Figure 1 shows the general idea.

In reality, the monitoring capability of an EMCS is presently far from the ideal of universal knowledge of facility conditions. An EMCS can monitor only those functions for which a sensor is installed. The cost of installing sensors and wiring limits monitoring to conditions that are easily measurable and that are likely to be monitored repeatedly.

The monitoring done by most EMCS's consists of little more than telling whether equipment is running, and reporting system and space temperatures. EMCS's have not yet fulfilled an early promise of universal diagnostics. For example, it is not economical to use an EMCS to report pump packing leakage or strange bearing noises, even though such conditions could be monitored in theory.

At present, facilities typically make little use of the monitoring capability of their EMCS's. The most common monitoring function is creating an alarm if some variable (space temperature, air flow, the operation of a pump, etc.) is outside limits that are specified at the computer. EMCS's are not yet ready to monitor system efficiency at a sophisticated level, because the software for this function is not available.

■ Reports

By combining monitoring capability with the analysis and graphical capabilities of a computer, an

EMCS can produce reports on the data that it collects. The usefulness of reports and their ease of generation varies between systems. This valuable function adds little to the cost of an EMCS because it requires only software.

“Trend logging” is the elementary level of reporting. This is simply a printout of selected variables at short intervals. Trend logging uses a lot of paper, and is tedious to use. Trend logging can be made more useful by presenting the data graphically, if the software has this capability.

The report generation capability of EMCS’s makes them potentially an important tool of energy management at the facility management level. To fulfill this potential, the computer should be able to produce easily understandable reports that show the energy consumption patterns of each item of equipment in the facility, and the energy consumption and cost patterns of the facility as a whole.

To prepare such reports, the computer needs input data about energy consumption. This means you have to provide metering and signal interfaces for each mode of energy consumption that you wish to monitor separately. For example, to develop a profile of boiler energy consumption, you need to install a boiler fuel flowmeter and interface it to the EMCS. To monitor chiller energy consumption, you need to install a wattmeter on the chiller input, and interface it to the

computer. To monitor lighting energy consumption, you need to install an ammeter on each lighting circuit that you want to monitor separately.

■ Controlling Many Items

An EMCS can control a virtually unlimited number of devices by switching between them. Is it better to have many individual controllers, or only one EMCS? The EMCS may have a reliability advantage because of its monitoring ability, especially in facilities with a large number of similar devices to be controlled. The occasional failure of a local controller could escape attention without the performance monitoring provided by an EMCS. From a statistical standpoint, a single EMCS may be more reliable than a large number of local controllers, provided that the EMCS is well maintained. However, EMCS’s generally increase reliability problems rather than reducing them, for reasons covered below.

At present, the ability of an EMCS to control many units does not save money compared to local control. For simpler control functions, such as time control and optimum start, installing an individual controller located at the equipment is typically less expensive than connecting the equipment to an EMCS, even if the facility already has an EMCS.

■ Coordinated Control

Since an EMCS has two-way communication, you can use it to coordinate the control of different items of

WESINC

Fig. 1 The person is important, the computer is not For an effective energy manager, an EMCS is a convenience. In the absence of an effective energy manager, an EMCS is electronic junk that increases construction cost, increases staffing requirements, and confuses the maintenance staff.

equipment to optimize overall system efficiency. Such applications are few, but they may save a significant amount of energy or money.

For example, this coordinated control capability makes an EMCS useful for demand limiting, in which the EMCS turns off selected items of equipment as the overall facility approaches a demand limit. (See [Reference Note 21](#), Electricity Pricing, about demand charges.) The EMCS can be programmed to turn off different equipment on a rotating basis, or to turn off equipment based on certain criteria, such as relative importance, the time of day, operation of other equipment, etc. However, specialized demand controllers are available to perform these same functions.

Another example is using an EMCS to control the running of a cooling tower that serves several self-contained air handling systems. The EMCS can sense when all the air conditioning units are turned off, and can then turn off the cooling tower fans. However, the same function can be performed cheaply by using a few relays and some low-voltage wire.

■ Complex Control Functions

Because an EMCS includes a powerful computer, it can perform any control function for which you program it, no matter how complex. Further, it can perform any number of different control functions.

For example, in a chiller system serving VAV air handling units, an EMCS could program the computer to continuously optimize the chilled water temperature, the supply air temperature, and the condenser water temperature settings to minimize the overall system energy consumption under all operating conditions. This assumes that the appropriate software is available, or that a highly skilled individual is available to program the system for this purpose.

The unlimited programming capability of EMCS's makes it possible to specify system performance in much greater detail than was possible with conventional controls. For example, some EMCS's offer the ability to tune the response characteristics of controls by specifying their proportional, integral, and derivative (PID) control characteristics. For some applications, such advanced features may provide a significant benefit. For other applications, they add an unnecessary burden of complexity.

The fact that you want to perform a complex control function does not necessarily mean you need an EMCS. Cheap microprocessors provide complex control at the local level for many common functions, such as supply air temperature reset, enthalpy control, and optimum start. These controllers cannot be programmed in the general sense, although they may offer ranges of settings. The additional capabilities of the EMCS, such as the ability to monitor and to change settings remotely, may justify the additional cost and complexity of the EMCS.

Inappropriate Applications

Many EMCS's have been purchased on the basis of vague expectations, rather than a clear idea of functions that an EMCS is expected to perform. As a result, most EMCS's operate at a rudimentary level. Even in cases where a permanent EMCS staff has been established to keep systems working, the EMCS typically does little more than serve as a remote timeclock.

EMCS's became a fad item toward the end of the 1970's as the public, already aroused to energy conservation, started to take an interest in computers. The sales pitch given to enthralled facility owners implied that installing a computer would in obscure ways make the facility more efficient. This claim could not be fulfilled, because energy waste is caused by many factors unrelated to control, including sloppy design, poor installation, and improper operation. These factors cause hundreds or thousands of inefficiencies to be scattered throughout a facility. Overlaying an electronic control system on a wasteful facility does not correct these inefficiencies.

Undoubtedly, a primary reason for the initial popularity of EMCS's was their expected entertainment and status value. Managers could play with the EMCS and show it off to visitors. Mechanics could pretend to be managers by sitting at the EMCS in an air conditioned room, and avoid getting dirty. This appeal soon wears out, and the staff has to get back to running the facility. Many EMCS's purchased as toys have been abandoned.

Like computers in general, EMCS's are often used in ways that produce more trouble than benefit. To justify the large investment, it is common to use the EMCS to control inappropriate functions, sometimes to the point of absurdity. For example, some facilities use an EMCS to control the conditioning of conference rooms, ballrooms, and other irregularly used spaces. This requires the EMCS operators to become involved in the scheduling of the spaces, and it requires all potential users of the conference rooms to know how to contact the EMCS staff. In addition to the increased workload and confusion, it becomes virtually impossible to reschedule the spaces on short notice.

A common abuse of EMCS's is remote setting of space thermostats. In most cases, occupants should be allowed to control space temperature locally. A central computer cannot compensate for variations in personal preference, cold spots, changing solar gain, etc. Connecting an EMCS to every thermostat in a building typically costs a lot of money that produces no benefit and reduces comfort.

(In general, equipment that is used for local functions should be started and stopped locally. For example, the air conditioning for a conference room is best controlled by the users of the space. Each Section of this book includes appropriate Measures for minimizing unnecessary equipment operation while

maintaining high comfort levels. Most of these Measures recommend local control by the users or occupants.)

Ability to control from a remote location is not an inherent advantage of EMCS's. Any type of control, such as a simple timeclock, could control equipment from any location, if remote control is desirable. In the case of simple controls, this may seem silly because of the high wiring cost. However, the wiring cost does not seem silly with an EMCS. The difference is psychological, not technical.

System Configurations

The original configuration of EMCS's was the simplest. A central computer was connected by wires to sensors at locations being monitored, and to actuators on equipment being controlled. Figure 2 shows this arrangement.

The early systems could do little more than turn equipment on and off. Additional electronic devices were then developed to allow the computer to interact at a more "intelligent" level with controlled equipment, such as making changes to thermostat settings. This required the development of complex digital thermostats and other local control devices.

The high end of clock controls, covered in [Reference Note 10](#), have evolved to the point that they have as much capability as the early EMCS's. These still depend on dedicated connections between the controller and each item of controlled equipment. Figure 6 shows a unit that straddles the boundary between clock controls and EMCS's.

Soon after EMCS's were introduced, it became apparent that failure of the computer would disable all the equipment connected to the computer, or make it impossible to control the equipment. Even failure of a cable, a telephone line, or other communication device would disable a large part of the EMCS. To reduce vulnerability to these failures, EMCS's evolved a configuration that uses distributed microprocessors, called "slave panels," "local panels," "standalone control units," "terminal equipment controllers," and other names, in addition to the central computer. For example, a university campus might have a single central computer, and a local panel in each building. Figure 3 shows this variation.

If the central computer fails, the local panels keep systems operating normally. In this arrangement, the central computer still performs the monitoring function, and it is used to reset or reprogram the local panels as needed. This configuration is presently the most common, and there is a trend for more of the "intelligence" to be put into the local panels, while the central computer is reduced to the role of a "dumb terminal."

The original system layout, with wiring that spreads out from a central computer, is being replaced by loop systems. Figure 4 shows this configuration. These are similar to the local area networks (LAN's) used in office computer systems.

Local panels, equipment controllers, sensors, and operator terminals can be connected to any convenient point in the loop. This makes wiring easier and increases reliability, at least in principle. It also allows information to be introduced at any point. For example, for load shedding, each item of equipment reports its electric load to the loop, which allows any local panel to calculate the total facility load. This allows each local panel to decide which equipment to shed as the facility approaches its maximum allowable demand.

The local panel itself may soon become obsolete by losing its role as middleman. At the center of the system, most EMCS's now use an inexpensive personal computer as the central computer. This radically reduces the cost of the most expensive component of the EMCS, and makes it a standardized item. At the remote ends of the system, the low cost of small microprocessors now makes it practical for equipment manufacturers to install

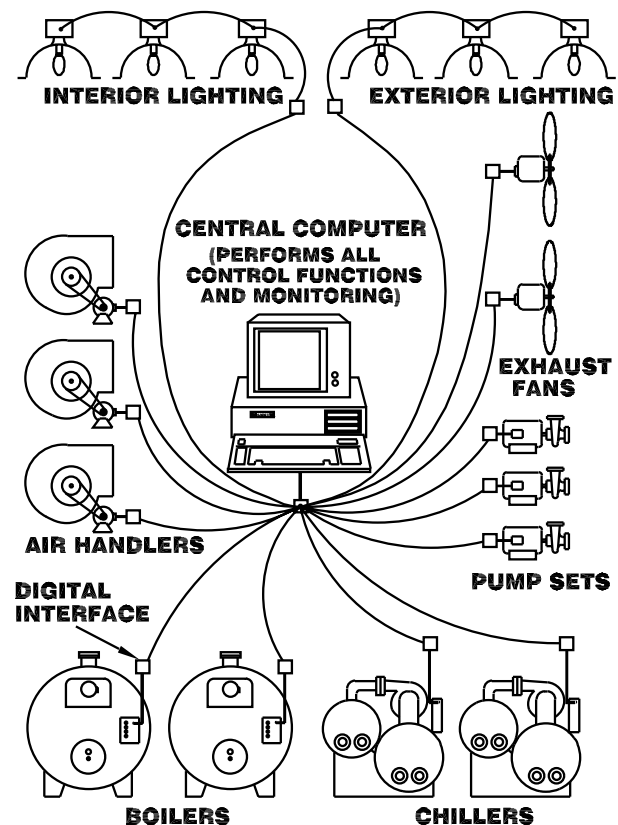

Fig. 2 Early EMCS layout A single computer performs all control functions, which makes the entire system vulnerable. The computer is connected to each item of equipment individually, which makes the equipment vulnerable to fragile wiring.

specialized, low-cost “smart controls” on each controlled item of equipment.

Equipment-mounted controls are being produced by both controls companies and equipment manufacturers. This allows anyone to build an EMCS around a standard personal computer. Furthermore, anyone can now produce software that would be usable by such a generic system. This squeezes out the need for local panels, which remain the most non-standard items of EMCS hardware, and collectively the most expensive.

True System Cost

If you compare the true cost of an EMCS to a realistic estimate of the savings that it can provide, you are likely to find a low rate of return. Remember, an EMCS is usually an alternative way of performing a function. It rarely lets you do something that would be impossible otherwise. The overall cost of control is usually much higher with an EMCS than it is with local controllers, although this comparison does not account for the unique capabilities of the EMCS.

The cost of the installed EMCS may be much higher than anticipated because the cost of the equipment

quoted by the vendor is typically only a small fraction of the installed system cost. Most of the system cost is in the wiring and interfaces needed to connect the central computer, local panels, equipment controllers, and sensors throughout the facility. Also, vendors may not be candid about the programming costs needed to make the system useful once it is installed.

If EMCS's follow the pattern of other electronic devices, costs may decline substantially in the future. Newer systems use common personal computers in place of expensive specialized computers. Eliminating local panels will save a substantial amount of money, if this development occurs. However, wiring costs, which are mostly labor, are unlikely to decline substantially unless new methods of low-cost communication are developed.

Continuing Problems

All new, complex equipment goes through a period when it is difficult to use, it is difficult to maintain, its reliability is low, and its capabilities do not match its potential. EMCS's are still in this phase. Be aware of the following sources of trouble that will continue to bedevil these systems for the foreseeable future. If you

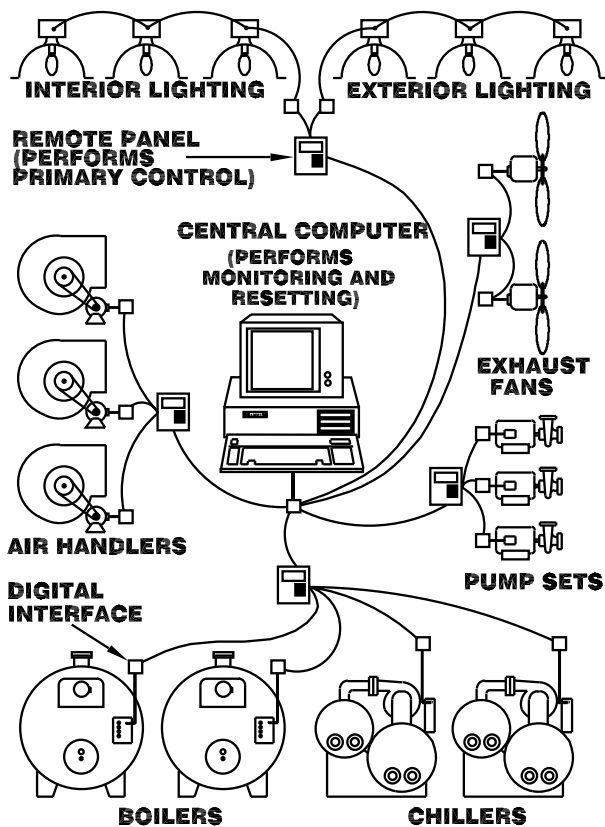

Fig. 3 Later EMCS layout Moment-to-moment control functions are performed by local panels, each of which controls a fraction of the equipment. The central computer monitors equipment performance, resets the local panels remotely, and prepares reports. The system continues to function if the central computer fails, or if a communication link is broken.

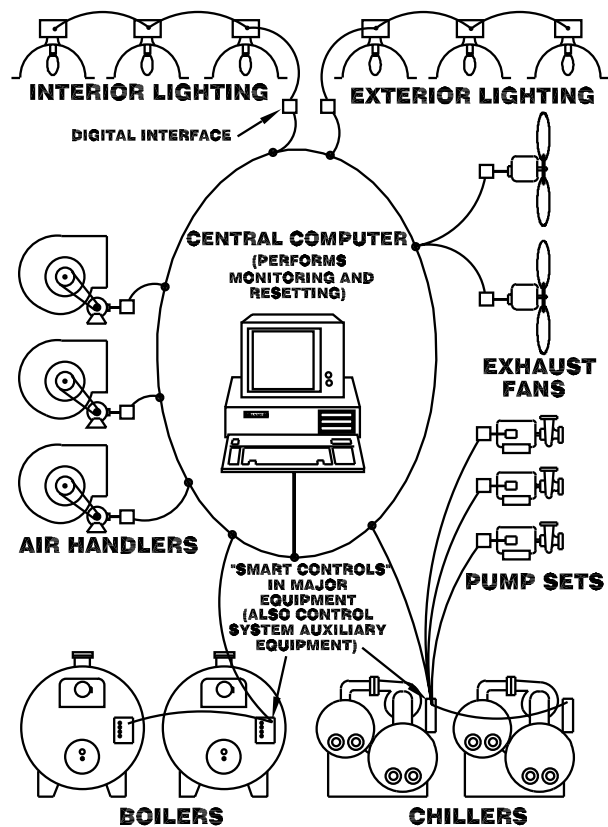

Fig. 4 Recent EMCS layout Communications occur on a loop, which increases reliability. A large part of the control functions are accomplished by microcomputers installed on major items of equipment. This allows optimum control of each system, without requiring the programmer of the central computer to know the details of individual equipment.

do not get all these potential problems under control, your EMCS will inevitably fail, either physically or by failing to deliver its promised benefits.

■ Management Failure to Use the System

Perhaps the greatest failure of EMCS's has been the failure of facility managers to effectively use the analysis and reporting capabilities of these systems as a tool of energy management. Even though managers may hire bright, highly paid individuals to operate and maintain the system, they themselves do not use it. This reflects a lack of appreciation by senior managers of the economic potential of energy management, and of their own roles in it. A practical problem is lack of software for producing reports that are easily usable by high-level managers.

■ Operator Confusion

An EMCS greatly increases the confusion and difficulty of plant operators. Indeed, from the operators' standpoint, the EMCS is much more difficult to deal with than the familiar equipment being controlled. Figure 5 shows the problem. An operator who is under pressure to keep an air conditioning system running is

Fig. 5 Can you tell what this does? Neither can the maintenance staff. This is a local panel of an EMCS. It is much more difficult to understand than the facility's primary equipment. The EMCS requires its own specialized skills and additional manpower. Without these, the EMCS will fail and be abandoned.

tempted to deal with an unfamiliar EMCS by taking the wire cutters from his tool pouch, lobotomizing the EMCS, and operating the air conditioning system in the old way.

The capability of EMCS's to customize control performance is a source of confusion. For example, if an EMCS is used to control a VAV air handling system, each VAV terminal may have a hundred control parameters. Some of these are obvious, such as temperature setpoints. However, others are incomprehensible to the building staff, such as the time constants for control response characteristics. In theory, most of these parameters are set by the installing contractor, but it is unlikely that all settings will be proper, even with the most conscientious installation. This glut of control parameters inevitably creates problems that are difficult to diagnose.

As with computers in general, the documentation provided with EMCS's tends to be obscure and incomplete. The problem is especially severe with EMCS's because they are produced in small quantities and are still evolving. Manufacturers presently try to deal with this problem by offering classes to operators. However, presenting an overwhelming subject in a class of two or three days is not the answer.

This situation should improve in time. Manufacturers will learn to make their hardware and software more user-friendly, and will document it better. The adoption of personal computers and the possible elimination of local panels will reduce the initial mystery of the system. However, EMCS's will never be as simple as hard-wired single-function local controllers.

■ Staffing

Labor saving was one of the major benefits originally claimed for EMCS's. In facilities of small and medium size, the opposite has been true. Systems that are working usually have one or more full-time operators who work exclusively on the EMCS, without providing a reduction of other staff. Talented people are needed continuously to monitor what the system is reporting, to analyze reports, to respond to trouble calls, and to keep the system repaired. Without a permanent staff of its own, an EMCS usually collapses.

In a dispersed group of facilities, such as a school system, the EMCS may save labor compared to installing local control systems and checking their operation with traveling maintenance personnel. However, even this is not certain. A large EMCS may generate so many faults of its own that keeping the EMCS in operation may require as much labor as it would take to monitor the facilities in the old way.

Maintaining an effective EMCS staff has proven to be difficult. The work requires individuals with exceptional talent and initiative, along with detailed knowledge of the specific system. If such a person leaves, he is not easily replaced. Another problem is

that talented EMCS operators tend to be diverted to solving other problems, leaving the EMCS neglected. The EMCS staff must be protected and supported by the facility's management to remain effective.

■ Inadequate Software

Software is what makes computers powerful. As of the late 1990's, EMCS's still lacked the software needed to make them an effective tool for energy administration or for system optimization. The software available is largely limited to graphics displays and static changes to system settings.

To generate reports for managing energy costs, you need to meter each item of energy consuming equipment. In addition, you need software to process the energy consumption information and present it in a useful manner. Such software is still inadequate, probably because of inadequate market demand from facility managers who understand its value as a cost saving tool.

Energy optimization software is an even greater development challenge. This function requires the software to perform systems simulations similar to those used in energy consumption modeling programs (which are explained in [Reference Note 17](#)). To perform system optimization, the software must be able to simulate the operation of the types of systems installed in the facility, including the part-load performance of the equipment. Then, the software must be able to calculate the combination of equipment operating conditions that yields the lowest overall energy consumption, and to send the appropriate signals to the equipment.

■ Inadequate Programming Support

Experience shows that EMCS vendors' dedication to service generally does not match their zeal to sell systems. The worst aspects of service have been programming support. Comprehensive, easy-to-use software is not yet available. This makes you dependent on the EMCS vendor to reprogram the EMCS when you make systems changes, such as adding sensors or new reporting functions. This service has not been dependable.

A common situation is that the vendor's local office has one individual who is competent to program the equipment at the time the system is installed. When that individual moves to a different job, no one is left who knows how to program the system. This can make it virtually impossible to add a new control function, to adapt to changes in the controlled equipment, or to correct defects in the EMCS.

This problem will remain as long as EMCS's are programmed by local vendor offices. Programming may become less of a problem if software is developed that allows the facility operators to do more of the programming, or to take over this function completely. The ultimate goal is to have a situation similar to the emerging "plug and play" installation of accessories in

personal computers, whereby the EMCS automatically integrates any new component without the need for additional programming.

■ Hardware Defects

The EMCS itself adds serious reliability problems to the facility. The processors, sensors, actuators, and communications links are complex and fragile. Historically, EMCS's have been more likely to fail than the equipment they control. Similarly, if the EMCS indicates an alarm, the problem is more likely to be in the EMCS than in the equipment being monitored. This tendency to indicate false alarms makes EMCS's almost useless for critical monitoring. For these reasons, some building code jurisdictions forbid the use of an EMCS for safety-related monitoring.

Reliability may improve dramatically in the future, but EMCS's will never be as reliable as dedicated local

Paragon Electric Company

Fig. 6 Consider going back to basics This is a high-end multi-channel controller that evolved from a timeclock. It has about the same control capability as an early EMCS, including demand limiting, outside air temperature reset, and daylight sensing. It can log performance data. It requires no special programming skill. It controls a limited number of items, so it is installed close to the equipment, limiting communication problems. One or more units like this may be all the central control you need.

controllers. The standardization provided by the use of personal computers improves reliability in the central computer and its peripherals. Custom components, especially local panels and signal converters on equipment, will continue to be a problem. Experience shows that new electronic components tend to be unreliable for the first few years of manufacture. The large number of sensors and actuators used in EMCS's will continue to contribute a certain level of defects. Each new edition of software will have bugs. Poorly protected sensors and wiring will continue to be damaged.

■ Rapid Obsolescence

EMCS's suffer from the rapid obsolescence that is characteristic of all evolving computer equipment. The effects are short service life, bugs that never get fixed before the next model appears, and inability to obtain maintenance and programming support. Continually improving performance and declining prices make it uneconomical for the manufacturer to support old models. Furthermore, the manufacturer wants to keep selling you newer equipment.

Expect to upgrade major components of the system at relatively short intervals, and perhaps to replace the entire system. EMCS models will probably continue to have short service lives well into the 21st century, especially if standardization of components and signals does not occur soon.

■ Lack of Standardization

Until the mid-1990's, manufacturers of EMCS's tried to keep their systems proprietary, so that the purchaser had to remain married to the manufacturer for programming, repair, and upgrading. The signals produced by sensors and the signal requirements of controlled devices have long been standardized in HVAC and process applications. However, the system components and the digital signals used with EMCS's themselves are still not compatible on a general basis. The components of one EMCS typically do not produce signals usable by the components of another. Even where standardized signals are used, components may not be compatible physically, meaning that one manufacturer's components will not plug into another manufacturer's sockets.

In the past, this situation made it desirable to purchase an EMCS from one of the major manufacturers, in the hope that the manufacturer will survive to support the system. However, any manufacturer may abandon support for a system as it becomes obsolete.

In 1996, the American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE) published an enormous document, Standard 135-1995, that specifies communications standards between building control components. The full name of the Standard is "A Communications Protocol for Automation and Control Networks." The common name

of the Standard is "BACnet," which is an ASHRAE trade mark. BACnet is intended specifically to solve the problem of compatibility among digital control components, especially in EMCS's.

The problem of incompatibility has long created pressure from users for standardization. However, early attempts at defining standards for EMCS's failed. Industry groups have often been successful in establishing standards, but not for an entire complex and evolving system. In the arena of personal computers, standardization arose primarily as a result of one manufacturer gaining a dominant sales position with a particular item of equipment. The characteristics of that manufacturer's equipment become a *de facto* standard, especially if the manufacturer takes a leadership role in establishing an "open architecture," that is, a set of characteristics that can be copied by others.

At the present time, a pattern similar to this appears to be evolving around a control technology called LonWorks, which is a trademark of the Echelon Corporation. LonWorks, introduced in 1991, is a distributed control system, which means that it does not require a centralized controller or computer. In 1994, 36 companies formed the LonMark Interoperability Association to develop design standards based on LonWorks. The Association certifies that particular items of control equipment conform to the LonMark requirements.

BACnet is oriented toward centralized control with high data transfer rates. LonMark is oriented toward localized control with lower data transfer rates. Some systems use both BACnet and LonMark. In these configurations, the BACnet system serves as a high-speed communication system and LonMark controls equipment locally. As of the late 1990's, it is too early to tell how either system, or a possible combination, will fare.

BACnet and LonMark illustrate how two different approaches to standardization work in a free market. BACnet, as a "standard," is established by consensus within an industry. Standards are immune from proprietary limitations that keep competing manufacturers from entering the field, but the consensus process that guides them is slow and is subject to resistance by individual members of the industry. In contrast, LonMark is an "open architecture" that is the product of a private entity, so it can evolve rapidly. However, open architecture, at least in principle, favors the company that produces it.

If any protocol becomes a successful standard, it is likely to make existing EMCS's obsolete. Any manufacturer can produce interface devices (called "gateways") to connect older equipment to a network based on BACnet or LonMark, but the cost and uncertainty of retrofitting older EMCS's may doom this prospect.

Control Signal Polling**Control Signal Discriminators
Using Energy Management Computer Systems
Minimize the Number of Signals to be Polled**

A common control function in optimizing the efficiency of a system is selecting the highest or lowest signal from a number of inputs. There is no standard name for this function, so we will call it “signal polling.” This Note briefly explains the methods used to perform this control function.

A typical application requiring signal polling is chilled air temperature reset. Signals from all the thermostats served by an air handling system are routed to a control device that picks out the signal calling for the greatest cooling load. This signal is used by the control system to adjust the supply air temperature of the air handling unit.

Signal polling can be done by standard control components designed for this purpose. There is no standard name for these components, so we will call them “signal discriminators.” Figure 1 is a typical unit. Signal polling can also be done with an energy management control system.

Control Signal Discriminators

A signal discriminator is a standard control component that senses the signals coming from a number of sources and selects the highest or lowest, as appropriate. This device is given many names, depending on the manufacturer. Variations of this

WESINC

Fig. 1 Pneumatic signal discriminator Attached to a piece of duct, this small device accepts eight pneumatic input signals. It sends out the highest and the lowest of the input pressures.

component are available for pneumatic, electrical analog, and electronic digital control systems.

Each discriminator typically accepts from four to eight inputs. Any number of signal sources can be sampled by cascading discriminators together. For example, if four-input units are being used, the outputs of four units can be fed to a fifth, so that the highest or lowest signal from sixteen sampling points can be selected. This method can be extended indefinitely.

Discriminators themselves are inexpensive. The main cost of signal polling is routing wiring or pneumatic tubing from dispersed locations to a central point. Labor is the largest cost in a discriminator system.

Discriminator systems are somewhat fragile because they require an extended network of pneumatic or electrical lines that are vulnerable to damage. Failure of any one of the sensed elements (e.g., a thermostat), or of any discriminator, or of any connection can disable the entire system. For example, if there are several pneumatic signal lines leading from thermostats to a discriminator, and there is a leak in one of the lines, the false low pressure signal in the leaky line may be selected as the controlling signal.

Using Energy Management Computer Systems

An energy management computer system can perform the same function as a discriminator network, if all the necessary signal sources are connected to the computer. A computer system is subject to the same requirements and weaknesses as a discriminator network that is made from discrete components, as well as to the weaknesses that are characteristic of computer systems. See [Reference Note 13](#), Energy Management Control Systems, about these systems.

Minimize the Number of Signals to be Polled

You can reduce the number of signal discriminators or signal connections if the maximum or minimum signal is always produced by one of a small number of sources. For example, if you use space temperature polling to start a heating plant, exploit the fact that the lowest temperatures always occurs in certain spaces on the north side of the building. For this application, there is no need to connect the rest of the thermostats in the building to the polling network.

Infrared Thermal Scanning

Capabilities and Limitations

A Quick Tour of the Infrared Neighborhood

How Thermal Scanners Work

Wait for Good Survey Conditions

How to Interpret Thermal Surveys

- Estimating Conductive Heat Loss

- Estimating Heat Loss Caused by Air Flow

Where to Get Scanning Equipment or Services

Thermal scanning equipment is used to detect heat radiation emitted by surfaces. For energy conservation, a thermal scanner is a powerful tool for quickly finding and interpreting heat loss through walls, roofs, equipment insulation, etc. This Note explains the basics, and helps you to decide when to use thermal scanning.

Capabilities and Limitations

Compared to other methods of measuring or estimating heat loss, thermal scanners have several unique capabilities:

- they can read temperatures from virtually any distance, even from a flying aircraft
- the temperature readings are practically instantaneous
- their sensitivity to temperature differences is ample for most energy survey work
- imaging-type scanners can provide a photographic depiction of the surface temperatures.

However, thermal scanning is not a casual activity, and it has significant limitations. These are its main drawbacks:

- the need for skill and experience to translate a surface temperature survey into reasonably accurate estimates of heat loss
- the need to survey at night and in cold weather when surveying for low-temperature heat losses (for example, building insulation defects)
- high cost for imaging-type scanners, although the equipment can be rented
- awkwardness in handling the equipment, although it is becoming much smaller and much lighter.

For a direct, visual indication of heat loss over a large area, there is no practical alternative to thermal scanning equipment. If you want to survey heat loss over any large area, this is the method you must use.

Contact thermometers can also provide surface temperature measurements, but only on a point basis. Furthermore, they are subject to error, measurements are too slow for survey work, and it may be difficult or dangerous to reach the surfaces being measured.

What a Thermal Scanner Sees

Any solid object is made of atoms. The atoms have kinetic energy but no place to go, so they jiggle around nervously. This nervous energy collectively is called the “heat” energy of the solid. The atoms are packed against each other, so they keep each other agitated with their jiggling. This continually excites the atoms’ electrons to higher energy states. The electrons continually get rid of this excess energy by emitting radiation. Most of this radiation is absorbed back into the solid, but some of it escapes from the surface of the solid. This escaping radiation is called “heat” radiation. (Note that the word “heat” is used in two entirely different ways.) Thermal scanners see this radiated energy.

The “temperature” of an object is a measure of the average amount of kinetic energy in the object’s atoms. Temperature has two major effects on the heat radiation that an object emits. One is obvious: hotter objects emit more radiation than cooler objects. This effect is very strong. In fact, the rate of heat radiation is proportional to the fourth power of the absolute temperature.

The second effect is that the object’s temperature determines the wavelengths (or frequencies) of the radiation. The jiggling of the atoms in the object is chaotic, so the radiation is emitted in a broad pattern of wavelengths. This pattern is a lopsided bell curve, with the short wavelengths dropping off abruptly, and the long wavelengths tailing off over a long range. The peak of the curve shifts toward shorter wavelengths as the object gets hotter. More precisely, the frequency of strongest radiation is directly proportional to the temperature, or the wavelength is inversely proportional to the temperature. (This relationship lets astronomers know the temperatures of stars located on the other side of the universe.)

Using this relationship, thermal scanners calculate temperature by determining the wavelength at the peak of the curve. Thermal scanners used for energy conservation work can discriminate temperature differences of a fraction of one degree (Celsius or Fahrenheit, take your pick).

A Quick Tour of the Infrared Neighborhood

Like light, heat radiation is electromagnetic radiation. The two forms of radiation differ only in wavelength. Heat radiation is next to light in the electromagnetic spectrum, in the range of wavelengths called “infrared.” The name means “below red,” in terms of frequency. For this reason, thermal scanners are commonly called infrared scanners.

Objects at room temperature radiate heat at wavelengths that are about 20 times longer than the wavelengths of visible light. If an object is very hot, it emits enough radiation at visible wavelengths for you to see it. “Incandescent” light is heat radiation that has wavelengths short enough to see. (For more about incandescent light, see [Reference Note 54](#), Incandescent Lighting.)

You can easily observe the transition from the infrared spectrum into the visible spectrum. Go into a kitchen with an electric stove, turn on a burner and turn off the lights, and watch the increasing light emission as the burner gets hotter. You will also see that the color changes as the burner gets hotter, showing that the average wavelength is getting shorter. If you hold your hand at a fixed distance from the burner, you can sense that the rate of heat emission increases radically as the burner gets hotter.

A thermal scanner discriminates temperature in the same way that the human eye discriminates color, by sensing the differences in the wavelengths. The human eye works in the region of 0.3 to 0.7 microns (millionths of a meter). Most imaging-type thermal scanners work in one of two wavelength bands, 3-to-5 microns or 8-to-12 microns. These wavelength bands are determined by the available detector and lens materials. Also, for scanning at long range, they are determined by the transmission spectrum of the atmosphere. Water vapor in the air strongly absorbs some infrared wavelengths.

For surveying buildings to find heat leakage, the 8-to-12 micron band is preferable, because objects near ambient temperature emit more heat in this band. Radiation from objects at ambient temperature effectively ceases at wavelengths below 3 microns. The 3-to-5 micron band is where objects at temperatures of 300°C to 700°C (approximately 600°F to 1,300°F) emit most of their energy. It is important to know this when selecting a scanner. Most scanners are sold for industrial monitoring applications, where the temperatures involved are much higher than ambient.

Incidentally, you cannot do thermal scanning by going to your local photo supplier and buying “infrared” film to use in a regular camera. This film senses only so-called “near infrared,” which means, near the visible spectrum in wavelength. This infrared radiation is reflected light from the sun, like visible light, and it can pass through the glass lenses of conventional camera lenses. In contrast, the heat radiation sensed by scanners

is classified as “middle” or “far” infrared, and this radiation cannot pass through ordinary lenses.

How Thermal Scanners Work

There are two broad types of thermal scanners. The simplest type is called a “pyrometer.” You point it at a surface, the heat energy is focussed on a detector, and the wavelength distribution is analyzed to determine the temperature. The process takes about one second. The field of view of pyrometers is narrow, because the temperature reading is averaged from the characteristics of all the radiation in the field of view. Pyrometers are small and light. They are usually housed in a pistol-grip enclosure that looks like an automotive timing light. They generally cost less than \$1,000.

When using a pyrometer, be aware of the field of view that it is scanning. In more expensive units, the field of view is variable, and the unit is equipped with an optical sight so you can see the field that is covered. This is important for measuring the temperature of a small object against a background of different temperature, such as an elevated steam line.

The other type of thermal scanning equipment is an imaging, or camera-type, device. Modern handheld units are similar in appearance and size to a video camera. In the most expensive units, a lens system focuses the heat radiation on a plate consisting of many separate sensors, or pixels. Temperature and intensity are calculated separately for each sensor, producing a photographic image of the scene. Less expensive units achieve the same effect by scanning across a small array of sensors.

Older scanners produce a “black and white” image, in which surfaces with higher temperatures appear brighter. Most modern units produce the image in color. Color is used to represent temperature, and brightness is used to represent the intensity of the radiation.

Imaging scanners allow rapid survey of large areas, and make it possible to detect problems that would not be apparent with a pyrometer. For example, an infrared camera can reveal waterlogged insulation on buried steam pipe from a subtle pattern of heating on the surface of the soil. Most camera-type units allow images to be preserved on film or using a video recorder. More expensive units can store images in digital form, allowing the images to be printed on an ordinary computer printer. Some vendors offer software that analyzes the digital data, although the direct photographic representation of the data is the most useful for energy conservation work.

A basic advantage of camera-type scanners over pyrometers is that they can depict differences in intensity as well as temperature. Because the amount of heat energy emitted by a surface rises rapidly as the surface temperature increases, even small differences in surface temperature result in easily perceptible differences in the amount of radiation emitted. Camera-type units can discriminate between much smaller temperature

differences than pyrometers because each pixel in the image covers a very small angle of view, eliminating errors due to variations of temperature on a surface.

Imaging scanners have unusual construction features. The lenses must be made of exotic materials to pass heat radiation. The interior of the camera is cooled to a very low temperature, so that heat emitted by the structure of the camera itself does not interfere with the image. Older units have an interior liner that must be continually refilled with a liquified gas coolant, typically nitrogen or argon. Contemporary units have miraculously small cooling units that require no external input, except for a small amount of power that can be provided by an easily portable battery pack.

Prices for imaging scanners start above \$20,000, and range to several times that amount.

Wait for Good Survey Conditions

To find heat loss through the building envelope, survey the building during cold weather. This makes the areas of heat loss show up with the greatest contrast.

To find conduction losses in cooling equipment, such as chilled water piping, make your survey during the warmest weather.

You can make heat loss surveys of hot equipment, such as steam lines, during any season. Be sure to keep all the heating systems in operation during the survey.

Regardless of the season, make outdoor surveys at night, starting several hours after sunset. This allows the exterior surfaces to cool off, and prevents false indications of heat loss from surfaces that were actually heated by the sun. Make the survey when there is little wind, as wind tends to obliterate variations in surface temperature.

If you survey for envelope heat loss from the inside of the building, start several hours after sunset. Solar heat gain on external surfaces may reduce internal cold spots, making them harder to find. Keep the HVAC equipment running when you do an indoor survey. This increases the temperature differential, and helps to reveal air leakage inside the envelope structure that may be induced by the operation of the HVAC equipment. It also helps to make indoor surveys during cold, windy conditions, with the wind coming from the prevailing winter direction.

You can survey indoor equipment for heat loss during the daytime, provided that it is not heated by direct sunlight through windows or skylights.

How to Interpret Thermal Surveys

Thermal scanners sense heat radiation, but heat radiation itself accounts for a relatively small fraction of heat loss at normal ambient temperatures. Most heat loss is by conduction, by air leakage, or by excessive ventilation. Thermal scanning can help to find all these types of heat loss, but it cannot directly indicate the rate

of heat loss due to each. The person doing the thermal survey must interpret the infrared scan to estimate these modes of heat loss.

■ Estimating Conductive Heat Loss

Surface temperature is the key to estimating conductive heat loss, because temperature differential is what drives conductive heat loss. If an external surface is warmer than the surroundings, then heat is coming through that surface. There are two ways to estimate the heat loss rate:

- calculate the heat loss from the surface to the outside air based on the measured surface temperature, the ambient temperature, and the surface characteristics. This method, described in the *ASHRAE Handbook*, is vulnerable to wind, which lowers the surface temperature and increases the heat loss rate. If you plan to use this method of calculation, make the survey under windless conditions.
- use the scanner to find the areas that need to be analyzed. Then, visually inspect the wall, insulation, or other component to determine its construction and condition. From this, perform a conventional heat flow calculation. This method works only if you can inspect the component. For example, you may not be able to inspect the structure and insulation inside the walls of an old building.

Infrared measurements of surface temperature are affected by differences in the “emissivity” of surfaces. Emissivity is the ratio of the actual amount of heat radiation to the amount of radiation that would be emitted by an ideal (“black body”) surface at the same temperature. The emissivity of most non-conducting materials is about 0.9. The emissivity of conducting surfaces ranges from 0.1 for polished metal to about 0.3 for dirty, heavily oxidized metal. Low emissivity keeps heat in the surface, which makes the surface warmer. The scanner indicates the correct surface temperature, but since less heat is being radiated, the user may be fooled into thinking that the rate of heat loss is lower than it actually is.

For example, when surveying a steam line that has an aluminum weather shield on the top surface, the scanner shows a different appearance for the shielded and unshielded surfaces, even though the heat loss is about the same for both.

Some pyrometers are dressed up as “R-value meters.” They are used mainly for surveying building envelopes from the inside. To use such a device, you first set up the device by measuring the outside and inside air temperatures. From this, the device calculates an R-value by measuring the inside surface heat radiation.

This method is subject to error because of draft effects on the internal surfaces, thermal lag in the structure, and variations in emissivity. To reduce this

error, “R-value” or “heat loss” meters usually have a manual setting for the emissivity. You have to estimate the emissivity of the surface you are scanning, and adjust the meter accordingly.

Even an imaging scanner cannot provide reliable information about conductive heat loss if the insulated surface is hidden from view by another surface. One of the worst cases is heat loss through an attic. The only external indication is the temperature of the roof. This provides no indication of the nature of the heat leaks within the attic, and only a vague indication of their location. In such buildings, you need to make a second survey within the attic to find the locations and intensities of the heat leaks.

■ Estimating Heat Loss Caused by Air Flow

Air emits virtually no thermal radiation. Therefore, thermal scanning cannot directly detect the escape of heated air or cooled air. Loss of heat by air movement is revealed only by the warming or cooling of solid surfaces in the path of the escaping air. For example, air leakage around windows and doors during cold weather appears as localized hot spots, which might be mistaken for areas that are poorly insulated.

If you can find the point of leakage by scanning, investigate to determine the amount of air flow and the reasons for it. For example, the heated air exhausted from a building for normal ventilation may carry away much more energy than the building walls and roof lose by conduction.

To find air leakage into a building, survey from inside the building. Air leaks may follow long, indirect paths through walls and ceilings. A thermal scanner can reveal such a path by sensing the reduced inside surface temperature along the path.

Where to Get Scanning Equipment or Services

It is not economical to purchase thermal scanning equipment unless you plan to use it often in facilities that lose a large amount of energy by heat leakage. The alternatives are to hire a specialist to perform a survey of your facility, or to rent the equipment and do the survey yourself.

There are companies that specialize in thermal surveys. If you decide to hire the service, be sure to select a company that knows how to do surveys for the purpose of energy conservation. A thermal survey company specializing in different applications, such as searching for defects in electrical distribution systems or checking coal piles for spontaneous combustion, may perform a poor energy conservation survey. Some utility companies offer thermal scans as an energy conservation service for their customers.

The person who does the survey may not be the best one to calculate heat losses from the survey results. Make sure that the person who does the calculations gets good images from the survey, along with color codes and other information needed to interpret the images.

Expect to make later localized scans to follow up your initial overall survey. For example, if the first scan shows serious heat loss through the roof, you will want to make a second survey of the attic and the inside surfaces to localize the problems.

If you decide to do the survey yourself (lots of fun, especially the first few times), you can rent the equipment from a number of places. Get adequate training, which is provided by some manufacturers and others.

Measuring the flow of water, steam, and other liquids and gases plays an important role in keeping systems at peak efficiency. For example, it is necessary for adjusting pump output in constant-flow systems and for controlling variable-flow systems.

Flow measurement is the most challenging part of measuring the energy content of hot water, chilled water, and steam. Measuring energy flow directly is essential in sophisticated control systems that optimize energy efficiency. It is also necessary for accurate billing of energy production.

Flow and energy measurement are important tools for monitoring system performance and for troubleshooting.

Flow and heat metering continue to be areas of difficulty. There are many types of flowmeters because no single type is entirely satisfactory in all respects. A given type of flowmeter may be best for some applications, but inappropriate for others. With all types, installation details are important. This Note reviews the basics, and helps you to select the best flow measuring device for your applications.

The Elements of a Flow Metering System

A flow metering system consists of three elements: (1) a sensor that responds to flow, (2) a device that converts the output of the sensor to a form that can be displayed or used for other purposes, and (3) a display device. A flow metering system may also include devices to compute information, such as total flow or heat flow, from the flow measurement.

Common Types of Flowmeters

The following are the most common types of devices used to measure flow of liquids and vapors for energy measurement purposes. This Note does not cover flowmeters used primarily in other applications, such as handling fluids that are caustic or of high viscosity. Some of the following types are fading out, and others are still developmental. Other types not listed here may

become prominent by the time you read this. When selecting a flowmeter, search the market for the best type currently available for the application.

The main distinction between the different types of flowmeters is the type of sensor. Any type of display, control, or calculation device can be attached to any type of sensor by using the appropriate interface.

■ Propeller Flowmeters

Propeller flowmeters, sometimes called “turbine” meters, use a propeller that spins freely in the fluid stream. Flow is measured by counting the rotation rate of the propeller, typically with an inductive pickup that offers no resistance to rotation.

This type works well with liquid, steam, and air, and in general, with low-viscosity fluids that are free of large particles.

Propeller flowmeters can be accurate and reliable, they can sense low flow rates accurately, and they can provide large turndown ratios. If the propeller diameter is a large fraction of the pipe diameter, the propeller tends to average the differences in flow velocity that exist inside the pipe because of pipe wall friction. This type is less sensitive to turbulence than most other types, and it is relatively insensitive to dirt.

Propeller flowmeters have been afflicted with bearing friction problems. There appears to be no reason why this problem cannot be eliminated by protecting the bearing from fouling. Check the performance record of any unit you are considering. Larger propeller diameters produce more torque to overcome any bearing friction.

Manufacturers recommend periodic maintenance of the propeller bearings, which is done by the manufacturer. The maintenance interval depends on the design, the propeller size, and the nature of the fluid. In some units, the propeller assembly is simply replaced.

Before the introduction of electronic revolution counters, the propeller was required to drive an indicator through a gear train. This caused the propeller to run

slow at low flow rates. This problem does not exist in modern units.

■ Vortex Shedding Flowmeters

When a non-streamlined object is placed in a moving stream, it creates vortices in the stream that are generated alternately from both sides of the object. As each vortex forms, it falls away from the object and continues downstream. The rate of vortex formation is related to the flow velocity.

(You can see these vortices easily by moving a paddle through calm water. They are named “von Karman” vortices after the aeronautical engineer who studied them.)

Vortex shedding flowmeters exploit this principle by inserting a small flat surface perpendicular to the flow in the pipe. The vortices shed by the flat surface strike a flexible vane located behind the surface. The resulting vibration of the vane is detected either by a piezoelectric sensor or by a strain gauge.

This type of sensor can be used with low-viscosity liquids at all normal velocities, and with air and steam at higher velocities.

Vortex sensors are sensitive to turbulence in the fluid stream, so installation is critical. Manufacturers typically require the sensor to be installed in a straight section of pipe, typically ten diameters in length upstream and five diameters downstream.

The turndown ratio is high in liquids, which shed vortices down to low velocities. With steam and other gases, the turndown ratio is narrower because the

vortices are too weak at low velocities to be sensed reliably.

Manufacturers recommend replacing the sensors periodically, typically every year or two, because the vibration sensing components wear out. This type of sensor is still new, so check with other users of the models you are considering.

■ Ultrasonic Flowmeters

Ultrasonic flowmeters are used with low-viscosity liquids. They sense the Doppler shift of particulate material carried in the stream, or they may sense turbulence carried along in the liquid. The technology is new, so check the current status of this type of flowmeter. In principle, the device should be accurate at any flow rate, providing an effectively unlimited turndown ratio. You should question the ability of ultrasonic flowmeters to work with clean water.

The major attraction of ultrasonic flowmeters is that they can be used from outside the pipe, needing no taps or other devices to be installed. This eliminates a major cost factor in flow metering for one-time measurements, such as are needed for pump throttling and pump impeller trimming.

■ Pitot Tube Flowmeters

The sensor of a pitot flowmeter is the simplest of devices, consisting of nothing more than a tube mounted in a holder. Figure 1 shows a typical unit for use in air handling systems.

The tube faces into the flow. Flowing gas or liquid has inertia. When the fluid is stopped inside the tube, the inertia is converted into pressure, which is called “velocity pressure.” The velocity pressure is proportional to the square of the velocity. A device called a “square root extractor” is used to derive the flow rate from the pressure signal.

Pitot tubes provide strong output pressures when they are used with liquids, but the output pressures are weak when measuring air or steam flow, especially at the lowest velocities that may occur. This invites error in the pressure transducer that converts the pressure to an output signal. (Pitot tubes are the primary type of sensor for air speed in aircraft. However, they function reliably only at the higher speeds needed to keep the aircraft flying.)

Liquid flow in a pipe is faster in the center than at the perimeter because of friction at the pipe wall. The resulting error in flow rate depends on the diameter and roughness of the pipe, and on the properties of the liquid. You can get pitot systems that have adjustments for these factors. Pitot tubes are sensitive to turbulence, making installation critical.

The accuracy of pitot tubes is not very sensitive to dirt in the tube, because there is no flow through the tube. Of course, the tube can be plugged by dirt, making the unit inoperative.

WESINC

Fig. 1 Pitot tube This pitot tube is easily installed through a small hole in a duct. Additional hardware is needed to convert the pressure to a control signal. The pressure generated in the tube is very small at low air flow rates, limiting accuracy.

Pitot tube systems are proven by long experience. Consider them for applications where flow rates are always fairly high. Do not use them in applications, such as variable-flow pumping systems, where velocities can fall into the range of poor accuracy.

■ Venturi Flowmeters

A venturi is a smooth contraction in a section of pipe. The fluid speeds up to get through the contracted area. The faster fluid has higher kinetic energy, so its pressure energy drops. The flow rate is determined by sensing the pressure difference between the throat of the venturi and the wide open pipe.

(The pressure drops in a venturi because of conservation of energy. The energy of a fluid stream consists of its kinetic energy and its internal pressure. If one of these increases at a particular point in the system, the other must fall to keep the fluid's total energy constant.)

Like pitot tubes, venturis are simple, they have no moving parts, and they are insensitive to dirt. The venturi restriction is smooth, so it dissipates very little energy. Venturis are proven by long experience.

Venturis are used with liquids, gases, and vapors. Unfortunately, venturis require relatively high velocities to provide a signal of adequate strength. For this reason, they have poor turndown ratio. This makes them undesirable in typical energy measurement applications.

■ Orifice Flowmeters

Flow can be measured by sensing the small pressure differential that is created between the upstream and downstream sides of an orifice in a plate that is inserted inside the pipe. The sensing element itself is nothing more than a hole. The cost and complexity come from the additional apparatus that is needed to convert the small pressure difference into a useful indication of flow rate. Figure 2 shows a typical orifice metering system.

Orifice flowmeters are used with liquids and vapors. They have the same advantages and disadvantages mentioned previously for pitot tubes and venturis. Of these, the main disadvantage is a limited turndown range. They have the additional disadvantage that the orifice dissipates pump energy in the form of turbulence. The energy loss is reduced somewhat if a specialized nozzle is used in place of a simple orifice.

Orifice plates can be installed in very little space. You may be able to slip an orifice plate into an existing flange joint. However, turbulence in the fluid makes an orifice plate inaccurate, so you have to install the orifice in a straight section of pipe. Orifice plates cannot be calibrated accurately in the field unless the installation conditions are almost ideal. There are few applications where orifice plates are the best choice. Better methods are making them obsolete.

Spirax Sarco, Inc.

Fig. 2 Orifice flow metering system The sensor itself is simply a hole. The hole is too big to be vulnerable to fouling. The main weakness of this method is poor accuracy at low flow rates. The orifice itself requires only a minimal length of pipe, but the pipe must be straight upstream and downstream to ensure accuracy.

■ Variable-Area Flowmeters

A variable-area flowmeter is a simple device that measures flow with reasonable accuracy. (This type is sometimes called a “rotameter,” although no rotation is involved.) It consists of a loose plug inside a vertical, slightly tapered, transparent body. Liquid flows upward through the body, lifting the plug. Because the body is tapered, greater flow is required to lift the plug higher. Flow can be read directly by marking the body in units of flow rate.

Variable-area flowmeters are used with clean liquids and gases. For energy measurement, they are generally limited to liquids. With gases, they require high velocity and they tend to stick.

Variable-area flowmeters are made in small sizes. They must be installed in a vertical orientation. Installation is not critical. Only a minimal amount of energy is dissipated in the device. They are relatively insensitive to turbulence.

The basic variable-area flowmeter is read directly by sight. With this type, no interface or other display is required. Some manufacturers may offer models that produce a signal for remote reading.

■ Spring-Loaded Variable-Area Flowmeters

There is a hybrid type of flowmeter that combines the characteristics of an orifice meter and a variable-area meter. In this type, a spring-loaded conical plug fits into a large orifice. Figure 3 is a cutaway of a typical unit.

Flow moves the plug out of the orifice. Pressure taps at each end of the assembly sense the pressure differential across the orifice, which is used to calculate flow rate. The relationship between the pressure differential and the flow rate is linear. This gives the unit a high turndown ratio. (In a simple orifice, the

Spirax Sarco, Inc.

Fig. 3 Spring-loaded variable-area flowmeter This device is compact, simple, and relatively insensitive to turbulence. It provides a linear output signal, which improves the range of accuracy. Its main drawback is significant resistance to flow, which dissipates energy.

pressure differential is proportional to the square of the flow rate.)

This type of flowmeter can be installed in any position. It is adaptable to any flow rate. It can be used with liquids and steam. It is relative insensitive to turbulence.

The main disadvantage of this flowmeter is that it dissipates a significant amount of energy by creating resistance to flow in the entire stream.

Totalizers

A totalizer is a device that uses the flow rate signal to calculate a running tally of the amount of substance that has passed through the flowmeter. It is commonly used as part of a heat metering system, for example.

Totalizers eliminate the need for separate consumption meters, such as gas, water, and fuel meters. Consumption meters measure the amount of material directly, usually by passing it through a positive displacement device.

Heat Meters

Heat meters are used to measure the amount of energy carried by a fluid, such as chilled water. (Heat meters are commonly called “BTU meters” in countries where that archaic unit is still used.) A heat meter is a combination of devices that:

- measure the flow rate
- measure the temperature difference between the supply and return
- calculate the rate of heat delivery by multiplying the temperature difference times the flow rate
- calculate the total amount of heat delivered.

The calculations are done by an electronic module. Any kind of flowmeter and temperature sensor can be used with the module, provided that they produce compatible signals. Figure 4 shows a basic system.

Equipment Quality

Instrument quality varies widely. In the HVAC industry, cheap, inaccurate instruments are the norm. There seems to be an assumption that instruments installed on HVAC equipment will not be used anyhow. To get adequate stability and ruggedness, consider so-called “industrial grade” controls. You may have to go to a different set of suppliers to get these.

Piping Issues

Accuracy requires smooth flow at the flow sensor. For this reason, the manufacturer usually specifies that the sensor should be installed in a long run of straight pipe. Typically, the manufacturer specifies a certain number of pipe diameters of straight pipe ahead of the sensor, and a smaller number of pipe diameters downstream.

Some types of sensors are much more sensitive to irregular flow than others. Orifice meters and pitot tubes require smooth flow. Propeller, ultrasonic, and variable-area sensors are most tolerant of turbulence, so they can be installed in sections of pipe that are less than ideal. Venturi and vortex shedding sensors are somewhere between these extremes.

Calibration

Calibration is the Achilles heel of accuracy in flow measurement. Installations in the field provide no opportunity for comparison with standards. Each type of sensor has its own calibration instructions, but these may be difficult or impractical. The installing contractor may not understand the calibration techniques, or may not bother with them. Accuracy of calibration depends on being able to fulfill all the installation conditions properly, especially on providing the specified lengths of straight pipe at the inlet and discharge.

The solution to this problem is to acquire a type of flowmeter that does not require field calibration. The newer types of flowmeters, including propeller, vortex shedding, and ultrasonic types, do not require field calibration, but they must be matched to the dimensions of the pipe in which they are used.

Displays

Select a display that is appropriate for the application. A good digital display is usually easier to read than an analog display. This is important for displays that are read often. On the other hand, any accurate display is satisfactory for one-time readings, as in adjusting pump throttling.

WESINC

Fig. 5 Chart recorders Charts display important aspects of system operation in a very obvious way. These recorders were installed to show system loads. They are also revealing serious oscillations in system controls. The old pen-and-ink versions are obsolete. Now, digital data logging and computer report processing lets you print out charts on a printer with perfect precision. And, no more mess with cleaning ink pens.

WESINC

Fig. 4 Chilled water energy meter The supply and return pipes are on the right. Each has a thermometer, and one has a flowmeter. The box at left calculates the heat flow rate from the chilled water flow and temperature signals, and displays it on the chart recorder. This is a pre-digital installation that allows considerable error in flow sensing, calculation, display, and reading the display. A digital system that is based on a reliable flowmeter would give much more accurate results, and in many more useful forms.

Any measurement system that uses analog components must be zeroed and calibrated periodically. This includes digital displays that are driven by analog-to-digital converters.

Digital displays may or may not lend accuracy to the measurement. For example, propeller and vortex shedding flowmeters have digital inputs from the sensors, so a digital display preserves the accuracy of the input. On the other hand, a digital display of an initially analog signal, such as that from orifice meters or pitot tubes, adds no accuracy. In fact, it may produce a false sense of accuracy.

Charts are a very effective method of displaying system information of many kinds. Charts of loads and usage patterns are an important tool for routine energy management. Charts can also indicate trouble in the system. For example, a wandering display may indicate

an unreliable flow sensor. An oscillating readout may indicate instability in control valves or in variable-flow pump controls. Figure 5 shows a real example.

Old-style chart recorders are now obsolete. No more ink pens! You get much better results by preparing charts digitally. Any good energy management computer system can do this. (See [Reference Note 13](#) for details.) You can also get good charts from digital data logging systems, without the computer hassles. Digital data reporting gives you a wide choice of formats, the ability to perform calculations, and perfect accuracy in computation and display. You do not need special display equipment, only an ordinary computer printer.

Use a totalizer to calculate consumption. In the past, estimates of consumption were often made by visually scanning chart recordings, or from hourly readings. These practices are inaccurate and misleading.

How to Select Your Energy Analysis Program

Energy analysis programs are used to analyze the energy efficiency of energy systems, building design features, entire buildings, and in some cases, whole facilities. Examples of these programs are DOE2, TRACE, HAP, BLAST, and AXCESS.

These complex, sophisticated programs require a great deal of input effort by the user. If used properly, they provide the best possible accuracy for making design and investment decisions. However, computer programs can also give a false veneer of authority to bad analysis. This Note gives you an overview of energy analysis programs, and tells you how to get results you can trust.

Originally, energy analysis programs had to be run on mainframe computers. Today, all the major energy analysis programs have been adapted to run on personal computers. You need a fast personal computer equipped with math coprocessing to achieve reasonably short calculation times.

The Structure of Energy Analysis Programs

All the sophisticated energy analysis programs perform four basic groups of calculations, which are described here. Different programs link these calculations in various ways. It is worth your effort to understand the general flow of calculations in the program you are using.

The facility's energy requirements change continuously, so the sequence of calculations is repeated many times to simulate a full yearly cycle of operation under different conditions of weather, occupancy, etc. At the end, the results of all the repeated calculations are summed to produce the total yearly energy consumption and costs.

For input and calculation purposes, the building is divided into "zones." Each zone is an area of the building that has particular load characteristics, and is served by specific types of conditioning, lighting, and other energy-consuming systems. The program does most of its calculations separately for each zone.

■ Space Loads

The program starts by calculating the end-use energy requirements of the spaces. It calculates heating and cooling loads in the usual way, by adding conduction gains and losses, solar gain, heat gained or lost from outside air, humidification or dehumidification, and internal heat gains.

Weather-related data needed for these calculations are usually taken automatically from a weather data library. Solar inputs are calculated by the computer based on the geographic location and building envelope characteristics, as well as weather data. The program requires manual input of the physical characteristics of the structure, the sources of internal heat gain (people and equipment), and temperature settings.

The program requires manual input of non-weather-related loads. These include lighting, electrical equipment (computers, etc.), domestic water heating, specialized process loads, etc. Typically, the user inputs the peak load of each type, along with an hourly schedule of the percentages of peak load.

Most energy analysis programs provide the option of performing these load calculations alone, without the need to perform the calculations described next. For example, in designing a new building, the space load calculations allow the designer to refine the building exterior to reduce solar cooling loads, or to find the most economical amount of wall insulation.

■ Systems Loads

The “systems” loads include the space loads, calculated previously, plus the extra energy needed to run the conditioning equipment, or “systems.” All or most of this extra energy is for fans, in typical systems. The “systems” include air handling systems, fan-coil units, air conditioners, radiators, etc., but usually not the central plant equipment.

The program also calculates energy losses that may be involved in the operation of the systems. The worst of these losses is reheat. For example, if a particular zone is conditioned by an air handling system with reheating terminal units, the program calculates the fan load, the reheat energy, and the extra cooling energy needed to offset the reheat.

This part of the program requires manual input to describe the efficiency characteristics of the equipment. The equipment operating schedules may also be entered manually, to account for schedules of occupancy. In some cases, the systems’ characteristics can be selected from the program’s equipment data library.

The program will pick out the maximum energy consumption that occurs during the yearly cycle, for each system. The designer uses these maximum loads to determine the sizing of the conditioning equipment.

■ Central Plant Loads

Up to this point, the program has calculated all loads on a zone-by-zone basis. Next, the program adds all the zone loads as a total load on the central plant equipment, which includes boilers, chillers, electric generators, cogeneration plants, thermal storage systems, solar collectors, etc. The program further adds the energy consumption of central plant auxiliary equipment, such as hydronic system pumps and cooling tower fans.

For this part of the calculation, the program requires manual input to describe the plant equipment and its operating schedules. In some cases, plant equipment characteristics can be selected from the program’s equipment data library.

This part of the program yields the “bottom line” energy input to the facility as a whole. This includes energy that is used directly, such as electricity consumption for lighting and receptacle loads.

■ Economic Calculations

All the programs can provide energy cost estimates, as well as raw energy consumptions. To do this, the program requires manual input of energy costs and rate schedules.

Some programs can also calculate the life-cycle costs of alternatives. This requires manual input of equipment and construction costs, at least for the features or equipment being compared. Most programs can incorporate desired interest rates, inflation factors, and other economic variables in the calculation.

The Difference Between Load Calculations and Energy Analysis

To avoid confusion, we will clarify the distinction between energy analysis programs and load calculations. A load calculation is used primarily to select equipment size based on maximum-load conditions. It includes only the space loads, as discussed above, and it is done only for the single instance of peak load conditions.

For example, when selecting an air conditioning system for a house, a contractor makes a load calculation to estimate the peak cooling requirement. This is done by calculating the individual load components, and then adding them. For cooling, the load components are solar gain, conduction gain through the walls and roof, the heat gained by air leakage, and dehumidification. The contractor typically uses a one-page worksheet to perform this calculation.

Basic peak-load calculations are simple. They can be done manually, and they are adequate for many applications. However, manual calculations are not very accurate. One cause of error is that the components of load do not all peak at the same time. Another limitation is inability to deal with thermal storage effects. The degree of detail is limited. For example, it is not practical to include the precise orientation of the surfaces in a manual calculation.

As a result, a number of computerized load calculation programs are now available. They provide greater accuracy, they eliminate the drudgery of arithmetic, and they provide a checklist to make sure that all components of load are included. There is a range of complexity among computerized programs. Some are relatively simple. The most detailed load calculations are provided by using the space loads portion of an energy analysis program, as discussed previously.

(Note that the capacity of heating and cooling equipment may be much greater than the peak conditioning load caused by weather conditions. Heating and cooling equipment is usually sized to provide a reasonably short warm-up or cool-down interval after starting. For this reason, many designers and contractors do not use load calculations. Instead, they select equipment capacity using simple rules of thumb that are based on the size and mass of the building.)

Typical Program Output

All the major programs offer the same types of output information. In order of calculation, the available output includes:

- **the input data.** The report usually repeats the input data for ease of review. This includes data drawn from the program’s data libraries, which are discussed below. For example, the output may

indicate the outside air temperature and humidity that were assumed for each hour.

- **building loads.** Loads are divided into heating, cooling, lighting, process, etc. Some programs may report the components of these loads. For example, cooling load may be divided into solar gain, conduction load, internal heat gain, and latent load. The loads for individual hours may be displayed. Most programs report the time of occurrence of each of the peak loads.
- **equipment sizing data.** You select equipment capacities by using the calculations of peak equipment load. For example, the program may report the peak air flow of air handling units, the peak steam flow from boilers, the peak energy input to individual chillers, etc.
- **energy consumption.** This can be reported in many ways, including totals by energy type; by types of loads (e.g., heating, cooling, lighting, process loads, etc.); by different intervals, including hourly, by day type (i.e., weekday, weekend, holiday), monthly, and yearly; and by system (e.g., chiller plant, air handling units, etc.).
- **energy costs.** These are derived directly from the consumption calculation, making corrections for variations in price at different times. The costs can be reported separately by energy type, e.g., electricity, fuel oil, natural gas, etc.
- **life-cycle cost.** This is the total cost for energy over a facility's life cycle, or other long period of time. This output includes the effects of changes in fuel price, inflation, and interest rates.

The major programs allow you to specify the type of output information you want, and the degree of detail. The program usually allows you to get output in the same subdivisions as input. The loads can usually be displayed by individual zones. Similarly, the characteristics of each system can be displayed separately. All the major programs can report in a variety of tabular and graphical formats.

How to Use the Program

You use an energy analysis program in the same way whether you are designing a new facility or making improvements to an existing facility. In both cases, the first step is to input the characteristics of a "baseline" facility configuration. In retrofits, the baseline is the existing facility. The baseline input is a lot of work. Once you make this investment of effort, you can easily modify the input and rerun the program to simulate changes to individual components.

To develop your design into an optimum configuration, you change the input characteristics of individual components or systems (windows, chillers, lights, etc.), and repeat the computer run to see the effect on overall energy consumption and cost. This is a cut-

and-try process. For example, analyzing the retrofit of a single system typically requires a few computer runs. Designing a big, complex facility may require hundreds of runs to achieve high efficiency.

Input is the main difficulty of using energy analysis programs. It is a slow, tedious, and often frustrating process. In order for the program to calculate loads and energy consumption with a useful degree of accuracy, you need to "describe" the facility and its equipment to the computer in detail. This typically requires many hours of sitting at a keyboard. It also requires knowing the energy characteristics of the structures and equipment.

For example, you need to specify the insulation value of each type of wall, window, roof element, and floor element; an occupancy schedule for each day type; a usage schedule for each type of light fixture; information about each type of heating and air conditioning unit; temperature reset schedules; the times that fuel types are changed; etc.

Each zone requires its own input. A small building usually has at least five zones. A large, complex building typically has dozens of zones. The more sophisticated programs allow you to copy input from one zone to another similar zone. For example, a building may have zones that are identical, except for the fact that they face in different directions.

Input requires a great deal of poring over drawings. When simulating existing facilities, it also requires a lot of legwork to inspect actual conditions. In existing facilities, you may need to measure some energy loads that are difficult to estimate, such as hot water consumption.

To calculate energy cost, you need to input energy prices, by type. This requires learning how to read rate schedules and fuel contracts. (Electricity rates are the most complex. See [Reference Note 21](#), Electricity Pricing, for details.)

The temptation is great to fudge the input data if it is not readily available. The person doing the input needs an intimate knowledge of the facility, so it is generally not advisable to get the analysis performed by a service bureau that is remote from the existing facility. For retrofit projects, input should be done at the site. In designing new facilities, the designer should do the analysis.

■ Input Data Libraries

An important advantage of energy analysis programs is that they include libraries of input data. Most importantly, they include libraries of weather data for many locations, including all major cities of the world and many outlying areas. The weather data are compiled from hourly observations, allowing a high level of detail in calculation. The weather in almost any location can be simulated by using data from some location that is available in the weather library.

Some programs have libraries of heat conduction characteristics for wall and roof components, which eliminates the tedium of defining a wall or roof as many thermal layers. For example, the program may have a pre-defined wall section that consists of common brick-and-block construction with one inch of foam insulation and an internal finish on furring strips.

There are major differences in the structural component data libraries of different programs. The programs also differ in their ability to accurately simulate the thermal characteristics of structures that you define in terms of raw components. However, the capabilities of most programs are good enough for typical applications.

Some programs have libraries of characteristics for mechanical and electrical equipment, including chillers, boilers, pumps, fans, engines, and other types of equipment. Again, there are major differences between programs in this regard. For example, if the program can simulate cogeneration systems, it may include efficiency characteristics of prime movers, such as steam turbines and diesel engines, that are not found in other programs. However, be wary of using these generic data, because of the accuracy limitations discussed below.

■ Sensitivity Analysis

“Sensitivity analysis” means changing a single input over a range of possible values to determine the effect of the variation on the overall output. (This is sometimes called “what-if” analysis.) Use sensitivity analysis when you are uncertain about the actual value of the variable. For example, you cannot predict future fuel prices. To determine the range of economic benefit of installing a dual-fuel boiler, repeat the computer run several times with different combinations of prices for the two fuels.

You should also use sensitivity analysis to optimize equipment characteristics. For example, it is difficult to size the tank capacity in a heat recovery storage system because it is difficult to predict the amount of recovered heat that may be usable. To analyze such a system, repeat the program for a range of tank sizes, and for a reasonable variety of heat recovery and heat usage profiles.

Sensitivity analysis tends to be neglected, resulting in projects that fail because actual conditions differ from those expected. Make a sensitivity analysis for each input that is in doubt, if it may have a significant effect on performance. Sensitivity analysis multiplies the number of computer runs, but you can do it quickly. You simply change the variable that is in doubt, and repeat the run.

How Accurate are Computer Simulations?

Computers do not make arithmetic mistakes. Even so, accuracy in simulating actual energy consumption is not a virtue of energy analysis programs. The problem

is that the actual characteristics of the building and its equipment will differ from the input to some extent. Furthermore, the characteristics of the building will change throughout its life.

Computer energy analysis is an example of measuring something with a micrometer that can only be cut with an axe. In other words, all those decimal places in the computer output don’t mean anything. Remember what your grade school teacher told you about “significant digits.”

Reasonable accuracy is possible only when comparing the difference between two alternatives, where only one or two variables differ and all other factors are the same. To keep from fooling yourself, understand the following limitations in the accuracy of energy analysis programs.

■ Range of Simulation Capabilities

An energy analysis program cannot precisely simulate the wide variety of building shapes, equipment, controls, and conditions that exist. The simulation capabilities of energy analysis programs are being expanded continually, but they always lag behind the latest developments. For example, the major programs only gradually acquired the ability to simulate window shading features, tilted glazing, VAV systems, temperature reset controls, variable-flow pumping, thermal storage, etc. If you are an innovator, you will not find a program that easily simulates all the configurations that you want to investigate.

Energy analysis programs differ in their strengths and weaknesses. For example, one program may be able to simulate the greatest range of equipment types, while another provides the most accurate description of wall thermal characteristics, and yet another provides the best simulation of complex glazing configurations. Be sure that the program you choose is able to simulate the engineering and architectural features that are important for your project.

Veteran users of energy analysis programs become adept at simulating equipment operation that is not explicitly available in the program. For example, heat recovery from a cogeneration plant can be simulated as a “boiler,” and a solar collector can be simulated as heat gain through a skylight. The effect of a temperature reset control can be simulated by running the program for different temperature settings, and averaging the results. These tricks can be tedious, and they usually involve inaccuracies.

■ Accuracy of Component Simulation

The program must be told the efficiency (input-output) characteristics of each component that uses energy, including part-load performance. Input this information by specifying percentages of maximum output for various percentages of energy input. You may have to call the manufacturer’s engineering department

to get part-load information for the equipment you are simulating.

Some energy analysis programs save you this work with libraries of efficiency curves for different types of mechanical equipment, such as fans, pumps, chillers, and boilers. But beware. It is a mistake to rely on generic efficiency curves for major items of equipment, because there are major differences among models.

For example, different models of centrifugal chillers differ widely in their part-load behavior and in their minimum loads, which are important factors in their overall energy consumption. Programs developed by equipment manufacturers may have accurate performance data for their own specific models of equipment, but not for the equipment of other manufacturers.

Data for pumps and fans may be used if they are sufficiently specific as to type. For example, a generic curve for “forward-curved fan” may be satisfactory for most applications, but a general curve for “fan” is not specific enough, unless the fan is a minor item.

You may have to manually calculate the efficiency curve for a complex combination, such as a pump driven by a variable-speed drive. In this example, the program may not be able to account for the efficiencies of both the pump and the drive at each percentage of load.

■ Number of Calculation Intervals

There would be no need for computer energy analysis if the energy loads were constant, or if the loads changed in regular, repeating patterns. In HVAC applications, changing weather conditions make it necessary to use a computer to achieve accurate estimates.

The computer achieves accuracy by repeating the entire sequence of calculations for many short time periods. Some energy analysis programs calculate for each hour of the year, assuming a constant load during each hour. This method repeats each calculation 8,760 times, the number of hours per year. This degree of refinement requires relatively long computing times. The newest personal computers may be able to run such programs in less than one hour per run, and perhaps much less.

At the other extreme are programs that use “bin method” calculations. The bin method was originally developed to allow energy consumption calculations to be done with hand calculators, and the method was later refined for use with computers of limited capability.

The bin method calculates energy consumption only for a series of discrete temperatures, typically in 5°F increments. The increments are called “bins.” The results are weighted by the number of hours that the ambient temperature falls within each bin. There are only twenty 5°F increments in a yearly ambient temperature range of about 100°F, so the bin method requires far fewer calculations than the hourly method.

To use the bin method, you need weather data for the total number of hours that the temperature falls within each increment. The U.S. Government publication, *Engineering Weather Data*, provides temperature and humidity data arranged by bins for many geographic locations. This publication subdivides the bins by month. This allows you to assign different cloud cover and solar characteristics for each month. Of course, breaking down the calculations by month increases the number of calculations by twelve.

The main weakness of the bin method is that not all energy consumption is based on temperature differential. For example, cooling load is also determined by sun position, sky clearness, and internal loads, which vary over wide ranges. The bin method can be extended to deal with these factors by repeating the calculations for different ranges of these conditions, but this requires weather data in a form that is not published, so the computer itself must create bin weather data from actual weather data. Attempting to refine the bin method increases the complexity of the program and the computer running time. The widespread availability of fast personal computers has made the bin method an unnecessary compromise. It is still used in some energy analysis programs, but it is probably a dead end for future development.

Some programs take a path between these two extremes of detail by creating a single day of synthetic average weather for each month of the year. This makes weather the only compromise. Sun angles, usage schedules, and other variables that change on an hourly basis can be calculated properly for each hour of the day. If there are several day types (e.g., weekday and holiday), these can be calculated separately for each month.

■ Weather Data

Even an 8,760-hours-per-year simulation does not account for variations in weather from one year to the next. If the program uses a true hourly calculation interval, the year is probably an actual calendar year of weather data that is selected to be typical. If the program does not use an hourly calculation, it generates synthetic weather input data from actual weather data or from a bin method.

It is a good idea to repeat the program using different years of weather input to represent extremes of weather conditions. Some programs allow different years to be selected. If the program does not provide this option, you can work around this limitation by repeating the calculation with weather data from other locations that are similar to the extremes of weather at the actual location. For example, for a building in Cincinnati, run the analysis with weather data from Atlanta and Chicago. If this produces big differences in energy consumption, there are aspects of the design that are too sensitive to weather conditions.

■ Number of Zones

All energy analysis programs are designed to divide the building into zones. They do this as an easy way of dealing with differences in load characteristics. The program user defines the number of zones, and the way that the building is divided into zones. This is a major decision that the user has to make at the beginning of the input process. A larger number of zones provides greater accuracy, but requires more input work. The computer program calculates the energy requirements of each zone separately, so more zones require longer computer runs.

It is conventional to create separate zones for each exterior orientation of the building, plus interior zones. For example, the user may divide a simple, single-story building into five zones: north, south, east, west, and interior. All five zones in this example differ in solar gain, daylighting, and heat loss, and they may differ in internal heat gain. Users typically define major spaces with distinct energy characteristics as separate zones. Examples of such spaces are kitchens, computer rooms, large conference rooms, and atriums.

More sophisticated programs may require fewer zones, because they allow the user to specify a greater variety of features per zone. For example, the program may be able to deal with several window types in each zone. Such capability does not reduce the input work by much, because the additional description detail requires more input work for each zone.

■ Equipment Defects and Unpredictable Behavior

The program's simulation may differ substantially from real performance because components are not ideal. For example, some energy analysis programs calculate theoretical thermal characteristics of walls in excruciating detail. Real wall construction includes sloppy insulation, thermal short circuits through studs, air infiltration, and other factors that substantially degrade thermal performance. Sophisticated program users try to compensate for such predictable flaws by adjusting the input, but it is not possible to predict the performance of bricklayers and carpenters with a great deal of accuracy.

The program cannot simulate factors that change during the life of the facility. For example, you have to assume a particular chilled water temperature in the input, as this affects chiller efficiency. However, this setting is likely to be changed repeatedly. Use sensitivity analysis to estimate the effect of unpredictable changes.

■ Program Errors

There are only a few energy analysis programs in existence that have proven to be reasonably reliable, and all have limitations and flaws. These programs have bugs for the same reasons that all large computer programs have bugs. A common bug in energy analysis programs is failure of the program to accurately simulate

the way equipment behaves. For example, a leading energy analysis program of the 1970's was abandoned after years of use when it was discovered that some of its equipment simulations were written incorrectly.

This is a continuing problem. Few people have a thorough understanding of the energy behavior of systems, not many of these write energy analysis programs, and those who do may not remain involved with the program to upgrade and debug it.

■ Input Errors and Misunderstandings

The computer cannot read your mind to determine what you really mean, and it will not fix your input errors. The computer is completely literal in reading the input. A typically analysis requires hundreds or thousands of input numbers. An error in any single number will cause an error in the output. Therefore, your input needs to be meticulous.

Some programs can flag input data that falls outside a normal range. This is helpful in catching gross input errors, but errors can still slip through this screen.

How to Catch Errors

Your first computer run usually contains mistakes. Serious mistakes keep the program from running, while subtle mistakes produce wrong answers that may look right. Anticipate the problems discussed previously, and make a careful effort to debug the run and verify the validity of the results. Use the following methods to do this.

■ Read the Output in Detail

The first step is to print all the summary reports. Examine them in detail to see if they make sense.

If the summary reports appear credible, print the entire output. This produces a large stack of paper. If the stack would be too large, at least print the months of January, April, and August. Track through the calculations to see if the trends make sense. Expect to spend hours in checking the output for a building of average complexity.

■ Check with Pencil Calculations

Use pencil calculation to check the computer analysis for several different hours, at different times of the day and different times of the year. To do this, get a complete printout for a particular hour, showing all the inputs. Based on the inputs for that hour, manually calculate all the loads and equipment energy inputs. What you calculate should match what the computer calculates.

A difference may be caused by an input error. Or, you may not be understanding the output correctly. Or there may be a difference between your assumptions and the computer's assumptions. You may find that the program is not calculating what you think it is calculating. For example, the computer may model the behavior of a system differently from the way you intend

the system to work. Only a pencil check can reveal such a misunderstanding.

■ Use Sensitivity Analysis

When running a sensitivity analysis, see whether the changes in output make sense. For example, separate runs for progressively larger tank sizes in a thermal storage system should yield progressively greater energy recovery, but in progressively smaller increments.

■ Analyze the Relative Performance of Dummy Configurations

Calculate the performance of several dummy configurations in addition to the desired configuration, where you know the relative performance of the different configurations.

For example, you may wish to analyze the benefit of converting a constant-volume air handling system to a variable-volume system that uses supply air temperature reset. As a dummy configuration, also analyze a variable-volume system without supply air temperature reset, with everything else remaining the same. You expect the dummy configuration to have higher overall energy consumption than the proposed system, but lower fan load. If the computer does not produce these results, there is probably an error or misunderstanding somewhere.

■ Compare to Measured Energy Consumption

In retrofit applications, check the program's baseline calculation (i.e., the existing configuration) against actual consumption. Use past utilities bills and measurements to determine actual consumption.

■ Check the Computer Code

If you know how to read the computer language in which the program is written, you can check the code itself. Energy analysis programs are huge, so finding errors this way is like searching for a needle in a haystack. Still, the portion of the program that applies to a particular problem may be fairly small. If the program vendor will not supply the computer code, you can use various computer utilities that are available for making computer code visible. If you achieve nothing else, you can satisfy yourself that the program is calculating what you think it is calculating.

How to Select Your Energy Analysis Program

When you select an energy analysis program, consider both the features of the program and the support that will be available for it. In summary, look for:

- **simulation capabilities.** The program should be able to make accurate distinctions between options you are considering. Accuracy is less important

for features of your project that are common to all the options. For example, if you are doing a sophisticated envelope design to minimize solar cooling loads, you need a program that can accurately calculate complex glazing and shading configurations. On the other hand, you may not need an elaborate calculation of wall thermal characteristics. All the major energy analysis programs can simulate common building features and systems. The programs differ widely in their ability to simulate unusual features, such as complex envelope shapes, cogeneration, solar energy, thermal storage, and sophisticated control systems.

- **library data.** Consider the types of weather data, equipment data, envelope component data, and other library data that are offered with the program. Consider whether they contain sufficient detail and specificity to distinguish between alternative designs that you are considering.
- **output options.** All programs offer the same general types of output, but some offer considerably more detail than others. Some output formats are more user-friendly.
- **ease of input.** Some programs, such as the raw government version of DOE2, require you to write elaborate input text. Other programs have a simple, orderly fill-in-the-blanks format.
- **technical support.** You will have trouble, no matter which program you choose. This makes it important to acquire the program from a vendor who provides competent technical support on short notice. Energy analysis programs developed by private companies usually include technical support as part of the purchase price. Check with other customers about the quality and availability of the support provided. Typically, only one or two individuals at each company are well versed in the details of the program. If a critical person departs the organization, the program may become orphaned.

Government-sponsored programs are not copyrighted, so there is no single party with an ownership interest in supporting them. For these programs, there may be several private parties that offer program interfaces for personal computers, which are mainly a vehicle for charging for technical support. The quality of support from such vendors can be poor or spotty, because the interface vendor may not have a good understanding of the main program or of the building systems you want to simulate.

Fossil Fuels

Efficiency Characteristics

- Chemical Composition of Fossil Fuels
- Combustion End Products
- Energy Content of Fuels
- Excess Air Requirements
- Minimum Flue Gas Temperature

Fuel-Related Costs

The name “fossil fuel” applies to solid, liquid, and gas fuels that are believed to be products of the decomposition of ancient plants and animals. In some coal deposits, the outlines of the original prehistoric plants are plainly visible. Petroleum appears to contain components of biological origin. The simple molecules of natural gas cannot be traced to their origins, but natural gas also seems to be of biological origin.

Fossil fuels have been the primary energy source of civilization for about one century, and they will continue to be the primary energy source for the foreseeable future. No other energy source has their combination of desirable characteristics, including high energy density, ease of use, ease of storage, portability, and relative safety. However, fossil fuels are a limited resource that is being rapidly depleted.

Selecting fuel sources is more complicated than simply selecting the source with the lowest price. Nowadays, fuel selection involves environmental considerations, which may limit your choices of fuels, or make it more expensive and difficult to burn them. It involves equipment for transportation and storage, and perhaps for disposal of residue. It affects the efficiency

of the fuel burning equipment. It affects maintenance requirements. This Note will give you a basic knowledge of fuels that will help to deal with these considerations rationally.

Efficiency Characteristics

The purpose of a boiler, a furnace, or an engine is to release the energy of fuel in a useful manner. The following characteristics of fuels affect the efficiency of this process. Table 1 summarizes some of the key features of the common fossil fuels.

■ Chemical Composition of Fossil Fuels

In their “pure” form, all fossil fuels are hydrocarbons, which means that they are compounds of only two elements, hydrogen and carbon. The main difference between fossil fuels is the ratio of the two. Table 1 gives the carbon and hydrogen contents of typical fuels by weight.

Methane, the main constituent of natural gas, consists of one carbon atom and four hydrogen atoms, and it has the highest percentage of hydrogen. At the other extreme, coal has mostly carbon as its combustible component, and contains little hydrogen. A hydrogen

Table 1. EFFICIENCY-RELATED CHARACTERISTICS OF FUELS

Fuel	Heat Content, Total BTU/lb (kJ/kg)	Volumetric Heat Content *BTU/cu.ft. (kJ/cu. m) **BTU/gal. (mJ/cu. m)	Components Percent by Weight		
			H	C	S
Hydrogen, pure	61,100 (142,000)	325 (12,000)*	100	--	--
Carbon, pure	14,100 (32,800)		--	100	--
Sulfur, pure	4,000 (9,250)		--	--	100
Natural gas (mostly methane)	23,800 (55,300)	1,000 (37,000)*	24	76	--
Propane	21,600 (50,200)	2,600 (96,800)* 91,600** as liquid	18	82	--
No. 2 Oil (average)	19,600 (45,600)	138,000 (37,300)**	13	86	0.0 to 0.5
No. 4 Oil (average)	19,200 (44,700)	145,000 (40,500)**	12	87	0.5 to 1.5
No. 6 Oil (average)	18,800 (43,700)	150,500 (41,900)**	12	86	0.3 to 4.0
Coal, bituminous (typical)	14,000 (32,600)		4	84	0.5 to 4.0
Wood (typical)	8,600 (20,000)		6	49	--
Bagasse (typical)	8,200 (19,000)		6	45	--

atom has an atomic weight of 1, while a carbon atom has an atomic weight of 12, so carbon dominates the weight of fossil fuels.

Some fossil fuels are almost perfectly pure, in the sense that they consist almost entirely of hydrocarbons that have high fuel value. Other fossil fuels stray far from this ideal. Fossil fuels contain various contaminants. These may be a major factor in the design of the equipment that burns it. We can divide fossil fuel contaminants into these groups:

- **other types of hydrocarbons.** For example, fuel oil is contaminated by waxes. The waxes have high fuel value, but they cause equipment problems in storage and burning.
- **non-hydrocarbon materials that burn.** A common contaminant of this type is sulfur. It burns, but its fuel value is lower than that of the hydrocarbons. In the process of burning, it causes compounds that are serious pollution sources.
- **non-combustible materials.** Minerals, metals, and water are common contaminants of solid fuels and heavy oil. These cause a variety of problems in storage and combustion.

Natural gas is mostly methane, but it also contains small amounts of ethane, propane, and other light hydrocarbon gases. Contaminants include free nitrogen, oxygen, and carbon dioxide, along with trace amounts of inert gas and sulfur oxides. The foul smell of natural gas is a chemical added in retail distribution to reveal leaks.

Fuel oil is a mixture of many different liquid hydrocarbons. The characteristics of fuel oil represent an average of the characteristics of its components. The energy content, viscosity, and other characteristics of fuel oil vary widely. Fuel oils are commonly classified by numbered grades, from Number 1 (light, least carbon) to Number 6 (heavy, highest carbon content).

The properties of fuel oil can vary significantly, even within a grade. Properties depend on the location of origin, the refining and “cracking” processes used, and blending that is done by the seller to achieve certain properties. Common contaminants of fuel oil include water, sulfur, dirt, and trace amounts of metals.

Coal varies widely in carbon content, being the residue of the decay and cooking of ancient vegetation and animals, along with a substantial amount of inorganic matter. Coal is categorized by grades that have different names. The grades, in order of diminishing carbon and energy content, are bituminous, anthracite, sub-bituminous, and lignite. There are sub-classifications within these grades.

The energy content of coal is affected more by its water and dirt content than by the nature of its hydrocarbon content. Contaminants include anything that is in the ground where the coal is mined. Sulfur is a major contaminant, and metals may also cause trouble.

Sulfur deserves special mention because it occurs in large quantities in oil and coal, and because it has major detrimental effects on efficiency, air quality, and maintenance. Ranges of sulfur content for different fuels are given in Table 1.

The efficiency effects of contaminants are to reduce the energy content of the fuel, to absorb some heat from the combustion gases, and to dilute the hot combustion gases. Only coal has enough contaminants to have a major effect on energy content.

Coal and other solid fuels typically contain a large amount of non-combustible material that becomes slag and fly ash. This inert matter requires special boiler design and auxiliary equipment for disposal. Solid contaminants also create particulate air pollutants. The types and amounts of contaminants vary widely, depending on the geographic location of the source, the type of mine or well, the refining process, the method of transportation and storage, and other factors.

■ Combustion End Products

In combustion, fuel gives up its chemical energy by a chain of reactions that convert the fuel into end products that have no energy left to release. With hydrocarbon fuels, these end products are always carbon dioxide and water vapor. Carbon dioxide is produced by the carbon in fuel. Water vapor is produced by the hydrogen. Thus, for example, natural gas produces a large amount of water vapor, and coal produces little. (However, water that contaminates oil and coal, often in large amounts, ends up as water vapor in the flue gases.)

In perfect combustion, no oxygen would be left in flue gases, because any excess oxygen is deadweight and would absorb combustion heat. By the same logic, the presence of oxygen is an excellent indicator of boiler or engine efficiency. Similarly, the quantity of carbon dioxide in the fuel is also used to measure boiler efficiency. [Subsections 1.2](#) and [1.3](#) cover this in detail.

The sulfur in fuels burns to form sulfur dioxide. This produces a relatively small amount of energy, but it causes major problems.

■ Energy Content of Fuels

The energy content of a hydrocarbon fuel depends primarily on the relative amounts of hydrogen and carbon in the fuel. Burning pure hydrogen produces about 61,000 BTU per pound, while burning carbon produces only about 14,000 BTU per pound. Thus, fuels with a high hydrogen content have the most energy per unit of weight. Table 1 gives the total heat content of common fuels.

Sulfur plays a minor role in the energy content of fuel, mostly by diluting the more energetic elements. Burning sulfur produces about 4,000 BTU per pound.

When purchasing fuel or calculating the efficiency of a boiler or engine from the fuel energy content,

distinguish between “high heat value” and “low heat value.” (These are sometimes called “gross” and “net” heat contents, respectively.) The high heat value is the total energy content of the fuel, with the flue gas reduced to room temperature.

The high heat value is generally unrealistic because the water that is produced escapes from most boilers and engines in the vapor state, so its latent heat is not captured. To account for this, the low heat value was defined as the high heat value minus the latent heat of the water vapor. Water vapor is produced only by the hydrogen in fuels, so the difference between high and low heat values is greatest in fuels with a high hydrogen content.

Even the low heat value overestimates the amount of heat that may be extracted from fuel, even in a conventional boiler. Conventional boilers extract less than the low heat value of a fuel because they need to maintain a margin of temperature in the flue gas, to prevent corrosion. The exhaust temperature of an internal combustion engine is limited by its compression ratio.

High heat value is generally used in calculating the efficiency of boilers, which provides a consistent baseline for comparing all types of boilers, including boilers that condense the water in the flue gas. Low heat value is commonly used in rating the efficiency of gas turbines, probably because it gives an apparent boost to the poor efficiency of these units. Be aware that low heat value may be used to embellish the efficiency of other equipment as well.

The energy content per unit of weight increases with relative hydrogen content for all fuels, because hydrogen has the highest energy content in relation to its weight. On the other hand, the energy content per unit volume decreases with hydrogen content. In the case of gas fuels, this is simply because the number of molecules per unit volume of gas is constant (Avogadro’s Law), and the heavier gases have more hydrogen along with a lower ratio of hydrogen to carbon. In the case of oil, the increased density of heavier oils more than compensates for their lower percentage of hydrogen. Table 1 gives heat content of gas and liquid fuels in terms of both volume and weight. The volumetric heat content is useful because gas and liquid fuels are usually purchased on the basis of volume.

■ Excess Air Requirements

The choice of fuel affects efficiency indirectly by dictating the amount of excess air needed to burn the fuel completely. Excess air wastes energy primarily by lowering the combustion gas temperature, which reduces heat transfer.

Little excess air is needed to burn gas fuels. More excess air is needed for fuels that take longer to be vaporized in the combustion chamber. The quantity of

excess air that is typically needed to burn oil and solid fuels has a significant effect on combustion efficiency.

The best modern burners greatly reduce the excess air requirement compared to earlier burners. Therefore, excess air no longer enters as a major factor in efficiency differences among fuels, except perhaps with solid fuel that is fired on stokers. Excess air requirements are covered in [Subsection 1.3](#), and burner improvements are covered in [Subsection 1.4](#).

■ Minimum Flue Gas Temperature

The flue gas temperature is the primary indication of the amount of heat that has been extracted from the combustion gases. The lower the flue gas temperature, the higher the boiler or engine efficiency, all other things being equal. In a boiler, the tube surface area is the main factor that determines the amount of heat that can be extracted from the flue gas, so it determines the minimum flue gas temperature that can be achieved.

Conventional boilers must keep the flue gas temperature higher than a certain temperature, which is called the “acid dew point.” The acid dew point is the temperature at which corrosive acids can condense out of the flue gas and corrode the boiler. The acid dew point of some fuels is high enough to impose an efficiency penalty on the boilers. The acid dew point is determined primarily by the sulfur content of the fuel, because it is sulfur that forms the corrosive acids.

Conventional boilers remove only sensible heat from the flue gases. In contrast, a special class of boilers lowers the flue gas temperature enough to recover the latent heat of the water vapor in the flue gas. Recovering this latent heat may provide a substantial increment of additional efficiency. This general class of boilers is called condensing boilers.

[Subsection 1.7](#) explains acid dew point limitations in greater detail, and presents methods of dealing with acid in flue gases.

Fuel-Related Costs

Everyone understands that there are large price differences between fuel types. Consider these other cost factors as well:

- **future changes in relative fuel prices.** The relationship between the prices of different fuels can vary radically over time. These changes are caused by a number of factors, such as exhaustion of a nearby source, changes in political policy, developments in energy technology, and other factors. For example, political policy in the U.S. once made natural gas much cheaper than other fuels, but gas may now be more expensive than oil. Most of these factors cannot be predicted with any accuracy.
- **effect on combustion efficiency.** A boiler that is designed to burn several types of hydrocarbon fuels

will burn all the them with about the same efficiency. All oils will burn within one or two percent of the same efficiency. Natural gas burns at a few percent lower efficiency than oil, in conventional boilers. However, only gas can burn in condensing boilers, which have the highest efficiency. Liquid and solid fuels with higher sulfur content require higher flue gas temperatures, which lowers efficiency.

- **environmental protection costs.** Burning some fuels requires expensive equipment to minimize the adverse environmental effects of the combustion products. This is especially true with coal, which requires equipment and special processes to reduce sulfur emission, to minimize creation of nitrogen oxides, and to prevent emission of airborne particulates. These costs depend on the nature of the fuel, the location of the boiler, and the technologies used. For example, sulfur emissions can be reduced by burning low-sulfur coal (which is more expensive), by using a fluidized bed boiler, or by using stack gas scrubbers. Fuels may be penalized for their contribution to atmospheric carbon dioxide by a “carbon tax” that is based on the carbon content of the fuel.
- **effect on maintenance cost.** Cleaning firesides is a major maintenance cost related to the choice of fuel. Boilers may fire indefinitely with gas fuels without the need for fireside cleaning, whereas burning heavy oil may require fireside cleaning several times per year. Solid fuels may require

considerable maintenance of fuel handling and preparation equipment. Oil burning requires a lesser degree of maintenance for fuel strainers, heaters, etc. The choice of fuel also affects long-term maintenance. For example, burning oil instead of gas in a boiler hastens deterioration due to fireside corrosion, such as tube sheet leakage.

- **storage and handling equipment.** Natural gas requires no storage facilities and delivery costs are low, assuming that a pipeline is nearby. Oil requires storage tanks, pumps, and heaters. Coal requires expensive facilities for unloading, storage, transfer to the boiler, crushing or pulverizing, and removal of ash. Burning coal may also require storage and handling of limestone for removing sulfur, and for disposal of the calcium sulfate that results from this treatment.
- **availability options.** Large variability of price, and possible interruptions of supply, make a strong argument for having the capability of burning different fuels in a boiler or engine. This option requires specialized burners, perhaps some compromises with efficiency, and the purchase of storage and handling equipment for each type of fuel. If availability is a significant concern, select your combination of fuels so that they are least likely to become scarce at the same time. For example, if you feel vulnerable to imported oil, install burners to burn natural gas that is available domestically. In some cases, it may even be desirable to have separate boilers for different fuels.

Competitive Purchasing of Electricity

Negotiating Rates

You can reduce your electricity cost in three general ways:

- use less electricity
- obtain electricity under the most favorable rates
- modify your facility’s pattern of electricity consumption to exploit the utility’s pricing structure.

The first of these is classical energy conservation. The second is a matter of intelligent shopping. The last allows the utility to generate more efficiently, or to generate with a less critical energy source, for which the utility rewards the customer with a lower rate.

To exploit the last two possibilities for reducing electricity cost, you need to understand the factors that an electric utility considers in setting its prices. By understanding electricity pricing, you may be able to reduce your electricity cost, often with little effort and sometimes by a large amount. As with income taxes, those who understand the rules may pay much less than those who do not. This Note explains the basics of electricity pricing and suggests ways that you can exploit the pricing structure to reduce your costs.

The price of electricity reflects its origin. Electricity from large hydroelectric generators is cheap. The price marches upward as the source progresses from nuclear reactors to lignite, coal, heavy oil, light oil, and natural gas. At this time, electricity generated from “renewable” sources of energy, such as wind and sunlight, is the most expensive.

There are many other factors that affect electricity prices. Electricity pricing varies from one locale to another, from one utility to another, and from one customer category to another. Negotiation is an important factor in pricing for larger customers.

Rate Schedules

Unlike the prices of other energy sources, the price of electricity is regulated. This occurs even in countries with free markets because a public utility is granted a monopoly to provide electrical service within a specified

geographical area, so its prices are not restrained by competition. In the United States and in some other countries where electric utilities are privately owned, each utility publishes its own prices and method of pricing in the form of “rate schedules.” Figure 1 shows a key extract from a typical rate schedule.

In the United States, utility regulation is done by each state. The state regulatory agency audits the rate schedules, negotiates changes requested by utilities, and sometimes initiates changes on its own. Each electric utility operating within a state establishes its own rate schedules subject to regulation by that state. An electric utility that operates in more than one state has a different set of rate schedules for each state.

The central principle in utility regulation has been to make the utility’s charges reflect its actual costs. The utility’s main cost categories are:

- **generating plant**, the cost of which varies greatly with the type of equipment. For example, gas turbines are much cheaper to install than nuclear or coal-fired power plants.
- **distribution equipment**, such as that shown in Figure 2. Distribution cost depends mostly on the distance covered, the nature of the terrain, and the power capacity. For example, it costs much less to serve a single large customer located near the power plant than to serve many residential customers distributed over a large area.
- **fuel or energy**, which differs greatly in cost for different types of generating equipment. For example, gas turbines need more fuel than boilers that drive steam turbines, and gas turbine fuel is more expensive. On the other hand, dirty boiler fuels incur a large equipment cost for reducing air pollution. Generation with water power, wind, solar, geothermal heat, etc., involves little fuel cost, but it may have a high initial cost and low reliability.
- **administration**, which is distributed over all aspects of utility operation. Administration is a larger fraction of the electric bill for smaller customers.

- **ability to buy electricity from, and sell to, other utility systems.** Utilities use their excess generating capacity to sell electricity to other utilities. Likewise, a utility may purchase electricity at times when it lacks capacity. The price of electricity transferred between utilities fluctuates from moment to moment, depending on the load characteristics of all the utilities that are connected together.

These cost elements are reflected in the rate schedule by a variety of charges. Most rate schedules have three major categories of charges that customers pay:

- **commodity charge**, which is based on the number of kilowatt-hours purchased
- **demand charge**, which is based on the maximum rate of consumption, expressed in kilowatts, during certain time periods defined by the utility
- **fuel surcharge**, which accounts for fluctuations in the utility's fuel cost.

It is essential to understand the difference between the charges that are based on kilowatt-hours, and those that are based on kilowatts. See Figure 3.

The names and details of these charges differ between utilities and jurisdictions. Rate schedules also include a somewhat random sprinkling of charges that reflect less important cost factors, such as power factor and supply voltage. Each of these types of charges is discussed in greater detail, below.

It is impractical to match the utility's actual cost of serving each customer to its charges to that customer. For each customer, there are differences in the cost of distribution, billing, and customer service. Different customers use electricity in different ways. Political considerations create pressures to shift costs between classes of customers. To deal with these variations in cost of service, the utility creates different rate schedules for different classes of customers, and for different consumption patterns.

As a rule, the actual cost of electricity is tailored more closely for larger customers with more complex rate schedules. Smaller customers, which include individual residential accounts, are served under simple, standardized rate schedules.

"Riders" are supplements or variations of a basic rate schedule. The number of schedules and riders generally increases with the size of the utility and the diversity of its customers.

For example, one typical large utility has separate rate schedules for general residential service, time-metered residential service, commercial facilities in several size ranges, time-metered commercial service in several size ranges, several types of interruptible service, electric heating, outdoor lighting, street lighting, traffic signals, electric vehicles, electric mass transit, and cogeneration.

	Billing Months of June - October (Summer)		Billing Months of November - May (Winter)	
A. Customer Charge	\$292.20	per month	\$292.20	per month
B. Energy Charge

E. Minimum Charge - The Customer Charge				

Fig. 1 Key portion of an electric rate schedule This is the core of one rate schedule created by a large electric utility. This rate applies to medium and large commercial customers. The charges vary by the time of year. The charges also vary by the time of day, and by the day of the week. The hourly and daily variations are covered by the three periods under the "energy charge," which are explained elsewhere in the rate. There is a "demand charge," which is made only during the utility's peak generating hours. The charges are calculated based on the pattern of consumption during individual months. The full rate schedule is several pages long, defining the terms used in this table, establishing various conditions, and specifying variations, or "riders." The same utility has about a dozen other rates for different classes of customers.

Electric utilities structure their rates to encourage actions by their customers that are advantageous to the utilities. For example, utilities faced with the cost and difficulty of constructing new generating facilities increase their demand charges to encourage their customers to find ways of reducing peak power consumption.

In most cases, the utility selects the rate schedule and riders that apply to a particular customer. However, a customer may be eligible for several rates or riders. The difference in electricity cost between alternative rate schedules is not always obvious. For example, a time-of-day rate may reduce electricity costs if the facility has a low daytime peak, while it may increase costs otherwise.

Rate schedules are often written in a manner that is inscrutable, incomplete, or illogical. A call to the utility's rate department may be necessary for clarification. Some utilities cannot interpret their own rate schedules, making it necessary to divine from actual billings how the utility is charging for electricity.

In recent decades, new regulatory principles have influenced rate schedules. Some regulatory bodies use rates to transfer costs from one class of customer to another. Many regulatory bodies have been requiring utilities to promote "demand-side management" (DSM) and energy conservation. This skews existing rate schedules and creates entirely new rate schedules for certain activities, such as interruptible service and thermal storage.

Commodity Charges

A commodity charge is an electric rate that is based on the amount of electrical energy delivered. The billing

units are kilowatt-hours (KWH). A commodity charge may be called an "energy charge" or some other name. A commodity charge is similar in form to the prices of other energy sources, which are sold per-barrel, per-ton, etc. A rate schedule may have different commodity rates for different months or seasons.

For small customers, including most residential customers, a commodity charge and a fuel surcharge are the only types of charge that are found on the bill. For such customers, the commodity charge reflects all the utility's costs, except fuel.

For larger customers, a commodity charge is usually one of several charges. In this case, the commodity charge tends to reflect the utility's major fixed costs, especially the generating plant and long-range distribution equipment. For this reason, the commodity rate tends to remain unchanged for long periods of time.

Fuel Surcharges

The utility's fuel costs change continually, sometimes over a wide range. Rate negotiations with the regulatory agency take too long to reflect changes in fuel cost, so the utility is allowed to adjust for its fuel cost with each billing by using an approved formula. This is simplified by the fact that a utility is generally not allowed to make a profit on its fuel costs. (In effect, a utility is allowed to make a profit only by operating and renting out its equipment.)

Fuel surcharges usually do not discriminate by time, even though the utility's fuel cost may vary widely from on-peak to off-peak periods because of differences in generating equipment. This is another compromise to simplify billing.

WESINC

Fig. 2 Utility distribution equipment Customers pay for this largely by demand charges, because the size of the equipment and wires is determined by the customers' peak rate of consumption. Demand charges are higher if there are fewer customers served by this substation to average the peaks in consumption.

Demand Charges

“Demand” is defined as the highest rate of consumption, expressed in kilowatts, during a defined time period. The time period is usually a calendar month. Note that demand is measured in kilowatts (KW), not in kilowatt-hours (KWH). Demand is a peak rate of consumption, not an amount of consumption.

A demand charge can be considered a surcharge on customers who use electricity in large amounts during the utility’s peak generating periods, thereby forcing the utility to install extra generation and distribution capacity. Demand charges are highest during time periods when the utility is forced to use supplemental (“peaking”) generators that are inefficient and use expensive fuels. Demand charges may differ by the hour, the day, or the season, as discussed below. Most larger customers are subject to a demand charge, which may be given a variety of names.

The demand charge is often a large fraction of the total electric bill, and in many cases, it may account for more than half of the bill. The distinction between the demand charge and other charges is important, because the facility often has the ability to reduce its demand separately from its total consumption. Utilities base demand charges on their own load, not on the individual customer’s load. By shifting your peak consumption to a time that is more favorable for the utility, you may reduce your demand charges substantially.

The demand charge becomes a larger fraction of the total electric bill if the customer’s electric load profile is “peaky,” for example, if there is a large, brief air conditioning load on an unusually hot day. In effect, a

demand charge is a penalty for having high peak loads. By the same token, a customer can reduce its demand charges by reducing its load peaks, for example, by “peak shaving” or using thermal storage.

Demand billing requires special metering equipment and extra billing work, so demand charges are usually not levied on small users. Instead, peak-related costs for a given class of customers, such as residential or small commercial, are averaged into a rate that is expressed in terms of a commodity charge. (There has long been pressure to include demand charges in residential billing. Improvements in metering technology may make this practical in the near future.)

■ How the Demand Peak is Measured and Calculated

The “demand” that appears on the monthly electric bill is not an instantaneous value. In most cases, billing demand is the highest average consumption during a short period of time, which is usually 15 to 30 minutes. Therefore, you don’t need to worry about surges of motor starting current that last only a few seconds.

The utility typically measures demand by installing special metering equipment that totals the number of kilowatt-hours used during each interval of this duration, and uses a computer to find the highest total. In some cases, the measurement intervals start exactly on the hour, and at intervals of 15, 20, or 30 minutes thereafter. This is called a “fixed window.” In some cases, a “sliding window” is used by the utility company, which means that the demand measurement interval can be selected to cover the customer’s actual highest peak period.

Utilities with old equipment may still measure demand visually by scanning a continuous chart recording of power consumption.

Almost all utilities start the demand measurement afresh on the first day of each billing period, which is typically a calendar month. However, “ratchet charges,” discussed below, may cause the demand recorded in one month to affect demand charges in succeeding months.

■ Variations of Demand Charges

Demand charges may occur in the electricity bill under a variety of names other than “demand.” There may be a single demand charge designed to recover all the fixed costs of the utility, or there may be different types of demand charges that recover different types of costs. The different rate schedules of a given utility typically express demand charges in different ways.

For example, some utilities define a “generation charge” covering the generation equipment at the power plant, and a separate “distribution charge” that compensates the utility for its equipment at the user site and in the adjacent geographic area. The “distribution charge” typically is charged at the same rate per kilowatt all year, while the “generation charge” typically is based on the demand measured during peak generation periods.

Fig. 3 Be clear about the difference between kilowatts and kilowatt-hours This electric power monitor in a commercial building shows the highest demand peak of the current billing month, expressed in kilowatts. It also shows the current cumulative total of electricity consumption for the month, expressed in kilowatt-hours. You need to know how these numbers relate to your utility’s rate schedule.

There is logic in this. The distribution charge is simply a way for the utility to recover its cost of installing equipment to deliver electricity to an individual customer. This includes the cost of transformers, meters, and local power lines. The distribution charge is like a mortgage payment for equipment that has already been bought.

In contrast, the generation charge largely relates to central generating equipment. It applies to future costs as well as past costs. It is structured to discourage customers from using electricity during time periods when the utility is generating near maximum capacity. Consumption during the utility's peak periods forces the utility to build more plants. It also forces the utility to generate electricity using equipment, such as gas turbines, that have a higher unit energy cost. (This is because the gas turbine is less efficient, and because it uses fuel that is more expensive.) For these reasons, demand charges depend on the utility's present reserve capacity. It also depends on the types of generating equipment that the utility owns.

This is not to say that all electricity rate schedules are logical or consistent. Many utilities lack the capability to develop rate schedules that reflect their costs in a proportional manner. Any rate schedule is a compromise between complexity and accuracy in proportioning costs. This is one reason why utilities reserve their most complex rate schedules for their largest customers.

■ Time-Related Aspects of Demand Charges

The price of any commodity changes with time. Some commodities have price fluctuations that are cyclic, such as strawberries (more expensive in winter), air fares (more expensive in summer), swimsuits (more expensive in spring), newspapers (more expensive on Sunday), and telephone calls (more expensive during business hours).

The price of electricity may vary in several sets of time cycles. This is because the cost of producing electricity varies with the hour of the day, the day of the week, and the month of the year. The term "time-of-day rate" is used for any rate schedule that varies the price based on the time that electricity is delivered. In most cases, time variations in electricity price are included in demand charges.

If the utility experiences its highest loads in summer, it is called "summer-peaking." Summer demand peaks are usually created by air conditioning loads on exceptionally hot days during the mid-afternoon. Therefore, summer-peaking utilities typically have high demand rates that apply during the daytime hours of the summer months.

Similarly, winter demand peaks are usually created by electric heating equipment on exceptionally cold days. Heating peaks may occur during the night, if the utility serves primarily residential customers. Or, a

heating peak may occur during the daytime, if the utility serves a large commercial heating load.

Some utilities have both summer and winter peaks, which are factored into demand charges for both seasons.

Some utilities levy demand charges without regard to the time of consumption. Usually, such rate schedules are a mistake, and they may motivate customers to make changes to consumption patterns that are pointless, or even contrary to the interests of the utility.

■ Ratchet Provisions

A "ratchet charge" is a demand charge that carries over from one month to later months. For example, a summer-peaking utility may have a three-month period of high demand charges during the summer. Its demand rate may have a ratchet provision that stipulates that the highest demand measured during this three-month period will be used to calculate demand charges for each of the following nine months, although the demand charge may be lower outside the summer months. In some cases, a ratchet provision stipulates that the demand for months outside the peak period is considered to be a certain fraction of the demand that occurs within the peak period.

The logic of a ratchet charge is that the utility must pay for equipment that it owns all year, even though the equipment is used to its full capacity only during a small part of the year. A customer who contributes to the utility's peak load is penalized by a ratchet charge, whereas a customer whose demand peak occurs outside the utility's peak load period receives a lower demand rate.

■ "Hour Charges" and Load Factor

In constructing its rate schedules, a utility faces the dilemma that it wants to encourage sales of energy while discouraging demand. Some utilities respond to this dilemma by using "hour charges," which are demand charges discounted for high consumption. (The term "hour charge" stems from the fact that it is calculated on the basis of kilowatt-hours per kilowatt, which results in the dimension of hours.)

Hour charges benefit customers who have a high "load factor," which is the ratio of the average load to the peak demand.

■ Effect of Energy Conservation on Demand

An energy conservation measure will reduce demand charges if it operates continuously, at least during the period when demand charges are levied. For example, installing light fixtures of lower wattage reduces demand as well as consumption. On the other hand, an energy conservation measure may not reduce demand if it fails to operate, even one time, during the demand charge period.

For example, an expensive thermal storage system will not reduce demand if it experiences even one failure during the demand measurement period. Likewise, the

“demand limiter” controls commonly installed on chillers do not reduce demand charges if the chillers are allowed to operate at full output during periods of high cooling load.

Electricity Charges Based on Customer Equipment

Some aspects of electricity pricing are based on the characteristics of the customer’s electrical system or equipment. The customer may be able to change his equipment to reduce electricity costs.

■ Power Factor Penalties

Power factor is a measure of the phase relationship between the voltage of the power system and the current that is drawn by a device in response to this voltage. Power factor is 1.00 if the current is perfectly in phase with the voltage, and is less than 1.00 if the current is out of phase with the voltage. It is also common to express power factor as a percentage, with 100% indicating that the current is perfectly in phase with the voltage.

(Mathematically, power factor is the cosine of the phase angle between the voltage and the current waveforms. This assumes that both waveforms are pure sine waves. Some modern electrical equipment, such as variable-frequency motor drives and electronic transformer ballasts, distort the waveform in the electrical system. This may create an effective reduction of power factor.)

If a device is essentially a resistor, such as an incandescent light bulb filament, the current flows in phase with the voltage, and power factor is high.

Some major electrical equipment, especially motors and magnetic lighting ballasts, are inductors. The current flow through an inductor rises slowly (lags) after the voltage is applied. The current through a pure inductor lags the voltage across the inductor by 90°.

Conversely, the current flow through a capacitor leads the voltage by 90°. (This does not mean that the current in a capacitor has a magical ability to anticipate what the voltage will be. It simply means that voltage cannot develop across a capacitor until it accumulates electric charge. Perhaps it is more realistic to say the current flow in a capacitor lags the voltage by 270°.) Hardly any modern electrical equipment is capacitive.

Utilities are concerned about power factor because low power factor raises their distribution cost. If the current is significantly out of phase with the voltage, more current is required to deliver a given amount of power. (Power is delivered only by current that is in phase with the voltage.) The additional useless current is called “reactive current.” The reactive current increases the utility’s costs for wiring, transformers, and switchgear. To compensate for this, utility rate schedules often include a penalty for low power factor. This is sometimes expressed as a discount for high power factor.

Power factor penalties typically commence when the power factor falls below about 85%.

Power factor penalties vary widely from one utility to another. Some utilities do not include power factor in their rate schedules, while others charge a fairly severe penalty for low power factor. Low power factor is commonly caused by inductive loads, especially by electric motors and old-style magnetic lamp ballasts. The customer can improve power factor by installing capacitors in his power circuits.

The manner in which the utility measures power factor may be important. The utility may measure a facility’s power factor during the facility’s peak demand period, or at other times. The measured power factor is lowest when equipment that operates with low power factor comprises the largest fraction of the overall load. For example, if the facility has electric resistance heating, the power factor will be relatively high during the peak heating period. On the other hand, the power factor may be low during a cooling period, when the load is dominated by electric motors and fluorescent lights.

An odd case occurs with variable-frequency motor drives of a type whose power factor declines with motor speed. These drives may reduce the facility’s overall power factor during periods of low load, but not during periods of high load. (For details, see [Reference Note 36](#), Variable-Speed Motors and Drives.)

■ Delivery Voltage

Rate schedules for large customers may include a discount if the electricity can be provided at a specified high voltage. Delivery at the utility’s distribution voltage saves the utility the cost of a step-down transformer.

■ Ownership of On-Site Distribution Equipment

The customer may have the option of owning the electrical distribution equipment (transformers, poles, wires, etc.) on its own property. This may reduce the electricity rate, since the utility does not have to purchase this equipment.

■ Incentive Rates

Many utilities offer favorable rates to motivate customers to install equipment that benefits the utility. Some rates are intended to increase electricity sales, such as discounted rates for heat pumps and electric heating. Other rates are intended to reduce the utility’s peak load, such as discounted rates if thermal storage is installed. Some rates promote both purposes, as for electric storage heating.

Many utilities offer a one-time rebate or subsidy to promote the installation of such equipment.

■ Effect of Multiple Meters

It is generally cheaper to purchase electricity in larger quantities. This quantity discount often takes the form of a commodity charge that declines in several steps as more kilowatt-hours are used. The rate of

decline between steps may be steep, with the last kilowatt-hours purchased during a month costing only a fraction of the first.

In many facilities, electricity is provided through multiple utility meters, each of which has a separate billing account. Multiple meters are often the residue of successive additions to a facility. In each account, the charges for electricity start at the highest rate. This often makes it advantageous to combine billings on a single account.

But, be aware that this may not be true, especially if there are differences in the demand rates. For example, combining metering might require a different rate schedule having a lower commodity charge but higher demand charges. Combining metering may reduce total demand charges if the different users operate on different schedules, so that the demand peaks are not superimposed. Conversely, if the demand peaks of all users occur simultaneously, the net demand charge may be increased.

Administrative Charges

A common feature of rate schedules is a fixed monthly charge that covers the administrative costs of servicing the account. This can take a number of forms. A “customer charge” is a fixed monthly charge for each customer. A “meter charge” is a fixed monthly charge for each meter. Another type of administrative charge is a minimum charge for KWH that applies even if a smaller quantity of electricity is actually used.

Excess-Consumption Charges

An excess-consumption charge is a rate that increases with the amount consumed above a certain amount. This is opposite the usual practice, which is to give a discount for increased consumption. Excess-consumption charges usually are limited to periods of energy shortage, when they may be initiated by the regulatory authority.

Competitive Purchasing of Electricity

Ordinarily, a customer deals with the one electric utility that serves his geographic area. However, new utility regulation may allow the customer to negotiate with electric utilities serving adjacent areas. In effect, the customer may shop around for electricity among

various sources. The local utility may be required to serve as a conduit for electricity purchased from another utility, although it may charge a fee for the use of its lines.

This procedure is called “wheeling.” This area of utility regulation is evolving and controversial. Larger customers should look into competitive purchasing to determine whether it offers any potential for reducing electricity costs.

Negotiating Rates

As with other commodities, the price of electricity is negotiable, especially with large customers. As in any negotiation, know when to negotiate, know what your alternatives are, and understand the desires of the other party. The best time to negotiate is before building a facility, when you have the greatest variety of options. However, conditions in the utility market change continually, providing new opportunities for negotiating rates.

You may negotiate on the basis of competition from other suppliers, including the possibility of generating your own power, perhaps with a cogeneration plant. You may offer to change consumption in a way that benefits the utility, such as by installing a thermal storage system. Changes in utility industry regulation that allow competitive purchasing provide an opportunity for negotiating with your present supplier.

Before negotiating, develop an understanding of the utility’s situation, including its load profiles, its reserve generating capacity, the combination of generating equipment it owns, the type and availability of fuels that it uses, its ability to buy and sell electricity in the adjacent power pool, and its future plans and projections. Changes in the utility’s load characteristics, e.g., whether it is summer-peaking or winter-peaking, can make the utility more or less willing to negotiate rates, depending on how the customer’s load affects the utility.

Also, assess external factors, such as political pressure on utilities to promote demand-side management, the fuels that are presently considered to be the most environmentally acceptable, and whims of regulatory agencies. Such factors tend to change more quickly and erratically than changes to the situation of the utility itself.

Low-Temperature Heat Sources & Heat Sinks for Heat Pumps and Cooling Equipment

Soil
Ground Water
Surface Water

Solar Collectors
Waste Heat

You can increase the efficiency of cooling equipment by lowering the temperature at which the equipment rejects heat. The most common heat sink for cooling is the atmosphere. The disadvantage of the atmosphere as a heat sink is that it gets warmer at the same time you need cooling. In many cases, you can reject heat at lower temperature by using the soil, well water, or surface water as a heat sink. These alternative heat sinks can typically lower the average condensing temperature by 20°F to 30°F (11°C to 17°C), substantially increasing cooling efficiency.

Similarly, you can increase the efficiency of a heat pump, when it is heating, by increasing the temperature of the heat source. Again, if the atmosphere is the heat source, its main disadvantage is that it gets colder when you need heating. Soil, well water, and sometimes surface water are warmer heat sources during cold weather. Depending on climate and the nature of the heat source, the average heat source temperature may be 10°F to 30°F (6°C to 17°C) higher than the air temperature.

Using an alternative heat source for heat pumps is especially important because the capacity and efficiency of heat pumps drop radically as the temperature of the heat source drops. In fact, heat pumps must cease operating and rely on a secondary heat source (typically electric resistance heat) when the outside air temperature becomes too cold. Using a higher-temperature heat source eliminates this problem, and greatly extends the range of climates in which heat pumps can be used for heating.

Heat pumps can also use solar collectors and waste heat as low-temperature heat sources. These sources are available at all times of the year. Certain types of solar collectors offer the possibility of using the collector as a heat radiator at night, so this type of collector can operate as both heat source and heat sink.

Use this Note to help you screen the possibilities for heat sources and heat sinks other than the atmosphere. If you find a likely candidate, study it further. Each of the sources has an ample literature, so we won't repeat a lot of detailed information here. A good starting point for more detail is the *ASHRAE Handbook*, which in turn offers additional references.

But, beware of the optimistic claims of promoters, who write much of the literature on this topic.

[Reference Note 23](#), Non-Fossil Energy Sources, covers an entirely different group of free energy sources, which provide heat at much higher temperatures than is available from the heat sources covered in this Reference Note.

Soil

The temperature of the earth's surface tends to remain constant below a certain depth, which is typically about 12 feet (4 meters). This makes deep soil a potential heat source and heat sink. Heat pump systems exploiting this principle were first promoted during the 1980's as a way of using heat pumps in colder climates where air-to-air heat pumps are considered uneconomical. Such systems have been called "ground source" or "earth-coupled." Recently, promoters have started calling them "geothermal" systems, which is a misapplication of a term that describes an entirely different class of heat sources. (Geothermal sources typically are hot enough for direct use, without needing heat pumps to raise their temperature. See "Non-Fossil Energy Sources" for details.)

The distinguishing feature of an earth-source heat pump installation is its buried heat exchanger, which consists of a great length of pipe in which the loop water is circulated. The pipe may be buried in a horizontal grid pattern or in deep vertical hairpin loops. The pipe may be standard plastic water or gas pipe, or specialized copper alloy tubing. The pipe must be able to resist soil conditions, such as acidity, for many years. It must also be compatible with any antifreeze material that is used.

With horizontal fields, the pipe is laid in trenches spaced one or two meters (three to six feet) apart. This requires a large amount of trenching and many pipe joints. Figure 1 shows a horizontal field being installed.

An alternative method of installing a horizontal field is to excavate the entire field, lay down the pipe, and backfill over the pipe.

With vertical installation, one or more hairpin loops may be buried in holes that typically range in depth from 100 feet (30 meters) to 400 feet (120 meters). Figure 2 diagrams this method. The holes are filled with a grout,

such as bentonite clay, that must be kept in a slurry state. The grout provides heat transfer, allows for thermal expansion and contraction, and prevents penetration of surface contaminants into the ground through the bore holes. The need for grout is a potential problem in locations where the grout can dry out.

Earth-source heat pumps are still in the experimental stage of development, notwithstanding the fact that some promoters have been pushing them aggressively. By the 1990's, many earth-coupled heat pump systems were being installed, including systems for large facilities. However, major problems were continuing to come to the surface. Anyone contemplating designing or using soil as a heat source should study the latest experience, and be prepared to take risks.

Burying the heat exchanger is the largest part of the system's cost, and the pipe itself is not cheap. Engineering cost may be relatively high because these systems are novel. Certain contractors specialize in earth-source heat pumps, and they do the engineering as well as the installation. The disadvantage of this arrangement is that the contractor will lean toward minimizing his own costs rather than toward maximizing the efficiency of the system.

The installation cost of an earth source is comprised mostly of the labor cost and equipment rental required to dig holes in the ground, to bury the heat transfer pipe in a suitable bedding material, and to make piping connections. These costs are subject to great variation, but generally are high.

Trenching becomes much more expensive as the depth increases below about one meter, which tempts

installers to bury horizontal fields too shallow for good efficiency. It has been claimed that safety regulations requiring shoring of deep trenches makes it uneconomical to bury horizontal fields at an efficient depth.

The main advantages of using soil as a heat source and heat sink are:

- **good compromise temperature.** In most locations, the temperature of deep soil is a good compromise for use in both heating and cooling. Vertical heat exchangers are buried at depths where the soil temperature is essentially constant. With horizontal fields, it is usually not economical to bury the heat exchanger deep enough to reach a constant soil temperature.

To date, most heat exchangers are horizontal fields that are buried at depths ranging from just below the frost line down to about 6 feet (2 meters). At these depths, the temperature of soil varies seasonally. A redeeming factor is that soil temperature lags several months behind air temperature. This provides a useful storage effect that cools the soil in advance of the cooling season, and warms the soil in advance of the heating season. The heat exchanger itself changes the temperature of the soil. This may substantially reduce the efficiency of system operation. The importance of this effect depends on soil type and water content, as well as the heat exchanger size and system operating schedule. Engineering data on this issue is still sketchy.

WESINC

Fig. 1 Horizontal soil heat exchanger field This field is being installed to serve as the heat source and heat sink for a church in Minnesota. The climate here would not allow efficient operation of an air-source heat pump. Obviously, a large amount of open space is required. Loose soil makes it too expensive to bury the pipe at a depth that would provide the best efficiency.

- **no need for supplemental heat sources or heat rejection equipment.** Soil temperature remains fairly constant below a certain depth, so there is no need for either a supplemental heat source (boiler) or heat rejection equipment, provided that the buried heat exchanger is made large enough. On the other hand, economics or limitations in land area may dictate a hybrid system, most likely involving a cooling tower to supplement cooling operation.
- **simple control.** Complex loop temperature control is avoided because the soil temperature controls the loop temperature directly.

The main disadvantages of using soil as a heat source and heat sink are:

- **land area requirement.** If horizontal fields are used, a large amount of bare ground is required for installation of the piping field. The entire area must be trenched to lay down the piping, and the ground cannot be used for other construction. Vertical heat exchanger coils need much less land area.
- **uncertain heat exchanger reliability.** The long-term reliability of the heat exchanger piping is unknown. Although the pipe appears to be well protected, it is subject to stress from thermal expansion and contraction, and from soil conditions. One type of plastic originally used

WaterFurnace International, Inc.

Fig. 2 Vertical soil heat exchanger field This requires much less surface area than a horizontal field. The cost of trenching is replaced by the cost of drilling. Leakage is less of a potential problem. However, tricky methods are needed to maintain good contact between the pipe and the soil while allowing for thermal expansion.

(polybutylene) has experienced serious failures. Polyethylene pipe is now being used, but is subject to softening from some antifreeze impurities. The long-term performance of buried copper heat exchangers is untested.

- **shortcuts in design and installation.** System efficiency and reliability are in conflict with the desire of the owner and the contractor to limit costs. The efficiency of the system may be seriously degraded by inadequate heat exchanger size, or failure to bury horizontal fields deeply enough.
- **failure-prone installation.** Damage in installation and defective joints are serious problems. Especially in horizontal fields, rough handling of the heat exchanger pipe is virtually unavoidable. These problems cause long-term failures that may occur long after the warranty has expired and the original occupants have departed.
- **repair difficulties.** If a leak occurs in a horizontal field, it may be extremely difficult and expensive to find the leak. Leaks are less likely to occur in a vertical heat exchanger, but they may be virtually impossible to repair. Leakage is usually handled by plugging and abandoning the leaking loop. This reduces heat exchanger size and system efficiency.

In terms of thermal characteristics, soil is similar to ground water. A ground water system is usually less expensive to exploit, but the water must be pumped out of the ground, and often, pumped back.

Ground Water

Ground water is water that comes from wells. Water may be taken out of the ground, passed through the heat pump system, and then used on the surface for other purposes, such as irrigation. Figure 3 shows this arrangement.

Or, it may be necessary to inject the water back into the aquifer. This requires two wells. One draws water out of an aquifer at one depth, and the other returns the water to a different aquifer at a different depth. It may be possible to use a single bore hole to reach both aquifers with a coaxial pipe.

The cost of tapping ground water varies widely, depending on the depth, the nature of the ground, the need for reinjection, and other factors.

The main advantages of ground water as a heat source and heat sink are:

- **good compromise temperature.** Wells are deep, so the temperature of ground water remains essentially constant. In most locations, the temperature is a good compromise for use in both heating and cooling.
- **no need for supplemental heat sources or heat rejection equipment.** Ground water sources usually have enough capacity to eliminate the need for either a supplemental heat source (boiler) or heat

rejection equipment. This is a major factor in reducing the system's initial cost.

- **simple control.** Complex loop temperature control is avoided because the ground water temperature dictates the loop temperature.
- **ability to use water extracted for other purposes.** If well water is used for other purposes, such as service water, irrigation, lawn watering, and industrial processes, it can first be used as a heat source or heat sink. If the water requires heating for the application, using it as cooling water warms it, providing a double saving in energy.

The main disadvantages of ground water are:

- **limited availability.** Ground water is not available in all locations, at least not at an economical depth.
- **restrictions on use.** Even in areas where ground water is available, environmental restrictions may limit its use in heat pump systems. Environmental restrictions may be based on several objections. One is wasting of the resource. This objection can be overcome by returning the water to the aquifer ("reinjection") after it is used.

Another objection is that an internal leak in the heat pumps may cause refrigerant to be injected into the aquifer. It may be possible to allay this concern by isolating the ground water from the refrigerant with a double-wall heat exchanger.

Another objection is that altering the temperature of the water may cause some harm. There appears to be no strong scientific basis for this concern, but projects may be halted during the public debate about it.

WaterFurnace International, Inc.

Fig. 3 Ground water (well water) heat source and heat sink This is an open loop, in which the well water is discharged to the surface after passing through the heat pump system. In some locations, the water would have to be injected back into the ground, at a different depth.

- **heat exchanger maintenance.** Ground water usually is saturated with minerals. When ground water is used as a heat source, it is cooled in the heat exchanger, and becomes less able to dissolve minerals. As a result, the minerals are deposited in the heat exchanger, which requires periodic cleaning.

Surface Water

Surface water is water that originates on the earth's surface from rain. Large bodies of surface water, such as oceans, lakes, and rivers can serve as heat sinks. Inland bodies of water change in temperature with the seasons, but they are generally cooler than the atmosphere throughout the cooling season. Exposed bodies of water are cooled by evaporation and by radiation into the night sky. On the other hand, water that is darkened by contaminants absorbs solar heat during the day.

Surface water may also serve as a heat source. However, the air temperature may often be warmer than the water temperature during the heating season, especially in spring. For this reason, surface water is usually not a good alternative to an air source for heat pumps.

Surface water is dirty and corrosive, so it is generally not used directly in the system loop. (Surface water is corrosive because exposure to the atmosphere keeps it saturated with oxygen.) One way of dealing with this problem is to use a heat exchanger located on dry land. Figure 4 shows this arrangement.

Another approach is to keep the entire water loop closed, and circulate the water through heat exchange loops that are submerged in the body of water. Figure 5 illustrates this approach. The pipe may be made of inexpensive material, such as plastic. This arrangement normally requires no cleaning, but it is more vulnerable to leakage. The submerged pipe should be kept under positive pressure to ensure that no dirt from the body of water can enter the system.

Piping is usually the major cost component in exploiting surface water. This cost varies widely from one location to another, depending mainly on the accessibility of the body of water.

The main advantages of surface water as a heat sink are:

- **lower temperature.** In many locations, surface water is cooler than ground water.
- **no need for heat rejection equipment.** Almost any permanent body of surface water has enough heat rejection capacity to eliminate the need for other heat rejection equipment.

The main advantage of surface water as a heat source is:

- **in warmer climates,** there is no need for supplemental heat sources. This requires the body of water to be warm enough and large enough so

that the heat exchanger does not become encrusted with ice at any time.

A disadvantage of surface water as a heat source and heat sink is:

- **uncertain future availability.** Environmental restrictions already exist against the use of surface water for cooling large power plants. The objection is that altering the temperature of the water may harm fish, and this assertion might be extended to other organisms. These restrictions may be extended to smaller applications.

Another concern is that an internal leak in the heat pumps may cause refrigerant to be released into the body of water. It may be possible to allay this concern by isolating the water from refrigerant contamination with a double-wall heat exchanger.

Another disadvantage of surface water as a heat source is:

- **lower temperature.** The water temperature falls below the air temperature much of the time, especially in spring.

Solar Collectors

Using solar collectors as a low-temperature heat source for use with heat pumps is one of the more promising applications of solar energy. Heat is provided

at a temperature much higher than is available from other low-temperature sources, maximizing the heating efficiency of the heat pumps.

Using solar collectors with a heat pump system improves the efficiency of the collectors themselves. When solar collector are used alone, they provide no benefit until the temperature of the collectors rises enough to drive heat into the facility's distribution system. On the other hand, heat pumps can exploit any heat that is collected. By the same token, using solar collectors as input to heat pumps allows the collectors to operate at lower temperature, which reduces their losses.

For the same reason, you can use less expensive types of solar collectors in which the collector plates are exposed. These units avoid the cost of glazing, rigid frames, insulation, and thermal seals. The lack of an insulating jacket increases the heat loss of these collectors, but this disadvantage is lessened when they are used at low temperature with heat pump systems.

The main advantage of solar collectors as a heat source for heat pumps is:

- **high temperature.** The average operating temperature of solar collectors is high enough to keep heat pumps at peak efficiency.

WaterFurnace International, Inc.

Fig. 4 Surface water heat sink, and possibly, heat source Surface water is almost always cool enough to be a good heat sink, if there is enough of it. It can also be a heat source, if no ice forms in the system. This system uses a heat exchanger to keep dirt out of the building water loop.

WaterFurnace International, Inc.

Fig. 5 Surface water heat source/sink with enclosed water loop This arrangement is similar in performance to the one shown in Figure 4. It is more vulnerable to leakage, but it may be less troubled by ice when the water is being used as a heat source.

The main disadvantages of solar collectors are:

- **lack of heat input at night.** If the facility requires heating at night, the system must have another source of heat.
- **high cost.** Combining solar energy with heat pumps may reduce the cost of solar heating, but it raises the cost of the heat pump system considerably.
- **complexity.** The number of factors that need to be addressed can be overwhelming, especially if the system has thermal storage and/or other heat sources.

If you use unshielded solar collectors that are non-metallic, these can also function as heat rejection devices at night. In addition to rejecting heat to the night air by conduction, they also radiate heat into the night sky. The night sky has an effective temperature that is colder than the air temperature. The difference between the night air temperature and the night sky temperature ranges from less than 10°F (5°C) to almost 50°F (28°C). The difference depends primarily on the cloud cover and the amount of moisture in the air. For example, over the entire western United States, the average sky temperature in summer is more than 20°F lower than the air temperature.

(You can't use conventional solar collectors with glass covers as heat radiators, because heat radiation does not pass through glass. Also, unshielded metal surfaces are not good radiators because they have low emissivity.)

Even so, if you want to use this unusual method of getting rid of heat, be aware that the heat rejection

capacity at night is much less than the heat collection capacity during the day.

Waste Heat

Potential waste heat sources include any gas, liquid, or solid that is discharged from the facility in sufficient quantity to satisfy at least a substantial fraction of the heat input requirements of the heat pump system. Exhaust air, sewage, and process effluent have all been exploited as heat sources.

Figure 6 shows a system for recovering heat from industrial waste water. If the water is dirty, the system needs a flushing system to clean out the heat exchanger periodically.

Figure 7 shows an interesting method of recovering the heat from domestic water drains. This figure shows a special type of heat exchanger, but the same function could be performed by a conventional heat exchanger.

The typical advantages of waste heat sources are:

- **higher temperature.** The temperature of most waste heat sources is higher than that of soil, well water, or surface water.
- **low cost.** With many waste heat sources, only rudimentary heat exchange equipment is needed to convey the heat into the loop system.

The typical disadvantage of waste heat sources is:

- **limited and/or sporadic availability.** Many waste heat sources can provide only a fraction of the heating requirement, so other heat sources are required.

Ludell Manufacturing Company

Fig. 6 System for recovering heat from process waste or sewage This is a conventional tube-and-shell heat exchanger combined with an automatic backflush system. Flushing is needed to keep the heat exchanger effective if the waste fluid is dirty.

Vaughn Manufacturing Company

Fig. 7 System for recovering heat from domestic water drains This could be scaled up for major hot water users, such as gymnasiums and swimming centers. The heat exchanger here is a special type that replaces a section of the drain pipe. It must be almost perfectly vertical, so that waste water will drain uniformly down the sides of the drain pipe. A conventional heat exchanger would also work in this application.

This Note is a quick review of energy sources that are alternatives to conventional fossil fuels. These energy sources are commonly called “renewable energy” or “free energy.” We use the somewhat clumsy term “non-fossil” for this category of energy sources because none of them is literally free, either in terms of money or natural resource consumption. Some of them are not actually renewable or non-depleting.

These energy sources are capable of producing temperatures that are high enough for direct use, or of producing electricity or mechanical work directly. [Reference Note 22](#), Low-Temperature Heat Sources and Heat Sinks for Heat Pumps and Cooling Equipment, covers a different category of “free” energy sources that have temperatures so low that they are generally usable only as heat sources for heat pumps.

This Note is limited to energy sources that may be exploited at the present time, even though some of them are still in the experimental stage. It is also limited to sources that are appropriate for exploitation by individual sites, although the sites may have to be large. This Note does not cover sources that require action at a regional

or governmental level, such as nuclear energy, ocean thermal energy, tidal energy, and solar arrays in space.

Solar energy is potentially so important that three of its major applications are discussed separately here. Daylighting and passive heating applications of solar energy are covered individually in [Subsections 8.3](#) and [8.4](#), respectively. For the general characteristics of sunlight as an energy source, see [Reference Note 24](#), Characteristics of Sunlight.

This Note will help you make an initial screening of the non-fossil energy sources that may be available to you. If you decide to go further with any of these sources, you have more study ahead. Each non-fossil source involves many issues, and the details are important. You will also want to learn the current status, as some of these sources are still evolving. Each source has an ample literature. Two good starting points for further reading are the *ASHRAE Handbook* and Marks’ *Standard Handbook for Mechanical Engineers*, both of which include references to leading books on each topic.

As you study “renewable” energy sources, beware of the widespread nonsense and unrealistic assumptions

that confuse the discussion. Much of the literature, and perhaps most of the public comment, is by enthusiasts who either know little about the subject or are blinded by their fervor. As a rule, the most credible reference sources tend to be dry and technical. Sorry.

Active Solar Heating and Cooling

An active solar heating system uses collectors outside the structure to capture the energy of sunlight in a heat transfer medium, which usually is water. Air is occasionally used as the heat transfer medium. The system usually includes a tank to store excess heat. The flow of heat from the collectors or the storage tank can be regulated precisely, as long as the available supply of energy exceeds the requirement.

The name “active” distinguishes these systems from “passive” systems, in which sunlight is admitted directly for space heating. Passive solar heating is simpler in concept, but it is proving to be difficult to accomplish well. It is covered in [Subsection 8.4](#).

■ Equipment

An active solar system consists of collectors, structural supports for the collectors, a storage tank, structural support for the storage tank, piping, valves, and thermostatic controls. In addition, there is the conventional heating equipment within the space. Solar systems can be piped in a variety of ways, which differ in their ability to avoid freeze damage and deal with excess solar input. Solar collectors come in two general types, flat plate and focussing.

The typical flat collector is a shallow sealed box. The sunlight is captured by a metal plate that contains water passages. Insulation is installed behind the metal plate to reduce conductive heat loss. Heat loss from the

front of the collector is minimized by one or two transparent cover sheets. Figure 1 shows an array of flat plate collectors.

Flat collectors usually are fixed, but some are installed on pivoting bases to improve collection efficiency.

Flat plate collectors are limited in the temperature they can produce. At flow rates that provide reasonable output, the best units produce temperatures that range from 120°F to 170°F (50°C to 80°C) on sunny days.

The collector is a major part of the system cost, so various types of cheaper flat collectors have been developed. The cheapest consists of continuous rolls of black plastic with extruded water passages. The material is cut to any desired length and fitted with snap-in headers. Such collectors have higher losses and produce lower temperatures, but they may be satisfactory in warmer climates for preheating domestic water and boosting heat pumps.

Focussing collectors use reflectors to focus sunlight on small water tubes. Most systems use parabolic reflectors that rotate to track the sun. Figure 2 shows an array of such collectors. These can provide temperatures of 200°F to 300°F (90°C to 150°C), depending on their design and the flow rate.

Focussing collectors are disabled by any cloud cover, haze, or fog that renders the sun indistinct, because the sunlight cannot be focussed under those conditions.

Some focussing reflectors are designed to remain stationary. These focus less accurately, so their efficiency is lower. Some hybrid arrangements supplement non-directional collectors with reflecting skirts to increase the sunlight collection area. These provide somewhat higher temperatures, and they operate well with diffused sunlight.

WESINC

Fig. 1 An array of flat-plate solar collectors This installation shows typical dimensions and mounting of flat-plate collectors. Sadly, it also illustrates the poor design and maintenance that is given to this basically simple technology. Individual collectors had to be removed because no access was provided for maintenance of the connecting joints. These are subject to rapid wear because of the large thermal expansion coefficient of aluminum and the large temperature cycles in daily operation. The system was eventually abandoned because of avoidable freeze damage.

At times when the solar system collects more heat than is needed, where does the excess heat go? This design issue is a major factor in system failure and reduced collector life. When there is no place to reject the heat, the collector temperature rises until the heat radiation from the collector equals the heat input, which occurs at the “stagnation temperature.” The stagnation temperature may be well above the boiling point of water.

The problem is easiest to solve with movable focussing collectors. Heat input can be halted by aiming the collectors away from the sun, as shown in Figure 2. Some systems are controlled in a fail-safe manner, so that the collector points downward if the controls fail or if safe temperatures are exceeded.

With flat plate collectors, various methods are used to keep collector temperature within limits. None of them are entirely satisfactory. For example, see Figure 3. A common method is installing an external heat rejection coil to vent excess heat from the solar system. Movable shading would be more efficient, and would reduce weathering of the collectors during idle periods, but this approach has not yet been brought to market.

Avoiding freezing is easier. If the system uses a heat transfer loop, an antifreeze solution can be used in the collector circuit. Alternatively, the collectors can be designed to drain into a holding tank when the outside temperature approaches freezing.

Solar cooling is not a distinct technology. Instead, the heat from an active solar system is used to operate a conventional absorption chiller. The cooling output of an absorption chiller is degraded severely if the input temperature of the input heat is below the design temperature. For conventional lithium bromide absorption chillers, the rated minimum input temperature is about 250°F (120°C). Therefore, the absorption chiller needs high-temperature solar collectors, which typically are parabolic tracking units. These are more expensive than flat plate collectors, for a given heat input, so adding the absorption machine increases the cost of the solar system that feeds it, making the overall system very expensive. (Some solar cooling systems have been built with flat plate collectors, but they required the chiller to be horrendously oversized.)

“Solar cooling” has also been accomplished by using a photovoltaic source to power a conventional electrical air conditioner, but there is nothing inherently “solar” about either method of cooling.

■ Applications

The usual applications for active solar systems are space heating and service water heating. Figure 4 shows a typical installation for these purposes. Solar systems can be used to provide thermal energy for any application if the temperatures are compatible. The same is true of solar cooling systems.

WESINC

Fig. 2 Focussing solar collectors The parabolic reflectors track the sun, focussing the heat on the small tube containing water. This array, in a sunny climate, uses the high-temperature water to drive absorption cooling equipment for a government hospital. The individual rows of collectors are fail-safe. If there is a defect or excessive temperature, the row tips upside down, as on the right. This avoids stagnation damage and protects the reflecting surface. Electrical power for tracking is provided by batteries. Maintenance is simple, but when a key individual goes on vacation, the arrays start to fail within days. Several abandoned batteries have been left in the foreground.

Solar water heating is simpler, more efficient, and less expensive than solar space heating. The fact that the system heats a liquid from a cold state substantially improves the efficiency and output of the collectors. Storage costs are lower because a water heating system requires some storage anyhow.

Solar collectors can be used to boost the efficiency of heat pumps, without much additional equipment. This application is covered in [Reference Note 22](#), Low-Temperature Heat Sources and Heat Sinks.

■ Development Status and Economics

As a technology, active solar heating systems are mature. They do not require exotic technology, and the principles are well known. Maintenance requirements are modest, but many have failed from lack of maintenance.

Simple solar water heaters proliferated in Florida before World War II, and more recently in Israel. The American systems were abandoned as energy prices dropped, and even Israelis are reported to be losing enthusiasm for their solar heaters.

As a result of the energy crises of the 1970's, active solar space heating went through two periods of intense testing in the United States. The first was the installation of many solar systems as research projects sponsored by the U.S. Department of Energy and its predecessor

agencies. The second was the installation of many commercial solar energy systems by private parties in response to a Federal solar energy tax credit that was in effect during the 1970's and 1980's.

The resulting experience confirmed calculations showing that active solar heating has a long payback period. Unfortunately, this fact was deliberately obscured in Federal demonstrations by mandating cost factors that were absurdly understated, and by including tax credits and other adjustments into the calculations for private sector installations.

The experience of the 1970's and 1980's was sufficient to indicate where the bottom of the cost curve lies. The cost of collectors is proportional to collector capacity, while the cost of other system components is subject to a substantial economy of scale.

The systems installed during this period suffered a high failure rate, and many of them are now abandoned. Figures 1 and 3 are sad example. The high failure rate of solar energy is not caused by a fundamental flaw in the concept, but by incompetence and sloppiness in design and installation. These factors were aggravated in demonstration installations by the easy availability of government money, and by lack of continuing interest. Also, many systems failed because of a blatant disregard for their modest maintenance requirements. In many cases, a solar system is abandoned before it collects as much energy as was invested to build it.

Better design, installation, and maintenance can keep solar systems operating, but they can never have a good economic rate of return. The diffuseness of sunlight gives solar heating inherently poor economics.

Fig. 3 Pressure relief valves to protect against stagnation This abandoned solar heating system failed to provide adequate protection against stagnation. The pressure became high enough to repeatedly vent the liquid, which contained antifreeze. The replacement water did not contain antifreeze. Eventually, the system was destroyed by freeze damage.

Fig. 4 Typical space heating and domestic water heating application for solar energy This array is nicely integrated into the architecture of the building. It even faces in the correct direction, unlike many solar installations.

Solar energy is what heats the great outdoors. People want solar heat where it is cold, but the reason it is cold is that there is not much solar heat available. Concentration of solar energy costs money and takes up space. Even cheap methods are expensive in relation to the value of the energy recovered.

A number of solar cooling installations have been built, all as demonstration projects. As of this writing, several larger installations powered by focussing solar collectors continue to operate. Other installations have been abandoned because of poor economics and excessive maintenance requirements.

■ Energy Density and Availability

The energy density of sunlight is low. At the earth's surface, the maximum solar energy density is somewhat less than one kilowatt per square meter of collecting area. Night, clouds, haze, collector losses, and failure to point collectors directly at the sun greatly reduce the average amount of energy that can be collected.

Another limiting factor of active solar systems is that the collector temperature must be higher than the temperature of the space or the medium being heated. This reduces the operating time of active systems during cold weather, especially with flat plate collectors. (Passive solar energy collection does not have this limitation.)

■ Environmental Considerations

Solar heating is almost ideal in its lack of direct environmental hazards or nuisances. It is quiet, it emits nothing into the surroundings, and it requires nothing

from the surroundings, such as cooling water. The usual antifreeze solution, propylene glycol, is harmless.

The main environmental cost of solar systems is the energy and materials required to produce them. Unfortunately, this is a large amount of energy in relation to the amount of energy that they can collect over their service lives.

Solar systems can have a major effect on architectural appearance and/or space requirements, because collector area typically is large in relation to the size of the facility. The faces of efficient solar collectors are dark and blotchy, which makes it desirable to hide them. They are often installed on the flat roofs of commercial buildings.

■ Need for Conventional Energy Back-up

Almost any location has occasional long periods of low sunshine that will deplete the economical storage capacity of a solar system. Therefore, most solar heating and cooling applications must be backed up completely with conventional energy sources.

Photovoltaic Electricity Generation

Photovoltaic electricity generation is the direct production of electricity from sunlight, without any thermal processes. Photovoltaic generation is potentially an ideal energy source. It has no moving parts, requires no maintenance, makes no noise, requires no input of water or other substances from the environment, and produces no pollution. The main problem is high cost, which may be reduced in the future by technological developments.

WESINC

Fig. 5 Large photovoltaic system This is part of an array of many similar rows of photovoltaic cells that cover the roof of a large classroom building. The array provides a peak capacity of about 100 kilowatts, which is one fourth of the peak load on the building. The system supplements power provided by a public utility. The panels are light, thin, easy to mount, and easy to connect together.

■ Photovoltaic Cells and Their Development Status

At the present time, photovoltaic electricity generation is accomplished primarily using materials that have semiconductor properties. In these materials, electrons are held fast, preventing conduction. Photons of sunlight are sufficiently energetic to release the electrons in these materials. If a thin conducting film is overlaid on such a material, electrons released by light are collected in the conducting layer, where they can flow as an electric current. An assembly of this type is called a solar cell. To achieve higher voltages and currents, cells are connected in arrays.

The first solar cells were made from thin slices of silicon, germanium, or other semiconductors cut from pure crystals of the material. This part of the process is essentially the same as used in the semiconductor electronics industry. Cells made in this manner are expensive. Achieving lower cost is helped by the fact that the purity of photovoltaic semiconductors is less critical than in electronic semiconductors. At present, crystalline semiconductors have a peak efficiency of about 20%.

Amorphous (non-crystalline) semiconductors have been developed. These are less expensive than crystalline semiconductors, but they are also substantially less efficient. They also lose efficiency rapidly in service. At present, amorphous semiconductors have a peak efficiency of about 9%, but efficiency soon drops to a fraction of that value.

The ultimate goal is to produce fairly efficient photovoltaic material that can be produced in large sheets, without the need to connect arrays of discrete small cells. Effort in this direction continues, but a fundamental breakthrough may be needed to achieve an acceptable combination of cost and efficiency for widespread application.

Solarax

Fig. 6 Residential photovoltaic system Photovoltaic cells cover one side of the roof of this house in Japan. The system provides enough power for the average needs of the house, but batteries are needed to match the generation of power to the time of use.

■ Photovoltaic Systems and Applications

The most common photovoltaic systems serve small direct-current applications, such as navigation lights and remote radio transmitters. These simple systems consist of an array of photovoltaic cells that charge a battery. The battery stores power for periods when sunlight is inadequate and it helps to regulate the voltage.

Batteries are a major part of the cost of such systems. They are typically responsible for most of the maintenance cost and trouble. Also, they may create a serious environmental problem.

If a photovoltaic system is going to operate equipment that requires alternating current, the system needs additional equipment to convert the direct current of the cells to the desired voltage and frequency. This equipment is now well proven, and it is fairly inexpensive.

Many photovoltaic systems have been installed in recent years to provide power to buildings and facilities, mostly as demonstration projects. Figures 5 and 6 show two of these. Most of these systems provide power as a supplement to a public utility system.

Photovoltaic systems that supplement other power sources avoid the need for batteries. They require extra equipment for producing alternating current, and for keeping their output in phase with the public utility's power. Such applications have most promise for large photovoltaic arrays. Large installations provide economy of scale, provided that the cell arrays can be installed on space that has little other value. Such systems may be owned by an electric utility or by an individual customer who has available space, such as the roof of a large building.

Another possibility is that a customer may have an independent photovoltaic system, and switch between it and the public utility. This arrangement might be desirable for "load shedding," especially for daytime applications. The battery capacity can be reduced to the minimum necessary to carry the load during interruptions of sunlight by clouds. The battery capacity depends on the pattern of sunlight and how often it is acceptable to switch between solar and conventional power. If the system operates at night, the cost of purchased electricity must be balanced against the greatly increased battery capacity that is needed to carry the load through the night.

■ Energy Density

The energy density of sunlight is low. At the earth's surface, the maximum solar energy density is somewhat less than one kilowatt per square meter of collecting area. Using an optimistic cell efficiency of 20%, surface coverage of 50%, and a clear climate, the annual average power output of a photovoltaic array might be about 30 watts per square meter.

If photovoltaic generation is concentrated in large arrays, this translates to an average power output of about

30 megawatts per square kilometer. This is lower by a factor of about 100 than the energy density of conventional generating plants and their surrounding space.

Focussing mirrors can be used to concentrate the sunlight on the photovoltaic material. This does not increase the energy density in terms of surface area, although it reduces the cost of the photovoltaic material.

The energy density in terms of weight is much more favorable. The active area of a photovoltaic cell consists of a thin film of semiconductor overlaid with an almost weightless film of conducting material. Almost all the weight in a photovoltaic system is in the mechanical support of the active material. With typical cell weights, photovoltaic generation has the highest energy density of any energy conversion device, and the fuel weight is zero.

■ Availability

The availability of sunlight varies widely with location and time. Detailed data are available on the average daily, monthly, and yearly amounts of sunlight for many locations. The yearly figures tell how much energy can be collected. Design the collector capacity and the storage capacity to provide for several successive days of low sunlight. Weather data is available to indicate the length of overcast spells.

■ Environmental Considerations

Photovoltaic electricity generation is almost ideal in its lack of direct environmental hazards or nuisances. It is quiet, it emits nothing into the surroundings, and it requires nothing from the surroundings, such as cooling water. It is not especially ugly. Unlike wind machines, photovoltaic arrays do not interfere with communications or endanger wildlife.

Even disposal and recycling of photovoltaic equipment is free of major problems. Most of the weight of the apparatus consists of steel and aluminum, which is common, benign, and easily recyclable. The small weight of plastic materials can be incinerated easily. Any exotic materials that may be used in the cells, such as selenium or gallium, is sufficiently localized in the cells to be easily recovered, if desired.

In a large photovoltaic system, the required land area is a major environmental consideration. Land requirements are large in relation to power output because of the low average energy density of sunlight and the low (at present) efficiency of photovoltaic cells. This consideration does not apply to many smaller systems, especially if the cells can be attached to buildings or other existing structures. Even if the cells are mounted on the ground in large arrays, it may be possible to use the land for other purposes, such as grazing.

Batteries are the malign intruder to this idyllic scene. To date, lead-acid batteries are the preferred storage

medium for photovoltaic systems. Batteries are limited to a number of charging cycles, after which they must be replaced. Batteries are difficult to move out of remote locations, and recycling is an environmentally dirty process. In some less developed areas, photovoltaic systems are surrounded by huge piles of discarded batteries that drip acid and leak lead into the environment.

Many other types of energy storage exist, and some have been studied extensively. For example, excess electricity can be used to pump water to an elevated reservoir. The water is later released through a turbine to recover the stored energy. Most types of storage other than batteries have promise only on a large scale.

■ Economics

The cost elements in a photovoltaic system are the cells, their supporting structures, electricity storage, power conversion equipment, switchgear, and land. The cells, batteries, and mechanical supports account for most of the cost.

As noted previously, there is presently an inverse relationship between cell efficiency and cost. With lower efficiency, the size of the collecting array must increase, which increases structure and land costs.

At present, electricity from photovoltaic systems costs roughly ten times more than electricity from conventional sources. Of course, this ratio varies widely with location. In order for photovoltaic systems to become competitive, the cost of cells must be reduced by approximately a factor of ten, and systems must be designed to minimize the need for storage.

■ Relationship to Conventional Energy Sources

At the present time, most photovoltaic systems are installed where conventional sources of electricity are not available, or where they would be prohibitively expensive.

In principle, a photovoltaic system can be operated along with a conventional source of electricity. This would eliminate most of the storage requirement, but the present cost of photovoltaic cells still keeps the system from being economically competitive in areas served by conventional utilities.

In the U.S., such systems receive various advantages from the federal Public Utilities Regulatory Policy Act (PURPA). The major advantage is the privilege of buying supplemental power from the public utility when needed and selling excess power to the utility. Public utilities are not fond of such projects, because the sporadic excess electricity produced by a photovoltaic system is of little value to the utility. Public utilities are allowed to levy connection charges that reflect their cost of protecting their systems against faults and power quality problems caused by private generators. These charges can be prohibitive for small installations.

Solar Thermal Power Generation

By using mirrors, solar energy can be concentrated to produce high temperatures. The concentrated solar energy can be used to produce steam or hot water. It is possible to sustain temperatures that are high enough for efficient operation of steam turbines. The name “solar thermal” is used to distinguish this use of solar energy from photovoltaic power generation, which produces electricity directly, without going through a thermal process.

■ Equipment and Development Status

The highest operating pressure in a solar thermal power plant is probably produced by a U.S. Department of Energy demonstration project that is rated at 10 megawatts. This installation uses mirrors to focus sunlight on a boiler installed in a tower, producing exceptionally high temperatures.

Another approach is to use tracking parabolic reflectors to concentrate sunlight on water-filled tubes. The water is routed to a drum, where steam is produced. This design is used in the world’s largest solar thermal electric generating plant, a 300 MW installation located in a sunny area of California. Reliable figures on the operating cost of this plant are not available, but it does not seem that this facility is competitive in the absence of subsidies.

Direct storage of high-temperature hot water or steam is not practical, because the storage vessels would have to be massive to contain the pressure. The only means of storage is to convert the energy to some other form that can be stored. All such possibilities involve significant losses, which degrade the economics.

■ Energy Density and Availability

The basic limitation of this technique is the low energy density and the irregular availability of sunlight, which were discussed previously.

A major limitation is that the sky must be clear in order for this technology to work. If the sun is not visible as a distinct point, the mirrors cannot focus, and energy collection virtually stops. Therefore, this technology is limited to areas of continuously clear skies, which are usually deserts.

■ Environmental Considerations

From an environmental standpoint, solar power production is like conventional power production, but without any of the pollution that is related to fuels. The only effluent is a small quantity of water treatment chemicals. If turbines are used, cooling water is required. On a relative scale, this is a very clean technology for power production.

■ Economics and Feasibility

At first glance, it appears that the cost of solar-powered boilers ought to be roughly comparable to the cost of fuel-fired boilers, if they are designed for economy and produced in sufficient quantity. Solar-

powered boilers require mirrors and tracking systems, but they are much simpler in construction, and do not require fuel handling and storage facilities.

The big barrier to economic feasibility is the low density and the intermittent availability of sunlight, which limits the amount of energy that can be collected by the equipment. An analogy is operating a boiler with a burner that has only a small fraction of the boiler’s capacity, and that fails to function over half the time.

■ Relationship to Conventional Energy Sources

Because storage is not feasible with this technology, it can be used only if conventional power is also available with sufficient capacity to carry the full load. In this regard, it is similar to photovoltaic and wind installations.

Wind Power

Windmills are perhaps the oldest power producing technology that is not dependent on human or animal muscle. Modern wind generators are direct descendants of the older technology, but problems of an elementary nature are still being worked out. The major inherent problem is the sporadic nature of wind.

■ Equipment and Applications

Modern wind turbines are used almost exclusively for generating electricity. By far the most common configuration consists of a propeller, a speed-increasing gear, and an electric generator. The assembly pivots on top of a tower to face into the wind. Various methods are used to control the speed of the propeller and to protect the equipment from exceptionally high winds. Figure 7 shows a large wind generator that uses variable-pitch blades for these purposes.

Vertical-axis wind turbines, typically with one end resting on or near the ground, have attracted a great deal of attention. These avoid the expense and complication of the tower and the mechanism to aim a propeller into the wind, but they have not yet provided strong competition to propeller-type wind machines.

If the wind generator operates in parallel with the public utility system, it requires expensive equipment for paralleling the two power systems, and for protecting each system from faults in the other.

If a wind generator operates independently of the public utility system, it usually requires energy storage. In smaller systems, storage usually takes the form of batteries. In larger systems, it may take many forms, such as pumping water into a tall tower. Storage is expensive in relation to the overall cost of the system.

About the only direct application of mechanical energy is the classic one of pumping water into storage tanks. For example, windmills are used for cattle watering, irrigation, and other purposes where sporadic pumping is acceptable. Such applications still use old-style, high-torque, multi-blade windmills. Although

these machines look antique, their efficiency is fairly good.

■ State of Development

Wind machines have been used for two thousand years, the earliest known machine being used in Persia about 200 BC for grinding grain. The famous Dutch windmills were pumping water reliably and in large numbers by the fifteenth century. These large structures produced from 20 to 80 kilowatts. In the United States, several million windmills were installed for water well pumping since the middle of the nineteenth century. These machines produce less than one kilowatt.

The largest wind generator built to date was constructed on a mountain in Vermont and operated during the years of World War II. It could produce over one megawatt in winds of 50 kilometers per hour (30 miles per hour). It was abandoned because of blade failure and lack of economic advantage. During the next two decades, the Danes built on earlier experience to construct wind generators that served their public utility network. These were abandoned because they could not compete economically with steam turbine plants. Britain, France, and Germany developed wind generators larger than 100 KW during the 1950's and 1960's. The U.S. government responded to the energy crisis of 1973 by funding the development of wind generators. This work, accomplished largely by the aerospace industry, produced highly refined designs with many blade failures.

At the present time, a large fraction of the world's total wind generation capacity is located in a windy valley area near Palm Desert, California. Several thousand wind generators there, ranging in size from about 30 KW to several hundred kilowatts, are connected to the public utility network. These machines, especially the newer ones, have demonstrated reasonably good reliability. Much of this effort was subsidized. Wind generators are not yet quite competitive with other sources of electricity, even in this favorable environment.

Many wind generators, even very large ones, have been installed in locations where there is little wind. Stationary windmills decorate the landscape across the United States. This is the result of government grants, government pressure on electric utilities to use "renewable" energy, excessive optimism about wind availability, and scratching an itch to build windmills.

■ Energy Density and Availability

When wind is blowing, it is a very desirable energy source. Wind is capable of producing about one kilowatt per square meter of rotor disc area in windy locations. Large wind generators are typically designed with a capacity somewhat less than one kilowatt per square meter.

The output of a wind generator is approximately proportional to the square of the wind speed. The fraction of the wind's energy that can be extracted by a

wind turbine has a theoretical upper limit of 0.59, which is called the Betz Coefficient. The best wind machines extract about 40% of the wind's energy.

The main shortcoming of wind energy is that high wind speeds occur for only a small fraction of the time. As a result, the average output of a wind machine is much less than its power rating. The average power density of wind over most of the continental United States ranges from less than 50 watts per square meter to over 400 watts per square meter, with the higher values being limited to a small fraction of the total land area.

To get good power output from a wind machine, the location must have wind speeds consistently higher than about 35 kilometers per hour (22 miles per hour). There are few such areas, and the high winds make them

Fig. 7 Large wind generator This unit has a maximum capacity of several hundred kilowatts. The pitch of the blades is varied to maintain a fixed rotation speed when operating. The average output of this expensive machine is only a small fraction of its capacity. The placid water of the lake reveals a human weakness of wind power, which is a tendency to build windmills where there is insufficient wind to justify them.

inhospitable for residential or commercial purposes. Such sites may be acceptable for remote wind farms that serve utility networks.

In order for wind to be a reliable energy source, it must be anchored to a particular topographical feature that creates high wind speed. The shoreline of oceans, seas, and large lakes may be windy on a daily cycle if the temperature of the land and water reverse on a daily basis. Mountain gaps funnel wind, especially if the mountain range is perpendicular to a prevailing wind direction. This is true of the major U.S. mountain ranges. Wind speed may increase at the top of a hill that lies perpendicular to a prevailing wind, but only if the hill is well rounded.

High winds are also found sporadically on open plains. These winds wander too much to be useful. A wind survey conducted in one year may show that an area is favorable for wind energy, whereas the winds may fail to occur the next year.

At altitudes of 1,000 meters to 3,000 meters (3,000 feet to 10,000 feet) above ground level in the mid-latitudes, there are prevailing winds over a large fraction of the earth's surface that would be fast enough to sustain good energy output for a large fraction of the time. The trouble is that wind speed declines rapidly toward the surface, because of ground friction. The rate of decline varies widely with the nature of the terrain and ground cover. Trees and buildings seriously reduce wind speed. Open water and flat land (desert) are best, which is one advantage of shoreline locations. In any event, it is important to install a wind generator as high above the ground as possible, which adds the cost of an expensive tower. The fact that larger wind turbines require taller towers anyhow contributes to their better economics.

The limitation imposed by ground friction suggests installing wind turbines on tethered blimps. This idea has not yet received serious attention. It probably should. Balloons used as radar platforms are already tethered at altitudes up to 10,000 feet (3,000 meters), and they approach the size needed to carry wind machines.

■ Environmental Considerations

It comes as a surprise to those unfamiliar with wind machines that noise is a major problem with them. Wind machines have an insistent, choppy whooshing sound. The sound has a low frequency that travels far. This problem may contribute to the fact that so many wind machines are shut down. Frederick the Great complained about the noise of a grain mill adjacent to his hideaway palace, Sans Souci, but the miller refused to shut down. Modern neighbors may not be so tolerant.

Wind machines have also been found to cause communications interference, such as with television reception. This problem occurs with large machines

that are installed where their spinning blades can reflect signals.

There are some wildlife concerns. For example, in California, there is a concern that wind machines pose a hazard to the giant condor.

Installing wind machines on balloons would avoid the previous problems. However, this approach would pose a hazard to aircraft, and would make the machines visible over a much larger area.

Wind machines are presently sanctified in the eyes of environmentalists, and hence to legislators, so installing them may face little in the way of permit hurdles. The neighboring community may raise bigger objections.

■ Economics

The experience of the past two thousand years indicates that wind machines can produce enough energy to pay for themselves. However, at the present time, wind machines cannot compete with the contemporary large-scale energy sources.

By the late 1970's, it became well understood that the economics of wind machines improve with size, up to an optimum size that is somewhere between several hundred kilowatts to one megawatt per machine.

■ Relationship to Conventional Energy Sources

In the U.S., private operators of wind generators are given various advantages by the federal Public Utilities Regulatory Policy Act (PURPA). Among these are the privilege of buying supplemental power from the public utility when needed, and selling excess power to the utility. This option is crucial because of the sporadic nature of wind.

Public utilities are not fond of interconnected wind generators because they produce power in irregular quantities that bear no relationship to the load on the utility network. Unlike other types of private power production, wind generation cannot help the utility to shave its peak demand, which is the utility's major concern in acquiring generating capacity.

Public utilities are allowed to levy connection charges that reflect their cost of protecting their systems against faults and power quality problems caused by wind generators. These charges can be prohibitive for small installations.

Interconnection charges and other problems can be avoided if the wind power system can operate independently of the public power system. For example, the wind power system can operate through storage batteries to provide a separate part of the facility. If the storage batteries are depleted, that part of the system can be switched over to public power entirely while the wind generator recharges the batteries.

Local Hydropower

Hydropower is presently second only to nuclear power as a non-fossil source of energy. Favorable sites can be very economical. Adverse environmental effects are related to damming, which costs land area and alters ecosystems. Exploiting hydropower on a local basis has become uncommon. It probably deserves revived attention in the relatively small number of sites where it is a potential source.

Opportunities for hydropower can be divided into high-head and low-head, although there is no clear dividing line between the two. High-head hydropower requires a large fall in height for the water source, but it produces a given amount of power with a much smaller volume of water. Low-head hydropower operates with relatively small height differences, typically a few meters, but it requires large streams to produce much power.

■ Equipment and Stream Preparation

The basic elements of hydropower have remained the same for the past thousand years:

- *a turbine or wheel*, which converts the potential and/or kinetic energy of the water to mechanical energy
- *a watershed*, which is a geographic drainage area that provides a sufficient volume of water
- *a watercourse*, which is a stream or channel that has an adequate drop in elevation between the points that water is taken from the stream and returned to it
- *a flume*, which is a conduit from the upper portion of the watercourse to the water turbine.

Low-head hydro typically is installed at a river or stream, where a dam is constructed to provide the vertical fall through the turbine. With the old-fashioned overshot water wheel, all the vertical fall occurs in the wheel itself. If a turbine is used, it is installed in the bottom of the dam, so that the effective water column is from the surface of the stream to the turbine outlet. With low-head hydro, damming of the stream usually is necessary to produce an adequate fall, and this may flood upstream areas adjacent to the original stream. Alternatively, it may be necessary to build up the banks upstream of the dam.

High-head hydro is simpler and much more compact. A closed flume pipe is extended to a watercourse as high above the facility as feasible. High-head hydropower usually requires much less damming of streams than low-head hydro. Only a small dam is needed to feed water into the pipe, but storage requirements may dictate the need for a larger storage basin. The turbine can be installed on dry ground, even at a distance from the stream. This avoids the cost of a structure to isolate the turbine from the stream.

The hydrostatic pressure that develops in the pipe is delivered to the turbine, which is located as low as possible. The flume pipe is inexpensive. It must only be strong enough to withstand the hydrostatic pressure of the water column, and it must be large enough and smooth enough to avoid dissipating the energy of the water by friction.

High-head hydropower is generally limited to mountainous terrain, which provides the needed difference in height over a short distance. The stream at the high end must be fed by a watershed of adequate area.

■ Applications

In most hydropower applications, the turbine or wheel is used to drive an electric generator. This provides a great deal of versatility, and eliminates the need for expensive mechanical transmissions. When used to generate electricity, hydropower can serve virtually any type of facility. Also, this provides the hydropower installation with the option of purchasing additional power or selling excess power to the utility. Hydropower is no longer used to produce mechanical work directly, although it could be.

Hydroelectric generators require little tending. However, generating electricity is a dangerous activity, so you probably would not install a system unless it is large enough to justify the cost of continuous monitoring.

■ State of Development

Hydropower is an old and stable technology. There probably will be no further technical developments that significantly affect its economics or availability.

■ Energy Density and Availability

The available amount of energy is determined by the water supply and the vertical fall that acts on the water wheel or water turbine. For example, one inch of rainfall that accumulates on one acre of watershed has an energy potential of 55 kilowatt-hours per foot of fall. Information on stream flow may be available from government sources, or you may have to measure the stream flow. Stream flow usually varies widely over the course of a year, so it is best to collect a year of data. In many locations, stream flow also varies widely from year to year. You can estimate this variation from historical precipitation data.

Topographical maps are available for most areas that indicate the potential drop in elevation that is available, as well as the area of the watershed.

Water wheels and water turbines are remarkably efficient, given their simplicity. If properly applied, either will yield efficiencies greater than 50%.

The basic limitation of hydropower is that the facility must have access to a watercourse that is served by a watershed with sufficient drainage to make the effort

worthwhile. Low-head installations are limited to rivers and streams with substantial flow.

High-head installations require steep, mountainous terrain with an overlying watershed. The high pressure developed in high-head hydro installations provides substantial power from a modest stream flow. For example, water turbines with flumes several hundred feet or more in elevation were used to power mining camps in the Rocky Mountains early in the twentieth century.

■ Environmental Considerations

Hydropower has minimal effect on the water resource itself. It does not change its quantity, content, or temperature. However, it may have a substantial effect on the watercourse and its surroundings, if only esthetically. Aside from any objective effects on the environment, anything related to bodies of water evokes strong and often irrational responses that make their way into law. Therefore, it may be difficult to get permission to build a hydropower installation, even on one's own property. Once an installation is built, it may appear sufficiently benign to avoid further attack. However, environmental regulation is likely to remain uncertain and quirky.

■ Economics

The cost of hydropower varies widely. The ubiquity of hydropower demonstrates its economy. The fact that remaining hydropower is mostly in large installations does not mean that smaller installations are uneconomical.

Low-head installations have a high initial cost for damming and conditioning the watercourse, and for building a heavy structure to contain the turbine or wheel. Equipment cost is increased by the low power density.

High-head hydro may be much less expensive. It requires only a few thousand feet of pipe, a compact turbine and generator, and controls.

In large installations, operating and maintenance costs are lower than for fuel-fired generators, aside from the fact that there is no fuel cost. The relative maintenance costs of small systems depend on local details.

■ Relationship to Conventional Energy Sources

In some low-head installations, stream flow is continuous, allowing hydropower to be a primary source. In most cases, hydropower should be backed up by purchased electricity. High-head hydropower is likely to be seasonal, depending on rain patterns and snow melting at high elevations. Also, the equipment must be shut down occasionally for maintenance.

In the U.S., private hydropower producers are given various advantages by the federal Public Utilities Regulatory Policy Act (PURPA). Among these are the privilege of buying supplemental power from the public

utility when needed, and selling excess power to the utility. The attractiveness of a hydropower facility to the local utility, and hence the rates, will depend primarily on the extent to which the utility can use the hydropower as a supplement during the utility's peak load periods.

Geothermal Hot Water and Steam

Geothermal energy consists of hot water, steam, or a mixture of hot water and steam that is created by hot geological features below the surface of the earth. The energy is tapped by drilling wells down to a source.

(The term "geothermal" is now being used by promoters of earth-source heat pump systems, which are unrelated to this topic. For more about those systems, see [Reference Note 22](#), Low-Temperature Heat Sources and Heat Sinks. Also, see [Measure 5.5.10](#).)

■ Origin, Availability, and Energy Characteristics

The source of geothermal energy is the molten core of the earth, which is kept hot by decay of radioactive isotopes. If the solid outer crust of the planet were uniform and unbroken, the temperature of the earth would increase by about 14°F for each 1,000 feet (25°C per 1,000 meters) increase in depth. In fact, variations in the conductivity of rock formations cause the temperature gradient to vary from 5°F to 27°F per 1,000 feet (9°C to 50°C per 1,000 meters).

Most geothermal sources do not depend solely on these temperature gradients, but on localized irregularities in the earth's crust that provide higher temperatures. The most dramatic of these are geologic faults that allow the molten core of the earth to penetrate to the surface to become volcanoes. There are also numerous underground faults that bring the molten core near to the surface. These faults are concentrated along the boundaries of tectonic plates, which accounts for the prevalence of geothermal sources in the western United States.

Geothermal sources are also created by subsurface radioactive rock formations, which generally have high thermal conductivity. At some locations in the eastern United States, such deposits are covered by sediments of low thermal conductivity, trapping the heat and increasing the temperature of the resource.

The temperature of any particular geothermal resource is fairly constant. To date, most geothermal wells produce water at temperatures ranging from tepid to about 300°F (150°C). A small number of wells produce much hotter water and steam, up to about 600°F (320°C).

The life of a typical geothermal resource is fairly long. Some geothermal sources are continuously replenished by heat from the earth's core, by convection, or by radioactive decay. If heat is extracted at a rate less than the rate of replenishment, the source should produce indefinitely. On the other hand, if the source is

an isolated hot rock formation, its heat will become depleted. Useful lives over 30 years are reported, but such numbers are dependent on the rate at which the resource is tapped. Overdevelopment of a particular site could result in a much shorter life. In this regard, geothermal energy is similar to extracting oil from an oil well, or water from an aquifer.

The required well depth varies considerably from one site to another. Hot sources in the western United States can be tapped with relatively shallow wells, typically 500 to 2,000 feet (200 to 700 meters) in depth. Other geothermal sources may require much deeper wells.

The government energy agency is the place to start in determining whether there are useful geothermal resources in your area. Geothermal resources have not been surveyed thoroughly, but they are most likely to be documented in areas of greatest promise.

■ Extraction Techniques and Development Status

Hot water breaking the surface near volcanic activity has been used for heating for centuries. Deeper drilling for geothermal energy received an impetus from the energy crises of the 1970's. Geothermal energy is less visible than other non-fossil sources, so it has received less attention, even though its economics are often comparable or better. Most modern geothermal applications can be classed as demonstration projects. Major commercial development of geothermal energy is limited to sources near the surface, as in Iceland.

In all geothermal developments to date, water acts as a heat transfer medium between the hot rock and the heating application. Natural convection of water from a hot source can bring water near the surface at a much higher temperature than is produced by the normal temperature gradient. This requires geological faults or fractures that are oriented vertically.

Extraction technology is well developed, consisting mostly of conventional drilling techniques and equipment. Hot water or steam may emerge from a geothermal well under its own pressure. More commonly, hot water must be pumped from the well. In some areas, such as the Gulf coast of the United States, water is highly pressurized by overlying formations and bodies of water. These sources produce very hot water from very deep wells.

The water comes from aquifers near the heat source. An exception is hot dry rock, which requires circulating water from the surface through a naturally occurring fracture system. If the aquifer does not provide sufficient water for the application, there must be a supply of surface water to feed or replenish the wells.

For most applications, a heat exchanger is needed because the raw water from the well typically has a high concentration of dissolved minerals. As the water is cooled, the solubility of the minerals is reduced, and

they come out of solution. The heat exchanger should be designed for ease of cleaning.

■ Applications

The applications for geothermal heat are determined by the available temperature and flow rate. Geothermal wells producing lower temperatures have been used for greenhouse heating and aquaculture. Warmer sources are used for heating and food processing. Even if the geothermal source is not as hot as the application, it can be used for preheating cold water and other liquids. If the water is free of noxious dissolved materials, it can be used directly. Sources hotter than about 300°F are being used for generating electricity. Many other applications are possible.

Individual geothermal wells typically produce about 200 to 1,000 gallons per minute (800 to 4,000 liters per minute). Systems are designed to operate at a high temperature differential, from 30°F to 100°F (17°C to 55°C), to exploit as much of the energy as possible. This translates to heat outputs for individual wells ranging from 3 million to 50 million BTU per hour (1 to 15 megawatts, thermal). The cost of well drilling makes geothermal energy inappropriate for smaller applications.

■ Economics

Geothermal energy has a high initial cost, and relatively low operating cost. The drilling and equipment for the well account for most of the initial cost. A heat exchanger adds a modest cost. Geothermal wells are usually located at or near the site, so surface piping costs are low. Increasing the distance between the geothermal well and the user adds major piping cost.

Unlike most other unconventional energy sources, geothermal sources are usually constant and reliable once they are developed. On the other hand, there is a big gamble at the beginning, when the depth of the well, the amount of flow, and the temperature are uncertain.

■ Environmental Considerations

In many cases, the water from geothermal wells is similar to the water from shallow wells. After the heat is extracted, it can be used for irrigation or other purposes, or it can be discharged to the surface.

Using the water at the surface depletes the aquifer. For this reason, local regulations may require the water to be reinjected into the aquifer. It may be possible to use a single coaxial well if the water can be reinjected at a level higher than the source level.

The water from a geothermal source may contain noxious or dangerous materials that are not acceptable in the surface environment. These include sulfur dioxide, fluorine, boron, and radioactive isotopes. Water containing excessive concentrations of undesirable materials must be reinjected into the same aquifer. This requires an additional well located at a distance from the source well.

■ Relationship to Conventional Energy Sources

The capacity of a geothermal source is constant, so it can be used as a substitute for conventional energy sources. The useful life of geothermal sources, if not overused, is comparable to the life of conventional heating equipment.

Geothermal sources are expensive to develop, so they are most economical when used near full capacity. This may make it worthwhile to use geothermal energy to carry a base load, while other energy sources are used for peaking.

Waste Product Combustion

Consider burning waste products as an energy source at sites where a significant amount of combustible waste is available. This usually requires a specialized boiler. The adverse environmental effects vary widely with the nature of the waste.

■ Types of Combustible Waste

Almost any kind of waste that has a significant energy content can be burned to produce energy. The waste may be gaseous, liquid, or solid. For example, the trademark flares of the petroleum industry were long recognized as a wasted energy source, and steel smelting produces a gas rich in combustible carbon monoxide. The petroleum industry also produces heavy liquid end products of distillation that can be used as fuel, and paper processing produces “black liquor,” a liquid that contains dissolved combustible components of wood. A great variety of combustible waste occurs in solid form. A common example is bagasse, the solid residue of sugar cane refining.

There is usually a well developed technology for recovering heat from the combustion of waste that is specific to a particular industry, such as the burning of black liquor in the paper industry. Such applications tend to be integrated into the overall production cycle, optimizing efficiency and minimizing cost. If you are in the industry, you will know about these specialized waste recovery opportunities.

Untapped sources of waste energy are most likely to be found in smaller, less common, or evolving operations. There remains considerable opportunity for economic exploitation of waste that is not an inherent part of the process, for example, packaging discarded from sales and warehousing facilities. Take inventory of the materials you are discarding, and see whether it makes sense to use them as a fuel.

■ Equipment and Applications

Waste is almost always burned in a boiler to produce hot water or steam, which can be used in the same way as hot water or steam produced by any other boiler. Waste burning is a branch of boiler technology that is mature. Advances are related primarily to reducing environmental pollution. Waste burning boilers typically

are different from those that burn fossil fuels exclusively, but some boilers are designed to burn both specific wastes and conventional fuels efficiently. In new installations, this allows waste to be used as a supplemental fuel without a large cost penalty for separate equipment.

Waste can also be used for purposes other than combustion, such as fertilizer, construction materials, etc. Consider the broad range of possibilities.

■ Energy Content

Waste fuels have a wide range of energy content, from 20% to 100% of the energy content of conventional fuels, on a mass basis. Waste with the lowest energy content requires boilers of the largest size and most specialized design.

Low energy content does not argue against waste burning as strongly as might be expected. The waste has to be discarded in any event, and the distance to an on-site boiler is shorter than the distance to a landfill. Even though it is still necessary to dispose of the products of waste burning, the reduction in volume may have substantial value in terms of reduced disposal costs.

■ Availability

Obviously, the availability of waste suitable for burning varies widely among different activities. In most processes, the amount of waste is roughly proportional to the amount of product that is manufactured or handled. Liquid and solid waste can be stored until the heat is needed, or until there is enough of it to be worth burning as a batch.

■ Environmental Considerations

Waste burning reduces the solid waste disposal problem, and adds a local air pollution problem. From the standpoints of permits and public relations, waste burning tends to be viewed as the lesser evil in lightly populated areas, but is likely to encounter strong opposition in more heavily populated areas. Well designed waste burners can operate with stack emissions that are almost invisible, without using technology that is particularly exotic. However, minimizing air pollution requires careful control and a well trained staff. Along with equipment cost, these factors tend to limit waste burning to larger installations.

■ Economics and Feasibility

There are many applications where waste burning can be profitable, even to the point that it makes a major contribution to the economics of the overall process. Such applications tend to include waste burning as an integral part of the process, but this is not always true.

In applications where waste burning is not closely related to the activity of the facility, the chief obstacle may be the need to train the staff for an unfamiliar and unrelated function. While this may not add much to staffing cost, it is a management challenge. An abandoned waste burning boiler makes no money.

■ Relationship to Conventional Energy Sources

In most cases, waste burning is not able to satisfy all the energy requirements of the facility. Therefore, waste is a supplemental energy source that must be backed up with purchased energy.

Wood and Biomass Combustion

Organic matter that is used as a fuel is called "biomass." Almost all biomass that is burned directly consists of wood or woody plants. Wood was once the primary fuel of mankind, and it is still a primary fuel in less developed countries. In developed countries, wood that is used primarily as a fuel is presently limited to smaller applications, and it has special requirements and problems. The burning of wood waste in industrial applications involves the same general considerations as burning other waste fuels, discussed previously.

■ Energy Content

Wood has an energy content of about 5,000 to 7,000 BTU per pound. Pine bark, which is exceptionally resinous, has an energy content of about 9,000 BTU per pound. Therefore, wood and wood waste have about half the energy content of petroleum, on a mass basis. This qualifies it as an exceptionally good non-fossil fuel.

■ Equipment

In larger applications, wood is burned in specially designed boilers. The wood is usually a manufacturing byproduct, such as sawdust, chips, small pieces, and bark. These forms have large surface areas and burn to completion readily. Wood that is to be burned in industrial boilers may be further processed for ease of handling and burning, if necessary.

At the other end of the spectrum are wood stoves that burn whole or split logs. Combustion is incomplete, air pollution is a problem, and a great deal of labor is required for fuel preparation and tending the fire.

In response to the problems of safety and soot that are created by wood stoves, small externally installed wood heating boilers have been introduced. Heat is conveyed into the building with a water loop, which requires the installation of hydronic heating equipment. The long-term performance of external wood burning systems is not yet well documented. Smaller contemporary units are typically crude contraptions that lack adequate access for fireside and waterside maintenance, which is needed for efficiency and longevity. The fact that wood burning fell from favor during the 1980's has halted the refinement of this type of equipment.

■ Applications and Limitations

Wood stoves are widely used for direct radiant space heating. Wood-fired boilers can produce hot water or low-pressure steam for any application.

A serious limitation of small-scale wood burning is the need for tending the fire. Wood stoves require

repeated dampering and restarting. Some newer, larger types can burn unattended for many hours at reduced load, but require periodic refueling.

Where wood is grown or recovered whole as a fuel, another serious limitation is the work required for preparation and storage. Many wood burning enthusiasts have abandoned wood because of the annoyances of starting the fires, cutting and storing the wood, and removing ashes.

Serious injuries are related to the harvesting, storage, and handling of wood, including chain saw accidents, hernias, trees falling on people and equipment, heart attacks from unaccustomed exertion during cold weather, and other causes.

Wood burning has been a major cause of house fires. As a result, some jurisdictions are banning wood stoves, and insurance companies are imposing limitations and penalties on the use of wood stoves. In addition, overuse of portable electric heaters that may occur in conjunction with wood heating is another fire hazard.

■ Availability and Economics

At the present time, the growing scarcity of timber makes it unusual to grow wood specifically for burning, except in lightly populated rural areas. Most log wood that is burned in developed areas is the residue of land clearing and tree trimming. Wood is cheap and available when such supplies exceed the demand, the cost being determined largely by the need for cutting and transportation. However, if the demand exceeds this incidental supply, the cost of log wood becomes prohibitive in relation to the cost of other energy sources.

■ Environmental Considerations

Wood contains far less of environmentally troublesome elements, such as sulfur or mercury, than fossil fuels. It has a somewhat lower ratio of carbon to hydrogen than fossil fuels. Therefore, wood burning has the potential of being relatively clean from an air pollution standpoint. However, thorough burning is necessary to achieve this. Specialized industrial boilers designed to burn wood refuse are capable of thorough burning, but smaller boilers and wood stoves that burn logs are not.

In small furnaces or boilers where only a few logs are burned, the temperature in the firebox typically is not hot enough to completely burn the volatile compounds that are distilled out of the logs. This is especially true at the beginning of the burn, and when output is dampered back. The result is the formation of a great variety of intermediate organic compounds, which contribute to air pollution. In addition, small furnaces and boilers lack provisions to remove particulate matter, which is a major element in wood smoke.

Newer models of small, log burning wood furnaces are being equipped with catalytic afterburners that are

claimed to substantially increase the efficiency of combustion. However, catalytic burners appear to be difficult to keep in operation because they are fouled by the particulates of wood smoke. Interest in small-scale wood burning declined so rapidly in the 1980's that development of clean-burning wood stoves petered out, along with research into their effectiveness.

Attitudes toward wood burning illustrate the mood swings that can occur in environmental issues. As late as the 1970's, wood burning was one of the darlings of energy conservation. Now, it is asserted that the products of incomplete wood combustion are seriously carcinogenic, and small-scale wood burning is accused of being a major atmospheric polluter.

■ Relationship to Conventional Energy Sources

Wood burning can be a primary source of heating energy if the supply of wood is adequate and dependable. However, even in such cases, the inconvenience of burning wood causes it to be used as a secondary or occasional fuel.

Some rural electric utilities have promoted wood burning as a means of demand reduction during periods of high electric heating demand. However, this policy backfired because dependence on wood heating prompts customers to use portable electric heaters at times when it is inconvenient to operate a wood fire, and this is especially likely to occur during the peak cold period. A related problem is that the typical wood heater does not effectively heat the entire house, so portable electric heaters are likely to be used in areas of the house remote from the location of the wood heater.

**NOTE FOR READERS IN THE
SOUTHERN HEMISPHERE**

To keep the discussion simple, the compass directions given in this Note are based on locations in the northern hemisphere. The corresponding situations for the southern hemisphere are obvious. Simply substitute “south” where the text says “north,” and vice versa.

To use sunlight effectively, or to limit its effects, you need to know its characteristics. This Note covers the energy content of sunlight; how light is emitted by the sun; how the sun moves through the sky; and, how sunlight is affected by the atmosphere, by glazing materials, and by surrounding surfaces.

More than with any other important energy source, sunlight is variable. Some of the variations are predictable, especially those caused by the earth’s motion and by the location and orientation of the facility. Some of the variations are unpredictable, especially those caused by weather and air pollution. More unusual occurrences, such as the construction of a tall building next door, may also have a major effect on sunlight.

Amount of Energy Available

Here are some handy facts about the amount of solar energy in its different forms:

- A beam of bright sunlight one square foot in cross section delivers energy at the rate of about 240 BTU per hour in clear air. This number varies somewhat with latitude, altitude, and time of day.
- In middle latitudes, vertical glass collects about 300,000 BTU per square foot per year, assuming a continuously clear sky. This number is substantially reduced by cloudy weather, smog, glazing orientations that face toward the north, and shading by adjacent features.
- A significant amount of solar energy comes from the sky indirectly by scattering. Half of a clear sky, with the direct sun blocked (for example, the amount of energy falling on the east side of a building when the sun is in the west) delivers about

20 to 40 BTU per hour per square foot of building surface.

- The amount of solar energy falling on a horizontal surface from an overcast sky typically ranges from 20 to 60 BTU per hour per square foot.
- As a light source, the sun provides an illumination of about 6,000 footcandles (60,000 lux) on a clear day. An overcast sky typically provides an illumination of 500 to 1,500 footcandles (5,000 to 15,000 lux). By comparison, typical office lighting ranges from 50 to 100 footcandles (500 to 1,000 lux).
- At night, the amount of solar energy is essentially nil.

Various ASHRAE publications and other references provide data on solar heat input for different latitudes, dates, hours, and glazing orientations. The more sophisticated energy analysis computer programs have the ability to calculate these data, as well as programs designed explicitly for glass shading and daylighting.

Wavelength Characteristics

The sun is an incandescent light source. This means that the sun’s wavelength spectrum is determined by its surface temperature, which is about 10,000°F (5,500°C). By comparison, an ordinary incandescent light bulb has a filament temperature of about 3,800°F (2,100°C), and an arc lamp has a temperature of about 6,000°F (3,500°C). The characteristics of incandescent light sources are covered in [Reference Note 54](#), Incandescent Lighting.

A small fraction of sunlight is absorbed at specific wavelengths as it passes through the earth’s atmosphere. Most of this absorption is by water vapor. An even smaller fraction is absorbed by carbon dioxide, mostly at the longest wavelengths of sunlight. (Carbon dioxide absorbs a much larger fraction of the heat radiation emitted by the earth at very long infrared wavelengths. This is the basis of the “greenhouse effect.”)

Visible and Invisible Components

All sunlight that is absorbed by a building becomes heat, but only a portion of sunlight is useful for vision. The light sensitivity of human vision falls within the

peak portion of the solar spectrum, which is probably not an evolutionary coincidence. About 35% of solar energy that penetrates to sea level is in the visible spectrum. Most of the remainder consists of invisible “infrared” radiation, i.e., light of wavelengths longer than the red end of the visible spectrum. Only about 3% of sunlight arriving on earth is “ultraviolet” radiation, i.e., light of wavelengths shorter than the violet end of the visible spectrum.

The percentage of sunlight in the visible spectrum depends on how broadly the visible spectrum is defined. People see little at the extreme red and blue ends of the vision spectrum. If this sunlight is filtered out, very little vision is lost, but a lot of heat energy is stopped. Blocking all sunlight except the 20% to 30% in the middle of the visible spectrum would provide almost unimpaired vision while minimizing heat gain.

A major challenge in juggling cooling load, passive heating, and daylighting is balancing solar input from the visible and invisible portions of the solar spectrum. Methods exist to filter sunlight by changing the characteristics of the glazing materials. Current methods are not variable. Once the glass is made and coated, its light transmission characteristics are fixed. This may change in the future. The only exception at present is retrofit plastic films, a compromise solution with major drawbacks.

The Ultraviolet Component

Unlike incandescent light sources on earth, the sun is hot enough to produce a significant amount of ultraviolet energy. The amount reaching the earth, 3% of total sunlight, is not important in terms of its heat contents. However, at approximately the boundary between visible light and ultraviolet light, photons become energetic enough to break chemical bonds in organic materials. (The energy of individual photons

depends only on their wavelength.) As a result, ultraviolet light can cause skin cancer, kill microorganisms, weaken fibers, bleach dyes, and create other chemical effects. Most of these effects are undesirable.

A fortunate coincidence is that ordinary window glass blocks the most energetic ultraviolet component of sunlight. With typical windows, ultraviolet damage usually is limited to bleaching of curtains that are exposed to direct sunlight for years. However, if you increase the amount of sunlight enough to provide passive heating or daylighting, expect to take steps to limit ultraviolet damage.

How the Sun Moves Through the Sky

Solar motion is completely predictable. The sun moves with respect to a point on the earth for three reasons, shown in Figure 1:

- the earth rotates about its own axis once per day
- the earth revolves around the sun once per year
- the axis of the earth’s rotation is tilted 23.5° with respect to the plane of the earth’s revolution around the sun.

The earth is farther away from the sun during the northern hemisphere summer than during the southern hemisphere summer. You might suspect that this would make the seasonal change from summer to winter more severe in the southern hemisphere. However, this factor is obscured by other factors, such as differences in land mass, ocean currents, jet streams, etc.

Figure 2 shows how the sun appears to move with respect to the earth’s surface. The tilt of the earth’s axis is what causes the change of seasons and what complicates solar motion. Here are a few key aspects of the solar motion we observe:

Fig. 1 How the earth moves around the sun The most important directional aspects of sunlight result from the daily rotation of the earth about its own axis, and from the tilt of the earth’s axis with respect to the earth’s orbit. The seasonal differences in distance from the sun have relatively little effect on solar energy use.

Fig. 2 How the sun moves through the sky More solar energy is available in summer than in winter because the sun’s path is longer and because sunlight strikes the earth at a higher angle.

- ***The path of the sun's motion through the sky moves north in summer, south in winter.*** The sun literally “rises in the east” and “sets in the west” only on two days each year, the spring equinox (March 21) and the autumn equinox (September 21). The sun's path reaches its extreme northern limit at the summer solstice (June 21), and its extreme southern limit at the winter solstice (December 21). The northward movement of the sun's path is what causes the sun to be higher in the sky in summer. This is one of two reasons why it gets hotter in summer.
- ***The length of the sun's path through the sky increases as the sun's path moves north.*** The sun moves through the sky at a constant angular rate, so the sun remains in the sky longer as its path moves north. This is the second reason why it gets hotter in summer.
- ***The azimuth of the sun at sunrise and sunset varies more radically at higher latitudes.*** (The sun's azimuth is its horizontal position with respect to the horizon, i.e., its compass direction.) At latitudes closer to the poles, the sun rises and sets farther north in summer, and farther south in winter. (Above the Arctic Circle, in summer, the sun may move all the way around the horizon without setting at all.)
- ***The tilt of the sun's path never changes at any given location,*** but the path itself shifts north and south with the seasons. The tilt of the sun's path across the sky is equal to 90° minus the latitude. For example, at a latitude of 30° , the sun's path is tilted at angle of 60° to the horizon.

You need a detailed knowledge of how the sun moves through the sky in order to exploit solar energy effectively, or to minimize solar heat gain. You need the most detailed knowledge of the sun's motion to design shading, either to limit heat gain or to provide effective daylighting. For example, the noontime sun at the summer solstice is 47° degree higher than the noontime sun at the winter solstice. You can exploit this difference easily to provide shading for south-facing surfaces that blocks sunlight in summer but admits it in winter.

(In the northern hemisphere, the difference of 47° is constant anywhere at latitudes between the Tropic of Cancer and the Arctic Circle. Below the Tropic of Cancer, the sun crosses into the northern sky at noon during the summer. Above the Arctic Circle, the sun may remain below the horizon at noon during the winter. In the southern hemisphere, the same situation applies to the Tropic of Capricorn and the Antarctic Circle.)

The best tool for laying out shading is a set of solar position charts. Each chart depicts the position of the sun for all seasons and times of day, for a given latitude.

Such charts are available from the Smithsonian Institution and in some books on solar energy.

Weather and Atmospheric Effects

Weather changes make sunlight unpredictable. The largest changes come from clouds, which result from both local and long range atmospheric behavior. For sites in the United States, information on cloud cover is given in the *Climatic Atlas of the United States*, published by the U.S. Government Printing Office.

Atmospheric moisture affects solar input, because water vapor is the most potent absorber of sunlight in a clean, cloudless sky. Most absorption by water vapor occurs in the infrared spectrum. Arid climates get about 10% more total solar energy than average, and humid coastal climates get about 10% less than average. The effect of atmospheric moisture is accounted for by a calculation factor called “clearness number.” This is given for different U.S. locations in the *Fundamentals* volume of the *ASHRAE Handbook*.

Air pollution is a major factor in some urban areas. The effect of pollution on solar energy is localized and highly variable.

For a given elevation of the sun above the horizon, heat gain is usually somewhat higher in winter than in summer because the atmosphere is clearer. Of course, total heat gain is less in winter because the sun spends less time above the horizon.

Water vapor, dust, and pollutants not only reduce the intensity of sunlight, but also diffuse it. The increased diffusion usually is not troublesome for exploiting daylighting and passive heating, or for reducing cooling load. However, it reduces the efficiency of directional devices, such as concentrating solar collectors and sun tracking light pipes.

Effect of Glazing Orientation

People tend to assume that the greatest amount of solar gain occurs when the sun is high in the sky. This is not true for most buildings, because solar energy typically enters a building through windows that are vertical. Figure 3 shows how the height of the sun above the horizon affects solar heat gain through vertical glazing. Solar heat gain is greatest through vertical glazing when the sun is about 30° above the horizon. When the sun is close to the horizon, its energy is absorbed heavily by the atmosphere. This effect varies with the clarity of the atmosphere.

At low and middle latitudes, the greatest total solar gain occurs through windows and other vertical glazing that face east and west. At higher latitudes, the greatest total heat gain occurs through windows that face south. Figure 4 shows hourly heat gain for vertical glazing that faces east, west, and south, at a latitude of 40° .

The compass orientation of a vertical window obviously has a major effect on its heat gain. This is illustrated in Figure 5. What this figure does not reveal is that relatively small changes in orientation may have a major effect on shading. This is discussed in [Subsection 8.1](#).

Virtually all methods of controlling sunlight must be tailored to the orientation of the glazing. A building that has been designed to control sunlight effectively will have different sun control techniques on different sides. If a building looks the same from all directions, the designer was not serious about using or controlling sunlight.

Effect of Glazing Materials on Sunlight

Three things may happen to light that strikes a window or skylight. It may pass through the window, or it may be reflected, or it may be absorbed by the glazing material. There are three corresponding characteristics that describe a window or other glazing element: its “transmittance” (the fraction of light that passes through), its “reflectance” (the fraction that is reflected), and its “absorptance” (the fraction that is absorbed). Each of these characteristics is expressed as a fraction or percentage. For any given wavelength and incident angle, the sum of these three numbers equals one, or one hundred percent. Controlling sunlight largely consists of controlling these three characteristics of glazing.

(A note on terminology. You will see variations of each of these terms. For example, you may see “absortance,” “absorptivity,” or simply, “absorption.” In most cases, there are no differences in meaning that you need to worry about.)

Fig. 3 The effect of the sun's height on heat gain through vertical glazing Maximum solar gain through windows occurs when the sun has an elevation of about 30 degrees. Sunlight is absorbed heavily by the atmosphere at lower elevations. Also, the sun is more likely to be obstructed by foliage, other buildings, and terrain at lower elevations. At high sun elevations, much of the sunlight reflects off the outer surface of the glazing.

Almost all glazing in buildings uses a single basic type of glass. Clear glass has transmission characteristics that are easy to remember. By a remarkable coincidence, window glass has a high transmittance across the spectrum of sunlight, including both visible and infrared portions, and it has almost zero transmittance at other wavelengths. For typical thicknesses used in glazing, the transmittance of clear glass is about 90% in the visible spectrum, and is slightly less in the solar infrared spectrum.

At wavelengths longer than solar infrared radiation, window glass absorbs the energy almost completely. This characteristic reduces loss of heat from the interior of the building by radiation, especially if the glazing has multiple panes. It also reduces heat gain during warm weather from outside objects, such as pavement and adjacent buildings. The latter mode of heat gain is minor compared to heat gain from the wavelengths in sunlight.

By another happy coincidence, the light transmission of glass cuts off just above the blue end of the visible spectrum. Thus, glass absorbs the shorter, more damaging ultraviolet wavelengths at the extreme end of the solar spectrum. The filtering of ultraviolet light by glass has only a minimal effect on plant growth.

Plastic glazing materials, such as acrylic and polycarbonate plastics, are similar to glass in their transmittance for visible light. They have lower transmittance in the solar infrared region, and they may allow more ultraviolet to pass. Plastics are diverse in their optical characteristics.

In principle, you can block entry of sunlight through glazing as much as you want by increasing its reflection

Fig. 4 The effect of orientation on solar heat gain through vertical glazing, at 40 degrees latitude At this middle latitude, solar gain is much more intense through windows that face east and west than through windows that face south. The difference is even greater at more southerly latitudes.

after John Yellott

Fig. 5 The effect of azimuth on solar heat gain through vertical glazing This shows that the sun's altitude is as important as its azimuth. Also, the heat gain from clear daylight sky is about 10% of maximum direct solar radiation, for a given sun elevation.

or absorption, or both. Reflection is increased by applying a reflective coating to the surface of the glass, either as part of the glass manufacturing process or by adding a retrofit reflective film. Absorption is increased by adding dyes during manufacture, or by using a retrofit absorptive film. In practice, you cannot block more than about 80% of visible sunlight without making the view of the outside look too dark.

Controlling the characteristics of glazing is one of the most important tools in using and controlling sunlight. Further details of glazing characteristics are provided in [Subsections 8.1](#) and [8.3](#).

Smooth-Surface Reflectance

Glass, plastic, and other non-conducting materials with a smooth surface inherently have a certain amount of reflectance, which is independent of the absorptance or transmittance of the material. (This is why you see reflections in store windows and polished table tops.) This smooth-surface reflectance depends only on a physical property called the index of refraction, which is loosely related to the density of the material.

If light strikes glazing from directions near perpendicular, the smooth-surface reflectance is only a few percent. At grazing angles less than about 30° from the glass surface, the reflectance starts to increase rapidly, becoming about 50% at an angle of 10° , and 100% as the angle becomes zero.

Smooth-surface reflectance can be a desirable design feature. For example, in passive heating with vertical windows, smooth-surface reflectance reduces heat gain during warm weather, when sun angles are high, yet it does not reduce heat gain much during cold weather, when sun angles remain low.

Sunlight Reflected from Exterior Surfaces

A substantial amount of solar input may occur by reflection from surrounding terrain features or from other structures. The *ASHRAE Handbook* lists reflectances of about 20% for most common ground surfaces, such as weathered concrete, gravel, and grass, and about 10% for asphalt. Reflection from an adjacent body of water may increase solar energy input by 50% or more. Adjacent highrise buildings with a large fraction of glazing act as huge mirrors, especially if they have glazing with reflective coatings.

Boiler Types and Ratings

Types of Boilers

- Firetube Boilers
- Watertube Boilers
- Cast Iron Sectional Boilers
- Condensing Boilers
- Electric Boilers

This Note gives you an overview of boiler types. It also defines terms that you may encounter in accomplishing the Measures related to boilers.

Boilers are old technology, and they have been used for many applications. As a result, they are rated in a variety of ways. The rating methods that you may encounter are explained at the end of this Note.

The best source of information about boilers that you already own is the manufacturer's literature. A good selection of manufacturers' literature is also the best source of detailed information about boilers that you may be interested in purchasing.

Types of Boilers

Someone has described a boiler as "a bunch of tubes and a furnace." This is a reasonably accurate picture of the construction of most boilers.

In terms of energy efficiency characteristics, it helps to think of a boiler as a heat exchanger that has its own heat source. The boiler exists to transfer heat efficiently from a heat source to water. The heat source is usually a fuel burner or an electric heating element. The type of burner is determined primarily by the type of fuel being burned.

The heat transfer layout is what gives each boiler type its name. The two main layouts are "firetube" and "watertube." In both types, the name derives from the fact that tubes are used as the heat transfer surfaces. If the combustion gases are on the inside of the tubes and the water is on the outside, the boiler is called a "firetube" boiler. If the water is on the inside of the tubes and the flame on the outside, the boiler is called a "watertube" boiler. Both types have been used since the beginning of the industrial age, and each continues to dominate its own size and pressure range. Other types of boilers are significant in narrower ranges of applications.

■ Firetube Boilers

Firetube boilers are the most common type in small and medium commercial sizes, at lower pressures. Firetube boilers are most economical in this range because their construction is simple. Figure 1 diagrams of number of different variations of firetube boilers. In

Boiler Capacity Ratings

all these, the construction consists of a large number of straight tubes held in place by "tube sheets" at each end.

Modern firetube boilers almost all have a cylindrical outer shell, because this provides the greatest strength in relation to weight, and it is easy to fabricate. For the same reasons, the combustion chamber is a smaller round tube installed inside the bottom of the shell. Figure 2 is a cutaway drawing of an efficient modern firetube boiler.

Firetube boilers usually have a number of "passes" to increase the heat transfer area and to accommodate the shrinking of the combustion gases as they cool. Each pass is a bundle of tubes through which the gases travel. At the end of each pass, the gas reverses and goes into the next pass, and finally into the flue. Figures 1 and 2 show the passes clearly. The most efficient firetube boilers have three or four passes.

Firetube boilers cannot be used at high pressures, because they would be too heavy. The wall thickness of any pressure vessel is proportional to its own diameter and to the pressure. Therefore, a firetube boiler would require an enormously thick shell at larger sizes and higher pressures. Also, the flat tube sheets of a firetube boiler cannot be supported properly at high pressures.

Firetube boilers can make either hot water or steam. The shell of a hot water boiler is filled with tubes. The shell of a steam boiler has a steam space without tubes inside the top, where a steam separator typically is installed. Steam boilers also have external equipment to maintain the water level.

■ Watertube Boilers

Watertube boilers come in many configurations. Most have a large number of individual tubes that extend between a single upper header, called the "steam drum," and one or more lower headers. The lower header, or the lowest of several lower headers, is often called the "mud drum." This is because dirt and the residue of water treatment settles here.

Figure 3 diagrams a variety of older types of watertube boilers, many of which are still in service. These were designed to use straight tubes, or tubes with only simple bends.

Figure 4 shows two watertube boilers of modern design. These are more compact because they are made with tubes that have complex and diverse bends, made economical by modern tube bending machinery. These boilers also make more efficient use of materials, so they are lighter.

Modern watertube boilers are better adapted to including superheaters than older types. A superheater is a section of boiler tubes that continue to heat the steam after it has been vaporized. Superheated steam may be hundreds of degrees (Celsius or Fahrenheit) hotter than saturated steam at the same pressure. Superheated steam

operates steam turbines more efficiently than saturated steam, and it minimizes turbine damage that is caused by droplets of condensed steam passing through the blades. Steam may also be superheated to keep it from condensing in long distribution pipes.

The design of superheaters is critical because the steam inside them has little ability to cool the tubes to prevent burnout by the hot combustion gases. Therefore, the superheater tubes reside in a portion of the boiler where the gases have already been cooled sufficiently by evaporating water in the primary boiler tubes, which are called "generating" tubes.

Fig. 1 Firetube boilers The basic design consists of many straight tubes held at the ends by "tube sheets." Water surrounds the tubes. The combustion gases work their way through the tubes in a series of "passes." Most modern firetube boilers are enclosed in a cylindrical steel shell. Many older boilers were set on brickwork, or were enclosed in iron casings of many shapes.

Industrial Combustion

Watertube boilers are used in all high-pressure applications and in most larger sizes. For the reasons stated previously, the tubes can be relatively thin, although the headers become quite thick at high pressures. The capacity of a watertube boiler is determined by the number and length of the tubes.

The relatively small water volume of watertube boilers allows them to heat up more quickly than firetube boilers. This is an advantage for producing hot water as well as for producing steam. Also, watertube boilers may have more desirable dimensions than firetube boilers because the tubes can be bent to provide the desired overall shape. Figure 5 shows a relatively simple watertube boiler for producing hot water. Figure 6 shows a larger, more complex unit.

Watertube boilers can be designed to produce hot water or to produce steam. As a practical matter, only watertube boilers can produce superheated steam. The layout of watertube boilers can be adapted readily to accommodate superheater tubes, whereas there is no space for superheater tubes in a firetube boiler. For the

same reason, watertube boilers can easily be designed with integral economizers. (In boilers, the overworked term “economizer” means a heat exchanger that captures the heat of the leaving flue gases to heat the feedwater entering the boiler.)

Maintaining water circulation through all the tubes is a critical aspect of design and operation with watertube boilers, and especially with steam boilers. The water in the tubes protects the steel from the heat of the gases by acting as a coolant. Inadequate circulation allows the tube space to fill with steam, which is much less effective as a coolant. This is a delicate balance, because circulation in most small and medium watertube boilers is by convection, which requires the formation of small steam bubbles inside the tubes to lighten the water column.

Some large, complex boilers use pumped circulation. This becomes necessary at very high pressures, because the density difference between steam and hot water becomes smaller, and the temperature of the steam is higher. (The extreme case occurs in

Cleaver-Brooks

Fig. 2 Modern firetube boiler This boiler has four passes, which includes the cylindrical combustion chamber. The only exterior surface contacted by the combustion gases is the rear end of the casing. In some boilers, even this end contains boiler water, in which case it is called a “wetback” boiler.

Fig. 3 Older types of watertube boilers Watertube boilers are complicated by the need to provide effective water circulation to prevent tube burnout, which is much easier to avoid in firetube boilers. Also, the combustion gas must circulate around the tubes by a path that efficiently removes the heat from the gas over a wide range of firing rates. These boiler designs were further complicated by the inability of early manufacturers to bend tubes into complex shapes. Many boilers of these types are still in service.

Industrial Combustion

“supercritical” boilers, where the pressure is so high that the physical differences between liquid water and steam disappear.)

All hot water boilers depend on pumps for circulation, because no steam forms inside them to provide convective circulation. In simple systems, boiler circulation may be provided by the hot water system distribution pumps.

In watertube steam boilers, the upper drum (called the “steam drum”) serves mainly as a steam separator. Steam-separating baffles are usually installed in the steam space of the drum. Water level is critical because the volume of the steam drum is small. If the water level falls to the level of the tubes, the dry portions of the tubes will burn out, causing an explosion. If the water level rises too high, the baffles are flooded, and water carries over into the steam system.

Conventional watertube designs tend to be uneconomical in smaller sizes. They are expensive to design and manufacture because each row of tubes must be bent at different angles. The boiler needs an outer casing lined with heavy refractory material because the hot combustion gases are not contained inside a water vessel. These cost factors become less of a disadvantage in larger boilers.

Industrial Combustion

Fig. 4 Modern watertube boilers These are more compact and simpler in construction than older types because they can exploit an unlimited combination of complex tube shapes to optimize water circulation and heat transfer. These types can also include superheater sections that safely heat the steam to high temperatures.

Coil boilers are specialized watertube boilers that are usually found in smaller sizes. As the name implies, they contain only one or a few long coils wound in a tight helix around the combustion chamber. Their major advantage is rapid warm-up, since they have an exceptionally high ratio of surface area to water volume. The coil configuration accommodates rapid thermal expansion. These boilers may require forced circulation to avoid coil burnout. Figure 7 shows an example.

■ Cast Iron Sectional Boilers

The “cast iron sectional” boiler does not use tubes. Instead, it is built up from cast iron sections that have water and combustion gas passages. Figure 8 shows a cross section of this boiler type. The iron castings are bolted together, much like an old steam radiator. This type of boiler usually does not have separate headers, but it achieves the same effect with openings that line up between adjacent sections. Although this type of boiler looks crude, it is capable of high efficiency. Cast iron boilers are available for producing either steam or hot water.

The main advantage of cast iron sectional boilers is that they can be assembled inside the boiler room, requiring only a small door for the sections. For this reason, they are often found as replacement units where no other type could be brought into the boiler room.

The main disadvantage of this type of boiler is that the sections are sealed together with gaskets. This invites leakage as the gaskets age and as they are attacked by boiler treatment chemicals. By the same token, the

Parker Boiler Co.

Fig. 5 The inside of a watertube hot water boiler designed for atmospheric gas burners This simple design is compact, and it heats up quickly. However, the atmospheric burner design causes large standby losses.

presence of the gaskets is a factor to consider in water treatment. Cast iron boilers are limited to smaller sizes. They are also limited to low pressure by the presence of the gaskets, and by limitations in the strength of the tension rods (“stay rods”) that hold the sections together.

■ Condensing Boilers

Condensing boilers are the newest major type. They are important because they have higher efficiencies than conventional boilers. Their defining characteristic is a large, corrosion-resistant heat exchange surface, which allows the water vapor in the flue gases to cool enough to condense while still inside the boiler. Condensing recovers the latent heat of the water vapor in the flue gas. Another major advantage is that these boilers require minimal flues, because the flue gases are cool and reduced in volume. In many installations, the flue gases are expelled directly through the wall of the boiler room.

(Condensing furnaces have also become popular. They are based on the same principle.)

Condensing boilers are different in their internal configuration from conventional firetube and watertube boilers. A major design consideration is minimizing the amount of expensive stainless steel that is required.

Condensing boilers and furnaces are generally limited to clean burning fuels, especially gas fuels. At present, they are made only in smaller sizes, but you can easily achieve greater capacity by installing many units in parallel.

Cleaver-Brooks

Fig. 6 A larger, more complex watertube hot water boiler Watertube boilers are commonly used for producing hot water as well as for producing steam. Water circulation is similar in both types. Water enters the tubes at the lower header, and the tubes discharge into the upper header.

■ Electric Boilers

Electric boilers come in two types. One uses an electric resistance element to heat the water. The other, called an “electrode boiler,” has electrodes that use the water itself as the resistance element.

Electric boilers are exceptionally efficient as energy conversion devices, suffering only surface heat loss and losses in the electricity supply system. They also have the major advantages of requiring no flue and little maintenance.

A severe disadvantage is the high cost of electricity, at least in most locations. If the electricity is produced in a thermal power plant, electric boilers can be considered as having large losses, which occur at the generating plant rather than in the boiler itself.

Boiler Capacity Ratings

Boiler capacity is expressed by a jumble of different rating methods. Some of these methods are obsolete, but it is useful to know about them when trying to figure out the capacities of older boilers.

Boilers may be rated either by fuel input or by energy output. Input is usually expressed in power units, typically BTU per hour. In many cases, the output is not stated and is assumed to be a standard percentage of the fuel energy input. In particular, smaller gas boilers and furnaces made in the U.S. until recently assumed that the output is 80% of the input.

Boiler output is stated on the nameplates of most larger boilers, and on newer boilers and furnaces of all sizes. Boiler output may be expressed as:

WESINC

Fig. 7 A coil boiler This is a watertube boiler in which a coil of tubes surrounds the combustion chamber. The arrow points to a 50-horsepower pump that must circulate water through the tubes continuously to keep them from burning out. This boiler is appropriate only for applications requiring fast warm-up and short durations of operation. It was a very bad bargain for this building heating application.

- **power units.** Metric practice is to express boiler output in watts. Where English units are still used, the usual units are BTU per hour.
- **boiler horsepower,** which is an archaic rating that still persists needlessly. One boiler horsepower equals 33,475 BTU per hour. This method of rating originated as a means of sizing boilers to operate old non-condensing steam engines.
- **heating surface,** found mainly on older boilers. By convention, one square foot of heating surface is considered to be one fifth of a boiler horsepower, or about 6,700 BTU per hour. This rating refers to the area of the heat transfer surface within the boiler itself. If the heating surface is given on the boiler nameplate, be sure that the figure is intended as an output rating. If the figure refers to actual heat transfer surface, the actual boiler output may be lower or higher than indicated by the nominal heating surface.
- **square feet of equivalent direct radiation (EDR)** is used with older boilers intended to make steam for radiators. The rating refers to the surface area of the radiators, not to the heating surface of the boiler. One square foot EDR equals 240 BTU per hour if the boiler is intended to serve steam radiators, or 150 BTU per hour if the boiler is intended to serve hot water radiators.
- **“net output”** is a rating used on some boilers intended for space heating applications. The net output is equal to the actual output of the boiler divided by a capacity safety factor. Institute of Boiler and Radiator Manufacturers (IBR) ratings

Industrial Combustion

Fig. 8 Cast iron sectional boiler The boiler can easily be assembled at the site from many individual sections. The sections are sealed by gaskets and held together by compression rods. The main advantage of this type is that the individual pieces can be transported into the boiler room through a small entrance.

assume a factor of 1.13, and Mechanical Contractors Association (MCA) ratings assume a factor of 1.25. To calculate the actual output of the boiler, check the nameplate to see whether the IBR or MCA rating is used, and multiply by the appropriate factor.

Many older boilers have been upgraded with retrofit burners. If the burner capacity is fixed, check the capacity shown on the burner nameplate. Burner capacity is commonly expressed as fuel input rate, such as gallons per hour of fuel oil. In this case, you need to calculate the energy input by looking up the energy content of the fuel. To convert this to an accurate estimate of output, do an efficiency test of the boiler, as explained in [Subsection 1.2](#).

Rating Temperatures

COP's of Direct-Fired Absorption Chillers
Auxiliary Equipment Energy Consumption
Consider Part-Load Efficiency

Energy flows through a cooling machine (an air conditioner or water chiller) in this way:

Energy enters the machine at two points (the evaporator and the drive motor) and leaves at one point (the condenser). For this reason, the term “efficiency” does not apply to chillers in the usual sense. Efficiency is defined as useful energy output divided by total energy input. However, the energy output of a chiller is the amount of heat rejected to the outside, which is not of primary concern.

What really matters is the amount of heat withdrawn from the space, and the energy required to operate the chiller, which are two different modes of energy input. For this reason, the performance of chillers and air conditioners is defined in a special way, in terms of “coefficient of performance.”

Coefficient of Performance (COP)

Chiller performance is expressed as the ratio of the amount of heat removed from the space to the amount of energy required to operate the chiller. This ratio is called the “coefficient of performance,” commonly abbreviated as “COP,” so

$$\text{COP} = \frac{\text{heat removed from load}}{\text{energy to operate chiller}}$$

COP is defined using common units, i.e., BTU's removed per BTU input, or watts per watt, etc. Therefore, COP is “dimensionless.” Since the COP has no units, it applies equally to metric and non-metric engineering.

Other Performance Ratings

In the U.S., the performance of smaller cooling equipment may be rated with a bastard measure called

the Energy Efficiency Ratio (EER), which has units of BTU cooling per KWH input. Therefore, EER equals the COP times 3.413. A variation of this is the Seasonal Energy Efficiency Ratio (SEER), which is the average EER of the unit when operated over a standard load profile.

A common way of expressing the performance of large chillers in the U.S. is “kilowatts per ton.” Unlike COP, a smaller number is better. The “ton” is an archaic but common term used to express the rate of cooling. (A ton equals 12,000 BTU's per hour. The name originated in icehouse refrigeration, and derives from the fact that a ton is the rate of heat removal needed to freeze one ton of ice per day.) At the present time, the highest efficiency achieved by chillers is about 0.55 kilowatts per ton, at standard rating conditions.

Rating Temperatures

The COP rating is meaningless unless the evaporating and condensing temperatures are specified. This is because the COP and cooling capacity of a chiller are affected strongly by the evaporating and condensing temperatures. In the U.S., the Air Conditioning and Refrigeration Institute (ARI) has established standard rating temperatures for different types of cooling equipment.

For example, water chillers are rated on the basis of the chilled water temperature as it leaves the evaporator and the cooling water temperature as it enters the condenser. The specific rating temperatures differ among manufacturers, equipment types, and applications. For example, one chiller may be rated at 44°F chilled water temperature and 95°F condenser water temperature, while other chillers may be rated at different temperatures. Be sure to make chiller comparisons using the same temperatures.

COP's of Direct-Fired Absorption Chillers

The purchased energy that operates direct-fired absorption chillers is in the form of fuel. Therefore, the COP rating depends on the energy content of the fuel. However, the energy content of fuels may be expressed in two different ways, “high heat value” and “low heat value.” The COP's of direct-fired chillers are usually based on the “high heat value” of the fuel. Be aware that a manufacturer may artificially boost the COP figure

by using the “low heat value” of the fuel. [Reference Note 20](#), Fossil Fuels, explains this difference in fuel ratings.

Consider the Energy Consumption of Auxiliary Equipment

Even when using standard rating conditions, the COP or EER does not necessarily provide a valid comparison between cooling systems. For example, the COP quoted for a large packaged chiller includes only the energy input to the compressor. In contrast, the EER or SEER of a window air conditioner includes the energy input to all the system equipment, including the evaporator and condenser fans. The SEER of a packaged split system may include the energy input to the condenser and evaporator fans, or if the evaporator is specified separately, for just the condenser fan.

COP’s quoted for absorption chillers typically include only the heat input, and not the electrical input for pumps, which is substantial.

To make the most valid efficiency comparison between cooling systems, include all energy consuming devices in the chiller system as part of your efficiency calculation. This means taking into account the energy consumption of auxiliaries, especially pumps and fans.

The energy consumption of other auxiliaries, such as purge units, is usually minor, but it is easy to include.

When you do this, account for efficiency effects caused by the auxiliary equipment. For example, reducing the energy consumption of condenser or evaporator fans increases the compressor power requirement.

Consider Part-Load Efficiency

Manufacturers rate their chillers at their most efficient operating points, which typically are near full load. However, most chiller systems operate at low loads for a large fraction of the time. Therefore, the average COP of a chiller may be substantially lower than its rated COP. There are large differences in part-load performance between different types of chillers.

Auxiliary equipment usually is even worse in this regard. For example, the pump power needed for chilled water distribution may remain fixed at all cooling loads.

To compare the efficiencies of different systems, you need to compute their energy consumptions when operated over a typical range of loads. You may need help from a computer program to do this accurately. See [Reference Note 17](#), Energy Analysis Computer Programs, for details.

The great majority of cooling equipment worldwide operates by compression. This Note is an overview of compression cooling systems, emphasizing the aspects of design and equipment selection that affect system efficiency.

In principle, you could select a system with the highest efficiency simply by using manufacturers' efficiency quotations. However, this is not a prudent approach. The efficiency of a cooling system is determined by a variety of factors involving cost, safety, space requirements, maintenance, and other issues. You need to consider all of these to achieve a good system.

There is fierce competition among manufacturers with different designs, and each touts its own advantages while being silent about its own disadvantages. This Note will help you to navigate through the competing claims by understanding the principles of compression cooling. It will enable you to ask the right questions when selecting new equipment, and it will give you a solid foundation for making efficiency improvements to existing cooling systems.

How Compression Cooling Works

All contemporary space cooling and process cooling equipment exploits the fact that a liquid absorbs heat when it evaporates. (There are a few exceptions, which are limited to unusual applications.) A liquid used for cooling is called a "refrigerant." The energy absorbed by the refrigerant in changing from a liquid to a vapor is called its "latent heat." When this heat is drawn from a body, the body is cooled. For a good demonstration

of this, swab some alcohol on your arm. The wet spot will chill your skin until it all evaporates.

You can create cooling without any machinery if you have enough liquid to evaporate. Water has been used for cooling since before the dawn of humanity. However, it is not very satisfactory as a coolant under ambient conditions because it evaporates too slowly. There are many liquids that provide a large evaporative cooling effect, but they are not cheap enough to be used on a once-through basis.

Mechanical cooling can use more effective refrigerants and recycle them indefinitely. The process of doing this is called a "cooling cycle." The outer shell or casing of the cooling equipment serves as a pressure vessel, isolating the refrigerant from air and atmospheric pressure. This allows the cooling cycle to operate under conditions that provide the greatest cooling capacity and efficiency from the refrigerant.

The most common kind of cooling equipment uses a compression cooling cycle. After the refrigerant has been evaporated by heat from the cooling load, the vapor is compressed. This raises the temperature of the gas well above ambient temperature, so that the heat in the gas can be removed by cooling it with air or water at ambient temperature. Removing the heat causes the compressed gas to condense back to a warm liquid.

The warm refrigerant liquid from the condenser is metered into the cooling area (evaporator) by a flow control device of some kind. The pressure in the evaporator is determined by the suction of the compressor and by the rate of evaporation. Because the

evaporator pressure is lower than the condenser pressure, a small portion of the liquid refrigerant “flashes” into vapor when it passes through the control device. This flashing cools the remaining liquid to the temperature of the evaporator. The liquid refrigerant is now ready to absorb heat from the cooling load, repeating the cycle.

Refrigerants

Nowadays, selecting the refrigerant may be the first choice you make in selecting or designing a cooling system. The choice of refrigerant limits the system’s efficiency and affects the design of all the system hardware. Safety concerns with some refrigerants dictate where the equipment can be located, and how the surrounding space must be designed. Refrigerant selection has recently become more important and complex because of environmental concerns. To learn more about refrigerants and how to select them, see [Reference Note 34](#), Refrigerants.

The Components of a Compression Cooling System

All compression cooling systems have five basic elements. As illustrated by the typical system in Figure 1, they are:

- the **compressor**. On its discharge side, the compressor increases the pressure of the evaporated refrigerant vapor to raise its temperature. On the suction side, the compressor lowers the pressure of the liquid refrigerant, causing the refrigerant to evaporate more rapidly, and at a lower temperature. In most systems, cooling capacity is regulated by varying the output of the compressor. There are several major types of compressors, discussed below.
- the **evaporator**, which is a heat exchanger on the suction side of the compressor. This is where the liquid refrigerant evaporates to do its work. If the machine is designed to cool air directly, as in Figure 1, the evaporator is an air coil. If the machine is designed to cool liquid, the evaporator typically is a tube-and-shell heat exchanger. (A cooling machine that is designed to deliver cooling by means of a liquid is commonly called a “liquid chiller,” or simply a “chiller.”)
- the **condenser**, which is a heat exchanger on the discharge side of the compressor. The high-pressure refrigerant gas from the compressor is cooled in the condenser so that it returns to a liquid state. If

Carrier Corporation

Fig. 1 The elements of a compression cooling system In this system, the evaporator is the coil in the fan-coil unit. An expansion valve, installed on the side of the fan-coil unit, serves as a refrigerant metering device. The condenser is an air coil on the outside of the building. The system does not have a distinct refrigerant accumulator, but the bottom of the condenser coil and the refrigerant liquid pipe serve this function.

the cooling medium is air, the condenser is an air coil. If the cooling medium is water, the condenser is usually a tube-and-shell heat exchanger, or sometimes a coaxial tube heat exchanger.

- an **accumulator** or **receiver**, which is a reservoir that holds the liquid refrigerant until it is needed. Many cooling systems do not have a separate accumulator, instead depending on the volume of the condenser, evaporator, and/or refrigerant lines to hold the liquid refrigerant. For example, packaged water chillers typically use the evaporator shell as the liquid storage vessel. In Figure 1, the bottom of the condenser coil and the liquid discharge line act as the accumulator.
- a device or combination of devices for **separating the high-pressure side of the system (condenser) from the low-pressure side (evaporator)** and, in some systems, for **metering the flow of refrigerant into the evaporator**. The device keeps the hot refrigerant gas from blasting through the condenser

coil, and it maintains the discharge pressure that is necessary for condensing the refrigerant. In most liquid chillers, a simple **orifice** or **float valve** between the condenser and the evaporator serves this purpose. If the evaporator is partially wetted, rather than flooded, the flow of refrigerant into the evaporator is controlled by a metering device called an **expansion valve**. Most air coils and some water-cooled evaporators use expansion valves. A recent development is the use of a small **turbine** to act as a metering device. This design recovers energy from the pressure difference that exists between the condenser and evaporator.

A compression cooling system may also have accessory devices or specialized features, such as crankcase heaters, purge units, hot gas bypass circuits, valves for controlling the flow of refrigerant to different parts of a coil, etc. Most of these accessories are specific to particular types, models, or system designs.

Trane Company

Fig. 2 Packaged water chiller The machine packages all the primary elements of a cooling system together. This model has a three-stage centrifugal compressor. The cooling output of the machine is controlled by throttling the flow of gas into the compressor with an inlet vortex damper. The evaporator, at bottom, is flooded with refrigerant. Tubes for chilling water are immersed in the refrigerant. The refrigerant evaporates under the reduced pressure of the compressor suction, chilling the water. The vapor is compressed to a hot gas by the compressor, and is discharged to the condenser in the rear. Cool water from a cooling tower flows through the tubes in the condenser, absorbing heat from the hot gas and condensing it. The warm refrigerant liquid drops down into the evaporator through an orifice. Upon exposure to the lower pressure in the evaporator, a portion of the warm refrigerant liquid evaporates, cooling the remaining liquid to the saturation temperature that corresponds to the evaporator pressure. The cycle continues as long as the compressor runs.

System Layouts

The five elements of a compression cooling system can be grouped in a variety of ways. You can find virtually all possible combinations in practice.

For example, Figure 1 shows a common arrangement where the compressor is located in the basement, an air-cooled condenser and accumulator is installed on the roof, and air coils with their expansion valves are installed on each floor.

In the popular “split system,” the compressor is packaged with the condenser outside the building, and liquid refrigerant is piped to air coils or to a water chilling evaporator inside the building. This keeps the noisiest equipment outside the building.

Large water chillers generally include all their components in a compact package that is assembled at the factory. Figure 2 shows a typical packaged water chiller. Such packaging is becoming increasingly common in smaller systems as well. On the other hand, a cooling system may distribute its components throughout the facility.

If a system distributes its cooling by means of chilled water, this is called “hydronic” distribution. If liquid refrigerant is evaporated inside an air cooling coil, this is called “direct expansion” or “DX.”

Larger systems generally use water for condenser cooling, because this allows the condensing temperature to be reduced by evaporative cooling of the water in a cooling tower. Smaller systems, and systems used in locations where the supply of water is limited, may reject heat directly to the outside air through an air coil that is called an “air-cooled condenser.” A compressor that is packaged with an air-cooled condenser is called an “air-cooled condensing unit.” An intermediate approach is spraying water over a condensing coil that is cooled by air flow. This arrangement is called an “evaporative condenser.”

The Effect of Operating Temperatures on COP

The amount of power needed by the compressor depends on the difference in pressure between the compressor inlet (from the evaporator) and outlet (to the condenser). You know from basic chemistry that the temperature of a gas is proportional to its pressure. Therefore, we can express the power needed to compress the refrigerant vapor in terms of the difference between the evaporator and condenser temperatures.

This is a useful way of looking at compressor power, because the evaporator and condenser temperatures are determined largely by factors that are under the control of the equipment manufacturer, the system designer, and the plant operator. These factors are discussed below. But first, we need to understand the relationship between system temperatures and COP. If you need an explanation of COP, see [Reference Note 31](#), How Cooling Efficiency is Expressed.

Maximum Theoretical COP

In 1824, the French engineer Sadi Carnot developed an analysis of compression cycles that allows their theoretical maximum efficiency to be expressed in terms of temperature alone. Carnot found that the maximum possible COP of a compression cooling machine is determined by this remarkably simple formula:

$$\text{Ideal COP} = \frac{\text{lowest temperature}}{(\text{highest temperature}) - (\text{lowest temperature})}$$

In this formula, the temperatures are absolute. You can use any system of absolute temperature units in this formula because the units cancel. (The Rankine absolute scale equals Fahrenheit plus 460°F. The Kelvin absolute scale equals Celsius plus 273°C.)

The lowest temperature in the system occurs at the compressor inlet. The highest temperature occurs at the compressor discharge. These temperatures are not fixed by the compressor. Instead, they are imposed on the compressor by the cooling application, by the

Fig. 3 The effect of system temperatures on COP The top curve shows the theoretical maximum COP that is possible, which is determined solely by the system temperatures. The second curve shows the efficiency loss related to a highly efficient real refrigerant. The bottom two curves show the COP's of real cooling machines with the same refrigerant.

temperature of the environment to which the heat is rejected, and by many system design factors.

This formula reveals the crucial role of the evaporator-to-condenser temperature differential in system efficiency. Cooling equipment moves heat from one place to another. The energy input to a cooling system is needed to overcome the “resistance” of the temperature differential. This viewpoint is evoked by the term “heat pump,” which is used when a cooling machine is turned around to make it a heating device rather than a cooling device.

In Figure 3, the top curve shows the maximum theoretical COP’s that can be achieved with an ideal cooling machine and an ideal refrigerant. This curve is calculated using Carnot’s formula, assuming a cooling temperature of 40°F and a typical range of condensing temperatures.

■ The COP of an Ideal Machine with Real Refrigerants

In Figure 3, the second curve shows the COP’s that would be achieved by an ideal cooling machine using HCFC-22 as a refrigerant. The curve assumes a cooling temperature of 40°F and a typical range of condensing temperatures. HCFC-22 (originally called Freon-22) is the most common refrigerant at present, and it is one of the most efficient.

This curve shows that some real refrigerants can approach the theoretical maximum COP. However, there is wide variation in efficiency among different refrigerants. The theoretical COP’s of the most popular refrigerants are tabulated in [Reference Note 34, Refrigerants](#).

■ The COP of Real Systems with Real Refrigerants

In Figure 3, the bottom two curves show the manufacturer’s COP ratings for two typical chillers, both using HCFC-22 refrigerant. As with the other curves, the cooling temperature is 40°F.

These two curves show that the COP’s of real machines are considerably lower than the theoretical maximum, even accounting for limitations in the refrigerants. The losses are caused by mechanical inefficiencies in the compressor, by inefficiencies in the compression process, by energy waste in the expansion of refrigerant when it returns to the evaporator, and by heat transfer losses within the system. There is potential for improvement in all these areas.

The two curves also show that there is a considerable difference in COP between screw compressor machines and reciprocating machines. The COP of a good centrifugal machine would be somewhat higher than the COP of the screw machine.

Condensing temperatures below 75°F are not shown for the two real machines, because various design features keep them from operating with lower condensing temperatures.

The System Temperature Differential is Much Larger than the Cooling Load Temperature Differential

The temperature differential between evaporator and condenser is generally much higher than the temperature differential of the actual cooling load. This is a matter of great concern, because the temperature differential is the underlying theoretical factor that limits COP. As a realistic example of how the temperature differential builds up, consider the example of an air-cooled water chiller used for air conditioning. The temperatures throughout the system are depicted in Figure 4.

An air-cooled system was selected for this example to avoid the complications of temperature changes in cooling towers, which are really supplementary cooling systems. Other thermal complications, especially evaporator superheat, condensate subcooling, and interstage heat exchange, are discussed below. The illustration ignores small losses, such as the rise in chilled water temperature in the distribution system.

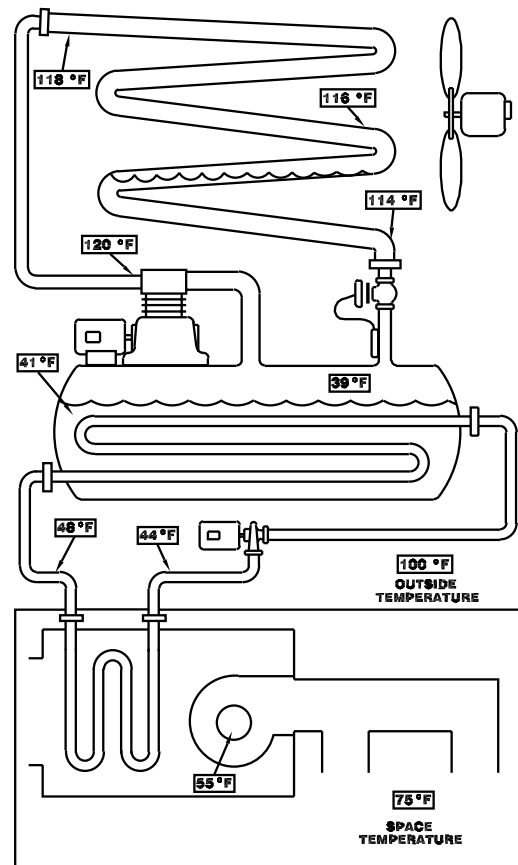

Fig. 4 The compressor temperature differential is much higher than the cooling load temperature differential In this example, the outside-to-inside temperature differential is only 25 degrees. Yet, the temperature differential on the compressor, which determines the system energy requirement, is 81 degrees! Of the excess, the evaporator side, including hydronics, accounts for 9 degrees; the condenser side accounts for 20 degrees; and, the air distribution system accounts for 27 degrees.

In this example, the original 25°F temperature differential created by the weather becomes an 81°F differential at the compressor! This has the effect of reducing the theoretical COP from 21.4 to 6.2, an enormous loss of efficiency. The COP of the actual chiller is reduced by roughly the same ratio.

Figure 4 shows that the compressor discharge temperature is determined primarily by the outside air temperature. However, the compressor suction temperature is much lower than the inside air temperature. This is mostly because of heat transfer losses in the cooling system and in the air handling system. Indeed, most of the temperature loss in this example occurs in the air handling systems.

This example illustrates an important point, namely, that *cooling system efficiency is determined largely by factors outside the design of the cooling equipment. Much of the waste in a typical cooling system occurs because the compressor must operate at a higher temperature (or pressure) differential than necessary.* The struggle to achieve better cooling efficiency is largely a war against temperature differential that is fought in many parts of the system.

Fig. 5 The effect of system temperatures on capacity. Increasing the temperature differential across a cooling machine reduces its capacity. The effect is important in typical applications. It varies with the type of compressor.

Reducing the temperature differential in air handling systems is accomplished by various Measures in Section 4. Increasing chilled water temperature and lowering condenser temperature is accomplished in Subsection 2.2. Reducing the temperature differentials inside the cooling system itself is a matter of selecting the best design options, which are explained below.

The greatest potential for reducing the system temperature differentials occurs during off-peak periods, when the system temperature differentials may be much larger than needed to satisfy the load.

The Effect of Operating Temperatures on System Capacity

The cooling system must overcome a temperature differential that resists the flow of heat. Reducing the temperature differential increases the cooling capacity of the system. This effect is dramatic. Figure 5 shows the loss of capacity for two typical machines, one with a reciprocating compressor and the other with a centrifugal compressor.

Conversely, by reducing the system temperature differentials that occur under peak load conditions, you can reduce the nominal capacity of the equipment that you need to buy for new installations. You do this by spending more money for larger heat exchangers, and by designing air distribution systems for more efficient flow. This extra cost is partially offset because the increased efficiency allows smaller compressors to satisfy the load.

The change in cooling capacity with temperature differential varies substantially among different types of compressors. Centrifugal compressors suffer more capacity loss than other types. This is because the gas is driven through the compressor only by its own centrifugal force. As the condenser temperature increases, this force is counteracted by the greater pressure in the condenser.

In contrast, positive displacement compressors push the gas through the machine without regard to the temperature differential. The cooling capacity of compressors with a fixed compression ratio, such as screw compressors, is affected least. This is because the refrigerant gas is isolated from the discharge pressure during the compression process.

The Compressor and System Efficiency

In a compression cooling machine, most of the input energy goes to compressing the refrigerant gas to make it liquify. Therefore, the design of the compressor and other aspects of the compression process play a large role in the system's efficiency. The following are the major factors that determine the efficiency of the compression process.

■ The Refrigerant

Until about 1990, it was possible to read a cooling equipment catalog without finding any mention of the refrigerant used by the equipment. That situation has reversed because of environmental concerns about refrigerants, so that the choice of refrigerant may be the first consideration in selecting a compressor. As discussed previously, the choice of refrigerant limits the potential system efficiency.

With respect to the system hardware, the refrigerant affects the system pressures, the types of metals that can be used, the handling of lubricants inside and outside the compressor, safety features, and other equipment selection considerations. See [Reference Note 34](#) for more about these issues.

■ Efficiency of Gas Flow in the Compressor

Refrigerant vapor has mass, so it has kinetic energy. If the flow through the compressor is turbulent, a portion of this energy is wasted by converting it to heat energy. Reciprocating compressors unavoidably generate a large amount of turbulence as a result of the oscillating piston motion. In contrast, the other major types of compressors have smoother gas flow.

In order to achieve ideal thermodynamic efficiency, a compressor would have to provide the minimum power at each incremental stage of compression. No type of compressor is perfect in this regard. For example, efficient compression is achieved in a centrifugal compressor by careful attention to the shape of the impeller and diffuser, but this shape achieves maximum efficiency only at one refrigerant flow rate.

Any leakage within a compressor wastes compressor energy by allowing compressed gas to re-expand uselessly. Leakage occurs around the piston rings of a reciprocating compressor, around the impeller of a centrifugal compressor, between the scrolls of a scroll compressor, and between the rotors and casing of a screw compressor. Minimizing leakage is a challenge in all types of compressors.

All types of positive-displacement compressors suffer re-expansion as a result of “clearance volume”, which is the volume of gas left to re-expand at the end of the compression process. This problem is most severe with reciprocating compressors, which leave a significant amount of compressed gas in the cylinder at the top of the piston stroke. After the exhaust valve closes, the remaining gas expands in the first part of the suction stroke. The energy consumed to compress this gas is wasted.

■ Interstage Heat Transfer

When a gas is compressed, the heat of compression creates an expansion force that opposes the compression and increases compressor power. In an ideal compressor, the heat of compression would be removed as the gas is compressed. (If you are interested in the theory, this

corresponds to the isothermal compression phase of the Carnot cycle.) Unfortunately, no conventional compressor design allows the gas to be cooled continuously during compression.

If the compressor has more than one stage, heat can be removed between the stages. Unfortunately, the interstage cooling cannot be done with ambient air or domestic water, because the heat exchange process occurs at low temperature. The compression process starts with a cold refrigerant gas and never gets very hot. The cooling is usually done by taking some liquid refrigerant from the condenser at high pressure, flashing it at a reduced pressure to get cool vapor, and injecting this vapor into the compressor between the stages. The mass of the added refrigerant also increases the cooling capacity.

The general technique of lowering gas temperature and/or increasing mass flow between stages is called an “economizer.” (The same name is given to efficiency measures in other types of equipment, including absorption chillers, boilers, and air handling units). The

Carrier Corporation

Fig. 6 Interstage heat transfer in a screw compressor system A portion of the liquid refrigerant from the condenser is flashed into gas, which is introduced part way through the compression process. This lowers the average temperature rise in relation to the mass of gas that is compressed, which lowers the average work of compression.

specific technique of using refrigerant flash gas for this purpose is called “flash intercooling.”

With compressors that convey an isolated volume of gas through the compression process, as occurs in screw and scroll compressors, ports can be built into the compressor to inject gas for flash intercooling. Figure 6 shows how an economizer operates with a screw compressor chiller.

Interstage heat transfer produces a significant efficiency gain only if the compressor has a fairly high compression ratio. In this case, the heat of compression adds substantially to the gas pressure, increasing the work required from the compressor.

■ Fixed or Variable Compression Ratio

If the compressor discharge is open to the condenser as the compression is taking place, then the discharge pressure never exceeds the pressure needed to condense the refrigerant (except for a small expansion loss between the compressor and condenser). The leading examples of such compressors are the centrifugal and reciprocating types. In such compressors, the compression ratio adjusts itself to the needs of the system.

On the other hand, some compressors work by trapping a volume of gas and then compressing this amount independently of the condenser pressure. The gas is released to the condenser only near the end of the compression process. This is true of some screw compressors and most scroll compressors, and of some other types, such as vane compressors.

If the compressor discharge pressure exceeds the condenser pressure, then a fraction of the compression energy is wasted in compressing the gas more than necessary. On the other hand, if the compressor discharge pressure is lower than the desired condenser pressure, the condenser is not able to condense the gas at higher coolant temperatures. Therefore, systems using compressors with fixed compression ratios always err on the side of excess discharge pressure, which wastes energy at reduced loads.

The compression ratio corresponds to a ratio of temperatures between the evaporator and the condenser. Therefore, energy conservation measures that attempt to improve efficiency by raising the evaporator temperature or lowering the condenser temperature are less effective with compressors having fixed compression ratios.

■ Efficiency of Output Modulation

In all common types of cooling machines, the method used to throttle output is an integral part of the compressor, and may account for much of its efficiency limitations. Some compressors that are efficient at high load become inefficient at low loads. Some compressors cannot operate at all below some minimum load.

In typical applications, cooling systems operate over a wide range of loads, with full-load operation being an exception that occurs mostly on start-up. Many older cooling plants were designed at a time when manufacturers did not stress part-load efficiency, and these commonly provide major opportunities for improving efficiency by substituting machines that respond more efficiently to partial loads.

Losses in throttling output are most severe in centrifugal compressors. In the past, economies of scale led to decisions to cool a facility with one or two large centrifugal machines, but this configuration is wasteful at low loads. To increase part-load efficiency, you need to use a larger number of smaller machines, or to use different types of compressors, perhaps in combination with centrifugal machines. Improving part-load efficiency in an existing plant may require installing an additional, smaller machine to serve low loads. ([Measure 2.8.1](#) recommends this technique.)

Reciprocating compressors retain their efficiency fairly well at lower loads, although part-load efficiency varies among different models. Smaller reciprocating compressors usually operate in an on-off mode, so they suffer efficiency loss only during the start of each cycle, while refrigerant flow in the system is stabilizing.

Scroll compressors usually operate in an on-off mode, so the efficiency of capacity reduction is not a factor. Other methods of modulation are being developed for scroll compressors, as discussed below. The efficiency performance of modulating scroll compressors is not yet well documented.

■ Limitations in Reducing Condenser Temperature

The previous discussion emphasized the importance of keeping condenser temperature as low as possible. With some compressors, the condensing temperature must be kept above a certain level. In such cases, the condenser temperature is kept artificially high by choking off the air or water that cools the condenser. This wastes energy in applications where the system may operate during cooler weather.

There are several reasons why a system may require an elevated condenser temperature. In some cases, the compressor is the limiting factor, because high condensing temperature may be needed to prevent migration of lubricants away from the compressor. More commonly, high condensing temperature may be needed for reasons not related to the compressor, such as maintaining adequate pressure for operation of an expansion valve or capillary refrigerant distributors. Other reasons are given in [Measure 2.2.2](#).

Types of Compressors and Throttling Methods

The following are the efficiency characteristics of the most common types of cooling compressors. One of the most important efficiency characteristics is the method used by the compressor to reduce its output.

■ Centrifugal Compressors

Centrifugal compressors are the most efficient type when they are operating near full load. Their efficiency advantage is greatest in large sizes, and they offer considerable economy of scale, so they dominate the market for large chillers. They are able to use a wide range of refrigerants efficiently, so they will probably continue to be the dominant type in large sizes. The peak efficiency of centrifugal compressors has improved dramatically and progressively since about 1980, and several major improvements to part-load efficiency have been made in that time.

Centrifugal compressors have a single major moving part, an impeller that compresses the refrigerant gas by centrifugal force. The gas is given kinetic energy as it flows through the impeller. This kinetic energy is not useful in itself, so it must be converted to pressure energy. This is done by allowing the gas to slow down smoothly in a stationary diffuser surrounding the impeller.

Figure 7 is a detailed drawing of a centrifugal compressor that has two impellers on the same shaft, for two stages of compression. The impeller speed is increased by using a gear train between the motor and the impellers.

Figure 2 shows a centrifugal compressor that has three impellers, for three stages of compression. The impellers are driven directly by an electric motor, which limits the rotation speed. Three stages are needed to achieve the needed condensing pressure with the particular refrigerant that is used in this machine. Using a large impeller diameter also compensates for the low rotation speed.

Figure 8 shows a centrifugal chiller in which the compressor has only a single, relatively small impeller. The motor speed is limited by the line frequency, so this machine uses gears to increase the impeller speed.

High energy efficiency in a centrifugal compressor requires efficient gas flow through the impeller and the diffuser. Unfortunately, the design of the impeller and

Carrier Corporation

Fig. 7 Centrifugal compressor with internal motor This model has two impellers on a common shaft, providing two stages of compression. To further increase compression, the impeller speed is increased by gears. Typical of most centrifugal compressors, the output of the machine is adjusted by throttling the flow of gas into the first stage using pre-rotation inlet vanes.

diffuser can be optimized for only one gas flow rate. To minimize efficiency loss at reduced loads, centrifugal compressors typically throttle output with pre-rotation vanes (inlet guide vanes) located at the inlet to the impeller(s). This method is efficient down to about half load, but the efficiency of this method decays rapidly below half load.

Older centrifugal machines are not able to reduce load much below 50%. This is because of “surge” in the impeller. As the flow through the impeller is choked off, the gas does not acquire enough energy to overcome the discharge pressure. Flow drops abruptly at this point, and an oscillation begins as the gas flutters back and forth in the impeller. Efficiency drops abruptly, and the resulting vibration can damage the machine.

Many older centrifugal machines deal with low loads by creating a false load on the system, such as by using hot gas bypass. This wastes the portion of the cooling output that is not required.

To improve both turndown range and low-load efficiency, some machines use two separate centrifugal compressors. The two compressors share a common condenser shell and a common evaporator shell. Figure 9 shows this approach used with a large chiller.

Another approach is to use variable-speed drives in combination with inlet guide vanes. This may allow the compressor to throttle down to about 20% of full load, or less, without false loading. Changing the impeller speed causes a departure from optimum performance, so efficiency still declines badly at low loads.

A compressor that uses a variable-speed drive reduces its output in the range between full load and approximately half load by slowing the impeller speed. At lower loads, the impeller cannot be slowed further, because the discharge pressure would become too low to condense the refrigerant. Below the minimum load provided by the variable-speed drive, inlet guide vanes are used to provide further capacity reduction.

Fig. 8 Packaged centrifugal water chiller Details and accessories vary from one model to another, and from one manufacturer to another. Here, the flash chamber provides cool gas for motor cooling and oil cooling. This compressor has only a single stage, so an economizer is not possible.

Carrier Corporation

Trane Company

Fig. 9 A large water chiller with two centrifugal compressors This is one way of maintaining efficiency at reduced cooling loads.

Unlike positive-displacement compressors, which are not subject to surge, the minimum load of a centrifugal compressor is sensitive to the evaporator and condensing temperatures. Raising the evaporator temperature and lowering the condenser temperature reduce the tendency to surge, and hence reduce the minimum load. The minimum load of an individual centrifugal machine varies widely, depending on these temperatures.

It is not advisable to turn a centrifugal compressor on and off to deal with low loads. Most centrifugal compressors use journal bearings, which are not positively lubricated until the shaft reaches a certain speed. Refrigerant flow within the machine may require several minutes to stabilize after each start-up. The types of motors used to drive centrifugal machines are more likely to overheat with frequent start cycles. And, the gears in gear-driven compressors are subjected to high stress on start-up.

The pressure output of a centrifugal compressor depends on the diameter and speed of the impeller(s). Refrigerants that have low condensing pressures can be compressed with a centrifugal machine that is driven directly from a 50 Hz or 60 Hz motor. Gases that require higher pressures require the compressor to have speed increasing gears, or several stages of compression (several impellers), or both.

For a given refrigerant, the equipment designer can choose to increase the number of stages of compression, while reducing the impeller speed and diameter. Using several stages allows an economizer (described previously) to be used between each stage. The theoretical efficiency improvement becomes smaller with each additional stage, and flow losses accumulate at the inlet and outlet of each impeller, so there is an optimum number of stages for each refrigerant. Increasing the number of stages increases cost and complexity.

Increasing the impeller speed by using gears incurs losses in the gears and in the additional bearings. It also eliminates the opportunity of exploiting interstage heat transfer.

■ Reciprocating Compressors

Reciprocating compressors are the oldest type, and they continue to be the dominant type in the small and medium size range. Figure 10 shows a typical unit.

In principle, reciprocating compressors can be designed for virtually any refrigerant. In practice, they are most economical for refrigerants that operate at medium and high pressures, because the higher gas densities provide more refrigeration effect for a machine of a given size.

The maximum efficiency of reciprocating compressors is lower than that of centrifugal and screw compressors. Efficiency is reduced by clearance volume (the compressed gas volume that is left at the top of the piston stroke), throttling losses at the intake and discharge valves, abrupt changes in gas flow, and friction. Also, reciprocating compressors tend to be used with systems having expansion valves, which are somewhat less efficient than the fluid metering methods used in larger systems. Lower efficiency also results from the smaller sizes of reciprocating units, because motor losses and friction account for a larger fraction of energy input in smaller systems.

For most air conditioning applications, reciprocating compressors can easily compress the refrigerant gas in a single stage, so there is no opportunity for improving the theoretical efficiency of compression by using an economizer (described previously). However, multiple stages of compression are commonly used in low-temperature refrigeration, and compression efficiency can be improved by using economizers in those applications.

Reciprocating compressors suffer less efficiency loss at partial loads than other types, and they may actually have a higher absolute efficiency at low loads

Trane Company

Fig. 10 Reciprocating compressor Capacity is controlled by disabling individual cylinders, which can be done in several ways, or by varying the speed. The large springs allow the cylinder heads to lift if liquid refrigerant enters the cylinders, avoiding destruction. This type of enclosure, with an internal motor and bolted access plates, is called "semi-hermetic."

than the other types. Smaller reciprocating compressors control output by turning on and off. This eliminates all part-load losses, except for a short period of inefficient operation when the machine starts.

Larger multi-cylinder reciprocating compressors commonly reduce output by disabling (“unloading”) individual cylinders. When the load falls to the point that even one cylinder provides too much capacity, the machine turns off.

Several methods of cylinder unloading are used, and they differ in efficiency. The most common is holding open the intake valves of the unloaded cylinders. This eliminates most of the work of compression, but a small amount of power is still wasted in pumping refrigerant gas to-and-fro through the unloaded cylinders. Another method is blocking gas flow to the unloaded cylinders, which is called “suction cutoff.”

If a multi-cylinder reciprocating compressor can reduce its capacity by more than 50%, a significant amount of additional complication is required to provide stable refrigerant flow through expansion valves, to avoid coil frosting, to achieve proper return of lubricating oil to the compressor, etc. For this reason, the trend in larger reciprocating systems is to use multiple compressors with independent refrigerant circuits, with each compressor unloading no more than 50% (i.e., in two steps of capacity).

Variable-speed drives can be used with reciprocating compressors, eliminating the complications of cylinder unloading. This method has not become popular yet, probably because the attention of designers is now focussed on newer types of compressors. Automotive air conditioning compressors, which are driven directly by the engine, operate successfully over a wide range of speeds.

■ Screw Compressors

Screw compressors, sometimes called “helical rotary” compressors, compress refrigerant by trapping it in the “threads” of a rotating screw-shaped rotor. There are two types of screw compressors, twin-screw and single-screw. At present, the twin-screw version is the most common.

In the twin-screw compressor, the refrigerant is pinched between the lobes (raised portions) and flutes (recessed portions) of two parallel mating screw rotors. Figure 11 is a cutaway drawing of a typical twin-screw compressor.

Figure 12 is a cutaway drawing of a chiller that uses a twin-screw compressor.

In single-screw compressors, the refrigerant is pinched between the threads of a single helical rotor and one or two star-shaped rotors (called “gaterotors”) that rotate at right angles to the main rotor and mesh

Fig. 11 Twin-screw compressor The two helical rotors mesh, squeezing gas from the rear toward the front. The capacity control slide valve, 9, is a movable part of the housing that surrounds the rotors. By sliding away from the rest of the housing, it creates a gap of variable size that disables the adjacent portion of the rotors.

Carrier Corporation

with the helix, like pinions being driven by a worm gear. The only purpose of the gaterotors is to block flow through the threads. They are idlers, and play no part in moving the gas.

Screw compressors have been used for a long time as low-pressure air compressors and engine superchargers, but leakage between the screws has made these units too inefficient for refrigeration work until

the 1980's. At that time, improved machining technology made it possible to achieve the close tolerances that are necessary for good efficiency, and improved designs reduced other efficiency losses. Now, the best screw compressors are significantly more efficient than reciprocating compressors at all loads, and they may be more efficient than centrifugal compressors at low loads.

Fig. 12 Chiller with twin-screw compressor Refrigerant gas enters the near end of the screw from the evaporator, in the lower rear. After a short passage through the rotors, the compressed gas is discharged into the condenser. The valves under the condenser flash liquid refrigerant for motor cooling, and perhaps, for an economizer.

Trane Company

Screw compressors have increasingly taken over from reciprocating compressors of medium sizes and large sizes, and they have even entered the size domain of centrifugal machines.

Screw compressors are applicable to refrigerants that have higher condensing pressures, such as HCFC-22 and ammonia. They are especially compact. The practical upper limit of screw compressor size is determined by competition from centrifugal machines, which offer greater efficiency in larger sizes. However, it may turn out that screw compressors are better able to exploit the efficiency potential of their refrigerants, especially in applications with high temperature differentials (such as making ice), so screw compressors may prove to have no economical upper size limit. The lower limit of size is determined by price competition from reciprocating compressors and other types.

A major distinction between screw compressors is whether the unit operates with or without oil injection into the rotors. Oil is used to cool the refrigerant as it is compressed, reducing the work of compression and improving cycle efficiency. It also seals the leakage paths, allowing the compressor to operate efficiently at lower speeds. The oil typically takes up less than one percent of the compression volume.

In twin-screw compressors, the oil serves as a lubricant between the rotors, allowing one rotor to drive the other by direct contact. Rotor wear is small in this drive arrangement because the shape of the rotors is designed to mesh them with a rolling contact.

The oil is cooled in an oil cooler to get rid of the heat of compression. Cooling may be provided by any available cooling medium, including condenser water,

Carrier Corporation

Fig. 13 What is all that stuff? Screw compressor cooling machines have some large accessories. Note the size of the oil separator, 14. Other models have equally large suction filters to protect the narrow clearances of the rotors from debris in the refrigerant system.

ambient air, refrigerant, or chilled water. Cooling the oil with refrigerant or chilled water reduces the overall system efficiency, so avoid these methods of oil cooling.

Oil-injected compressors also require an oil separator to remove oil from refrigerant after it leaves the compressor. The oil separator presents some resistance to the flow of refrigerant gas on the discharge side, so it adds an efficiency penalty. Also, it typically is larger than the compressor itself. Figure 13 shows a screw compressor chiller with all its accessories, including the large oil separator.

Some screw compressors have another large accessory, a suction filter. This protects the compressor, which has very close tolerances, from any debris that travels through the refrigerant system, such as pieces of solder, motor insulation, etc.

In twin-screw compressors without oil injection, clearance between the two rotors is maintained by driving them through meshed gears. This increases cost, size, and maintenance requirements. Dry compressors must operate at high speed to minimize leakage of gas between the rotors, which increases noise. Since there is no oil to seal the gaps, more elaborate mechanical seals are required. On the positive side, no oil separator or oil cooler is needed.

Single-screw compressors may also operate with or without oil injection. In machines that do not inject oil, liquid refrigerant may be injected into the rotor, achieving both sealing and improved mass flow. These compressors can operate with minimal lubrication because the gaterotors are made of a compliant plastic material that provides tight sealing against the main rotor.

A variety of methods are used to control the output of screw compressors. There are major efficiency differences among the different methods. The most common is a slide valve that forms a portion of the housing that surrounds the screws. When the valve slides away from the rest of the housing, it creates a gap that deactivates the adjacent portion of the rotors.

Using a variable-speed drive is another method of capacity control. It is limited to oil-injected compressors, because slowing the speed of a dry compressor would allow excessive internal leakage.

There are other methods of reducing capacity, such as suction throttling, that are inherently less efficient than the previous two.

Screw compressors can achieve a much better turndown ratio than centrifugal compressors, typically down to about 10% of full load. Screw machines tolerate frequent on-off cycling for low-load operation, as with reciprocating machines. This avoids the temptation to create false loads to keep the machine running.

The basic screw compressor has a fixed compression ratio, which has efficiency limitations discussed

previously. To minimize this problem, some screw compressors have a variable compression ratio. This is achieved with a variable discharge port that taps the compressed gas from different areas near the discharge end of the rotor(s). The most common form is a slide valve. The mechanism for this slide valve is sometimes combined with the inlet slide valve that controls compressor capacity.

The efficiency of single-screw and twin-screw compressors can be improved by flashing some liquid refrigerant and injecting the cool refrigerant gas into the rotor at a point downstream of the primary suction port. This feature is called an “economizer,” and it is described above.

Don’t confuse the economizer process with injecting liquid refrigerant into oil-injected compressors to cool the oil. The latter function has an efficiency penalty, because the oil heat adds to the cooling load.

Trane Company

Fig. 14 Scroll compressor The compressor itself occupies the upper third of the case. The rest is the motor.

■ Scroll Compressors

The scroll compressor is an old invention that has finally come to market. Figure 14 shows a typical unit.

The gas is compressed between two scroll-shaped vanes, shown in Figure 15. One of the vanes is fixed, and the other moves within it. The moving vane does not rotate, but its center revolves with respect to the center of the fixed vane, as shown in Figure 16. This motion squeezes the refrigerant gas along a spiral path, from the outside of the vanes toward the center, where the discharge port is located. The compressor has only two moving parts, the moving vane and a shaft with an off-center crank to drive the moving vane.

Scroll compressors have only recently become practical, because close machining tolerances are needed to prevent leakage between the vanes, and between the vanes and the casing. A variety of designs are used to achieve good sealing, including oil flooding and pressure-loaded sliding contacts between the scrolls.

Trane Company

Fig. 15 The parts of a scroll compressor The top scroll is fixed. The bottom scroll moves within the fixed scroll. It does not rotate, but moves with an eccentric motion that squeezes the refrigerant gas from the outside of the spiral toward the center, as shown in Figure 16. The slot on the side of the lower scroll engages a fixed pin that keeps it from rotating. In back is the drive shaft for the moving scroll, with a counterbalanced eccentric drive at the bottom. The performance of the compressor is dependent on very accurate machining of the scrolls.

Scroll compressors promise good efficiency because of their smooth gas flow. Unlike the gas flow in a reciprocating compressor, the gas moves through a screw compressor in only one direction, from the inlet port toward the outlet port. The absence of reversing gas flow greatly reduces the variation of motor torque during the compression cycle, as shown in Figure 17. This promises reduced vibration and noise.

Scroll compressors have a fixed compression ratio, which has efficiency limitations discussed previously. If they prove to be satisfactory, they seem likely to become prominent at the low end of the system size range.

Like other small compressors, scroll compressors usually control output by turning on and off. Variable capacity can be achieved by using several compressors. Electronic variable-speed drives have been used on some scroll compressors, but this method of capacity control is expensive in small sizes. Another method is to open ports that bleed gas from the early (outer) portion of the compression cycle, but this method wastes some energy.

■ Other Compressor Types

Mankind has devoted a great deal of ingenuity to finding ways of compressing gases, resulting in many compressor designs. The most efficient types approach the maximum achievable efficiency, but still leave room for significant improvement. Greater efficiency, reduced cost, reduced maintenance, and lower noise are all factors that may cause a new type of compressor to burst on the scene.

At present, there are no major contenders to displace the previous types, but this could change quickly, as witness the rapid commercialization of screw compressors and scroll compressors after years of dormancy. The best advice is to check the latest developments before selecting a compressor, but make sure that a model is well proven before buying it. The potential advantages of novel types are too small to justify reliability risks.

Vane compressors and trochoid compressors are types that have been used in various smaller refrigeration applications, such as residential refrigerators and air conditioners, but not yet in larger cooling systems. They are appealing because of their apparent simplicity, their compactness, and their ability to operate quietly. The major practical problem with both has been sealing.

Vane compressors use a rotor that is located eccentrically in a chamber. Sliding vanes in the rotor create spaces between the rotor and the chamber wall. The volume of these spaces changes as the rotor rotates. Refrigerant gas is drawn into the spaces in the half of the rotation where the size of the spaces is increasing. The gas is compressed as the rotor turns, and is discharged at the point where the spaces are smallest.

Trochoidal compressors are a general type in which a rotor rolls along the inside of a chamber, compressing the gas into pockets formed between the rotor and the chamber wall. (“Trochoid” is the name of a curve that is traced by the perimeter of a rolling circle.) The best known example of a trochoidal device is the Wankel rotary engine, a variant of which has been made into a commercial compressor.

Compressor Drivers

All the energy input to a compression cooling system goes into the compressor driver. This may be an electric motor, a reciprocating engine, a gas turbine, or other machine. Your selection of the compressor driver is a critical factor in efficiency and operation. The following are the most common choices to be made.

Internal vs. External Motors

If the compressor is driven by an electric motor that is located outside the compressor housing, a shaft must penetrate the compressor housing. This type of installation is called an “open drive.” Figure 18 shows a typical open drive.

The motor may also be installed inside the compressor casing, along with all the other moving parts.

Trane Company

Fig. 17 Torque characteristics of scroll and reciprocating compressors The scroll compressor has less torque vibration, largely because the gas does not have to reverse direction in going through compression.

Trane Company

Fig. 16 How a scroll compressor moves The dark scroll is fixed. The light scroll moves within it. The moving scroll does not rotate, but its center moves in a small circle. The effect is to squeeze gas from the outside toward the inside along a spiral path.

If the compressor and motor is totally encapsulated within a welded housing, the compressor is called “hermetic.” True hermetic compressors are found only in smaller sizes. Figure 19 shows a typical example.

If the motor or other components are accessible through bolted access plates, the compressor is properly called “semi-hermetic,” although it is common to call such compressors “hermetic” also. The compressor shown in Figure 10 is semi-hermetic.

Are open or hermetic compressors better? There is no definite answer. Both types work well within their appropriate applications. However, increasing concern about the environmental hazard of certain refrigerants has shifted the balance toward hermetic machines, at least for machines that use harmful refrigerants. The advantages of hermetic systems are:

- **reduced refrigerant leakage.** Installing the motor inside the compressor housing eliminates the shaft penetration, which is the main source of refrigerant loss with open drive compressors. Low leakage is an important advantage if the refrigerant has objectionable environmental properties.
- **motor longevity.** Refrigerant cooling promises long motor life because temperatures are lower, and the coolant is clean. However, all compression refrigerants have some solvent behavior, and they tend to be absorbed by the organic materials used for motor insulation. This may create unexpected problems with newer refrigerants.

Hermetic motors have these disadvantages:

- **reduced cycle efficiency and/or increased condenser size.** The motor of a hermetic compressor may be cooled by cold suction gas from the evaporator, or by liquid refrigerant from the

condenser. In both cases, the motor heat goes into the compression cycle.

For example, the efficiency of the large motors used with centrifugal chillers ranges from 92% to 96%. The remaining percentage becomes motor heat, which reduces the COP of the chiller by about one or two percent.

- **difficult access to the motor for maintenance.** Getting to the motor requires pumping the refrigerant out of the system, and removing the access covers.
- **need to clean out the entire refrigerant system in the event of a motor burnout.** The electric arcing that occurs in an insulation burnout creates corrosive materials from most refrigerants. This requires cleaning out the entire refrigerant side of the cooling system.
- **possible inability to retrofit variable-speed drives.** If a hermetic compressor was originally designed to operate at a constant speed, it may not be possible to retrofit an electronic variable-speed motor drive. This is because the full motor speed may be needed for proper bearing lubrication and motor cooling.

WESINC

Fig. 18 Compressor with open drive An important disadvantage of this arrangement is leakage of refrigerant around the drive shaft. On the other hand, the arrangement has several advantages.

Trane Company

Fig. 19 Hermetic compressor This arrangement virtually eliminates refrigerant leakage. However, it is not practical to repair this type of unit at the site.

■ Motor Efficiency

Motor efficiency is generally not an optional factor with hermetic compressors, where the motors are custom made for the machine. Motors of higher efficiency may be an option with open-drive compressors.

Controlling the compressor output with an electronic variable-frequency motor drive keeps the motor operating more efficiently at partial loads, although there is a small efficiency penalty at high loads. For more about this, see [Reference Note 36](#), Variable-Speed Motors and Drives.

■ Other Types of Drivers

The great majority of compression cooling machines are driven by electric motors, but there are circumstances in which a different source of shaft power may be appropriate. The first refrigeration compressors were driven by reciprocating steam engines. Modern compressors are sometimes driven by diesel engines, natural gas reciprocating engines, gas turbines, and steam turbines.

A decision whether to choose such a drive requires detailed knowledge of the engineering, operating practices, and economics of the drive in question. There may be a temptation to use non-motor drives for “obvious” but illogical reasons. For example, a large urban hospital uses a condensing steam turbine to drive a chiller, apparently because the facility was designed with a high-pressure steam supply for other reasons. The steam turbine drive in this facility is much more expensive to operate than an electric motor would have been.

In general, electric motors combined with variable-frequency drives provide better part-load performance than other types of drives, along with lowest first cost and minimal maintenance requirements. If you are interested in a reciprocating engine drive, you have to find out whether the compressor is vulnerable to the torsional vibrations of the engine drive. This requires a sophisticated analysis of the rotating components by the compressor manufacturer.

Packaged engine-driven cooling machines are available. These are sold primarily as a means of reducing electrical demand during peak load periods.

Evaporators

The design of the evaporator can have a significant effect on system efficiency. We will cover the most common types of evaporators. Then, we will discuss evaporator superheat, which is the most important factor in evaporator efficiency.

■ Flooded Evaporators

Flooded evaporators are used in a large fraction of packaged water chillers, as shown in Figure 2. Chilled water is cooled in tubes that are completely submerged

in liquid refrigerant. This provides complete utilization of the tube surface. The large free surface of the liquid refrigerant is directly exposed to the compressor suction so there is virtually no pressure loss between the evaporation area and the compressor suction.

This arrangement is simple as well as efficient. Liquid refrigerant from the condenser is simply drained back to the evaporator, typically using an orifice or float valve to isolate the evaporator from the pressure of the condenser.

The only significant disadvantage of flooded evaporators is that they require a larger quantity of refrigerant than evaporators where the refrigerant evaporates inside the tubes.

■ Liquid Overfeed Evaporators

In liquid overfeed systems, refrigerant is continuously pumped, or flows by gravity, through any number of evaporators. The evaporators can take any form needed by the application, such as an air coil or a plate ice maker. The name “liquid overfeed” derives from the fact that more liquid refrigerant is fed to each evaporator than evaporates, the excess liquid flowing back to a receiver. The receiver is open to the compressor suction, so the refrigerant liquid is kept at the temperature corresponding to the compressor suction pressure. Thus, each evaporator behaves almost like a flooded evaporator.

The system is flexible, in that it can serve any number and variety of evaporators. The only limitation is that all evaporators must operate at the same pressure, and hence, at the same temperature. Liquid overfeed has generally the same efficiency advantages as a flooded evaporator, except for a minimal energy loss in refrigerant pumping and piping pressure loss. There is no pressure difference between the evaporator receivers and the evaporators, except for any gravity head that may exist as a result of differences between the heights of the evaporators. As a result, the pumping power is minimal.

In addition to the low-pressure receiver for each evaporator, the system generally has a single high-pressure accumulator to allow for fluctuations in the quantity of refrigerant in the evaporators.

Since each evaporator in a liquid overfeed system is kept flooded with refrigerant, there is no way of controlling the evaporating temperature individually. To control the cooling output of each evaporator, it is necessary to throttle the flow of the cooled medium through the evaporator, or to bypass a portion of the cooled medium around the evaporator.

If only a single evaporator is needed, as in a central chiller system, liquid overfeed offers no significant advantage over a flooded evaporator, and it would be unnecessarily complex.

■ Evaporators with Expansion Valves

An expansion valve is an automatic valve for metering the flow of refrigerant into the evaporator. Figure 1 shows where an expansion valve is installed in the system.

Unlike flooded evaporators and liquid overfeed evaporators, the flow of refrigerant into evaporators that use expansion valves is restricted.

The name “expansion valve” is a misnomer. An expansion valve is actually a liquid refrigerant metering device. The only expansion that occurs at the valve itself is a relatively small fraction of the refrigerant that flashes because of the drop in pressure upon entering the evaporator. Most of refrigerant evaporates as a result of absorbing heat inside the evaporator.

Most air coil (DX) evaporators use expansion valves. Many smaller water chilling evaporators use them. Expansion valves limit the amount of refrigerant used in the evaporator to the minimum needed to satisfy the cooling load. This reduces the evaporator size and the refrigerant charge. Expansion valves are the most economical way of serving multiple evaporators in a single system. Compared to liquid overfeed, the piping is smaller and simpler. The main disadvantage of expansion valves is that they reduce the system COP, for reasons discussed below.

Trane Company

Fig. 20 An “electronic” expansion valve This expansion valve minimizes superheat under all load conditions by changing its throttling behavior. The valve receives input signals from a microcomputer that senses system conditions.

Until recently, virtually all expansion valves were set to maintain a constant difference between the temperature of the vapor leaving the evaporator and the temperature of the liquid entering the evaporator. This temperature difference is called “superheat” because it represents sensible heating of the vapor above its saturation temperature after all the liquid is evaporated. Typical superheat ranges from 5°F to 10°F. Using an expansion valve forces the vapor outlet end of the coil to be dry, so this portion of the coil provides only minimal cooling capacity.

Direct-expansion heat exchangers, such as air coils, are commonly divided into many separate refrigerant circuits to increase the effective cooling area. In order to use all the surface most effectively, the refrigerant must be distributed evenly to all the circuits. To do this, thin distributor tubes are installed between the expansion valve and the individual circuits. The distributor tubes all have the same resistance to flow, so refrigerant is distributed uniformly.

An important energy conservation principle is keeping the condenser temperature as low as possible. Unfortunately, using an expansion valve limits this technique during cooler weather, when it is most valuable. The reason is that the condenser pressure must be kept high enough to drive refrigerant through the expansion valve and distributor tubes.

In small cooling equipment, the function of the expansion valve may be performed solely by the distributor tubes, in which case the internal diameter of the distributor tubes is carefully selected so that they provide the proper amount of resistance to isolate the evaporator from the condenser pressure. In such applications, the distributor tubes are called “capillary tubes.” This method cannot accurately control superheat, or prevent liquid refrigerant from getting all the way through the evaporator. Therefore, it may require additional features to protect against liquid entering the compressor, such as using an accumulator at the compressor suction.

“Electronic” expansion valves are an improvement that became widespread during the 1990’s. An electronic expansion valve adapts to changing load conditions, minimizing the superheat at all times. Figure 20 shows an electronic expansion valve.

■ How Evaporator Superheat Reduces COP

In an ideal cooling machine, the liquid refrigerant in the evaporator would be cooled down to the compressor suction temperature. This condition is nearly met in flooded evaporators and in liquid overfeed evaporators. This is because the liquid refrigerant is exposed directly to the compressor suction.

However, if an expansion valve is used to control the flow of refrigerant through an evaporator, all the refrigerant must evaporate before it leaves the evaporator. To ensure that this happens, the evaporator

is oversized in relation to the refrigerant flow. As the refrigerant continues to travel through the evaporator after it has evaporated, it picks up sensible heat, increasing its temperature. The rise in vapor temperature above the evaporation (saturation) temperature is called “superheat.”

Superheat reduces the system COP. To understand this, consider the example of a direct-expansion air coil evaporator that is operating with a constant cooling load. Assume that the superheat is adjustable. Initially, the superheat is set at zero, so the coil is completely filled with evaporating refrigerant. Then, increase the superheat setting. The immediate effect of this is to restrict the flow of refrigerant into the coil. Since the quantity of refrigerant must be constant to satisfy the cooling load, there is a rise in the air temperature. The system controls sense the rise in temperature, and increases the compressor power input to compensate. The greater compressor suction restores the flow of refrigerant through the expansion valve to its former value (less a small amount that accounts for the sensible cooling of the air by the superheated refrigerant vapor).

The increase in compressor power can be expressed in terms of the temperature difference across the compressor. In the previous example, the compressor power increased as the suction pressure dropped, requiring evaporation to occur at a lower temperature. As we discussed earlier, the COP of a cooling system suffers if the temperature differential between the evaporator and the condenser increases.

It is a common belief that superheat improves the efficiency of the machine because the absorption of

sensible heat by the refrigerant provides additional cooling effect. This is not true. The sensible cooling is minor in relation to the increased compressor power required by the lower suction pressure.

Energy Recovery from Refrigerant Expansion

The refrigerant in the condenser is at high pressure and the refrigerant in the evaporator is at low pressure. When refrigerant is released into the evaporator, the reduction of pressure causes a fraction of the refrigerant to flash into vapor. In most large cooling machines, flow from the condenser to the evaporator is regulated by a float valve, a simple orifice, or an expansion valve. With any of these devices, refrigerant flashing is a free expansion process.

Free expansion wastes most of the energy that was required to compress the flashed refrigerant initially, because the expansion does no useful work. The flow of liquid refrigerant across the pressure difference also comprises a waste of energy, but this is a minor factor because the volume of the liquid is small.

Some new chiller designs recover this lost energy. The most direct approach is to pass the refrigerant from condenser to evaporator through a turbine. Figure 21 shows a machine that uses this approach.

The liquid refrigerant enters the turbine from the condenser. Inside the turbine, the liquid tends to flash into vapor, but it also tends to re-condense because it is losing energy. The turbine is designed to minimize the energy left in the refrigerant. The turbine, which is driven by the pressure differential and the expansion of the flash gas, helps to run the compressor.

Carrier Corporation

Fig. 21 Energy recovery from refrigerant expansion The condenser is at much higher pressure than the evaporator. Energy is recovered by passing refrigerant through a turbine on its way from the condenser to the evaporator. The turbine helps the motor to drive the compressor. In this machine, the turbine wheel is on the left end of the motor shaft, and the compressor is on the right. The turbine refrigerant flow is entirely independent of the compressor flow.

(A similar idea is used in steam plants, where pressure reducing turbines are used in place of pressure reducing valves to get useful work.)

Since energy has been removed from the refrigerant before it enters the evaporator, it has more ability to absorb heat from the load. It also has less superheat, which reduces the power needed by the compressor to compress the gas.

This method can be used with flooded evaporators and liquid overfeed systems. It has little or no potential with expansion valve systems and with air coils that use capillary tubes or other types of flow restrictors to distribute refrigerant within the coils. This is because these devices require a significant pressure differential to operate properly.

Evaporator and Condenser Heat Transfer

Temperature differentials that occur in the evaporator and the condenser are important factors in the amount of work that the compressor must do, because these temperature differentials translate to an increased pressure difference across the compressor. Typical evaporator and condenser temperature drops are shown in Figure 4. The temperature differential is proportional to three factors: the heat transfer coefficient of the surfaces, the area of the heat transfer surfaces, and the rate of heat flow, or cooling load.

The evaporator and condenser temperature differentials are determined largely when the cooling machine is selected. They are a compromise between efficiency and first cost that the engineer makes in the selection process. Larger heat exchangers improve heat transfer, but heat exchangers are a major part of the system cost. The efficiency benefit is subject to a severe limitation of diminishing returns as the temperature differentials become small. For example, reducing the temperature differential from 4°F to 2°F requires doubling the heat transfer surface. This makes it very expensive to reduce the last few degrees of temperature differential.

Heat transfer is not limited primarily by the conductivity of the metal, but by heat transfer at the interfaces between the metal, liquid, and gas. The refrigerant side of evaporators involves two heat transfer processes, from the gas to the liquid film on the tube surface, and from the liquid film to the metal. Where water is used in evaporators and condensers, heat transfer is reduced by fouling from the water. This is especially severe with open cooling towers.

With refrigerant-to-water evaporators and condensers, minimum water flow rates are required to maintain adequate turbulence for good heat transfer. In variable-flow systems designed to reduce pump power, a separate loop must be provided to maintain a minimum water velocity through the heat exchanger.

Major improvements in the heat transfer coefficients of evaporators and condensers have been made since the 1970's. These improvements are achieved primarily by giving the tube surfaces a texture that increases turbulence, enhancing contact between the different mediums.

Heat transfer in air coils involves air velocity, fin spacing, number of rows of coils, and refrigerant circuiting. Air-cooled (DX) evaporators may require separate coil sections to allow operation at partial loads. Distribution of refrigerant within a DX evaporator requires elaborate distributors, and is difficult to optimize.

Heat transfer efficiency improves at partial loads because the heat transfer surface is then larger in relation to the amount of heat to be transferred.

■ Fouling Factor

When a system uses water for heat transfer in either the evaporator or condenser, a "fouling factor" is used in the rating conditions to account for fouling of the tube surfaces by dirt in the water. The fouling factor is a measure of thermal resistance, like the R-value used to rate insulation. The units are the same, for example, square feet-°F-hour per BTU in U.S. practice.

In the U.S., a fouling factor of 0.00025 is commonly assumed in rating large cooling machines. Experience has shown that this figure is appropriate for both evaporators and condensers. It is assumed that the fouling factor is kept from rising above this value by the scrubbing action of the water flow. For this assumption to be valid, the equipment must be designed with appropriate water velocities to maintain turbulent flow at the tube surfaces. Also, if the condenser uses water from an open cooling tower, you need to maintain an appropriate water treatment program for the tower water. The rating also assumes that tube surfaces are cleaned at appropriate intervals.

When comparing cooling equipment specifications, be careful to check the fouling factor that is actually being quoted by the manufacturer in its efficiency and capacity ratings. Although a fouling factor of 0.00025 is a standard value, a manufacturer may fudge comparisons with competing equipment by using different fouling factors.

The refrigerant sides of evaporators and condensers are kept clean by the solvent and detergent properties of the refrigerant materials. (Halocarbon refrigerants were widely used for cleaning purposes, before they were banned for environmental reasons. Ammonia is still a common cleaning agent.) Therefore, no fouling factor is needed for the refrigerant sides.

Parallel and Series Evaporator Circuits

In most facilities that have multiple water chillers, the evaporators are piped in parallel. This allows the chillers to be operated in any combination. However, it

is possible to improve efficiency at high loads, at least in principle, by connecting the evaporators so that the chilled water flows through them in series.

To understand this, let's look at an example. Consider a facility that has two chillers of equal capacity, each operating at full load on a peak-load day. There is a large spread between the chilled water supply and return temperatures, for example, supply at 40°F and return at 52°F. If the chillers were operating in parallel, each would have to chill the water to 40°F. However, if the evaporators are connected in series, one of the machines can operate with a higher evaporator temperature. In this example, all the return chilled water is cooled in the first machine from 52°F to 46°F, and in the second machine from 46°F to 40°F. The COP of the first machine is increased substantially, while the COP of the second machine is reduced by a small amount. The average COP of the two machines might be increased by perhaps five percent under full load.

The efficiency advantage disappears below about half load, because one of the chillers is turned off in either the parallel or series arrangement. In most comfort cooling applications, the cooling load is less than half the peak design load for a majority of the time. Thus, the opportunity of exploiting a series connection is limited. However, if there are more than two chillers in the plant, the number of efficient operating hours may be extended by combining series and parallel connections.

The efficiency advantage of a series connection also drops rapidly below full load because the evaporator temperature of the chillers in a parallel connection can be raised to follow the load.

The main disadvantage of a series connection is that the chilled water must always flow through the evaporators of both chillers, even if one chiller is turned off. This wastes pump power. To minimize the pump power, the evaporators of series-connected chillers are usually designed for lower resistance, which wastes some efficiency and capacity in the individual chillers. For a given plant cost, these factors may eliminate any efficiency advantage that the series connection offers.

In principle, any number of chillers could be connected in series, but practical considerations limit the number to two.

Series-connected chillers should be similar in size, because the temperature drop across the evaporator of each machine will be proportional to its relative capacity. Some simple mathematics shows that the efficiency

advantage diminishes if the temperature drops across the chillers are not divided almost equally.

To maximize the benefit of this configuration, the chillers should be controlled so that they share the load while both are running, and that one of the chillers is turned off at the appropriate load, typically at half of the cooling load or somewhat less. Inefficient load sharing between series-connected chillers wastes more energy than inefficient load sharing among parallel-connected chillers, which is another reason to be cautious about this configuration.

Condensate Subcooling

In an ideal cooling machine, the liquid refrigerant in the condenser would fall to the same temperature as the cooling water or air. Because heat transfer is imperfect, the condensed refrigerant is actually somewhat warmer than the cooling medium. This reduces efficiency by holding the compressor discharge temperature higher, increasing compressor power.

A condenser may cool the refrigerant below the temperature at which it condenses on the condenser surface. This is called "condenser subcooling." It is a cheaper alternative to more efficient condenser heat exchanger design. Subcooling provides some additional sensible cooling of the refrigerant, but sensible cooling is a minor part of the cooling potential of the refrigerant. Note that condenser subcooling does not significantly reduce the compressor discharge pressure.

Subcooling can be done in several ways. Most commonly, the refrigerant is routed through the coldest part of the condenser on the way out to the evaporator. Most condensers are tube-and-shell units, with the cooling water running in the tubes. To achieve subcooling of the condensed refrigerant, the water is brought into the condenser through the bottom tubes, and the condensate is allowed to pool around these lower tubes before flowing out of the condenser.

Condensate subcooling can be combined with an economizer. To do this, a portion of the condensate is routed through a separate vessel that is intermediate in pressure between the condenser and the evaporator. A portion of the condensate is flashed into vapor, cooling the condensate, and the cool vapor is injected into an intermediate stage of the compressor, as described previously.

The term "condensate subcooling" is also used for methods of improving the overall cycle efficiency of multi-stage compressors. This involves more theory than we need to discuss here.

**The Effect of Cooling Water and Chilled Water
Temperatures on COP**
Part-Load Efficiency
The Effect of System Temperatures on Capacity
Heating with Direct-Fired Absorption Chillers
Compression Chillers vs. Absorption Chillers
Combination Chiller Systems

The distinguishing characteristic of absorption cooling equipment is that it produces cooling by using heat energy as an input, rather than by using mechanical energy. For this reason, absorption chillers were once common in facilities that had large boiler plants with excess capacity during the cooling season. Circumstances later changed, and absorption chillers appeared destined for extinction. However, absorption chillers are now experiencing a revival, for reasons explained below.

The components of an absorption chiller must be integrated much more closely than the components of a compression cooling system. As a result, all absorption chillers are contained within a single compact package. For the same reason, absorption chillers have few variations. The main differences between models are in the heat source and in the number of stages.

In all large absorption systems, cooling is distributed by chilled water. Similarly, all condensers are cooled by water, usually from a cooling tower. For a variety of reasons, large absorption systems do not use air coils for either evaporators or condensers.

How Absorption Cooling Works

As with compression chillers, absorption chillers operate by absorbing heat to evaporate a liquid. In all larger absorption chillers, the evaporating liquid is water.

In dry climates, water can be used to provide cooling without a chiller. Unfortunately, the evaporation rate of water approaches zero at high humidity and lower temperatures. Also, water does not evaporate rapidly under atmospheric pressure and normal temperatures, so its cooling capacity is limited.

To achieve a large cooling capacity using water as the refrigerant, an absorption chiller keeps the water at a pressure so low that the water boils at the cooling temperature. This pressure is about 0.1 PSIA, which is less than one hundredth of atmospheric pressure. An absorption machine is big because it must handle large volumes of water vapor. This is because the density of the water vapor is very low at the extremely low pressure needed to achieve rapid evaporation.

The absorption machine maintains continuous rapid evaporation of water under the very low pressure. This is done by absorbing the evaporated water into a highly hygroscopic (water absorbing) material. In absorption chillers large enough for commercial applications, the absorber is usually lithium bromide, a salt.

A more technical way of explaining absorption is that the vapor pressure of a salt solution is lower than the vapor pressure of pure water. This causes the vapor to move out of the evaporator toward the salt solution. For example, pure water has the same vapor pressure at 38°F as a strong lithium bromide solution at 110°F. Therefore, if a cooling tower can keep the salt solution cooled to 110°F, water evaporating at any temperature higher than 38°F will produce vapor at a higher pressure than the salt solution.

In order to keep the absorption process going, the concentration of the absorbing salt solution must be restored continuously. This is done by circulating the salt solution through a distiller, which is located in a different part of the machine. The distiller returns the pure water to the evaporating chamber, and returns the concentrated salt solution to the absorbing chamber.

Absorption Chiller Components

The simplest type of large commercial absorption chiller consists of these major components, which are sketched in Figure 1:

- the **evaporator**, which is a chamber that contains coils to transfer heat to an external water (“chilled water”) circuit. The water refrigerant inside the chiller enters the evaporator from the distiller in a warm state. A pump and an array of nozzles spray the refrigerant water inside the evaporator chamber, hastening evaporation and cooling it before it falls on the chilled water coils.
- the **absorber**, which is a chamber that contains the concentrated absorbent. The absorber shares a common shell with the evaporator, and water vapor flows freely from the evaporator to the absorber. The absorbing salt solution is cooled by distributing it over a bundle of tubes that are cooled by the

entering cooling water. This minimizes the vapor pressure of the absorbing solution, and most of the vapor is absorbed by the film of solution on the tube bundle. The tube bundles carries away the latent heat that the water vapor had acquired when it evaporated, as well as heat that is released by the dilution of the salt solution.

- the **distiller section**, which removes water from the salt solution to restore its concentration. The distiller consists of two chambers, a **concentrator** (sometimes called a **generator**) where the water is boiled out of the salt solution, and a **condenser**

where the water vapor is condensed for further use. The design of the distiller section is where major differences occur between different types of absorption chillers, as discussed below.

- a **heat exchanger** between the absorber and the concentrator. The salt solution in the concentrator should be as hot as possible to boil off water, while the salt solution in the absorber should be as cool as possible to absorb water. The concentrated salt solution flowing from the concentrator to the absorber is hot, and the diluted salt solution flowing in the opposite direction is cool. The heat exchanger

Trane Company

Fig. 1 How an absorption cooling machine works The “refrigerant” is water. The “absorber” is a strong solution of salt in water. The part of the machine on top is a distiller, which continuously separates pure water from the salt solution, while making the salt solution stronger. The pure water is pumped over cooling coils, where it evaporates rapidly in the extremely low pressure of the machine. The evaporated vapor is drawn to the salt solution in the chamber below, where the pressure is even lower, and it is absorbed in the salt solution. We want the salt solution to be hot in the distiller and cool in the absorber chamber, so the heat exchanger on the left keeps it that way. The purge unit on the upper right is a separate device that removes any foreign gases from the machine, as these would destroy the low vacuum needed for operation.

extracts the heat from the concentrated solution and transfers it to the diluted solution.

- the **solution pump**, which pumps the diluted salt solution to the distiller.
- the **refrigerant pump**, which circulates the water in the evaporator over the chilled water coils.
- a device for regulating the return of distilled water from the high pressure condenser chamber to the low pressure evaporator chamber. This is usually a simple **orifice** or **float valve**.
- the **purge unit**. The portion of the chiller where evaporation occurs must be kept at an absolute pressure around 0.1 PSI. This requires keeping all gases but water vapor out of the chiller. Gases that leak into the chiller are removed by the purge unit, which is a vacuum pump combined with a condenser. The purge unit's condenser captures water vapor that is drawn out of the chiller along with the contaminant gases, condenses it, and returns it to the chiller.

Figure 2 shows an actual absorption machine that has these components. Machines of this type have capacities ranging from several hundred tons to more than one thousand tons.

Refrigerant Materials and Absorber Materials

Water has three roles in a large absorption machine. Don't get confused about how the machine works because there is water in it everywhere.

As we said before, water is the actual refrigerant. In the part of the machine where water acts as a refrigerant, it is very pure. In fact, it is distilled water.

Most large absorption machines are water chillers. Water is used to distribute cooling energy to the facility. This water travels in a separate loop. It enters the machine only in the evaporator section.

Water also acts as the carrier for the absorber salt. It is not desirable to use the salt in the solid state because it would require too much energy to dry it out. Also, it would be harder to handle. A salt solution is easy to move around inside the machine by pumping. Also, the absorbing surface area of the salt solution can be increased greatly by spraying it inside the absorbing chamber.

The absorber material in machines that are large enough for commercial applications is lithium bromide. Lithium bromide has a very strong tendency to absorb water. It is chemically a close relative of table salt, which is sodium chloride. You can easily see the tendency of table salt to absorb water on humid days.

The lithium bromide absorbent is extremely corrosive. To be practical in chillers, lithium bromide needs to be used in combination with special corrosion inhibitors. Other materials are added to the absorbing solution to increase the rate of vapor absorption.

In very small chillers and refrigerators (up to several tons in capacity), ammonia is used as the refrigerant and water is used as the absorbent. These machines have lower COP's than lithium bromide machines, so they are unlikely to evolve into larger sizes. Their advantages are smaller size, less critical control, and freedom from the corrosion problems of salt solutions.

Number of Stages

A major variant among absorption chillers is the two-stage machine. The difference is in the distiller section. A theoretical analysis of the efficiency of absorption chillers shows that a large part of the energy input into the chiller is related to the operation of the distiller section. The efficiency of the chiller can be improved considerably by installing a distiller that works in a series of cascading temperature stages.

In any distiller, heat must be added to the solution to boil off the pure water. Then, this heat must be removed from the water vapor to condense it. In a two-stage chiller, water evaporated in the first (high temperature) stage of distillation is condensed by using the hot vapor to heat a second (low temperature) stage of distillation. Only the second stage water vapor gives up its heat to the condenser cooling water.

Figure 3 shows how the additional components of a two-stage machine are arranged. Compare this to Figure 1.

Figure 4 is a cutaway drawing of an actual machine. As you can see, absorption chillers consist mainly of huge numbers of tubes inside steel pressure vessels.

Two-stage absorption machines are approximately 50% more efficient than single-stage machines. The limitation of two-stage machines is that they require much higher input temperature for the first stage of

Trane Company

Fig. 2 Single-stage steam-powered absorption chiller This machine is constructed as shown in Figure 1. The three pumps shown there are combined in a common housing underneath the main shell.

distillation. Single-stage steam absorption chillers are usually designed to operate with 10 PSI steam or 220°F hot water, whereas two-stage chillers require approximately 100 PSI steam or 350°F hot water to achieve their full efficiency potential.

The present limitation to two stages is not a matter of technology. For example, distillers used aboard ships to make fresh water from seawater commonly operate with three or more stages. The major practical limitation is increased complexity and cost.

Externally-Fired and Direct-Fired Chillers

Until the 1980's, all large absorption machines used steam or high-temperature hot water as the heat source. Unless a facility could purchase steam, using an absorption chiller required the expense, the space, and the efficiency losses of a boiler plant. As stated previously, two-stage machines require much higher pressures and temperatures than single-stage machines.

Since that time, absorption chillers with internal fuel firing have created a resurgence of interest in absorption chillers. These machines are capable of burning natural gas and/or oil directly. Since flame has a very high temperature, direct firing allows multi-stage distillers

to be used. At present, all large direct-fired absorption chillers have two-stage distillers.

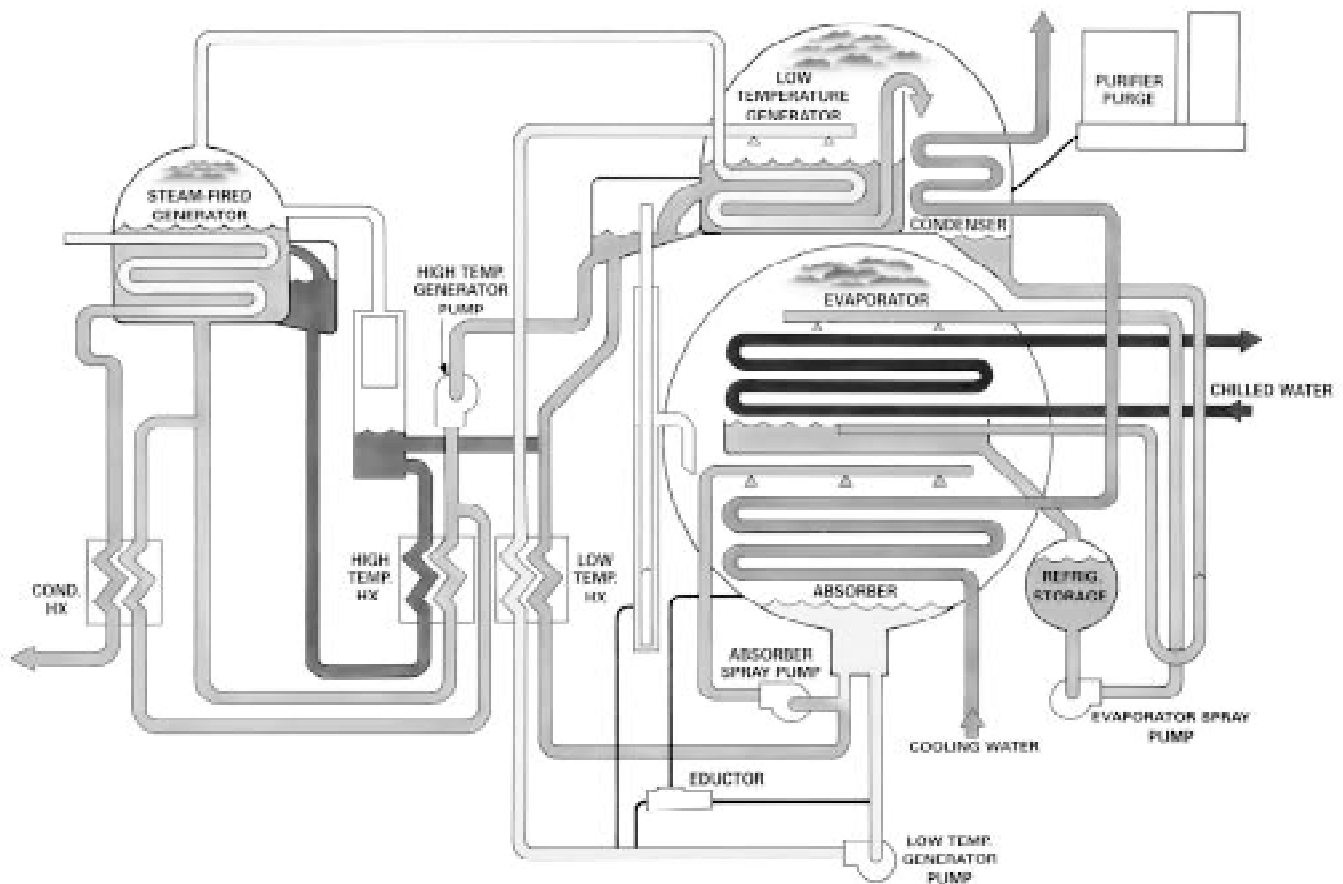

Figure 5 shows the components of a direct-fired absorption machine. As you can see, it is not much different from an externally fired two-stage unit.

Figure 6 is a cutaway drawing of a direct-fired chiller. It looks entirely similar to an externally-fired two-stage chiller, except that it has its own little boiler alongside.

Absorption chillers designed for direct fuel firing can be adapted for operation with hot exhaust gases from gas turbines, reciprocating engines, industrial processes, etc. These sources must be predictable, because sudden reduction of the heat input can cause crystallization of the highly concentrated salt solution.

The Problem of Crystallization

To achieve maximum capacity, the concentration of salt in the absorber solution is kept as high as possible. The salt solution is concentrated in the distiller. If the heat source is suddenly removed from the distiller and the solution is allowed to cool, the solution becomes supersaturated. The salt comes out of solution and encrusts the distiller heat exchanger and other surfaces

Trane Company

Fig. 3 Two-stage steam-powered absorption chiller This machine is mostly identical to the one shown in Figure 1. The main difference is having a two-stage distiller. The new equipment on the left is the first, high-temperature stage of the distiller. This machine is more efficient than a single-stage machine, but it requires steam at much higher pressure.

as a layer of crystals. The chiller cannot operate in this state, or it operates inefficiently.

If crystallization occurs, the chiller must be shut down. The crystals must be dissolved by circulating water from the evaporator through the distiller. After this is done, a period of operation is needed to get the water and salt distributed properly within the chiller.

The Effect of Cooling Water and Chilled Water Temperatures on COP

In addition to the temperature of the heat source, the temperatures of the cooling water and chilled water have a major effect on the COP of an absorption chiller. This is analogous to the effect of condenser and evaporator temperatures in compression chillers, although the physical processes are entirely different.

In an absorption chiller, the cooling water is first routed to the absorber section, where it determines the vapor pressure of the absorbing salt solution. Lowering the cooling water temperature lowers the vapor pressure in the absorber, which allows the concentration of the salt solution to be reduced. Since an absorption chiller uses its energy input to concentrate the salt solution, lowering the cooling water temperature reduces the energy requirement, provided that the chiller is able to reduce the salt concentration to match the load.

The cooling water also travels to the condenser section of the distiller. Lowering the condensing temperature in the distiller also reduces the amount of

energy needed to distill the water out of the salt solution, for a given concentration. Thus, the cooling water temperature affects efficiency in two separate ways.

The chilled water temperature determines the vapor pressure in the evaporator section of the chiller. A higher chilled water temperature increases the rate of evaporation, which allows the salt concentration to be reduced correspondingly, increasing the COP as before.

Part-Load Efficiency

The part-load efficiency of an absorption chiller depends on how the concentration of the salt solution is controlled as the load changes. The heat input to an absorption chiller is used to distill water out of the absorbing salt solution. The amount of heat required increases with the salt concentration. Therefore, efficiency can be improved by keeping the salt solution as dilute as possible. This is done by slowing the flow of liquid from the absorber to the concentrator, so that the liquid absorbs more water in the absorber. This feature has been called an “economizer” (that word again!). It is becoming a common feature of new machines, but be aware that you may still have to order it as an option.

On older machines, the concentration was changed at one specific load point. Newer designs adjust the concentration continuously as the load changes. The solution pump absorbs a substantial amount of energy, so it is worth using a variable-speed pump drive to

Trane Company

Fig. 4 Two-stage steam-powered absorption chiller This is the same machine diagrammed in Figure 3. Most of the material in the machine consists of huge bundles of copper alloy heat exchanger tubes that are enclosed in steel cylinders.

control the flow of salt solution, rather than simply choking the flow with a valve.

With present absorption machines, the purchaser has no options to improve the efficiency features of a particular chiller model, except perhaps for the concentration control economizer. Pay particular attention to the part-load efficiency specifications, where significant differences among models may appear. Ask the manufacturer to certify all performance figures.

Part-load efficiency has been improved in newer machines by microprocessor controls and improved sensors, which keep the machines' operating variables close to optimum at each combination of loads and temperatures. The efficiency features of newer machines generally are not practical to retrofit to older machines.

The Effect of System Temperatures on Capacity

The temperature in the concentrator section of the distiller determines the rate at which the salt solution is concentrated, and hence the capacity of the chiller. The rate of evaporation in the distiller is strongly affected by the input temperature.

Capacity is also determined by the maximum rate of vapor flow between the evaporator and condenser. Vapor flows in response to a pressure differential, so

the flow rate is increased by increasing the pressure in the evaporator and by lowering the pressure in the absorber. Raising the chilled water temperature increases the evaporator pressure, and lowering the cooling water temperature lowers the absorber pressure. Both have a strong effect on capacity.

Heating with Direct-Fired Absorption Chillers

Since direct-fired absorption chillers include their own boilers, they may offer the option of serving as a heat source. They can be used for space heating, domestic water heating, or other purposes. In new construction, this may save the cost of a separate boiler.

Figure 5 shows the simplest arrangement. Steam is simply tapped off the boiler and is used to heat a water loop. The heating function operates independently of the operation of the rest of the machine.

In some designs, the heating option may offer a net efficiency advantage, compared to heating with a separate boiler. If the unit is cooling and heating simultaneously, and if it is heating a cold water source, the cold water source may be heated in the condenser section of the chiller. This reduces the amount of cooling water required to operate the chiller, and it avoids the extra fuel needed to heat the water. However, this

Trane Company

Fig. 5 Direct-fired two-stage absorption chiller Compare this to Figure 3. The only major difference is that a fuel-fired boiler has been substituted for the steam-powered first stage of the distiller. As an accessory feature, the boiler can provide water heating independently of cooling operation.

Trane Company

Fig. 6 Direct-fired two-stage absorption chiller This is the machine diagrammed in Figure 5. Compare this to the steam-powered machine in Figure 4. This is essentially the same machine, except that it has its own small boiler.

capability complicates the internal plumbing of the machine. Also, no saving is possible when heating a hot-water system, such as a hydronic heating system.

Some models can provide heating simultaneously with cooling, although the capacity of the boiler unit will limit total heating and cooling capacity. With other models, you have to choose between cooling or heating operation.

Compression Chillers vs. Absorption Chillers

Of the two major types of chillers, compression chillers are the more efficient type, in terms of COP, by a considerable margin. For this reason, absorption chillers appeared to be headed for obsolescence, except in specialized applications. However, there has been a resurgence of interest in absorption chillers, for these reasons:

- utility regulatory agencies are making it difficult for utilities to build new generating plants. As a result, utilities are running out of generating capacity for periods of peak consumption, which are caused mainly by cooling load. Since absorption chillers have only a small requirement for electrical power, electric utilities have promoted absorption chillers as a means of reducing utility demand peaks. The incentives include demand-penalizing rate structures and direct subsidies to customers. (This costs the utility electricity sales.

Utilities prefer to promote electric storage cooling as a means of reducing demand without surrendering electricity sales.)

- gas utilities are marketing absorption chillers as a major market for natural gas, and a means of leveling annual gas sales.
- the refrigerants and absorbents used in absorption chillers are not considered harmful to the environment at a global level, unlike the CFC's and HCFC's used in compression chillers. However, environmentally safe replacement refrigerants are available for compression chillers, so this is not likely to continue as a significant factor.
- the development of direct-fired absorption chillers made it possible to achieve higher COP's while avoiding the need for a separate boiler system to drive the absorption machines.
- the direct-fired type of absorption chillers can be powered by waste heat, creating opportunities for improving overall efficiency in local power generation and industrial processes.

Combination Chiller Systems

Efficiency favors compression chillers, while other considerations may favor absorption chillers. In some applications, the optimum choice is a combination of the two types. This combination has lower electric demand than a compression chiller alone, higher

efficiency than an absorption chiller alone, and perhaps the ability to exploit waste heat and cheaper fuels. Typical combinations of the two types are:

- a steam turbine drives a compression chiller, and the turbine exhaust steam is used to drive an absorption chiller and perhaps other thermal loads
- a diesel engine, a gas reciprocating engine, or a gas turbine drives a compression chiller, and heat recovered from the engine is used to drive an absorption chiller and perhaps other thermal loads
- an engine is used to drive an electric generator, the electricity is used to drive electric compression chillers and perhaps other electrical loads, and heat recovered from the engine is used to drive an

absorption chiller and perhaps other thermal loads. This configuration is a common form of “cogeneration.”

The disadvantages of all combination chiller systems are greater complexity, and hence reduced reliability. Combination chiller systems are tricky to design, especially because their performance is sensitive to the load scenarios under which they may operate. Also, combination systems require enhanced operating skills, so they should not be installed unless the owner is certain that the necessary operating skills can be maintained. There have been many failures of combination systems because of insufficient attention to these issues.

This Reference Note covers the main points of refrigerant selection from the standpoint of the system purchaser and the system designer. You cannot select a refrigerant for efficiency alone. The selection of the refrigerant has other major consequences, such as environmental protection, safety, and equipment size. Refrigerant selection is presently in a state of uncertainty because of environmental concerns about the most popular contemporary refrigerants. This Note covers enough of the theory to enable you to understand how refrigerant selection issues may evolve in the future.

Table 1 lists the efficiency, environmental, and safety properties of the refrigerants that are commonly used today, along with the properties of newer refrigerants that are considered leading candidates for future use. For the person who must select a cooling machine, these are the refrigerant characteristics that matter most urgently. The table does not include refrigerants for specialized applications, such as low-temperature refrigeration and high-temperature heat pumps. For many refrigerants, the characteristics given in the table have not yet been determined.

Table 1. SELECTION CHARACTERISTICS OF COMMON REFRIGERANTS

Refrigerant	Theoretical COP (Note 1)	Ozone Depletion Potential (Note 2)	Global Warming Potential (Note 3)	Exposure Limit (PPM)	Safety (Note 4)
CFC-113	4.3	0.8			A1
CFC-11	5.0	1.0	4,400	1,000	A1
HCFC-123	4.8	0.02	85	100	B1
CFC-12	4.7	1.0	13,700	1,000	A1
HFC-134a	4.4	0	1,200	1,000	A1
HCFC-22	4.7	0.05	1,500	1,000	A1
HCFC-502	4.4				A1
Ammonia	4.8	0	0	25	B2
Ideal refrigerant (Carnot cycle)	6.7	0	0	unlimited	A1
Water		0	(Note 5)		
Carbon dioxide	2.8	0	1.0	5,000	

Notes:

1. These figures assume a condensing temperature of 86°F and an evaporating temperature of 5°F.
2. The figures are based on a value of 1.0 for CFC-11.
3. The figures are based on a value of 1.0 for carbon dioxide.
4. The letter is the toxicity class. The number is the flammability class. See ASHRAE Standard 34 for details.
5. Water is the most powerful atmospheric regulator of global temperature, by far.

The *ASHRAE Handbook* is the primary reference for the detailed engineering properties of refrigerants. Because it is published on a four-year cycle, it may not have the latest information about refrigerants that are currently exciting interest. Environmental concerns have triggered a frantic search for new refrigerants, and the leading contenders are still changing from moment to moment.

What is a Refrigerant?

The liquid that is evaporated in cooling equipment to produce a cooling effect is called a “refrigerant.” In the process of evaporating, the liquid absorbs heat. The heat needed to change a refrigerant from its liquid state to a vapor state is called “latent heat of evaporation.” For example, if a pound of water evaporates at room temperature, it absorbs about 1050 BTU of heat in the process. The change in state does not, in itself, involve a change in temperature,

How do we get a temperature reduction (“sensible cooling”) from this? You can think of it as a two-step process. First, the portion of the liquid that evaporates absorbs heat from the surrounding mass, which includes the remaining liquid, refrigerant tubes, etc. The withdrawal of heat from this mass lowers its temperature. The actual temperature drop depends on the amount of mass that is giving up its heat, and on its specific heat. If the material has a low specific heat, its temperature is reduced more for a given amount of heat that is removed from it. Therefore, the greatest cooling effect occurs if the refrigerant has a high latent heat, and a low specific heat.

The cooling effect of a liquid is determined by its tendency to evaporate, as well as by its latent heat. This tendency is related to the “vapor pressure” of the material. For example, at room temperature, alcohol has a greater cooling effect than water because it has a higher vapor pressure, even though its latent heat is only about half that of water.

(Any liquid has a tendency to eject some of its molecules from its surface. These molecules form a gas, which is called a “vapor” as long as it remains in equilibrium with the liquid. Like any gas, the vapor exerts a pressure, which is called the “vapor pressure.” The tendency to form a vapor varies greatly among different materials. For any given material, it increases greatly with temperature.)

Many substances that occur in nature have been used as refrigerants, along with many manufactured materials. Older refrigerants include ammonia, sulfur dioxide, carbon dioxide, propane, butane, and methyl chloride. Prior to the 1930’s, all practical refrigerants were flammable or toxic, or both. These were largely displaced by the modern “halocarbon” refrigerants, which will occupy most of our attention for the rest of this Note.

Halocarbon Refrigerants

The halocarbon refrigerants were developed by Thomas Midgely and his associates at the Frigidaire Division of General Motors. They were first marketed under the trade name of Freon by Kinetic Chemicals, Inc., which was formed in 1930 by GM and DuPont.

As their name implies, the halocarbon refrigerants are compounds of the halogens and carbon. (The halogens are the group of elements consisting of fluorine, chlorine, bromine, and iodine.) In all these refrigerants, the basic chemistry consists of mimicking the structure of simple hydrocarbon gases (methane, ethane, etc.).

To retain the good refrigerant qualities of the original hydrocarbons while avoiding their safety hazards, halogen atoms are substituted for some or all of the hydrogen atoms. The halogen compounds bind tightly to carbon, producing compounds that are relatively stable and non-reactive. The halocarbon refrigerants were a breakthrough because they combine good cooling properties with safety. In fact, the halocarbons are better refrigerants in general than the hydrocarbons of similar structure.

The most popular of the original halocarbon refrigerants, numbered 11, 12, and 22, are all variations of methane, the simplest hydrocarbon gas. Methane consists of one carbon atom surrounded by four hydrogen atoms. In the halocarbons, the hydrogen atoms of the methane structure are replaced with differing numbers of chlorine and fluorine atoms. Other refrigerants were developed that are based on the chemical structures of the other simple hydrocarbon gases.

The Naming System for Refrigerants

ASHRAE has developed a numbering system that covers all refrigerants. The original Freon numbering system has been carried forward for those refrigerants to which it applies. ASHRAE uses the term “Refrigerant” or “R.” For example, R-12 has the same composition as Freon-12.

For hydrocarbons and for the halocarbon refrigerants, the refrigerant number reveals the number of atoms of each type. The trick is to add 90 to the refrigerant number. For example, adding 90 to the number in R-22 gives 112. Then,

- the first digit is the number of carbon atoms
- the second digit is the number of hydrogen atoms
- the third digit is the number of fluorine atoms
- any remaining atoms are chlorine.

For example, R-22 has one carbon atom, one hydrogen atom, and two fluorine atoms. Because R-22 has the structure of methane (one carbon atom surrounded by four other atoms), there is one site remaining. The remaining atom is chlorine.

This numbering system turns out to be handy when considering environmental effects of refrigerants, because carbon, hydrogen, fluorine, and chlorine each has a distinct role in these effects. Unfortunately, the numbering system does not explicitly state the number of chlorine atoms, which is the main source of concern about ozone depletion among the common refrigerants.

Inorganic refrigerants (e.g., ammonia, carbon dioxide, water, etc.) have numbers starting with “7”, and the last two digits are the molecular weight. For example, ammonia is named R-717 because it has a molecular weight of 17.

In response to the concern about environmental effects of halocarbon refrigerants, the simple designation “R” for these materials is now replaced with identifiers that highlight their chemical compositions, as follows:

- CFC (“chlorofluorocarbon”) indicates that the carbon atom is surrounded with chlorine and fluorine. CFC-11 and CFC-12 are the most common CFC’s.
- HCFC (“hydrochlorofluorocarbon”) indicates that the refrigerant contains hydrogen as well as halogens. HCFC-22 is the most common HCFC.
- HFC (“hydrofluorocarbon”) indicates that the refrigerant has hydrogen and fluorine, but no chlorine. HFC-134a is an important example because it is presently a leading candidate as a replacement for CFC-12.

The Phase-Out of Chlorine-Containing Refrigerants

The greatest upheaval in the history of compression cooling is presently occurring as a result of concerns about the environmental effects of the halocarbon refrigerants. Some of the most commonly used halocarbon refrigerants must sooner or later be replaced with other types. International agreements and various national laws limit present and future choices of refrigerants. In turn, this affects the design and selection of cooling equipment.

The popular halocarbon refrigerants provide an almost ideal combination of efficiency, safety, and moderate cost. Alternative refrigerants with equally good attributes are not presently available, so replacing the present refrigerants involves serious compromises. At this time, it appears unlikely that the compromise will focus neatly on a few refrigerants. This because a larger number of competing selection factors (discussed below) must now be balanced against each other, and the search will continue for new refrigerants that can match the old refrigerants in performance.

■ Phase-Out Schedule

Curtailed use of CFC’s in developed countries was initiated by the Montreal Protocol, an international agreement signed in 1987. Meetings in subsequent years expanded the curtailment to call for complete phase-out of CFC’s, to limit other gases, and to include

developing countries in the agreement. As of the Montreal meeting of September 1997, ten years after the original agreement, the status of refrigerants is:

- CFC consumption for new equipment, in developed countries, was phased out at the beginning of 1996. CFC’s for servicing existing equipment are available only from stockpiles of virgin material produced before 1996, or from recovery of refrigerant from abandoned or converted equipment. Phase-out of CFC’s in developing countries is deferred until 2010.
- HCFC consumption, in developed countries, is reduced in a series of steps starting in 2004 and ending in 2030. The steps are percentages of HCFC consumption in 1989, plus an allowance based on 1989 CFC consumption. A small quantity is reserved in the period between 2020 and 2030 for servicing refrigeration and air conditioning equipment. In developing countries, phase-out is scheduled to start in 2016 and to be complete by 2040.

Individual nations may have additional requirements. In the United States, Section 608 of the Clean Air Act phases out individual HCFC’s on different schedules, based on their ozone depletion potentials (discussed below). Under this Act, HCFC-22 is available for new equipment until 2010 and for service until 2020. HCFC-123 is available for new equipment until 2020 and for service until 2030.

HFC’s are not subject to the Montreal Protocol. However, they are likely to come under some form of control under the Framework Convention on Climate Change.

■ Substituting Refrigerant Types in Existing Cooling Units

A question that looms in the minds of those who operate cooling equipment with banned refrigerants is whether acceptable refrigerants can be substituted in the existing equipment. The refrigerant must be closely matched to the equipment. Even if it is possible to substitute refrigerants, efficiency may suffer. Also, capacity may be lost. Here are the substitutions that are presently attracting the most attention:

- CFC-11 is being replaced by HCFC-123 in some machines. In older machines, this involves a capacity loss up to about 18%, and an efficiency loss up to 5%. These losses may be largely restored by changes to the impellers and/or gears. This is expensive, even assuming that the chiller manufacturer offers the conversion hardware. Chillers made in the era of the Montreal Protocol were designed with conversion in mind. Conversion of these chillers is easier, and provides better performance.

Expect to replace sealing materials in most machines, because HCFC-123 attacks previously

used sealing materials. With hermetic chillers, expect to replace the motor, because HCFC-123 attacks the original motor insulation. Replacement motors and seals adapted to HCFC-123 are presently available for most hermetic chillers.

Note that HCFC-123, the replacement refrigerant, is subject to phase-out itself, as discussed previously. HCFC-123 is not highly toxic, but less exposure is allowed than with CFC-11.

HFC-254ca has also been considered as a replacement for CFC-11. It contains no chlorine, so it is not subject to phase-out under the Montreal Protocol. However, it is flammable, which is a major disadvantage. So far, its other properties have received less study.

- CFC-12 is being replaced by HFC-134a in some machines. When making this swap, it is critical to leave no trace of the original CFC-12 or the original oil. HFC's must be used with synthetic lubricants. These react with any residual chlorine in the system to produce destructive substances.

HFC-134a attacks the insulation of some hermetic motors. Be sure that the motor is compatible with the refrigerant before making the change.

- HCFC-22, which is used in more than half of all commercial and residential cooling, does not yet have a fully satisfactory replacement. Various HFC's and HFC mixtures are being considered. At present, Refrigerant 407C is being considered as a near-term substitute, while Refrigerant 410A may take over from HCFC-22 in the long term.
- HCFC-502, which is a common refrigerant for refrigeration applications, also does not yet have a clear successor. Refrigerants 404A, 410A, and 410B are being considered.

Many other substitutions are being considered. The greater the difference in characteristics between the original refrigerant and its replacement, the less effective is the original equipment for the new refrigerant. Mismatches cause significant losses of efficiency and capacity beyond those related to the inherent characteristics of the replacement refrigerant. If the loss of efficiency with the new refrigerant is greater than the loss of capacity, the original motor may not be powerful enough to drive the compressor with the new refrigerant.

How to Select the Refrigerant for Your Cooling Equipment

In the past, purchasers of cooling equipment did not concern themselves much with the refrigerant used. Machines were selected on the basis of their capacity, efficiency, size, etc., and the refrigerant choice was a matter for the factory to decide. These days, environmental concerns make it prudent to start your selection by considering the long-term availability prospects of specific refrigerants.

After considering availability, place greatest weight on efficiency. The efficiency potential of the refrigerant is a dominant factor in the overall efficiency of the cooling system. The refrigerants designed to replace CFC's and HCFC's typically have lower efficiency. At the same time, be aware that equipment designers have been working hard to compensate. In fact, the best contemporary cooling equipment is more efficient than the best that was available before the Montreal Protocol.

The banning of chlorine-containing refrigerants forces you to consider refrigerants with varying degrees of toxicity and flammability. Keeping these hazards under control may add cost and complexity to the overall plant. These hazards make it impractical to use some refrigerants near enclosed concentrations of people. At the same time, recognition of these hazards by manufacturers and professional organizations is resulting in new codes, standards, and publications that you can use for guidance in dealing with the hazards.

After considering availability, efficiency, and safety, study the characteristics that determine the type of compressor, the size of the cooling unit, noise, and maintenance. The following discussion covers all these selection considerations in greater detail.

■ Availability

The future availability of any particular refrigerant is a gamble because of several uncertainties. The first uncertainty is future opinion regarding the environmental dangers posed by particular refrigerants. There is a wide spectrum of opinion, and few consider the issue settled. There is much uncertainty in the science. The perception of environmental danger in the coming years will be determined largely by the weather, by politics, and by commercial opportunities to sell new equipment and refrigerants.

The underlying assumptions about the environmental dangers of refrigerants may change. At this moment, attention is focussed on two types of environmental harm that may be caused by chlorine-containing refrigerants: depletion of the ozone layer and global warming. Of the two, concern about ozone depletion is presently having a stronger effect on the selection of refrigerants. Indeed, the phase-out of CFC's and HCFC's under the Montreal Protocol is related only to the ozone depletion issue.

Subsequently, global warming entered the discussion of refrigerants. Concern about global warming is partly the result of scientific findings and computer modeling of atmospheric behavior. It has also been used for marketing of environmental hysteria, and it has become part of the competition between cooling equipment manufacturers who have made major commitments to particular refrigerants. For this reason, it is important to understand the specific ozone depletion and global warming characteristics of refrigerants, which we discuss below.

It seems likely that the present popular refrigerants will remain in production until their scheduled phase-out dates because of the demands of existing equipment. It is presently assumed that HCFC 123 will be available because it is similar in refrigeration properties to the phased-out CFC-11, and that HFC-134a will be available because it is similar to the phased-out CFC-12. The production of these refrigerants as substitutes in old equipment guarantees their availability in new equipment for the short term, but not for the long term.

■ Won't New Refrigerants be Developed?

Another possibility is that new, more desirable refrigerants will be developed. However, there is a viewpoint in the industry that all possible refrigerants have already been identified, and that uncertainties are limited to exploring their properties further.

There is actually a fairly solid basis for this bold assumption. As we said earlier, a good refrigerant will have a high latent heat and a low specific heat. However, as molecules become larger, their latent heat diminishes and their specific heat increases. Thus, only small molecules can be good refrigerants.

Furthermore, a refrigerant must be a liquid that changes to a vapor, and back, at useful temperatures and feasible pressures. Also, it must not be highly toxic. Of the 92 naturally occurring elements, only eight produce compounds that satisfy these requirements. The eight are carbon, hydrogen, oxygen, nitrogen, sulfur, fluorine, chlorine, and bromine. Of these, the last two are being banned from future refrigerants for environmental reasons.

These requirements narrow the field so much that it is possible to list all possible materials that would have good refrigerant properties. In fact, Thomas Midgely did this in 1928, and he asserted that no other satisfactory refrigerants would be possible. However, history illustrates that it is risky to predict that radical new developments will not occur.

■ Refrigerant Mixtures and Azeotropes

By this time, the properties of individual refrigerants have been studied extensively. The search for substitute refrigerants is now extending to mixtures of refrigerants. For example, Refrigerant 407C is a mixture of Refrigerant 32 (23%), Refrigerant 125 (25%), and Refrigerant 134a (52%). Refrigerant 407C is a possible substitute for Refrigerant 22.

A fundamental problem with refrigerant mixtures is that they tend to separate. This occurs because the individual components have different evaporation and condensing temperatures, and different leakage rates. Thus, if a cooling system develops a leak, one component of the mixture will leak out faster than the other, resulting in a different mixture with different refrigerant characteristics. Refrigerant mixtures also tend to separate in storage and transit, so that the wrong mixture may be put into the system when it is charged.

For this reason, there is great interest in "azeotropes." An azeotrope is a combination of two or more refrigerants that behaves as a single material in all relevant characteristics. In this respect, an azeotrope is more like a compound than a mixture. Unlike a compound, the physical properties of the azeotrope are an average of the properties of the original materials, as in a mixture. A common azeotrope is Refrigerant 502, which is a blend of Refrigerant 22 (49%) and Refrigerant 115 (51%).

A combination of refrigerants may behave as an azeotrope only within a certain range of mixing ratios. This range may change with the temperature. Thus, azeotropes are not "foolproof."

■ Ozone Depletion Potential (ODP)

Ordinary atmospheric oxygen is a molecule consisting of two oxygen atoms. Ozone is a molecule consisting of three oxygen atoms. At the level of the stratosphere, the concentration of ozone is increased by the action of sunlight, where intense solar ultraviolet radiation breaks atmospheric oxygen into two single oxygen atoms. Individual oxygen atoms are extremely reactive, so the two individual atoms combine with two other molecules of oxygen to form two molecules of ozone. The high-altitude stratum of ozone concentration is called the "ozone layer."

Ozone strongly absorbs ultraviolet light. The main significance of the ozone layer is that it shields the surface of the earth from the sun's intense ultraviolet radiation. Depletion of the ozone layer is expected to increase the harmful effects of ultraviolet radiation. Present health concerns include an increase in skin cancers and cataracts, and harm to the immune system. More generally, ultraviolet light can damage any organic matter that it can penetrate. In addition to human skin and eyes, this includes microorganisms, insects, and even plants. There may be other adverse effects that are not yet recognized.

(Ozone has become notorious as an air pollutant at ground level. Refrigerants are not relevant to this issue. Ozone at ground level is harmful because of its powerful oxidizing effect. Ozone is produced by the action of sunlight on hydrocarbon vapors, such as gasoline fumes, and it probably promotes the formation of other harmful air pollutants.)

The ozone depletion theory asserts that the damage to the ozone layer is largely being done by the chlorine in refrigerants. (Many other natural and synthetic materials are suspected of causing ozone depletion. Some of these, such as methyl bromide and carbon tetrachloride, are being regulated under the Montreal Protocol.) Chlorine-containing refrigerants are the most important suspect because they exist in large quantities and are relatively stable. Their stability allows them to survive long enough in the open atmosphere to reach the stratosphere. Once there, the strong ultraviolet

breaks down the refrigerant molecules, releasing chlorine to do its damage. The atmospheric lifetime of halocarbon refrigerants ranges from about one year to about one century.

(There is a large amount of chlorine in the surface environment, such as in laundry bleach, but most of this is not a concern. Free chlorine is highly reactive, forming compounds that remain near the surface. Furthermore, chlorine is very soluble in water, so rain keeps bringing the chlorine back to earth.)

In the framework of this theory, the potential harm that a refrigerant may cause the ozone layer is defined by a relative number called the Ozone Depletion Potential (ODP), which is defined on a mass basis. The baseline of this ranking system is the ODP of CFC-11, which is defined as 1.0. Table 1 gives ODP ratings for the most common refrigerants and leading candidates.

From the standpoint of refrigerant selection, the most important aspect of this theory is that chlorine is the only component of common refrigerants that is responsible for ozone depletion. (Bromine, much less commonly used in refrigerants, is up to 50 times more damaging than chlorine.) Thus, refrigerants without chlorine (or bromine) pose no danger to the ozone layer. By definition, none of the HFC's contain chlorine, so they all have an ODP of zero.

One obvious approach to reducing ozone depletion is to substitute refrigerants that contain no chlorine. The leading new refrigerant of this type is HFC-134a. For the same reason, there is a resurgence of interest in ammonia, including greater consideration of ammonia in air conditioning applications.

Unfortunately, there are not enough chlorine-free refrigerants to serve the present spectrum of applications without serious compromises involving efficiency, safety, or machine design. Therefore, a second approach is being used, which is to use refrigerants that break down before they can reach the stratosphere. According to theory, it takes many years for CFC's to diffuse upward into the ozone layer. If the refrigerant molecule decomposes before it arrives there, its chlorine will be washed out of the atmosphere.

Refrigerants will decompose in the open atmosphere if they contain a chemical weak link. Hydrogen serves as the weak link. Halocarbon refrigerants that contain hydrogen are called HCFC's to distinguish them from CFC's.

For example, the estimated atmospheric lifetime of HCFC-123 is 1.4 years, so short that the actual ozone depletion caused by this refrigerant may be much less than the present ODP rating indicates. In contrast, the other major HCFC, HCFC-22, has an atmospheric lifetime estimated at 19 years.

(Some people suspect that the short atmospheric life of HCFC-123 may earn it a reprieve from the Montreal Protocol phase-out. However, HCFC-123 is used only

in large centrifugal chillers. These are less likely to be found in the developing countries from which most of the political pressure for a reprieve are likely to come. Anyway, the phase-out date for HCFC's is still an equipment lifetime away.)

For all CFC's and HCFC's, leakage of refrigerant from the cooling equipment is a dominant factor in ozone depletion. If refrigerant does not leak out, it can do no harm. The most important factors in leakage are:

- ***the pressure of the refrigerant.*** All other things being equal, leakage increases with pressure. Some refrigerants operate at much higher pressures than others. For example, HCFC-22 condenses and evaporates at relatively high pressure, whereas HCFC-123 condenses at about atmospheric pressure, and evaporates at sub-atmospheric pressure.
- ***for low-pressure gases, the efficiency of the purge unit.*** If a refrigerant operates at a pressure below atmospheric, some air leaks into the system and it must be removed. This is done with a purge unit. Unfortunately, the purge unit ejects some refrigerant along with the air. Operation of the purge unit, especially of older models, can cause as much refrigerant loss as using refrigerants that operate at higher pressures. Modern purge units cause far less refrigerant loss.
- ***whether the motor is open or hermetic.*** A compressor with an open drive requires a shaft penetration into the system. This is a significant leakage path that cannot be sealed completely throughout the life of the system.
- ***maintenance practices.*** Maintenance practices have a major effect on the amount of refrigerant leakage. Failure to repair seals, venting of refrigerant to clear air out of the unit, failure to recover refrigerant, and sloppy charging practices may all cause more loss of refrigerant than the design of the machine itself. These bad practices are actually outlawed in the United States, but such laws are unenforceable in practice.

■ Global Warming Potential (GWP)

The global warming theory asserts that the surface temperature of the earth is being raised as a result of "greenhouse effect," in which certain gases in the atmosphere act like the glass in a greenhouse. Incoming short-wavelength solar radiation passes through the atmosphere and heats the surface of the earth, without being affected by the gases. The warmed surface of the earth emits heat into space at much longer wavelength. This long-wavelength infrared radiation is absorbed by the "greenhouse gases," preventing its escape from the earth and heating the atmosphere.

In the framework of this theory, the potential of a refrigerant gas to cause global warming is defined by a relative number called the Global Warming Potential

(GWP), which is defined on a mass basis. This rating system assigns a baseline GWP of 1.0 to carbon dioxide. Carbon dioxide is used as the basis of comparison because it is the second most significant greenhouse gas in the atmosphere, after water vapor. Also, carbon dioxide is the greenhouse gas most abundantly produced by human activity. Table 1 gives GWP ratings for the most common refrigerants and leading candidates.

Global warming differs from ozone depletion in several fundamental ways that relate to refrigerants. The global warming potential of refrigerants is not related to the chlorine content in the refrigerant. Global warming may be caused by many types of gases, including CFC's, HCFC's, and some hydrocarbons. The heating effect occurs at all levels of the atmosphere. It commences as soon as the refrigerant is released into the atmosphere.

The contribution of refrigerants to global warming is much less important on a relative scale than their presumed contribution to ozone depletion. By far the most important gas regulating the earth's heat balance is water vapor. It does this in at least two important ways. One is that it absorbs a large part of the infrared spectrum of incoming solar radiation. Another is that it forms clouds that reflect both incoming and outgoing heat.

Of the other gases, the most important is carbon dioxide, because of the large amount of it in the atmosphere. Next in importance is methane, which comes from many natural sources, from landfills, and from domestic animals, especially cattle.

As of the early 1990's, halocarbon refrigerants were assumed to be next in importance. This included the used of refrigerant-type gases in non-refrigeration applications, such as blowing the bubbles in plastic foam insulation.

Next in importance are nitrogen oxides, which come primarily from combustion emissions. These are followed in importance by ozone.

The selection of refrigerant also influences global warming through its effect on the efficiency of the equipment. If the machine is more efficient, it requires less energy. Most of the energy for cooling is produced by the burning of fossil fuels, which produces carbon dioxide. The efficiency of the refrigerant may be more important with respect to global warming than its GWP.

Similarly, control of refrigerant leakage from the system is as important as the selection of refrigerant. Refrigerant leakage is determined by the factors listed previously in regard to ozone depletion.

The atmospheric lifetime of refrigerants is important in global warming, because the total warming effect is proportional to the length of time that the refrigerant survives in the atmosphere. The atmospheric lifetime is factored into the GWP rating. Of the major HCFC and HFC refrigerants, the atmospheric lifetimes are 1.4

years for HCFC-123, 16 years for HFC-134a, and 19 years for HCFC-22. For CFC's, which are very stable, the atmospheric lifetimes are much longer.

■ Energy Efficiency

Refrigerants differ in the amount of cooling they produce in relation to the energy required to compress them. As with the hardware, the efficiency of a refrigerant can be expressed in terms of COP, which is the COP of the refrigerant in an idealized cooling machine.

The refrigerants presently used for conventional applications all have fairly high COP's, within the range of 75% to 90% of the theoretical maximum. However, the differences between currently available combinations of refrigerants and cooling equipment have a significant effect on the system COP. This makes refrigerant selection a primary decision affecting efficiency. See Table 1 for the COP's of the most common refrigerants and leading candidates.

■ Toxicity

ASHRAE Standard 34 rates refrigerants according to their toxicity on a simple two-level scale, Class A and Class B. The wording of the Standard is technical. Both toxicity classes are based on exposure at a refrigerant concentration of 400 parts per million (PPM). In essence, the Standard says that a Class A refrigerant has a low degree of toxicity at this exposure level, while a Class B refrigerant has a higher degree of toxicity at this exposure level.

The toxicity rating of the refrigerant is only one of several safety considerations. Others are the average duration of exposure to the refrigerant, the ability of persons to escape rapidly from a massive leak, ventilation of the cooling equipment, using refrigerant detectors to warn of leaks, etc. For example, ammonia should not be used in a cooling system that is located where a leak in the system could allow the ammonia to leak into a crowded space. However, ammonia may be acceptable in a central chiller plant that distributes cooling via water.

ASHRAE Standard 15, Safety Code for Mechanical Refrigeration, sets forth the safety features that should be included in the design of cooling plants, based on safety considerations.

■ Flammability and Explosion Potential

ASHRAE Standard 34 also rates refrigerants according to their flammability. The flammability rating has three levels, Classes 1, 2, and 3. Class 1 refrigerants are not flammable in air under particular test conditions. The currently popular CFC's, HCFC's, and some of the HFC's are in this class. Class 2 refrigerants are moderately flammable and/or explosive. For example, ammonia is in this class. Class 3 refrigerants are very flammable and/or explosive. It will come as no surprise that propane and butane are in this class, for example.

Table 1 gives flammability ratings for the most common refrigerants and leading candidates.

ASHRAE Standard 15, Safety Code for Mechanical Refrigeration deals with the safety aspects of flammable refrigerants, as it does for toxicity. The Standard does not make a clear separation between design features for dealing with the two hazards. Instead, it suggests common techniques of isolation, ventilation, etc., to deal with both. This simplifies the design effort.

■ Condensing Pressure

The condensing pressure is (almost) the highest pressure that occurs inside the system. A large chiller is a major pressure vessel, and the condensing pressure determines the weight of the shell, piping, and accessories.

On the other hand, operation at higher pressure reduces the volume of the gas, all other things being equal (which they are not). This results in smaller machinery, which reduces cost. For example, HCFC-22

condenses at much higher pressure than HCFC-123, but it has about nine times the refrigerating effect per volume of gas.

The condensing pressure is a major factor in the rate of refrigerant leakage. This is important if the refrigerant has environmental hazards. Leakage also contributes to maintenance cost, but this is a relatively small factor in the overall operating cost of a plant.

■ Evaporating Pressure

The evaporating pressure is (almost) the lowest pressure that occurs inside the system. The major consideration is whether the evaporating pressure is below atmospheric, which is true of CFC-11 and HCFC-123. If so, there will be some leakage of air into the system. Air contaminates the refrigerant and reduces performance. For this reason, systems with evaporator pressures below atmospheric require purge units to remove the air. The operation of the purge unit expels some refrigerant into the atmosphere, as discussed previously.

This Note provides a quick introduction to the efficiency aspects of centrifugal pumps. It gives you a basis for selecting pumps for maximum efficiency in typical applications, and for improving the efficiency of existing pump installations.

How Centrifugal Pumps Work

Centrifugal pumps are one of the quiet mainstays of modern civilization, notable for their simplicity. Like those other technological marvels, the centrifugal fan and the electric motor, centrifugal pumps have only one moving part. That part is the impeller, which discharges liquid from its periphery by centrifugal force and draws in liquid at its center. The pump casing that surrounds the impeller is designed to feed the liquid into the impeller efficiently, and to discharge the liquid into the system efficiently.

The liquid velocity leaving the impeller is usually higher than needed. To slow it down, the pump has passages of increasing cross sectional area through which the liquid flows after leaving the impeller. A common configuration is an expanding passage that is wrapped around the perimeter of the pump. This gives the pump casing the classic spiral or “volute” shape, which is shown in Figure 1. The output velocity can be reduced further by installing an expanding discharge throat.

An alternative way of reducing the impeller discharge velocity is to use a set of diffuser vanes surrounding the impeller. Pumps of this design have a casing that is shaped like a pillbox.

Multi-stage pumps are used to achieve higher discharge pressures without resorting to large impeller diameters. In multi-stage pumps, a number of impellers are mounted on a single shaft, with the discharge from one stage being routed to the inlet of the next.

Names for Centrifugal Pumps

There is no consistent naming system for centrifugal pumps. A pump may be named for its number of stages, orientation (“horizontal” or “vertical”), type of case

(“end suction,” “double-volute,” etc.), method of disassembly (“split case,” etc.), impeller type (“propeller,” “mixed flow,” etc.), or other characteristics.

The Impeller Determines the Pump’s Characteristics

The main performance characteristics of a pump are its flow rate, pressure, and power input. These characteristics are determined primarily by the diameter, the width, and the rotational speed of the impeller.

From simple geometry, the volume of flow produced by a centrifugal pump is the product of the cross sectional area of the impeller passages multiplied by velocity of the liquid as it exits the impeller. The exit velocity is related to the peripheral velocity of the impeller by a constant relationship that depends on the curvature of the impeller blades.

Since the flow volume is directly proportional to the peripheral velocity of the impeller, it is proportional to the impeller diameter and to the rotational speed.

The pressure output of a centrifugal pump is derived from the kinetic energy that it imparts to the liquid. Kinetic energy is proportional to the square of the liquid’s speed. Since the speed of the liquid is related to the peripheral velocity of the impeller, the pressure developed by the pump is proportional to the square of the impeller diameter, and also to the square of the impeller speed.

The power consumed by a pump is proportional to the product of the pressure and the flow rate, so the power is proportional to the third power of the impeller diameter, and to the third power of the impeller speed.

Since the pressure and flow of a given pump are both related to the characteristics of its impeller, you cannot change one without changing the other. Changing the impeller diameter or speed has a larger effect on the pressure than it does on the flow rate. This is because pressure is proportional to the second power of the impeller diameter or speed, while flow is proportional to the first power.

The flow rate is not affected by the specific gravity, or mass, of the liquid being pumped. However, the

WESINC

Fig. 1 Centrifugal pump A simple impeller inside the case is spun by the motor. Water enters from the left through an opening in the center of the impeller. Centrifugal force flings the water toward the perimeter of the case. The spiral shape of the case collects the water as it follows the rotation of the impeller, and discharges the water into the vertical discharge pipe. The width of the impeller determines the flow rate through the pump. The speed at the outer rim of the impeller, which is determined by its diameter and rotational speed, determines the discharge pressure.

Table 1. PUMP PERFORMANCE RELATIONSHIPS

Effects of Speed		
flow rate	~	speed
pressure	~	speed ²
power	~	speed ³
Effects of Diameter		
flow rate	~	diameter
pressure	~	diameter ²
power	~	diameter ³
Effects of Specific Gravity		
flow	<i>is independent of</i>	specific gravity
pressure	~	specific gravity
power	~	specific gravity

NOTE:

- "~" means "proportional to".
- In each of these relationships, all other variables are held constant.
- These relationships are approximate, because any changes affect the efficiency of the pump.

kinetic energy of the liquid is proportional to the first power of the specific gravity. Therefore, the pressure and the input power are also proportional to the first power of specific gravity. The nature of the liquid usually does not change in a given pumping application, so this is usually not a factor in energy conservation modifications.

These relationships, which are sometimes called "affinity laws," are summarized in Table 1.

The fact that the impeller determines the pump characteristics is especially useful if you have an opportunity to modify existing pumps to reduce energy consumption. You can reduce pressure, flow, and power input on a one-time basis by trimming the diameter of the impeller. Or, you can adjust the speed of the impeller, usually with a variable-speed drive. The latter approach provides a great deal of flexibility in adapting pump power to changing system requirements.

Pump Efficiency and Operating Points

A pump has its best efficiency at a single combination of flow rate and pressure. This point

Fig. 2 Basic pump curve This relationship between the flow rate and the pressure that the pump produces is typical of all centrifugal pumps. Also, the point of maximum efficiency is usually near the point shown here. Operating far from this point makes the pump very inefficient, and may damage the pump.

typically is near the maximum pressure, and at about one third of maximum flow. At lower pressures, efficiency declines because the impeller is producing pressure internally that is not utilized. Similarly, at higher flow rates, the flow is occurring without the need for all the pressure that is being produced. At lower flow rates, efficiency declines because the impeller produces turbulence in trying to move the liquid into a system that will not take it.

A centrifugal pump is able to operate well away from its point of maximum efficiency, which simplifies system design and allows a margin for error in estimating system characteristics. The efficiency loss is considered moderate as long as the actual operating point is reasonably close to the point of maximum efficiency. On the other hand, if the pump is not well matched to system flow and pressure requirements, or if the system flow requirement varies widely, the pump may spend a large fraction of the time operating at substantially reduced efficiency.

Fig. 3 Typical catalog pump curves This important engineering tool displays all the information that you need for selecting or modifying a pump for most applications. Overlaid on the pressure-vs.-flow curves are curves of efficiency and input power. "NPSH" means "net positive suction head," which is the amount of pressure needed at the pump inlet to avoid cavitation.

Allis-Chalmers

Pump Curves

The relationship between a particular pump's pressure and flow is called its "pump curve." A typical pump curve is shown in Figure 2. All centrifugal pumps have pump curves similar to this one.

One characteristic of the pump curve is that the pressure produced by the pump decreases as the flow rate through the pump increases. For a given pump, the flow rate through the pump is determined by the resistance of the system, and the pump pressure is determined accordingly.

Another characteristic of the pump curve is that the point of maximum efficiency is part way down the curve, usually near the point shown in Figure 2. Efficiency falls rapidly above and below this point.

A pump that is properly selected and applied will operate within a limited range of flow rates, as shown in Figure 2. This keeps the pump operating at high efficiency. Also, throttling the flow excessively creates turbulence and cavitation, which damages the pump.

This basic curve of flow-vs.-pressure is commonly used as a platform to display other pump characteristics, such as power consumption, efficiency, and suction head requirements. Pump manufacturers typically provide combined sets of curves in their catalogs, as illustrated in Figure 3. Such sets of curves are your basic reference for selecting or modifying a pump.

The typical set of curves in Figure 3 includes a range of impeller diameters. This is because pump manufacturers make only a limited number of casing sizes, so they satisfy different customer requirements by varying the impeller diameter.

An increasingly popular method of modulating pump output is varying the speed of the pump. As discussed previously, impeller speed and impeller diameter have similar effects on flow, pressure, and energy consumption. Therefore, a set of pump curves similar to those in Figure 3 can be developed in which the curves for different diameters are replaced with curves for different impeller speeds. Such curves are needed for designing variable-flow pumping applications, where the flow is modulated by varying the pump speed.

Reducing either impeller diameter or impeller speed shrinks the pump curve. The curve shrinks along the flow axis proportional to the diameter or speed, while the curve shrinks along the pressure axis proportional to the square of the diameter or speed.

■ Flatness of Pump Curves

With all centrifugal pumps, the pump discharge pressure falls as the flow increases. (Alternatively, you can visualize that the pump pressure "backs up" as the discharge from the pump is obstructed by higher discharge pressure.) This tendency varies among pumps of different design. Pumps that tend to maintain their pressure as flow increases are said to have "flat" pump curves, while pumps that lose pressure rapidly with increasing flow are said to have "steep" pump curves.

Select a pump with a flat curve for applications that require a fairly constant pressure over a wide range of flow rates. Such applications include boiler feedwater pumping, pumping of service water in tall buildings, and pumping of chilled water in systems where the cooling coils have throttling valves. A flat pump curve is not needed in applications involving a single operating point, such as typical cooling tower water pumping.

The Formula for Pump Power Input

In the most general sense, power is consumed when some form of force is exerted at some rate of displacement. With pumps, the force takes the form of pressure. The displacement takes the form of flow rate times the density of the fluid.

Formula 1 expresses this relationship mathematically. This formula appears with a variety of units. For example, some metric versions express pressure in terms of kiloPascals and others express pressure as meters of water.

In existing installations, you can often save energy by reducing the pressure or flow rate, or both. For a given pump, changes to the system that reduce the average flow rate usually reduce the average pressure as well. Since pressure and flow are multiplied by each other in the formula, this results in a relatively large saving. Changes to pressure and flow also affect the pump's efficiency. The efficiency factor in the formula

FORMULA 1

$$\text{Pump power input} = \frac{(\text{discharge pressure} - \text{suction pressure}) \times \text{flow rate} \times \text{specific gravity}}{\text{constant} \times \text{pump efficiency}}$$

where the units are as follows:

	<u>metric</u>	<u>inch-pound</u>
power	kilowatts	horsepower
pressures	kiloPascals	feet of head
flow rate	cubic meters per minute	gallons per minute
constant	60	3960

Fig. 4 System curve and pump curve The pump must operate somewhere along the pump curve. The system must operate somewhere along the system curve. The point where the two curves cross is where the pump and the system will operate.

Fig. 5 Family of system curves for a system that has variable resistance These curves might represent a hot water heating system or a chilled water system that uses throttling valves on the coils. The operating point moves over a wide range on the pump curve.

Fig. 6 System that has constant pressure requirement This type of system curve is typical of open systems in which the pump must overcome gravity head in addition to piping friction.

depends on how close the pump's actual operating point comes to the point of maximum efficiency, as discussed previously.

In designing a new pump system, you have the additional option of selecting the pumps for higher inherent efficiency. The factors that determine inherent efficiency are covered below.

System Curves

To achieve efficient pump operation, you have to match the pump's pressure and flow characteristics to the pressure and flow requirements of the system. The characteristics of the system can be depicted by a

Fig. 7 System curves for throttling boiler feedwater system In this system, the pump must overcome the high pressure of the boiler and also the variable resistance of the feedwater throttling valve.

“system curve.” This is a graph of the pressure that would be required to drive liquid through the system at various flow rates. When a particular pump is used with a particular system, the flow rate and the pressure at the pump are determined by the point at which the pump curve intersects the system curve. A typical example is shown in Figure 4.

The system curve shown in Figure 4 is typical of a system in which the only pump load is overcoming the friction of pipe and other components. This is typical of closed systems. Gravity can be disregarded in most closed systems, because the weight of liquid in the return leg balances the weight of liquid in the supply leg. Such a system has a zero pressure requirement at zero flow, and the pressure requirement rises proportional to the square of the flow rate.

If the system has valves that throttle the flow, the position of the valves affects the shape of the system curve. Figure 5 shows how the system curve changes as the flow resistance increases. For example, Figure 5 might represent a hot water heating system or a chilled water system with throttling valves on the coils.

In open systems, such as domestic water systems and cooling tower systems, the pump must overcome gravity in addition to the friction of the pipe and fittings. The gravity head is constant, while the system friction varies with the flow rate. Figure 6 shows a typical system curve for such a system.

Boiler feedwater systems are different from the previous. These are closed systems, but they have a constant pressure requirement, which is the boiler pressure. In addition, the pump must overcome the resistance of the boiler inlet valve. If the boiler has a throttling feedwater valve, the system has a family of curves, such as those in Figure 7.

The system curve is useful for visualizing the effect of changes in operating conditions, and for visualizing the effect of changes to the system. In most cases, the system designer does not select a pump with a system curve, but instead selects a single operating point. This point is based on the calculated pressure and flow requirements of the system at the condition of maximum pump load.

When making changes to an existing system, you cannot determine the actual system curve with enough accuracy to be useful. Instead, make changes on the basis of pressure and flow measurements.

Pump Selection Issues that Affect Efficiency

The maximum efficiency that a pump can achieve depends on certain inherent design characteristics. You usually determine the efficiency of a particular pump from the catalog, but it helps to understand the underlying factors. In larger pump installations, understanding these factors is essential for selecting the

most efficient pump, and for designing the system to take advantage of pumps' characteristics. The following are the pump characteristics that determine efficiency.

■ Specific Speed

The “specific speed” of a pump is an abstract number used in designing pumps. It is defined by this formula:

$$\text{specific speed} = \frac{\text{RPM} \times (\text{flow rate})^{1/2}}{(\text{pressure})^{3/4}}$$

where the pump RPM, flow rate, and pressure are the values at the pump's point of maximum efficiency.

If the flow rate is expressed in cubic meters per second, and the pressure is expressed in meters of water column, the highest efficiency is achievable when the pump is designed for a specific speed in the range of about 30 to 100. If the flow rate is expressed in gallons per minute, and pressure is expressed in feet of water column, the corresponding specific speeds are in the range of about 1,500 to 5,000. Maximum achievable efficiency drops steadily at values above and below these ranges.

The specific speed is determined by the pump's geometry, but is not related to its size. Pumps having a similar shape have a similar specific speed, regardless of size. Low specific speeds are characterized by radial flow and narrow impeller passages. High specific speeds are characterized by increasingly axial flow, and large, open impellers that start to resemble propellers. Larger pumps tend to be designed for higher specific speeds because this reduces the size and cost of the pump.

■ Pump Size

Larger pumps tend to be more efficient, for a given shape or specific speed. The main reason is that mechanical imperfections and design compromises that reduce efficiency are relatively less important in larger pumps.

■ Liquid Viscosity

Viscous (thick) fluids reduce pump efficiency because the deformation of the liquid as it passes through the pump requires shearing force within the liquid. This is not a major factor with water and water-based solutions, but is important in pumping thicker substances.

■ Impeller Compromises to Handle Solids

If the pump is used for liquid that carries a content of solids, such as sewage and slurries, the impeller must be designed to pass the solids. This design compromise usually reduces efficiency.

■ Smoothness of Pump Passages

Surface roughness in the liquid passages reduces pump efficiency, especially in pumps where the passages are narrow. The efficiency loss declines as the impeller passages become larger. The loss also depends on the flow properties of the liquid.

Pump models with smoother liquid passages are an option in larger sizes. These models may use different materials and/or more expensive manufacturing techniques.

■ Internal Leakage

The high-pressure liquid in the discharge of the pump tends to leak back to the low-pressure inlet, wasting pump energy and reducing capacity. Leakage is worst in pumps with low specific speeds, i.e., in pumps where the pressure is high with respect to the flow rate. For a given specific speed, leakage loss is lower in larger pumps.

Leakage is minimized by maintaining small clearances between the inner and outer rims of the impeller and the pump casing, and in larger pumps, by using seals called “wearing rings.” Close manufacturing tolerances are needed to keep the impeller from changing its position with respect to the casing. This aspect of efficiency is a quality and price choice to be made by the system designer and the purchaser.

■ Mechanical Drag

Pumps require seals and packings to prevent the escape of liquid from the pump to the outside, to prevent internal leakage, and perhaps to prevent the entry of air into the pump. These items exert mechanical drag that must be overcome by the motor. The pump and motor bearings also exert drag. This drag absorbs a substantial fraction of motor power in small pumps, but relatively little in large pumps. In most pump sizes, this is a selection option for the system designer and purchaser.

DIRECT-CURRENT MOTORS AND DRIVES**How DC Motors Work****How DC Drives Work****Advantages and Disadvantages****Waveform-Related Problems and Solutions****Application-Related Selection Considerations****VARIABLE-PULLEY DRIVES****EDDY CURRENT CLUTCH DRIVES****WOUND-ROTOR MOTORS**

This Note covers all the contemporary methods of getting variable-speed output from electric motors. It will guide you to the best choice of a variable-speed motor drive for your application.

Types of Variable-Speed Motors and Drives

One broad class of motors, direct-current (DC) motors, are inherently variable-speed devices. These motors are historically the oldest type, and they are well

proven. However, since the end of the nineteenth century, they have been relegated to the status of specialty devices by the development of the alternating-current (AC) induction motor and the spread of AC power.

The three-phase AC induction motor is the workhorse of modern civilization, providing most of the mechanical power used in stationary applications. It is simple, compact, reliable, and cheap. About 60% of all electricity is used in these motors. Most of that is used in motors of larger sizes. Single-phase induction motors are more complex, and they are limited to smaller sizes.

The only major disadvantage of induction motors is that they are single-speed devices. Their speed is determined by the frequency of the alternating current that drives them. If the power requirement of the driven equipment depends on speed, and if the load varies, the excess input energy at partial loads is wasted. Many applications for fans and pumps waste energy in this way.

Now, efficient means are available for varying the speed at which induction motors can drive equipment. This opens up many opportunities for energy conservation. It also offers significant secondary benefits, such as reducing the average noise level of driven equipment, and extending equipment life.

The most direct method of varying the speed of an AC motor is to change the frequency of the power that drives it. The electronic variable-frequency drive (VFD) has become the primary method for applications requiring smooth speed modulation over a wide range.

An AC motor can change its speed in steps by having several distinct sets of windings. Speed is changed by switching between the windings. A similar result is achieved by driving the load with two different motors, each of which has a different number of poles.

One type of AC motor, the wound-rotor motor, attempts to mimic the behavior of DC motors. It controls speed by varying the rotor current. This type is inefficient and limited in speed range. It has become obsolete, except in combination with special equipment that is described below.

Older methods let the motor run at constant speed, and use a speed changing transmission. The transmission may be mechanical, hydraulic, or electromagnetic. Some of these methods are still worth considering.

This Note covers most of these types of variable-speed motor drives, except for ones that have virtually disappeared.

Consider Overall Efficiency

When selecting a method of achieving variable speed, calculate the total losses for each method you are considering. The total losses consist of these components:

- **motor losses.** Multi-speed motors, wound-rotor motors, and variable-frequency drives incur some energy losses within the motor itself.
- **drive losses.** Any type of drive that requires additional equipment, such as a variable-frequency drive or a variable pulley, incurs losses in that equipment.
- **losses in the power supply system.** Any drive that causes distortion of the input power incurs losses in transformers and other parts of the power supply system. This is a problem primarily with variable-frequency drives.
- **losses in the application.** Any drive that does not modulate speed precisely to minimize energy consumption in the drive equipment wastes energy. The amount of waste depends on the nature of the application. For example, a two-speed drive may capture most of the potential savings when driving a cooling tower fan, but it may be much less efficient than a fully modulating fan drive when used in a reheat air handling system.

Other Selection Factors

Efficiency is not the only important selection criterion for a variable-speed drive. The reason that different approaches remain in the market is that each has a number of advantages and disadvantages. The most popular type of drive is not necessarily the best for your application. Be prepared to research the market, and keep an open mind.

For example, multi-speed motors and multiple-motor drives are inexpensive, reliable, and free of electrical problems, but they cannot provide continuous modulation of speed. Variable-pulley drives are also simple, reliable, and free of electrical problems, but they are limited in capacity and speed range. Variable-frequency drives provide good efficiency and almost unlimited speed and torque range, but they may cause a variety of serious electrical problems. Direct-current (DC) drives are efficient and provide the best speed control, but they are expensive and require more maintenance than AC motors. Eddy current clutches and wound-rotor motors are simple and inexpensive, but they are less efficient than the other methods.

MULTI-SPEED A.C. MOTORS

Using 3-phase multi-speed motors is one of the most efficient methods of minimizing motor energy requirements, from the standpoint of the motor itself. Multi-speed motors are relatively inexpensive, simple to install, and free of the problems that plague some modulating types of variable-speed drives. Their main limitation is the stepwise nature of the speed change, which usually imposes an efficiency penalty in the overall application. The size of this penalty depends on the speed and load characteristics of the application.

The discussion here relates to 3-phase motors that change speed by switching poles. Switching poles is the only efficient method of changing the speed of a motor. Pole-switching motors are made in sizes ranging from fractional horsepower to several hundred horsepower (or kilowatts).

Speed and Number of Poles

The highest possible motor speed with 60-Hz power is 3,600 RPM, where the rotor turns 360° during a single cycle of alternating current. Doubling the number of poles produces a nominal speed of 1,800 RPM because the rotor makes only half a turn during the cycle. Tripling the number of poles produces a nominal speed of 1,200 RPM, and so forth. Thus, motor speed is inversely proportional to the number of poles.

(The actual speed of ordinary induction motors is somewhat lower than the nominal speed. This is because of the “slip” needed to induce the magnetic fields between stator and rotor. Slip increases with load. The motor speeds given in catalogs are usually the actual speeds at full load.)

Types and Speed Ratios of Two-Speed Motors

Most multi-speed motors have two speeds. There are two common types of 3-phase two-speed motors, “one-winding” and “two-winding.”

As the name implies, a one-winding motor has a single set of windings that drive the motor at both of its speeds. The speed is changed by switching the connections of the windings so that the number of

electrical poles is doubled to achieve the lower speed. One-winding motors are limited to a speed ratio of 2:1.

Figure 1 shows all the important characteristics of a one-winding, two-speed motor. Notice that all these characteristics are related to the amount of torque that the motor is producing.

Two-winding motors have two entirely independent sets of windings. This allows any combination of poles that is a ratio of whole numbers. Speed ratios of 4:3, 3:2, and 2:1 are common. Motors with higher speed ratios, such as 3:1 and 4:1, can be produced on a custom basis.

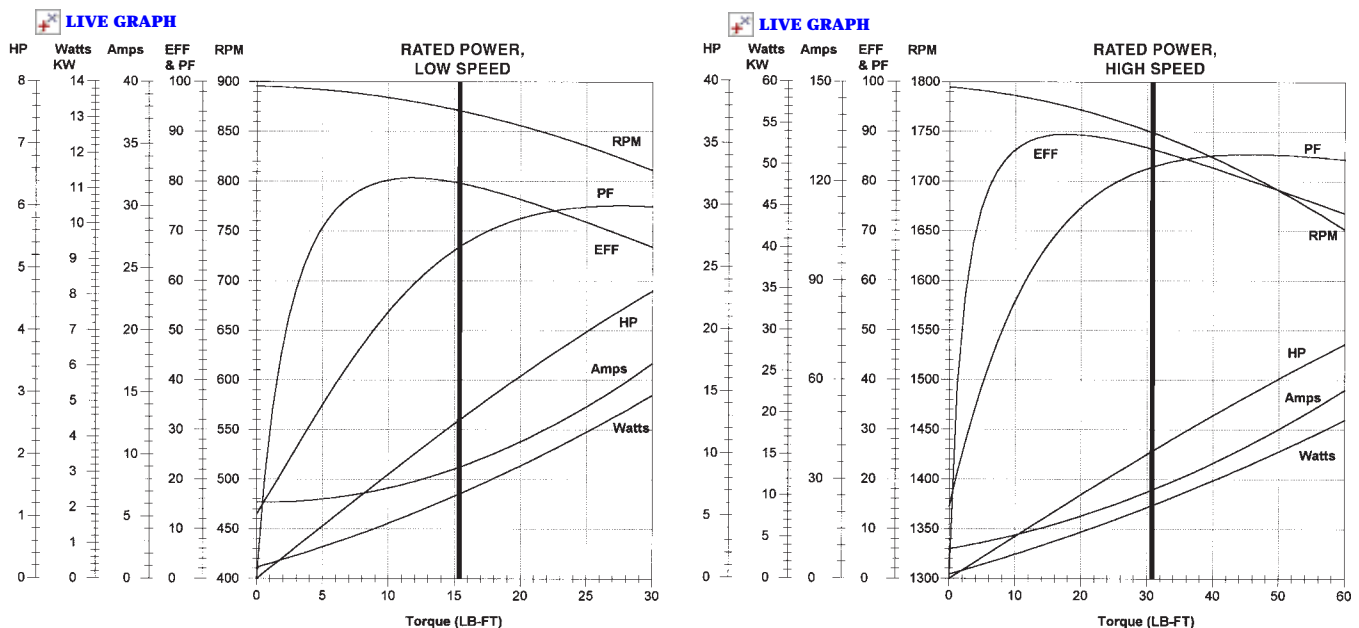

The two-winding design also allows the motor torque characteristics at each speed to be matched to the requirements of the application.

Two-winding motors are larger, heavier, and more expensive than one-winding motors. The inactive winding takes up space, which requires a larger core. This increases magnetization losses, which makes two-winding motors less efficient than one-winding motors.

Motors With More Than Two Speeds

It is possible to make 3-phase motors with three or four speeds. Such motors are made on a custom basis. Each speed is achieved with a separate set of windings. Alternatively, a four-speed motor can be made with two 2-speed windings.

These motors are even larger, heavier, and more expensive than two-speed motors. Efficiency is further reduced by increased losses in the magnetic circuit. These motors are worthwhile if the efficiency

Leeson Electric Corporation

Fig. 1 Characteristics of a two-speed, one-winding motor All the important operating characteristics of the motor are presented here. The curve on the left is for low-speed operation, at a rated output of 2.5 horsepower. The curve on the right is for high-speed operation, at a rated output of 10 horsepower. In this manner of presentation, the motor's performance is displayed in relation to the motor's torque load.

improvement in the application offsets the greater losses in the motor.

Efficiency Characteristics

At the present time, multi-speed motors are not covered by efficiency standards, and efficiency is usually not part of the catalog information. To get efficiency data, you must request it from the manufacturer for a particular model. This information will probably be a computer-generated estimate, since most multi-speed motors are built to custom order even though they may have standard catalog listings.

One-winding motors are somewhat less efficient than conventional single-speed motors when operating at high speed. Their efficiency drops further at the lower speed. For example, a typical 10-horsepower variable-torque motor has an efficiency of about 88% at high speed, and about 79% at low speed. The high-speed efficiency is slightly less than the current U.S. efficiency standard for single-speed motors.

As stated previously, two-winding motors have somewhat lower efficiency than one-winding motors, at least at the high speed. Motors with more than two speeds are even less efficient.

The overall drive efficiency of multi-speed motors compares favorably with that of variable-speed drives. Multi-speed motors require no additional speed control devices and they cause no degradation of power system efficiency. From an efficiency standpoint, the key question is whether the stepwise nature of the speed control is able to exploit most of the energy-saving potential in the application.

Torque and Power Ratings

The torque characteristics of single-speed motors are covered in [Measure 10.1.1](#). Multi-speed motors have the additional complication that the torque characteristics at each speed must match the torque requirements of the load at that speed. The relationship of the torque requirement to speed varies widely with the application. For this reason, it is conventional to manufacture multi-speed motors in three torque classes:

- **“variable-torque”** motors, in which the torque requirement increases with speed. The low-speed motor windings produce much less torque than the high-speed windings. The motor horsepower rating at each speed is proportional to the square of the speed. The most common variable-torque applications are centrifugal fans and centrifugal pumps, in which the load increases as the square of the speed.
- **“constant-torque”** motors, in which the maximum torque may be required at any speed. For these applications, the low-speed motor windings must produce as much torque as the high-speed windings.

The motor horsepower rating at each speed is directly proportional to the speed. Typical applications are conveyor belts, tumblers, and reciprocating compressors.

- **“constant-power”** or **“constant-horsepower”** motors, in which the torque requirement is related inversely to speed. For these applications, the low-speed motor windings must produce much higher torque than the high-speed windings. The motor horsepower rating at all speeds is the same. Typical applications are drill presses, milling machines, lathes, and some grinders and crushers.

Relative Prices

A two-speed motor is the least expensive way of achieving variable speed. A two-speed motor is considerably less expensive than any other method of changing speed, except for multiple-motor drives, which are discussed next.

A one-winding, variable-torque, two-speed motor may cost almost twice as much as a comparable single-speed motor. However, by comparison, it may still cost less than some single-speed motors designed to operate with variable-frequency drives.

Two-winding motors cost considerably more than one-winding motors. However, if a motor starter is needed, it is less expensive for two-winding motors.

Increasing the torque rating of a multi-speed motor increases the price considerably, but the same is true of any other type of speed control.

Three- and four-speed motors are custom items. They are more expensive than two-speed, two-winding motors.

Other Selection Considerations

Refer to [Measure 10.1.1](#) for general considerations related to the selection and installation of motors, such as service factor, power factor, etc.

Single-Phase Multi-Speed Motors

The only efficient method of changing speed in single-phase motors is switching the number of poles, as in three-phase motors. Old ceiling fan motors demonstrate the large speed ratios that are possible, along with the large number of poles required.

Single-phase motors require separate winding provisions for starting because the field of a single-phase motor does not rotate. This complicates two-speed operation, requiring compromises in efficiency and starting torque. At present, there is little interest in improving the efficiency in single-phase, multi-speed motors.

There are several other types of single-phase motors that provide speed variation. All of them are inefficient. Their size is limited to a small fraction of one horsepower

(or kilowatt) because their losses become heat that would burn up the motor in larger sizes.

MULTIPLE-MOTOR DRIVES

Another method of achieving multi-speed motor operation is to use two or more motors to drive a common piece of equipment. One motor runs while the other motor or motors idle. For example, two-motor arrangements are commonly used to drive fans in air handling units and cooling towers. Figure 2 shows a typical application.

You can achieve virtually any combination of speeds by combining single-speed motors. Motor speeds of 3600, 1800, 1200, and 900 RPM are readily available. (These are the nominal, or no-slip speeds. Also, we are assuming 60-Hertz power here.) Therefore, by using two motors, you can have speed ratios of 4:1, 3:1, 2:1, 3:2, or 4:3 in direct-drive applications. By using a belt drive for at least one of the motors, you can create any combination of two speeds.

This method of achieving multi-speed operation offers the highest motor efficiency. This is because each motor is conventional, so you can select it for high efficiency without making other compromises. Additional drive losses, compared to a single motor, are minimal. Also, this method provides increased reliability, since any motor can operate the equipment independently.

Equipment cost is modest, because the motors are conventional, and because the smaller motor is usually a fraction of the size of the larger motor.

This method is often impractical to retrofit, especially in smaller sizes. In larger sizes, where a lot of energy can be saved, it may be worthwhile to modify the equipment to take a second motor. This may be easier than it looks. There is often room to install a pulley somewhere on a shaft, allowing the second motor to be installed at some distance from the equipment by using a belt.

Baltimore Aircoil Company

Fig. 2 Two-motor fan drive for a cooling tower The two centrifugal fans are driven by a common shaft. The larger motor drives the shaft from the left side, for high speed operation. The smaller motor drives the shaft from the right side, for low speed operation. Each motor is connected to the shaft by drive belts, allowing any possible combination of two speeds to be selected. When each motor operates, the other idles. Multiple-motor drives can be used for many applications. The motors are entirely standard, and no special drive equipment is required.

VARIABLE-FREQUENCY MOTOR DRIVES

During the 1980's, the variable-frequency electronic drive (VFD) became the preferred method of driving many types of loads at continuously variable speeds. VFD's are used with ordinary types of AC induction motors or synchronous motors, although it is prudent to use special models designed to operate with VFD's. Figure 3 shows a typical installation.

Rather than using a speed changing mechanism between the motor and the load, the VFD changes the speed of the motor itself, a capability that previously was limited to DC motors. The VFD, which is totally electronic, changes motor speed by changing the frequency of the current that is supplied to the motor. The rotational speed of AC motors is tied to the frequency of the input power, so changing the frequency changes the speed.

VFD's can be reliable and trouble-free if they are selected and installed properly. There are many things you ought to know before selecting the equipment, including problems that VFD's can cause. At first, manufacturers kept silent about the problems, but the development of adequate solutions to these problems

now stimulates vigorous discussion, largely in the form of competing claims. Other selection considerations are important for matching the drive to the application. VFD's are still evolving. The following tells you what to look for, and gives you the background to understand future developments.

VFD's are a major breakthrough in energy efficiency because they make it practical to use precise motor speed control in a wide variety of applications. Figure 4 shows a realistic number of applications in a typical building HVAC system.

Advantages of Variable-Frequency Drives

■ High Efficiency

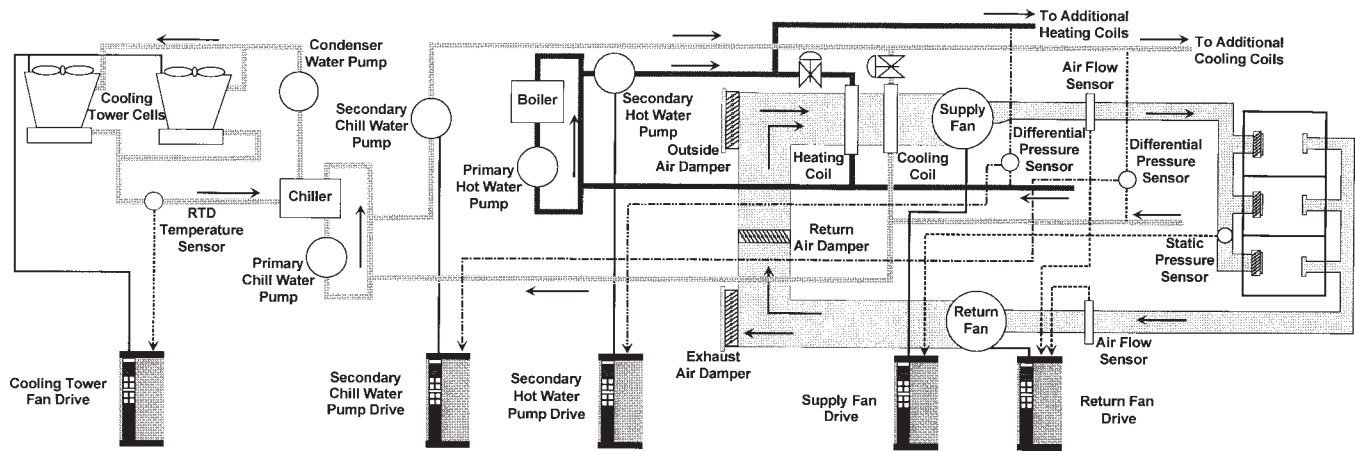

Variable-frequency drives are an efficient means of modulating the output of conventional induction motors and synchronous motors. For the drives themselves, full-load efficiencies above 95% are claimed. Efficiency falls with speed, with wide variation of part-load efficiency between drive types and models. Drive efficiency is discussed below.

When a motor is driven by a VFD, it wastes somewhat more energy as heat because the waveform

Reliance Electric

Fig. 3 Variable-frequency drives for large pumps The cabinets are full of solid state electronics and electrical filters. There are no moving parts, and little audible noise. The drives can be installed anywhere with respect to the location of the equipment. The size of the cabinets is roughly proportional to the power of the motors being driven.

Graham Company

Fig. 4 Typical applications for variable-frequency drives in a comfort conditioning system Consider a variable-speed drive for every motor of significant size that has a variable load. Consider all appropriate types, not just variable-frequency drives.

of the power produced by the VFD is not a good replica of a sine wave. This loss varies widely among different types and models of VFD's, and among different models of motors. For a given VFD and motor, the amount of energy waste depends on the speed reduction and the motor load. Major motor manufacturers now offer models that are designed for reduced losses with VFD's.

VFD's increase losses in the transformers that feed them because of distortion of the input waveform. This effect varies widely between drive types and models, but is usually minor.

The overall system efficiency when using VFD's is somewhat lower than the efficiency typically achieved with modern DC drive systems and variable-pulley drives.

■ Large Turndown Ratio

For equipment driven by AC induction motors or synchronous motors, VFD's offer by far the best turndown ratio. Older types of VFD's offer a turndown ratio of at least 10:1. The best of the new models approach the near-zero-speed capability of DC drives.

■ Ease of Installation and Retrofit

You can often retrofit a VFD easily, with no changes to the existing mechanical installation being needed in most applications. However, some VFD's may cause existing motors to run substantially hotter. With such drives, it is advisable to replace the motor as well.

The electrical components of the drive are contained in an enclosure whose size is proportional to the motor size. Drives for motors of several horsepower typically have the volume of a shoe box. Drives for larger motors are typically freestanding units. The largest are about one or two cubic meters in volume. The drive can be mounted anywhere convenient, even at a considerable distance from the motor. VFD's can be installed in almost any environment, provided that they have an appropriate enclosure.

■ Low Maintenance

Variable-frequency drives have no components that transmit mechanical power, and no moving parts other than pushbuttons. If proper enclosures are selected, the units require no routine maintenance or cleaning.

By the 1990's, the electrical reliability of VFD's improved to the point that electrical failures are rare. In most cases, repairs can be accomplished by exchanging easily removable components. Most manufacturers offer models with self-diagnostic capability. The drives can be adequately protected against electrical faults, either by internal features or by external protective devices.

Motor Limitations in Applications with High Low-Speed Torque

At the outset, it is important to understand that a VFD may not be usable with conventional AC motors in applications where the motor must maintain high torque as the speed is reduced. Over half of all larger motors are used in such applications. Torque requires current, and current produces motor heating. However, conventional AC motors lose their ability to get rid of heat as their speed is reduced.

This is a limitation of the motor, not the drive. These limitations disappear if motors are used that can reject heat effectively at low speed.

■ Torque Categories

The relationship of the torque requirement to speed varies widely with the application. It is conventional to group applications into three torque categories:

- “*variable-torque*” applications, in which the torque requirement increases with speed, typically with the square of speed. The most common examples are centrifugal fans and centrifugal pumps. These applications require the lowest motor current at reduced speeds.

- “*constant-torque*” applications, in which the maximum torque may be required at any speed. Examples are conveyor belts, saws, tumblers, and reciprocating compressors. The description “constant-torque” is not literally correct in many applications, since the torque may vary widely, for example, with a conveyor belt.
- “*constant-power*” or “*constant-horsepower*” applications, in which the torque requirement is related inversely to speed. Constant-power applications require very high starting torque. Examples are drill presses, milling machines, lathes, and some grinding and crushing applications.

■ Motor Cooling Limitations

Motor heat is generated in both the stator and rotor. The amount of heat generated in the stator depends on the motor current. The amount of heat generated in the rotor depends on the stator current and on the percentage of slip. (Slip is what induces circulating currents in the rotor.) Heat from both the stator and the rotor must be able to find its way to the outside.

The rotor has impeller blades on its ends to make it act as a centrifugal fan. In open motors, the fan circulates air through the motor, cooling the stator and rotor directly. In enclosed motors, the fan moves heat toward the inside surface of the exterior shell. The stator can lose heat by direct conduction to the motor shell, but the rotor depends almost entirely on the internal air circulation created by the fan. Many motors also have a

fan impeller installed on the external shaft that blows air over the outside of the shell.

As the motor is slowed by the VFD, the internal and external fans circulate less air. In “constant-torque” applications, the amount of heat produced at low speed may not decline much, if any. In “constant-power” applications, heat production may rise radically. The motor cannot get rid of the heat without a large rise in temperature. The rise in temperature may be severe enough to damage insulation and bearings within a short period of time.

■ Motor Ratings for Variable-Speed Operation

AC induction motors were originally designed to operate at a fixed speed, and most are still designed that way. VFD’s introduce a mode of operation for which induction motors are not designed. Figure 5 is a graph of the maximum torque and power that is allowable with a typical high-efficiency motor as the speed is reduced. Note that the allowable torque remains constant down to a certain speed, and then drops. (Some motors allow maximum torque down to minimum speed.) The graph also shows that the maximum allowable power drops immediately and inversely with speed.

Ironically, torque and power limitations may be more severe with “high-efficiency” motors. One of the techniques used to reduce the energy consumption of high-efficiency motors is reducing the capacity of the fan. Contrary to popular misconception, “high-efficiency” motors do not necessarily run cooler than conventional motors. In variable-speed applications, they may even run hotter.

This limitation can be removed by the development of motors for high-torque VFD applications that have cooling independent of motor speed. This is not a new idea. DC motors are commonly available with separate fans and filters that maintain a constant flow of outside air through the motors. At the moment, however, a custom AC motor is generally required to provide high torque at low speeds.

■ Adapting to Applications that Require High Torque at Low Speed

You can do several things to avoid motor overheating when using a VFD in an application that requires high torque at low speed:

- *select a motor specifically designated for maximum torque at reduced speed.* At present, such motors allow full-load torque to be maintained down to zero speed, so they can be used in “constant-torque” applications. However, allowable power is still inversely proportional to speed, so they cannot be used in “constant-power” applications.
- *use a motor rated for operation in a high-temperature environment.* Note that this is not the same as buying a motor that has a high rated temperature rise. Such a motor may be a cheap

Reliance Electric

Fig. 5 Operating envelope for an AC motor designed to be used with a variable-frequency drive The application’s torque and speed requirements determine whether this is an appropriate motor. This chart shows that there is danger in operating the motor at low speed with high torque. In this region, the motor cannot get rid of its heat adequately. This motor can be operated up to 50% faster than across-the-line speed. However, be careful to limit the torque at higher speed. Otherwise, the power rating will be exceeded.

Table 1. COMPARATIVE CHARACTERISTICS OF VARIABLE-FREQUENCY MOTOR DRIVES

	VVI	CSI	PWM

NOTES:

1. Efficiency depends more on the model and on the application than on the type of drive. In recent years, most efficiency development has occurred in PWM drives. Efficiencies of modern drives vary from 93% to 97%.
2. Six-step VVI and CSI drives are generally limited to a turndown ratio of about 10:1 by cogging. PWM drives have nominal ratios up to 100:1. Turndown ratios differ with model and application.
3. VVI drives are limited to equipment, such as fans and pumps, whose torque requirements are proportional to speed.
4. Depends on the type of rectifier and the number of steps.
5. In VVI and CSI drives, motor overheating is caused mainly by low-frequency harmonics. In PWM drives, motor overheating is caused mainly by high-frequency harmonics. Motors differ in their vulnerability to the two types of harmonics.
6. Depends on chopper frequency and cable length.
7. Depends on chopper frequency and other details.
8. Depends on chopper frequency, motor construction, other factors.
9. Depends on the type of devices used in the rectifier.

motor that runs hot. What you want is a motor that normally runs cool, but is rated for a hot environment. Insulation ratings are one factor that determines the ability of a motor to tolerate hot environments. For details, see “Insulation Temperature Ratings” in [Measure 10.1.1](#).

- **use a motor with a high service factor.** “Service factor” is the highest percentage of full load at which a motor can operate continuously under standard test conditions without overheating. Motors used in high-torque applications are usually selected with a high service factor, even without variable-speed operation.
- **use a “high-efficiency” motor.** High-efficiency motors have lower winding resistance and improved magnetic efficiency, so they carry more current and produce higher torque for a given amount of heat generation. Note that the torque ratings of some “high-efficiency” motors are reduced at lower speeds, limiting these motors to variable-torque applications.
- **use an oversized motor.** This may or may not cost a penalty in motor efficiency, depending on the design of the motor and the speed profile of the application.
- **cool the motor externally.** For example, install a fan to blow air over the motor. If the motor is installed in a hot location, duct air to the motor from a cooler location. This method cools the stator by conduction through the motor casing. Stator cooling is most critical in an induction motor because the stator has the windings that are most vulnerable to insulation failure. If you use external cooling, make it dependable. Interlock the motor so it cannot run without external cooling.
- **substitute an open motor for an enclosed motor.** This may be acceptable if the environment is not too dirty. If necessary, clean the motor periodically.
- **use a VFD with a minimum tendency to cause motor heating.** All types of VFD’s cause a motor to run hotter, but some add more heat than others. Motor heating caused by VFD’s is discussed below.

Graham Company

Fig. 6 How all variable-frequency drives work Alternating current from the power system is converted to direct current by the rectifier. The direct current is converted back into alternating current by the inverter, at a frequency that will drive the motor at the desired speed.

- **maintain a minimum speed.** If the application has a minimum speed, set the VFD so that the motor cannot be slowed below this speed. This method requires a fairly high minimum speed. Take steps to keep operators from inadvertently resetting the VFD to a lower speed.

None of these tricks alone may suffice to prevent motor overheating in a high-torque application, but a combination of them may be satisfactory. In the final analysis, there are some applications where a VFD should not be used with the types of motors that are presently available.

Sizes and Prices

There is no longer an upper limit on the motor power that can be controlled with a VFD. Standard models are available in large sizes, and virtually any size is available on a custom basis. The lower size limit of VFD’s is determined primarily by their relatively high price in small sizes. Although VFD’s are available for motors as small as 0.5 horsepower, prices fall only slowly below about 5 horsepower.

As with all semiconductor devices, the cost of VFD’s has declined steeply since their introduction, and cost may continue to drop. In the mid-1990’s, the price of large VFD’s ranges from \$50 to \$200 per horsepower (or kilowatt), depending on the type and options. The price of small VFD’s ranges from \$100 to \$400 per horsepower (or kilowatt). Installation cost is typically higher than equipment cost for small- and medium-sized drives, and may be less than equipment cost for large drives.

It may be advisable to replace the motor as well as the drive in some cases. The prices of motors range from \$50 to \$100 per horsepower (or kilowatt) in sizes larger than 10 horsepower.

Basic Operation of Variable-Frequency Drives

The basic operation of a VFD, as sketched in Figure 6, is simple: (1) a rectifier converts the three-phase alternating current from the power system to single-phase direct, (2) a DC circuit uses inductors and/or capacitors to smooth the direct current, and (3) an inverter switches the direct current on and off using semiconductor devices to simulate alternating current of any desired frequency. The synthetic alternating current (or voltage, depending on the type of drive) is supplied to the motor. The motor turns at a speed that corresponds to the supplied frequency.

The controls of the VFD also regulate the voltage supplied to the motor in proportion to the speed. This is because torque is produced most efficiently if the ratio of voltage to speed remains constant.

(The term “inverter” is also commonly used to mean the entire VFD. In this discussion, we will limit the term to the portion of the VFD that converts DC to

artificial AC. The term “converter” is sometimes used for either the rectifier or the inverter.)

Types of VFD's

At present, there are three major VFD designs, along with several hybrids and less common types. The design of the inverter gives each type of VFD its name. The three types are: variable-voltage input (VVI), current source input (CSI), and pulse-width modulation (PWM). Table 1 summarizes their comparative characteristics. This table emphasizes characteristics that distinguish the three types. Refer to the text for more detail, and for characteristics and options that are common to all drive types.

Most manufacturers are now concentrating their development effort on PWM drives, because this is the only type that can accurately simulate a sine wave current in the motor. For this reason, the other two major types are becoming less common. However, they are likely to remain on the market for some time because of their lower cost, and because they avoid some problems that are peculiar to PWM drives. Furthermore, existing units will remain in service for a long time.

The “load-commutated inverter” (LCI) and “cycloconverter” are custom types that have been used on very large applications. We will not discuss them further.

All VFD's use high-power semiconductor switching devices that are capable of controlling current only in an on-off manner. As a result, the alternating current that is provided to the motor is not a smooth sine wave. This makes the motor less efficient. It also causes a variety of problems in the motor and in the rest of the electrical system. The evolution of VFD's is driven largely by the desire to produce motor current that more closely resembles a true sine wave. There is also a major interest in reducing distortion of the input power voltage by the VFD.

As a first step in understanding these problems, let's get acquainted with the switching devices that are causing the design headaches. Then, we will look at the three types of drives in greater detail.

■ Types of Switching Devices

The drive design is related to the types of semiconductor switching devices that are used in the inverter and rectifier. Three types of switching devices are presently used in VFD's.

The silicon controlled rectifier (SCR) is the oldest type, and it still has the highest voltage and current ratings. As the name implies, the SCR is a modification of a high-current rectifier. The main difference is that conduction is inhibited until a starting pulse is delivered to the “gate” terminal of the device. The main disadvantage of SCR's is that they can switch only slowly. Therefore, drives that use them in the inverter can produce only pulses of long duration.

Once current starts to flow in an SCR, it will not stop unless the driving voltage across the device is stopped. Stopping the voltage for this purpose is called “commutation.” Commutation of SCR's used in rectifiers is usually simple. Commutation of SCR's used in inverters is more complicated. It is accomplished in a variety of ways, depending on the type of inverter.

The thyristor is similar to the SCR. The main difference is that the current flow can be stopped by applying a turn-off pulse to the “gate” terminal. For this reason, it is sometimes called a “gate turn-off” (GTO) thyristor. The GTO has smaller voltage and current ratings than the SCR, but its response is faster. This allows GTO's to control current in a larger number of steps per cycle. However, GTO's require a fairly large current for the turn-off signal, which produces heat and requires additional circuitry.

(The terminology in the VFD literature is not consistent. “Thyristor” is often used to describe an SCR, and vice versa.)

Power transistors provide faster response and more accurate control of current flow than SCR's and GTO's. These characteristics made it practical to develop the pulse-width modulation (PWM) type of drive. The main disadvantages of transistors has been limited voltage and current capacity, which makes it necessary to use more of them, and to use more complex circuits. The newest type of transistor used in VFD's is the “insulated gate bipolar transistor” (IGBT). This type of transistor has faster response than earlier power transistors, which were called “bipolar junction transistors” “Darlington transistors,” or simply “power transistors.”

In addition to these three actively controlled devices, diodes are widely used in the rectifier. A diode is a simple, passive device that allows current to flow in only one direction. Diodes start to conduct current as soon as any voltage is applied in the forward direction.

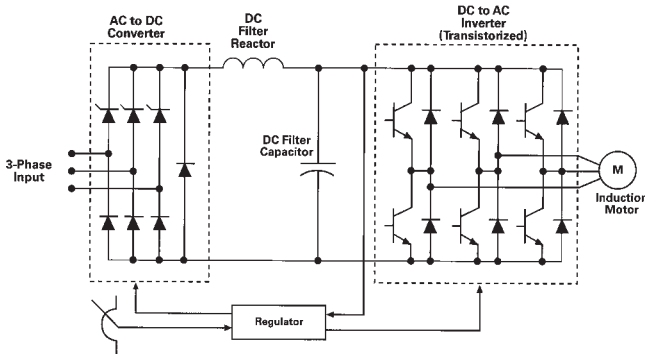

■ Variable Voltage Input (VVI) Drives

The variable-voltage input (VVI) type of drive is the simplest in design and concept. Figure 7 is a diagram of a VVI drive.

The rectifier is controlled to vary the DC voltage appropriately for the motor speed and torque requirements. The inverter switches SCR's or thyristors to produce a square-wave voltage waveform. This crude waveform is called “6-step” or “6-pulse,” because it is produced by the successive firing in pairs of the six output devices of the inverter.

The filter in a VVI drive consists of a large capacitor and a relatively small inductor. The filtering in the DC circuit isolates the input and output waveforms from each other.

Applying the abrupt voltage changes of a square wave to the motor produces a ragged current waveform in the motor windings. Motor windings are almost entirely inductive, so the response to the abrupt voltage

Reliance Electric

Fig. 7 Variable-voltage-input (VVI) drive This is the simplest type of variable-frequency drive. The output switching devices approximate a sine wave voltage for the motor by a series of square waves at different voltages.

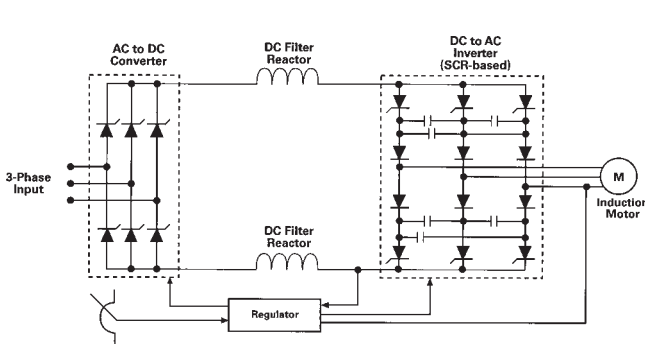

rise is a slow current rise, while the response to the abrupt voltage drop is an “inductive kick” that resists the reduction of current. (In contrast, if a sinusoidal voltage is applied to an inductor, the resulting current is also a sine wave.)

VVI drives yield the lowest overall motor system efficiency and starting torque. They were commonly selected for driving fans and centrifugal pumps, but they are now being displaced by PWM drives.

■ Current Source Input (CSI) Drives

The current-source inverter (CSI) type of drive operates in the same general way as a VVI drive. Figure 8 is a diagram of a CSI drive.

The major difference is that the CSI drive is able to force a square wave of current, rather than voltage, through the motor. This is accomplished by using large inductors in both legs of the DC circuit. Inductors resist change in current, and they are large enough to force a steady flow of current through the motor windings in sequence as the inverter switches the DC circuit from one phase of the motor windings to the next.

Reliance Electric

Fig. 8 Current-source-input (CSI) drive The main distinction in this type of drive is that the two inductors in the DC circuit are very large. They are able to force current through the inductance of the motor. Thus, the switching action of the drive simulates a sine wave of current in the motor windings, although the actual waveform is a series of square waves.

■ Pulse Width Modulation (PWM) Drives

In the PWM drive, the inverter uses transistors to switch the direct current at high frequency to deliver a series of voltage pulses to the motor. The width of each pulse is tailored so that the voltage pulses interact with the reactance of the motor windings to produce current flow in the motor that approximates a sine wave. Figure 9 is a diagram of a PWM drive.

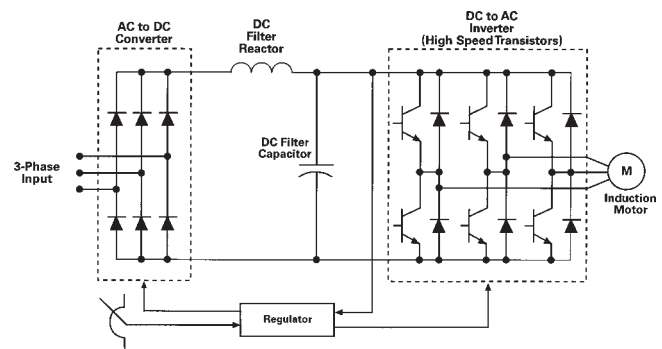

Most newer PWM drives also change their output voltage in steps that simulate a sine wave voltage. The filters in the DC circuit isolate the input and output from each other.

The inverter circuit in PWM drives is sometimes called a “chopper.” The pulse repetition rate is sometimes called the “carrier frequency.” (The latter is a misnomer, but evocative.) In contemporary units, the pulse rate ranges from 1,000 to 12,000 Hertz. The choice of pulse rate is a design compromise between factors discussed below.

The control circuitry of PWM drives is more complex than the control circuitry of VVI and CSI drives. This originally inhibited the development of PWM drives, but no longer. Microprocessors and integrated circuits allow essentially unlimited control complexity without much additional equipment cost. PWM drives were introduced at about the same time as the other two types, and they have been improving steadily.

The basic PWM concept allows more room for improvement than the other two types. Advances in power transistors have improved power handling capacity and the ability to tailor the current waveform in the motor.

PWM drives are not superior in all respects. Their high-frequency voltage pulses create a variety of problems that do not appear in the other two types. Most PWM development has been devoted to minimizing these problems.

Reliance Electric

Fig. 9 Pulse width modulation (PWM) drive This drive sends a stream of short voltage pulses to the motor. The voltage pulses react with the inductance of the motor windings to create a sine wave current in the motor that is closer to a true sine wave than is possible with other types of electronic drives.

Waveform Distortion: Introduction

VFD's may create a variety of electrical problems for the motor it drives and for the power supply system that serves it. In other words, a VFD may cause problems in its output and its input.

Motor problems are caused by the fact that the drive does not deliver a true sine wave voltage to the motor. Electric motors are designed to operate with a smooth sine wave voltage input. When such power is provided, the current in the motor windings is also a smooth sine wave. However, if voltage with an irregular waveform is supplied to a motor, the resulting motor current does not follow the voltage waveform. This is because a motor is a huge inductor, and inductors respond differently to different frequency components of the applied voltage. In extreme cases, the motor current waveform may be radically different from that applied voltage waveform.

All VFD's create voltage and current waveforms that are severely different from true sine waves. In turn, this creates very irregular motor current, with a host of resulting problems. Each of the three main types of VFD's has an entirely different set of waveform characteristics. Figure 10 shows the voltage and current waveforms produced by each of the drive types.

Power system problems are caused by the fact that the VFD does not draw current from the system as a sine wave, but in a pattern that is a serious distortion of a sine wave. This distorts the waveform of the power supply system, causing trouble for the system itself and for other equipment that draws power from the system. Figure 11 shows how different models of PWM drives affect the voltage and current waveforms in the power supply system at the input to the drive.

Distortion of the power system waveform is becoming more of a concern because there are more sources of waveform distortion, and because more types of equipment are coming into use that are sensitive to waveform distortion. New sources of waveform distortion include VFD's, electronic ballasts for fluorescent and HID lighting, and computer power supplies. Equipment that is vulnerable to waveform distortion includes electronic equipment that deals with small signals (communications, medical test equipment, etc.), power line carrier communications, transformers, and other induction motors served by the same power system.

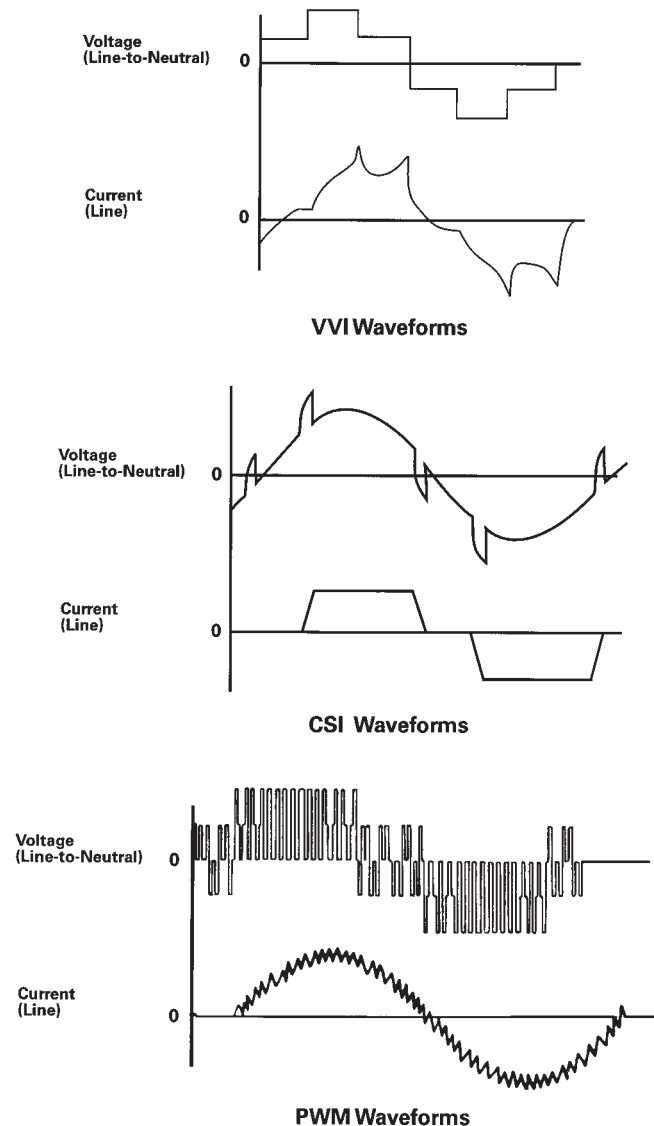

■ Input and Output Distortion, Voltage and Current Distortion

When considering the distortion caused by a VFD, be clear about whether the subject is output distortion (to the motor) or input distortion (to the power supply system). Also, be clear about whether the subject is distortion of the voltage waveform or the current waveform. In some cases, the relationship between

voltage distortion and current distortion may seem bizarre.

With respect to the motor, the output current waveform is the key issue. The current waveform in the motor windings determines the useful work produced by the motor. It is also a major factor in amount of heat losses.

The waveform of the voltage output supplied to the motor is of interest primarily in its ability to create a desirable current waveform. Contrary to what you might expect, it does not take a sine wave voltage to create a sine wave current in the motor. A reasonably good sine

Reliance Electric

Fig. 10 Voltage output waveforms and motor current waveforms VVI and PWM drives are designed to produce a particular voltage output. The voltage reacts with the inductance of the motor to produce a current waveform. PWM drives produce a current waveform that is much closer to a sine wave. CSI drives use brute force to directly create a square wave of current in the motor.

wave current can be created in the motor windings with a series of voltage pulses, if the timing and amplitude of the pulses are controlled properly. (This works because the motor winding is a big inductor. It accumulates the energy of the incoming pulses in its magnetic field.)

With respect to the power system, distortion of the input voltage waveform is the primary consideration. This distortion causes interference with other equipment served by the same power system, since voltage is what the other equipment sees. Distortion of the input voltage waveform is often called a “power quality” problem. (This term also covers interruptions of service, phase imbalance, and other problems that are not related to VFD’s.)

Distortion of the input current waveform can adversely affect the power supply system itself, with

effects such as reduced power factor. Also, abrupt distortion of the current waveform causes radiated electrical noise from the power supply system that may interfere with sensitive equipment.

■ Harmonic Analysis of Distortion

A useful fact of mathematics is that any wave shape can be described as a combination of pure sine waves, each of which is an integral multiple of a basic or “fundamental” frequency. Each of these multiples is called a “harmonic.” For example, the harmonics of the 60 Hz line frequency are 60 Hz, 120 Hz, 180 Hz, etc. Electrical engineers use this fact to analyze waveform distortion in electrical power systems, which is commonly called “harmonic distortion.”

Individual harmonic frequencies or narrow ranges of harmonic frequencies may cause particular problems.

6-PULSE
Total Harmonic Distortion (CURRENT) 25%
Total Harmonic Distortion (VOLTAGE) 10% —

12-PULSE
Total Harmonic Distortion (CURRENT) 8.8% —
Total Harmonic Distortion (VOLTAGE) 5.9% —

18-PULSE
Total Harmonic Distortion (CURRENT) 1.68%
Total Harmonic Distortion (VOLTAGE) 1.90% —

30-PULSE
Total Harmonic Distortion (CURRENT) 0.8% —
Total Harmonic Distortion (VOLTAGE) 1.2% —

Robicon

Fig. 11 Input current and voltage distortion If the drive draws current from the electrical system in a manner that is not proportional to the supply voltage, the voltage of the electrical system will be distorted. In these diagrams, the “source current” is the driving factor, and the “source voltage” is what results. Large, abrupt changes in current draw create the most voltage distortion. These curves are at the input of four different models of PWM drives. The characteristics of the electrical system, especially its “impedance,” determine the amount of voltage distortion that appears in other parts of the electrical system.

However, in most cases, the concern is “total harmonic distortion.” As the name implies, this is the total waveform distortion caused by all harmonics. This is calculated as the percentage of the total harmonic current compared to the current at the fundamental frequency. “Distortion factor” is another way of measuring total harmonic distortion, expressed as the percentage of the fundamental frequency current compared to the total current.

Any distortion of the basic sine wave could in principle be called “harmonic distortion.” However, this term is usually reserved for types of distortion that make a large change in the shape of the waveform. Other types of distortion, such as brief current spikes, may cause serious trouble even though they contribute little to total harmonic distortion.

■ Effect of Power System Characteristics on Waveform Distortion

The characteristics of the power system itself determines how severely a VFD may cause distortion. Relative size is important. Any given VFD produces more voltage distortion if it takes up a larger fraction of system capacity.

Another factor is the “impedance” of the transformer. A VFD produces less voltage distortion if the transformer feeding the system has a low impedance. The impedance of a transformer measures the sensitivity of the transformer’s voltage output to its current output. (Impedance is a general electrical term that means a ratio of voltage to current.) Transformers may be rated in terms of “percent impedance,” which is defined as the drop in transformer output voltage that occurs in going from no load to the rated transformer load.

For example, if a 460-volt system is served by a transformer that has a 4% impedance, the power system voltage drops about 18 volts at full load, compared to the voltage at no load. If a VFD draws a current pulse equal to half the system capacity, it will lower the system voltage by about 9 volts during the pulse.

Also important is the impedance of the power wiring. In contrast with transformer impedance, this is especially important with abrupt or high-frequency distortion. This is because the inductance and capacitance of the wiring itself can have a filtering or absorbing effect on high-frequency distortion components.

Figure 12 shows large differences in voltage and current input distortion among various drive models. Also, Figure 12 shows that the electrical characteristics of the power system have an enormous effect on the amount of distortion that appears in the power system.

■ How to Calculate Harmonic Distortion in Future VFD Installations

Some VFD manufacturers offer to perform a computer calculation of the harmonic distortion that may be expected from a VFD installation. As input, the

program needs the electrical characteristics of the VFD, the motor, and the transformer. It also needs the length and diameter of the wiring between the transformer and the drive, and between the drive and the motor.

This calculation is limited to predicting harmonic distortion. It cannot predict all potential problems, such as electromagnetic interference and motor overheating.

■ How to Measure Distortion in Existing Systems

You can measure and analyze the distortion in an existing VFD installation. A variety of equipment is available for this purpose. Some distortion measuring equipment is expensive, but you can rent it.

Simple handheld analyzers measure total harmonic distortion, along with measurements of basic variables, such as voltage, current, and reactive power (KVAR’s). These meters are limited to dealing with problems related to total harmonic distortion.

A harmonic distortion analyzer is a powerful tool that plots a graph of the harmonics that are present. It can indicate the percentage of power represented by each harmonic, making it possible to diagnose the likely cause of problems.

Robicon

Fig. 12 Voltage and current distortion in the electrical power system caused by variable-frequency drives These curves tell us that voltage distortion behaves differently from current distortion. They also tell us that the design of the drive and the characteristics of the electrical system have a large effect on the amount of distortion.

To pinpoint problems related to specific harmonics or transients, especially if they do not make up a large part of total distortion, you may need to use an oscilloscope. This displays the actual voltage and current waveforms.

Take measurements at various points to see how distortion varies throughout the power supply system. The worst distortion appears at the input to the VFD, unless there is a resonance effect in the system (discussed below). Check the distortion at the input to any equipment that may be affected by the operation of the VFD.

Unless you want to become an expert in finding distortion bugs, call in the electric utility or hire a consultant to do the analysis. If you plan to involve the utility, make a commitment to solving any power quality problem that affects their lines. Otherwise, if you attract the utility's attention to a power quality problem that you are causing, they may respond with a rate penalty.

■ Distortion Standards

How much distortion is acceptable in a VFD system? IEEE Standard 519 is intended to answer this question. Standard 519, which is updated occasionally, sets limits for the two worst forms of voltage distortion caused by VFD's. These are harmonic distortion and notching.

IEEE Standard 519 sets a limit on total harmonic distortion based on the type of facility. The present version limits total harmonic distortion to 3% for facilities having sensitive equipment, such as office buildings and hospitals. A limit of 5% is set for general industrial facilities. A limit of 10% is set for specialized industrial systems that can tolerate high distortion.

IEEE Standard 519 also sets a limit on "notching," which is discussed below. As the name implies, notching is a brief, severe cut in voltage that typically occurs several times per cycle. The Standard limits the "area" of the notch, which is the voltage times the duration, expressed in volt-milliseconds.

Unlike most standards, Standard 519 cannot be applied to a particular VFD in isolation. This is because the severity of waveform distortion depends on the characteristics of the power system as well as the characteristics of the VFD. Manufacturers of VFD's may claim that their drives satisfy the requirements of Standard 519, but you have to read the fine print to find out what assumptions are made about the system characteristics. In many cases, VFD's that satisfy Standard 519 will not cause trouble, but the Standard does not guarantee this.

IEEE Standard 519 requires that distortion be measured at the "point of common connection" in the power system. For practical purposes, this usually means the secondary of the transformer. This is not a conservative measurement. A VFD is likely to cause more distortion at points in the power system that are closer to the VFD.

Types of Distortion Caused by VFD's

Distortion is produced by the rectifier and by the inverter. Distortion produced by the rectifier is a problem primarily as distortion fed back to the power supply system. Distortion produced by the inverter is strongest in the direction of the motor and the motor circuit.

In PWM and VVI drives, the filter between the rectifier and inverter tends to prevent rectifier distortion from traveling to the motor, and to prevent inverter distortion from traveling back to the input. In CSI drives, especially those using SCR's in the rectifier, distortion caused by inverter operation can travel back to the power input. These are generalizations. Variations in drive design may greatly reduce the types of distortion produced by the basic types of drives, or they may introduce unexpected modes of distortion.

There is no standard way of classifying the types of distortion produced by VFD's. As mentioned previously, almost any distortion caused by a VFD could be considered as harmonic distortion. However, this is too general to be useful. The following breakdown distinguishes the types of distortion produced by different types of drives, and it provides a basis for the subsequent discussion of problems and solutions.

■ Harmonics of the Line Frequency

Harmonic distortion of the input power waveform occurs when the drive draws current at a rate that is not proportional to the applied voltage. In PWM and VVI drives, input harmonic distortion is caused primarily by the action of the rectifier. In CSI drives, input harmonic distortion may also be caused by the action of the inverter and the inductors of the DC circuit.

The rectifier acts in synchronism with the 3-phase input current, so it produces harmonics of the input frequency. It turns out that rectifier action produces only odd harmonics that are not divisible by three, i.e., the 5th, 7th, 11th, etc. For example, with 60-Hz power, these harmonics are 300 Hz, 420 Hz, 660 Hz, etc.

The harmonics decline in magnitude with higher number. Therefore, this type of harmonic distortion is a low-frequency problem. Fortunately, rectifiers do not produce much third-harmonic distortion. Third harmonics are especially troublesome in 3-phase power distribution because they create large return currents in the neutral leg.

The basic rectifier used by most VFD's consists of a simple full-wave bridge of six identical components. The components may be diodes, SCR's, or thyristors. The rectifier produces substantial harmonic distortion with any of these.

With a diode rectifier, each phase connection of the power system "sees through" the diode to the DC section during each half-cycle of conduction. During the conduction cycle, each phase sees two current pulses as the other two phases apply voltage to the DC section.

These current pulses distort the input voltage waveform to an extent that is determined by the load on the drive and the impedance of the power system. The total harmonic distortion of the current waveform is usually much larger than the distortion of the voltage waveform in percentage terms, but this does not imply that the effects of voltage distortion are less troublesome.

With an SCR or thyristor rectifier, conduction is delayed as load is reduced. This forces current flow even further out of synchronism with the applied voltage, further increasing harmonics. Most PWM drives use diode rectifiers. Some CSI and VVI drives also use diodes to reduce harmonic distortion and notching.

Total harmonic distortion can be reduced greatly by operating the rectifier in a sequence of steps. The so-called “12-step” drive, for example, actually has three input steps per half-cycle of line voltage. Some of the newest PWM drives have reduced harmonic distortion to low levels with a larger number of voltage steps.

■ Harmonics of the Motor Frequency

Harmonic distortion of the output waveform of a VFD is caused primarily by the abrupt switching action of the inverter. This occurs in synchronism with the motor speed, so it produces harmonics of the motor frequency. Therefore, this type of harmonic distortion is a low-frequency problem.

Large, low-frequency harmonics occur only in CSI and VVI drives, which deliver current and voltage, respectively, in large pulses. In contrast, PWM drives deliver voltage to the motor in small pulses, and they have high-frequency harmonic problems discussed next.

Robicon

Fig. 13 Phase shift between input current and voltage
This occurs with some variable-frequency drives because of delay in the action of the switching devices. The effect is lower power factor in the electrical system.

In CSI drives, depending on design details, the motor-frequency harmonics may be able to feed back to the input, increasing the total harmonic distortion of the input power.

■ Harmonics of the PWM Inverter Frequency

The inverters of contemporary PWM drives produce voltage pulses at fixed rates, which range from 1,000 to 12,000 Hertz in different models. The stream of pulses may produce significant harmonics at frequencies up to 100 times the pulse rate.

The pulse rate (or “carrier frequency”) is a design compromise. It was soon discovered that the low pulse rates of the original PWM drives create a high level of audible noise in the motors. To reduce this problem, the pulse rate was increased to the high end of the audible range, so that all harmonics would occur above the audible range. Unfortunately, under adverse circumstances, these frequencies have enough higher harmonics to produce a substantial amount of radiated electrical noise, and they may produce standing waves in the motor cables. In addition, PWM harmonics are associated with “voltage stress,” a poorly understood phenomenon that causes breakdown of motor insulation.

■ SCR and Thyristor Rectifier Notching

“Notching” is a deep, transient reduction of the power system input voltage, so called because it appears as a notch in the voltage waveform. Notching is caused by the action of SCR and thyristor rectifiers. These devices may not be switched on until there is a large voltage across them. Thus, the power system is subjected to a virtual short circuit during the brief period when the voltage in the filter section builds up to match the input voltage.

Notching could be considered a source of harmonic distortion, but it is treated separately in IEEE Standard 519. Notching pulses have very short duration, so they do not contribute much to total harmonic distortion, but their magnitude makes them potentially troublesome.

■ Voltage-Current Phase Shift

If the rectifier uses SCR’s or thyristors, current draw from the power line is reduced as the motor load falls by delaying the turn-on of the SCR’s or thyristors. This causes the average current input to lag the input voltage. Figure 13 shows this effect.

This phase shift is completely different from the lagging power factor of inductive devices, such as motors and fluorescent ballasts. However, it has the same effect of reducing the power factor of the drive system. Power factor is important in some applications, but not in others, as discussed below.

Diode rectifiers do not produce substantial phase shift between the input current and input voltage. This is because diodes draw current as soon as the voltage is applied to them.

Table 2. WAVEFORM-RELATED PROBLEMS AND SOLUTIONS IN VARIABLE-FREQUENCY DRIVES

Potential Problem	Cause	Solutions
MOTOR SYSTEM PROBLEMS		
■ motor overheating and energy waste	■ low-frequency harmonics caused by crude current waveform	■ select PWM drive (1) ■ select many-step inverter
	■ high-frequency harmonics produced by PWM inverters	■ select drive to avoid problem (1) ■ select "inverter duty" motor ■ select oversized (derated) motor (2)
■ electric resonance in drive-to-motor cable • insulation failure • blown fuses	■ high-frequency harmonics of PWM inverter pulses	■ limit length of motor cable ■ change cable length to avoid resonance ■ select PWM drive with lower chopper frequency (3) ■ avoid PWM inverter (1)
■ motor insulation voltage stress	■ (poorly documented) voltage spikes from PWM inverters and perhaps other types	■ select "inverter duty" motors ■ select drive to avoid problem (1)
■ cogging	■ large current steps in CSI and VVI drives	■ select PWM inverter (1) ■ select many-step inverter ■ keep motor speed high enough to avoid cogging (typically above 10% speed)
■ mechanical resonances	■ steps or distortion in motor current waveform, especially in CSI and VVI drives	■ select PWM inverter (1) ■ select many-step inverter ■ install resonance-absorbing coupling between motor and load ■ modify driven equipment to avoid mechanical resonances
POWER SYSTEM PROBLEMS		
■ effects of power system waveform distortion • interference with test equipment, computers, communications gear, etc. • interference with power line carrier communications • overheating and energy waste in transformers, lighting ballasts, other motors connected to the power system • accelerated reading of power meters	■ line-frequency harmonics caused by rectifier	■ select drive with many-step diode rectifier
	■ notching caused by commutation of SCR rectifiers	■ avoid SCR rectifier ■ install input filter or isolation transformer ■ electrically isolate affected equipment
	■ voltage spikes induced by large current steps in CSI and VVI drives	■ select drive to avoid problem ■ install input filter or isolation transformer ■ electrically isolate affected equipment
	■ high-frequency harmonics caused by PWM inverter	■ select drive to avoid problem (1) ■ install tuned filter in input ■ install input filter or isolation transformer ■ electrically isolate affected equipment
■ radiated electric noise	■ high-frequency harmonics of PWM inverter pulses, mostly in motor cable	■ select drive to avoid problem (1) ■ select PWM drive with lower chopper frequency (3) ■ limit length of motor cable ■ install drive and motor cable far from affected equipment ■ improve grounding of affected equipment ■ install input filter or isolation transformer
	■ notching caused by commutation of SCR rectifiers	■ avoid SCR rectifier ■ install input filter or isolation transformer ■ improve grounding of affected equipment
	■ current spikes in input and output of CSI and VVI drives	■ select PWM inverter (1) ■ select many-step inverter ■ install output filter ■ install input filter ■ improve grounding of affected equipment
■ electric resonance in power supply system • overvoltage damage to connected equipment • wiring insulation failure • blown fuses • blown power factor correction capacitors	■ triggering of resonance between power factor correction capacitors and system inductance, usually by input harmonics of CSI and VVI drives	■ select drive with low input harmonics ■ install input filter ■ eliminate capacitors served by same transformer (4)
	■ harmonics of PWM carrier frequency	■ select drive to avoid problem (1) ■ install input filter
■ reduced power factor (5)	■ voltage-current phase shift caused by SCR and thyristor rectifiers	■ select VFD having diode rectifier
AUDIBLE NOISE PROBLEMS		
■ motor noise	■ high-frequency voltage pulses of PWM inverters	■ avoid PWM inverter (1) ■ select PWM inverter with higher chopper frequency ■ select motor for low noise ■ acoustically isolate motor
■ drive noise	■ vibration of components, especially large coils	■ select drive for low noise ■ acoustically isolate drive
■ filter noise	■ coil vibration	■ select drive to avoid need for external filters ■ acoustically isolate filter

Notes:

1. The best PWM inverters have little input or output harmonic distortion, but they still have potential EMI, audible noise, and "voltage stress" problems.
2. Oversized motors operate with reduced efficiency at higher partial loads. Effect of oversizing motors with VFD's is not well documented.
3. However, higher chopper frequency is desirable to reduce audible motor noise.
4. This leaves the problem of improving power factor by other means, which may be difficult.
5. Power factor drops with motor speed. With centrifugal loads, current and power consumption drop with motor speed, reducing adverse effect.

Waveform-Related Problems and Solutions

The various types of waveform distortion create a variety of problems. Enough experience has been gained to predict where these problems may arise. After an initial period of denial during the 1980's, the VFD industry has become aggressive about reducing waveform distortion and its effects. The development of standards for waveform distortion, especially IEEE Standard 519, has attracted the attention of designers and users to the problem. As a result, some manufacturers have model lines specifically designed for low distortion.

Table 2 summarizes the problems caused by VFD waveform distortion, along with their causes and solutions. Use the Table as a checklist to avoid or minimize the problems that are discussed.

The number of potential problems may appear daunting, but this does not mean that VFD's are a rat's nest of troubles. Not all problems arise in all applications. However, some methods used to correct a particular waveform-related problem may cause a different problem. You can usually avoid problems, or keep them within acceptable limits, by knowing how to select the right equipment for the application, and by being aware of appropriate installation practices. At the same time, avoid the cost of features that you do not need.

■ Motor Overheating and Energy Waste

Motors are designed to operate with pure sine wave voltages at the line frequency. A large part of the output current harmonics created by VFD's cannot produce useful motor power. The unusable energy of the harmonics is converted to heat, which is a waste of energy and raises the temperature of the motor.

The tendency of harmonics to raise motor temperature depends on the application. In variable-torque applications, the reduced motor current at low speed more than compensates for the heat added by harmonics. However, this saves the motor only if it operates at substantially reduced speed most of the time. In "constant-torque" and "constant-power" applications, where motor current remains high at reduced speeds,

Graham Company

Fig. 14 Output chokes Inductors between the drive and the motor may be useful for reducing several problems, especially high-voltage transients that destroy motor insulation. However, they may also interfere with the efficiency of PWM drives, the type that has the worst problem with transients.

Graham Company

Fig. 15 Output voltage clipper This is a more elaborate method of reducing high-voltage transients in the motor.

heat generated by harmonics is a serious problem at all speeds.

The ideal solution to the problem of harmonics is to select a drive that produces a current waveform in the motor that approaches a true sine wave. Some of the newer PWM drives are capable of this. In retrofit applications, you can afford to pay a higher price for a better VFD if this avoids the need to replace the motor. (However, replacing the existing motor may be desirable as a separate energy conservation measure. See [Measure 10.1.1](#) for details.)

A less satisfactory solution is to install a motor that is designed to use more of the energy of harmonics. Such motors are named "inverter duty" motors. This classification is not the same as "high efficiency" motors, although inverter-duty motors generally have higher efficiency than average. The advantages of inverter-duty motors are not well documented. There is reason to suspect that they perform better with the low-frequency harmonics of CSI and VVI drives, but not much better with the high-frequency harmonics of PWM drives.

"High-efficiency" motors can use more of the low-frequency harmonics because they are designed to reduce the eddy current losses that convert these harmonics into heat. On the other hand, there have been reports of failures of "high-efficiency" motors when used with VFD's. Undoubtedly, some of these failures are due to the motors being used in higher-torque applications for which they were not rated.

■ Motor Insulation Failure with PWM Drives

Motors driven by PWM drives have been subject to a type of insulation failure that has been called "voltage stress." It is widely assumed that this occurs because the high chopper frequencies induce voltage spikes in the motor coils high enough to cause insulation failure.

One solution to this problem is to install an inductive filter between the drive and the motor to reduce the voltage spikes. Figure 14 shows this approach. However, this is a delicate balance, because PWM drives must send pulses to the motor to function properly, and too much filtering interferes with the pulses.

Another solution is to install a voltage limiter between the drive and the motor, as show in Figure 15. This eliminates any voltage at the motor input that exceeds a particular level. However, the large inductance

within the motor may create voltage spikes farther inside the motor.

You could minimize this problem by selecting motors that have insulation of high quality. However, you usually cannot judge insulation quality from the motor catalog information. Motors with higher temperature ratings may have insulation that is able to withstand higher voltages, but this is an indirect relationship.

Another possibility is that insulation fails from continuous hammering of the motor's coils by audible vibrations, for which PWM drives are notorious. However, this possibility has not been well investigated.

■ Mechanical Resonances

Especially with CSI and VVI drives, the abrupt steps in motor current produced by the drive cause torque pulses in the motor. If the motor vibrations occur at a resonant frequency of the equipment, they may drive mechanical resonances large enough to make noise, create noticeable vibration, or break equipment.

The most satisfactory solution is to select a drive that has a relatively smooth current waveform. Another solution is to install a vibration-absorbing coupling between the motor and the equipment. Still another is to modify the equipment so that it has no resonances that are triggered by the drive vibration.

■ Cogging in CSI and VVI Drives

“Cogging” is a form of torsional vibration that occurs at very low speed with CSI and VVI drives, typically below about 10% of full speed. This is generally not a resonance phenomenon, but direct hammering that is caused by the large current steps that occur with these drives. Cogging can be avoided completely by selecting PWM drives. With CSI drives, select a model that has stepped output current. Another solution is to set the low-speed limit of the motor above the speed at which cogging becomes noticeable, if the application allows this.

■ Audible Motor Noise with PWM Drives

Some PWM drives may make the motor noisy. The noise occurs because the frequency of the voltage pulses is high enough to induce vibration of the steel laminations that form the magnetic circuit inside the motor. Also, the coils may vibrate. These components are designed to avoid vibration at normal line frequency, but they may resonate easily at the pulse frequencies.

Any possible resonance is likely to be excited because the pulse frequency spectrum is broad. It includes a distribution of harmonics and sub-harmonics of the chopper frequency. Furthermore, the distribution of harmonics changes continuously as the pulse widths are modulated to create the current wave.

The noise problem in PWM drives cannot be solved by using filters between the drive and the motor, because

a filter would interfere with transmission of the pulses needed to produce the current waveform. The IGBT type of transistor, which is now common in PWM drives, is claimed to reduce audible noise.

Some manufacturers increase the inverter pulse rate to reduce the noise problem. This produces noise in a less sensitive portion of the range of human hearing, or at frequencies too high to be heard. Also, the motor components may be less excitable at the higher frequencies. This solution is reported to greatly reduce audible noise, but it may create a problem of electric noise, as discussed below.

If motor noise increases substantially at a particular speed, it may be possible to lock out this range of speed. However, this is a clumsy solution. If you plan to replace the motor, shop for a motor that is designed to remain quiet when used with your type of VFD.

Motor noise may be spread through the equipment in which the motor is installed. For example, if a fan motor is located inside an air handling unit, motor noise is transmitted by the ducts.

■ Audible Drive and Filter Noise

The VFD itself may produce audible noise at a level that is objectionable in quiet environments. The large coils used in the DC circuit of CSI are driven to hum by the large currents they carry. Also, PWM and VVI drives may have filter coils that may hum. Large inductors, or coils, may be installed externally to block electrical noise, and these may hum audibly.

The solution is careful selection of equipment. Also, you can isolate noisy equipment by enclosing it or by installing it away from sensitive locations.

■ Conducted Electrical Noise

Another nasty surprise of early VFD's was interference with other electrical equipment served by the same power system. VFD's may backfeed a large amount of electrical noise into the power supply system. This noise may interfere with computers, test equipment, medical instruments, communications equipment, and other electronic equipment involving small voltages. The electrical noise of VFD's is especially crippling to power line carrier communication systems, which use the power wiring of the facility to carry digital or analog signals. This problem was eventually forced into the open, leading to major improvements, but there is still a wide variation in the electrical noise generated by different models.

Most electrical noise is caused by transients and by high-frequency harmonics, rather than by the low-frequency harmonics that are responsible for most of a drive's rated “total harmonic distortion.” “Notching” is generally the worst source of electrical noise from VFD's that use SCR's and thyristors, especially in the rectifier. With some PWM drives, the carrier frequency and its harmonics may backfeed to the power system.

VFD's may also produce starting surges, like any other large piece of equipment. However, the effect of VFD's is usually to mute starting surges, compared to operating the motor across the line. Further, some VFD's have a "soft start" that further reduces the starting surge.

You can avoid interference problems by selecting a VFD that does not produce enough noise to cause trouble. As an alternative, install power supply filters at the equipment that is vulnerable to interference.

Or, if the entire power circuit is vulnerable to electrical noise, it is probably cheaper to install a filter at the input to the VFD. Figure 16 shows this approach. Filtering can be expensive because the filter on each drive must handle the entire motor current.

Select the appropriate type of filter for the kind of noise being blocked. In many cases, a simple inductor ("reactor") in the power line suffices. Another option is an isolation transformer, but this is more expensive and may not be significantly better. An isolation transformer is bulky, typically larger than the VFD itself, and it absorbs a few percent of the electrical power. In some cases, a filter that is tuned to an isolated objectionable frequency may be appropriate.

Don't bother trying to use surge suppressors of the kind that are used to protect computers and other equipment against lightning strikes. They will provide no benefit. These devices are intended to shunt high-voltage spikes to ground, whereas the noise signals from VFD's are a fraction of the line voltage.

■ Radiated Electrical Noise

Electrical noise from VFD's may be radiated through space, causing interference with equipment that absorbs the radiation. This type of noise transmission is called "electromagnetic interference" (EMI). EMI can occur at any frequency, from individual pulses to continuous high-frequency interference.

If the frequency of the EMI is high enough, it may be called "radio-frequency interference" (RFI). PWM drives may radiate noise at the low end of the radio frequency band, up to several hundred kilohertz or even up to several megahertz. Although the pulse rate of the drive is only several kilohertz, the abrupt nature of the pulses creates high-order harmonics that may affect sensitive equipment at much higher frequencies.

EMI generally has the same causes as conducted noise, and the same types of equipment are affected. The differences are in the manner of transmission and the preventive measures. EMI spreads by radiation from cables that carry drive input or output current. The cables act as a transmitting antenna. In order for interference to occur, the affected equipment must have unshielded components, such as test leads, that act as a receiving antenna.

The seriousness of EMI depends on the drive installation and the nature of the facility, as well as the drive itself. A problem can arise only if there is

equipment in the facility that is sensitive to the EMI produced by the drive. Interference is unlikely to occur if the equipment is far from the drive or affected portions of the power system.

There are several solutions to EMI. One is to select a drive that does not cause the problem. Another is to install filters between the drive and the cables. If necessary, use strict grounding and shielding procedures with the drive, the sensitive equipment, or both.

In the United States, devices that produce RFI are subject to regulation and classification by the Federal Communications Commission. There are two main classes of RFI sources, Class A and Class B. Class A devices are considered satisfactory for general industrial environments, while Class B is a more stringent standard intended for commercial-type environments. Neither classification may be satisfactory for specialized environments that are sensitive to RFI, such as laboratories or communications centers. The threshold frequency for regulation is 10 KHz. PWM drives generally are subject to this regulation, whereas CSI and VVI drives generally are not.

■ Resonance in the Drive-to-Motor Connection with PWM Drives

Under some conditions, PWM drives may create standing waves of voltage and current in the cable that connects the drive to the motor. Pulses produced by the VFD are reflected back into the cable at the motor, and again at the drive. If the cable is a resonant length, standing waves will occur in the cable. This means that each new pulse overlaps and reinforces the reflections of earlier pulses.

At the points in the cable where voltage peaks occur, the voltage may be high enough to break through the insulation. At the points in the cable where the current peaks occur, the current may be high enough to cause localized heating, including blown fuses.

Resonance cannot occur unless the cable is long enough to allow overlap between pulses. The minimum length for resonance depends on the pulse rate of the drive. Higher chopper frequencies allow resonance to occur in shorter cables. Manufacturers of PWM drives recommend a maximum cable length of about 500 feet (160 meters) for pulse rates of several kilohertz and a

Graham Company

Fig. 16 Input line filter These are large inductors that reduce the spread of electrical noise from the drive into the electrical power system. Inductors can also be used to reduce harmonic distortion.

maximum of cable length of about 200 feet (60 meters) for pulse rates of about 10 kilohertz.

If the motor cable may be long enough to allow a resonance problem to occur, use a drive with a low pulse rate. If a long cable is necessary, it may be possible to avoid resonance by carefully selecting the cable length to avoid any of the specific lengths that allow resonance to occur. (Like an antenna, the cable length must be “tuned” to a multiple of the wavelength to create standing waves. Any length that lies between these multiples will not resonate.) In the extreme case, avoid using a PWM drive.

Don’t try to avoid resonance by filtering the output pulses of a PWM drive. This would prevent the motor current waveform from developing properly in the motor.

■ Resonance and Blown Fuses in the Facility Power System

Resonance in the power system may occur at a relatively low harmonic frequency if power factor correction capacitors are installed in the system. This problem is most likely to occur with CSI and VVI drives. The capacitors and the inductance in the system form a tuned circuit that may resonate at one of the low harmonic frequencies produced by such drives. Resonance causes large standing waves of voltage and current to develop. It is not likely that this problem will arise, but the consequences may be severe if it does.

If power factor correction capacitors are a cause of the problem, it may be possible to move them to a different part of the power supply system. Power factor is important primarily to the power company, so it does not matter where the capacitors are installed within the facility. There should be no capacitors on the same side of the transformer that serves the drive, unless the drive has very low harmonic distortion.

If it appears that power factor capacitors are blowing fuses, resonance may not be the cause. The reactance of capacitors is inversely proportional to frequency, so the current at harmonic frequencies passes through the capacitors more easily than the line frequency current. If there is a large amount of harmonic current distortion, the additional harmonic current flow through the capacitors may blow the fuses.

Some PWM drives may create standing waves of voltage and current in the power system wiring, as they may do in the motor cables. The high peak voltages may harm other equipment connected to the same power system, and the high peak currents may overheat wiring and blow fuses. Fortunately, this problem is easier to avoid than resonance in the motor cable. Any chopper pulses are much smaller at the input end of the drive, since they must leak through the rectifier and filter section of the drive to get to the input wiring. The pulses have a much higher frequency than the line frequency, so it is relatively easy to suppress them with a filter

installed at the input end of the drive. Some drive models have such a filter built into the unit.

■ Overheating and Energy Waste in Other Inductive Equipment

Distortion of the power supply system waveform by VFD’s causes overheating and energy waste in other inductive devices connected to the system. Affected equipment includes transformers, other motors, and magnetic lighting ballasts. This problem occurs because the harmonics cannot be used by the equipment, and are converted to heat. The general solution to this problem is to select a drive that produces a low value of total harmonic distortion.

Input filters can be used to reduce high-frequency harmonics that cause “skin effect” in wiring and in the coils of affected equipment. Skin effect is an interaction between the current in the wire and its own alternating magnetic field that forces the current toward the outer surface of the wire. Skin effect reduces the effective area of the wire, which increases resistance losses.

■ Accelerated Readings of Induction Power Meters

It is reported that harmonics injected into the power supply system by VFD’s can cause electricity meters to run faster. This causes the customer to donate money to the utility.

Application-Related Selection Considerations

Now that we know how to avoid problems caused by waveform distortion, we have a firm basis for understanding drive choices that relate to specific applications. As VFD’s have evolved, more features have become standard, or at least common. Nowadays, you rarely need to order a custom VFD. The key to a satisfactory and economical installation is knowing what is available and selecting the appropriate characteristics. You can get information about the following features from the catalogs. If the information is too scanty, call the manufacturer for details.

■ Control Input Provisions

At the outset, limit your search to those manufacturers who offer VFD’s having the control capabilities needed for your application. For example, some manufacturers offer only models with manual speed control. For most energy conservation applications, the drive should be equipped to accept standard pneumatic, electric, or electronic control signals, depending on the type of control system that you need or prefer. If your system uses power line carrier communications, select a model that can understand the signal protocol used by your carrier system.

■ Torque and Current Characteristics

Torque is the turning force produced by the motor. Match the torque characteristics of the drive to the torque characteristics of the load, as discussed previously.

Torque is directly related to the motor input current. Therefore, the torque characteristics of a VFD are essentially equivalent to its current-producing characteristics. The maximum torque that a VFD can produce is limited by its current rating.

All three types of VSD's are capable of producing high torque, but torque ratings differ among models intended for different applications. Recall that the inrush current of a motor connected across the line is several times higher than its full-load current. In an application where the motor needs a high starting torque, the drive must be able to deliver much more starting current than the full-load current. For this reason, drives are rated in terms of percentages of motor power. The ratings may be much higher than 100% to provide for starting. Operation at currents higher than "100%" is usually limited to a short period of time.

In variable-torque applications, starting torque is needed primarily to overcome the inertia of the load. With loads having high inertia, such as centrifugal fans, the VFD can operate with a modest torque capability because it can accelerate the load over a period of time, as discussed below.

Many constant-torque applications are jerky, i.e., subject to brief overloads. For such applications, the drive should be rated to provide adequate overcurrent for brief periods of time. A cheaper alternative is a drive that is designed to slow down under brief overloads without tripping out.

■ Current Limits

The maximum output current is usually adjustable. This feature is intended primarily to protect the motor from excessive current. The catalog rating of the drive is usually defined as "100%" current. Drives for variable-torque applications typically have a maximum current limit of about 110%, while drives for constant-torque applications typically have a current limit around 150%.

■ Voltage-Speed Ratio Adjustment

The drive reduces the voltage to the motor as the speed is reduced. This keeps the drive from over-exciting the magnetic circuit of the motor, which would waste energy. Most modern drives provide for a variety of voltage-vs.-speed characteristics. This adapts the drive efficiently to applications with different torque requirements. The voltage-speed characteristic is usually set at the time of installation, and is not changed thereafter.

A fixed ratio of voltage to speed may not provide enough voltage at low speed to overcome resistance losses in the motor windings, resulting in inadequate torque. To compensate for this, the drive increases the voltage-speed ratio at slower speeds. This feature may be called "IR compensation," "current boost," or "voltage boost."

■ Soft Start

Any VFD provides soft starting, compared to starting the motor across the line. This is simply because the drive cannot produce a starting current as strong as the across-line inrush current. In addition to this effect, many models offer a "soft start" option, which provides a gradual or staged build-up of the motor current when starting. This feature further reduces bearing shock, drive belt wear, and the motor heating that occurs from large inrush currents.

■ Acceleration Control

Acceleration control allows the operator to set the time for the drive to reach full speed. Acceleration control is useful for reducing mechanical stress when starting variable-torque loads that have a high moment of inertia, such as large fans. Acceleration control is also useful for providing smooth speed increase with hoisting machinery, conveyors, and other materials handling equipment.

When starting a load with a high static torque, such as a loaded conveyor belt, the load will not start to move at all until the motor torque exceeds the load torque. The acceleration should proceed smoothly from this point. Therefore, acceleration control differs between loads having different starting torque characteristics.

■ Ability to Drive Multiple Motors

PWM and VVI drives are able to drive multiple motors without problems. These two types produce a controlled voltage output that is independent of the motor characteristics. This voltage can be used by any type and number of motors for which the voltage waveform is appropriate, and the motors can be turned on and off individually.

CSI drives may have difficulty driving multiple motors. This is because the reactance of the motor is an integral part of the output circuit of the drive. In particular, the drive must be matched with the motor reactance to provide proper commutation of the SCR's in the inverter. If a CSI drive is connected to more than one motor, and one of the motors is turned off, commutation may not occur. This may burn out the SCR's or cause the drive to be halted by its safety devices. Some CSI drives are advertised for use with multiple motors. These may have additional circuitry to avoid problems.

■ Full- and Part-Load Efficiency

Except near full load, the VFD itself contributes only a relatively small part of the total losses in a VFD drive system. Even at full load, losses in the VFD itself amount to only a few percent of energy input. More important is the effect of the drive on the efficiency of the motor and the electrical power system, as described previously. To review, the drive reduces losses in the motor by making the current flow in the motor as close to a sine

wave as possible, and it reduces losses in the power system by minimizing total harmonic distortion.

The efficiency of all drives drops with speed. There are large differences in the low-speed losses of different drive models. Drives that use SCR's waste energy in commutation. This loss is proportional to the square of the speed, and becomes small at low speeds. PWM drives have a fairly constant loss across the speed range. As with most equipment, larger drives are more efficient, other factors being equal. In recent years, most development has been focussed on PWM drives, so the best PWM drives are becoming more efficient than the other types.

Low-speed efficiency tends to be higher in applications where the torque remains high at reduced speed. This is because the losses within the drive are smaller in relation to the amount of power delivered to the motor.

■ Turndown Ratio

With VVI and CSI drives, the minimum speed is determined by "cogging" (explained previously) and by the crudeness of the output waveform. Single-pulse (often called "six-step") outputs limit the turndown ratio to about 10:1. A larger number of steps allows larger turndown ratios.

PWM drives do not suffer from cogging. In principle, they can produce a fairly smooth current waveform of any frequency. Some PWM drives advertise capability to operate at essentially zero speed, but this capability increases cost.

Some less expensive drives simulate operation at very low speed by "jogging." This consists of cycling the drive on and off at the drive's lowest speed or at some other speed that can be selected by the operator.

For a given drive, motors can operate at lower speed with variable-torque applications than with constant-torque applications. This is because the currents are lower.

■ Speed Increase

Most VFD's can operate the motor faster than its rated across-the-line speed. Typical maximum drive speeds range from 110% to 200% of across-line speed. PWM and VVI drives can easily be designed to provide high motor speeds. CSI drives can provide only limited overspeed, because speeds much higher than the input frequency interfere with commutation in the inverter.

Regardless of the drive capability, it is generally not prudent to operate a motor much faster than its design speed. Bearing wear is accelerated, any vibration due to rotor imbalance is increased, and serious overspeeding may cause failure of the rotor from centrifugal force.

VFD's typically cannot increase output power once the motor has reached the across-line speed. This means that torque must decline as the speed increases above the normal motor speed. Most applications call for more

power at higher speed, so you may have to increase the power rating of the drive if you want to operate at higher speed. By the same token, motor heating is increased at higher speed.

If you want to increase your motor speed above the line frequency speed, consider replacing the motor with one that is designed for this purpose. Some manufacturers offer motors designed to operate with VFD's at speeds much higher than the line frequency speed. Some of these motors can maintain their torque output at the higher speeds.

■ Speed Precision

For most applications, any type of VFD will control speed with sufficient accuracy. However, certain applications, such as winders in paper mills, require exceptional accuracy in speed control that can be satisfied only by certain combinations of drive and motor types.

Induction motors inherently operate with "slip," which is a loss of speed compared to the speed that corresponds to the frequency of the input power. Standard-torque induction motors (e.g., NEMA Design B) slip no more than a few percent, so variation in speed is less than this amount. High-torque motors have higher slip, up to about 5%, so they have greater speed variation.

Synchronous motors provide the greatest speed precision because they have no slip. The magnetic field of the rotor does not depend on induction from the stator, but is created by its own source of direct current. As a result, the rotor speed is locked to the stator frequency.

Most VFD's control the frequency of their motor current within a fraction of one percent. "Slip compensation" is used in conventional VFD's to improve speed regulation. Even better speed precision is possible with a controller that uses feedback of the motor speed or shaft position from an encoder that is mounted on the motor. "Vector control" is one term for this capability.

■ Fixed Speed Settings

An option with all three types of drives is operation at fixed speeds that may be set by the operator. The drive may be switched to operation at one or more fixed speeds at various times, in addition to normal variable-speed operation. A fixed speed may be used for night temperature setback and air purge cooling in HVAC systems, for smoke purging in fire control, etc.

■ Speed Range Lockout

An option with all three types of drives is the ability to lock out one or more ranges of operating speeds. The speed ranges are set by the operator. This feature is used most commonly to avoid mechanical or electrical resonances related to motor speed. For example, operation of a cooling tower fan at a certain speed may cause serious vibration of the cooling tower structure. Speed lockout is usually a poor alternative to fixing the

problem at its source, but it may be the only practical option.

■ Reversing

The ability to start motors in either direction is a simple, inexpensive feature that is standard in many models of VFD's. Simple reversing must occur with the motor at a dead stop, which is sometimes called "static reversing."

Even if reversing is not needed routinely, consider getting the capability for rare occasions when it may be useful. For example, reverse operation of cooling tower fans may be useful for clearing ice from the tower structure during freezing weather. Reverse operation may also be used for clearing jammed equipment, such as conveyors and drill presses.

■ Ability to Start Drive with Motor Turning

Basic VFD's are intended to start motors from a fully stopped condition. Some drives allow the VFD to be started with the motor turning. This is useful with equipment that may be turning while idle, such as fans that are kept moving by air flow. Also, this feature deals with brief interruptions of power. Without this feature, the drive will trip out, the load must be stopped, and the process restarted from zero speed. To provide this function, the drive must be able to sense the motor speed and to synchronize the drive frequency with the motor before starting.

■ Automatic Restart

If the motor system is stopped by a power outage, it may be necessary to restart the VFD manually. To avoid this nuisance, select a model that offers the option of automatic restarting. However, do not get this feature where unexpected restarting of equipment may create a safety hazard.

■ Braking and Regeneration

Some models of VFD's can act as a brake to slow or stop loads such as hoists and conveyors. This requires absorbing power from the load. "Regenerative" braking feeds the power absorbed from the load back to the power supply system, conserving energy. CSI drives with SCR rectifiers have inherent regenerative braking capability. The effectiveness varies with the design of the drive. PWM and VVI drives must have special components and control circuitry to provide regenerative braking. Braking is accomplished in some models by dissipating the absorbed power in resistors.

"Four-quadrant control" is a term sometimes used for the ability to provide braking in both the forward and reverse directions. This is a quaint way of expressing the four possible conditions that may occur, namely: forward direction and forward torque, forward direction and reverse (braking) torque, reverse direction and reverse torque, and reverse direction and forward (braking) torque. Some drives provide "four-quadrant control" with regeneration, and some without it.

■ Emergency Bypass

The drive may offer an internal bypass that allows the motor to be operated directly across the line in the event of drive failure. This feature is useful with applications that allow for emergency motor operation at full speed, such as ventilation fans, cooling tower fans, and chilled water pumps.

If the application makes a bypass useful, try to select a drive that has a "test" position in the bypass. This allows the drive to be connected to the power supply for test purposes independently of the bypassed motor. Any bypass circuit, whether part of the drive or external, must include an appropriate motor starter and fuses for operation of the motor directly across the line.

■ Power Factor

Power factor is important primarily as a possible factor in electricity pricing. It is also a minor factor in energy losses within the power distribution system of the facility. See [Reference Note 21](#), Electricity Pricing, for an explanation of power factor.

When a motor is driven with a VFD, the power factor that appears on the power system depends primarily on the type of rectifier used by the drive. The characteristics of the motor itself have little effect on power factor when the motor is driven by a VFD.

Drives that use diode rectifiers have high power factor at all motor speeds. The power factor of SCR and thyristor rectifiers drops almost linearly with decreasing motor speed, for reasons discussed previously. Diode rectifiers are used on virtually all contemporary PWM drives, so PWM drives have high power factor as a class. Some PWM drives even improve the power factor of the power system to which they are connected, to the extent that their capacity exceeds the momentary requirements of the motor. Diode rectifiers are also used on some models of VVI and CSI drives.

The power factor of a VFD matters most if the utility charges a power factor penalty. If the utility measures power factor at the time of the facility's peak load, the power factor of the VFD may still not matter much. All types of VFD's have high power factor under heavy load, and the absolute amount of "reactive power" (KVAR's) produced by the drive does not increase much with declining load, if at all.

In any event, the drive will not reduce the power factor of the facility unless the VFD is large in relation to the facility's peak load. Utilities do not charge a power factor penalty unless the power factor falls below a stated threshold, which is typically 85%.

For similar reasons, the power factor of a VFD generally does not cause overloading of the power system within the facility.

It may be dangerous to try to improve the power factor of the facility with capacitors if a VFD is installed.

This problem is discussed above, under “Resonance and Blown Fuses in the Facility Power System.”

■ Protection from Electrical Faults

Different VFD models can be damaged by different types of electrical faults. All modern drives have the ability to protect themselves against common electrical faults. Some modes of protection may be extra-cost options. Select protective features that are appropriate for your type and model of drive, and for the faults that are likely to occur in your power system.

Drives that use SCR’s to control the output to the motor (VVI and CSI drives, generally) are vulnerable to any fault that can interfere with the reverse voltage needed to turn off the SCR’s at each power cycle. These include shorts to ground and across the line. If the current is not interrupted, the SCR will burn itself out. CSI drives are fairly easy to protect from faults and grounds because the large inductors in the DC section prevent rapid increase in current. This gives fuses or other protective devices time to work.

Drives using transistors (PWM drives, generally) are less vulnerable because transistors can be shut off simply by turning off their control current. Also, the most modern type of transistor (IGBT) has a faster response time than earlier types of power transistors.

■ Resistance to Tripping of Drive by Transients

A feature commonly called “ride-through” keeps the drive from tripping off when there are brief interruptions of power. Ride-through relies on energy stored in the DC section of the drive, and a separate power supply may be used to keep the DC section charged. The ride-through capability of different models ranges from a small fraction of a second to several seconds, depending on the drive and the load.

■ Diagnostics and Displays

Any electronic device is subject to unpredictable component failure. This makes it desirable to have diagnostic capability that allows the unit to be returned to service quickly. Smaller, cheaper units have indicator lights that warn of a few specific conditions. More sophisticated units have readouts that can indicate most failure conditions. Try to get readouts that display in plain language, rather than in codes.

A useful feature available with larger units is a recording of drive conditions during the time immediately prior to a fault. For example, this would record if an overvoltage occurred prior to a fault. Another useful diagnostic feature is a history of previous faults.

■ Altitude, Cooling, Heating, and Humidity

VFD catalogs commonly list a maximum altitude of 1,000 meters (3,300 feet) without saying why. This is not because the drive needs oxygen to breathe, but because the thinner air at higher altitude is less effective in cooling the drive. You can use a VFD at any altitude,

but you have to provide extra cooling at higher altitudes, or limit the drive to a lower output.

A VFD must be kept above a minimum temperature. This keeps electrolytic capacitors from freezing and keeps the electrons from getting stuck in the silicon. A small thermostatically-controlled heater installed inside the housing can take care of this requirement.

Humidity must be limited to prevent condensation on the circuitry. This starts with an appropriate enclosure. The internal heat of the drive should keep the relative humidity low enough during operation. If the drive may become damp when it is shut down, an electric heater may be installed inside the housing to lower the relative humidity prior to starting. If the environment makes this step advisable, install a humidity sensor inside the housing to prevent the drive from starting until the heater reduces the relative humidity.

DIRECT-CURRENT MOTORS AND DRIVES

Before variable-frequency AC motor drives (VFD’s) were developed, DC drive systems were the only means of achieving a high turndown ratio while maintaining efficiency and torque. VFD’s are now making heavy inroads into the applications that were once dominated by DC drives. In the foreseeable future, DC drives will continue to be the best choice for some specialized applications. There are few retrofit applications, if any, where a DC motor drive is the best choice to replace a constant-speed AC motor. We will treat DC drives lightly, covering only the main features that contrast them with VFD’s.

How DC Motors Work

The DC motor is slightly more complex in construction than an AC induction motor. Figure 17 shows a DC motor with all the main parts visible.

A DC motor has two sets of windings. A set of field (stator) windings inside the motor case create a stationary magnetic field. (In small motors, the field may be created by a permanent magnet.) The armature (rotor) has a large number of separate windings distributed around the shaft like a squirrel cage. External current is passed through both sets of windings, creating magnetic fields. Interaction between the two fields creates the force that turns the rotor.

The current flow in the rotating armature windings is switched by the “commutator,” which consists of the electrical contacts for all the windings, arranged around one end of the rotor shaft. Stationary carbon brushes mounted on the motor case keep switching current to successive armature windings as the commutator turns under the brushes. Therefore, the windings are always energized at the same position in space, located where the windings are subjected to greatest torque from the

magnetic field of the field windings. This allows DC motors to produce high torque at all speeds, and provides rapid response to changes in the applied voltage.

Different methods of connecting the field and armature windings are used to establish the torque and speed control characteristics of DC motors. In a “shunt-wound” motor, voltage is applied to the field and to the armature in parallel. Shunt-wound motors have torque that is relatively low, but the torque remains constant with changing speed. Shunt-wound motors have good speed stability. In “series-wound” motors, the current passes through the field on the way to the armature. This type has high starting torque, but the torque declines sharply with increasing speed. Series-wound motors have poor speed stability. A common hybrid type, “compound wound,” has a small series field winding in addition to a larger shunt field coil.

How DC Drives Work

A DC drive unit controls motor speed by varying the voltage supplied to the armature windings, and hence the current. The drive may also vary the voltage and current to the field windings, if this is necessary to achieve the desired torque characteristics.

In the past, a DC drive was a cumbersome affair, as you can tell by visiting the elevator machinery room of an older building. A conventional AC motor was used to drive a DC generator, which produced direct current to drive a DC motor. The DC motor and DC generator were controlled by a bulky electro-mechanical panel. In all, an old DC drive required four big, expensive components.

Modern DC drives are much smaller and simpler, and correspondingly less expensive. The DC drive rectifies and filters the incoming AC power to make DC current. Speed control is entirely electronic. In applications that need precise speed control, the drive uses a tachometer mounted on the motor to provide speed feedback.

A DC drive is similar in size and appearance to a variable-frequency AC drive. The rectifier and filter in a DC drive are similar in function to the first two sections of an AC drive.

Advantages and Disadvantages

DC drives and AC variable-frequency drives are close competitors for some applications, so let’s compare the two. The main advantages of DC drives over VFD’s are:

- **higher turndown ratios.** DC motors can slow down almost to zero speed with some drives. However, the same capability is appearing in some VFD’s.
- **greater speed precision.** DC drive systems are capable of better speed precision than VFD’s. DC drives will probably retain this advantage because the motor torque can be controlled more positively

by the drive unit. Figure 18 shows an application where speed control is critical.

- **higher efficiency.** DC drive units have lower losses than VFD’s because they have no inverter sections. The overall efficiency of DC drive systems is higher than for VFD systems, especially at lower speeds and percentages of load. This is largely because DC motors use their magnetic fields more efficiently under these conditions.
- **absence of torque-related overheating at low speeds.** DC motors have long been employed to provide high torque at low speeds. They have

WESINC

Fig. 17 Direct-current motor This elevator motor clearly shows the major components of a DC motor. The six stator poles and the rotor windings are energized by electric current. Current reaches the rotor windings through carbon brushes that slide over the commutator on the near end of the rotor. The commutator keeps the magnetic field of the rotor stationary in space as the rotor turns. Note that there is a rotor brush corresponding to each stator pole. The rotor and stator fields remain aligned for maximum torque. Speed and torque are varied by changing the current in the windings.

evolved the ability to survive at low speed with the high currents needed to produce high torque. DC motors may have separate cooling fans, which are independent of motor speed. A similar approach could be used with AC drives, eliminating this as an advantage.

- **relative simplicity.** The rectifier section of a DC drive has about the same design as the rectifier section of a VFD, but it needs no inverter section or complex inverter controls.

The main disadvantages of DC drives, in comparison with AC drives, are:

- **need for motor maintenance.** The commutator rubs against the carbon brushes, creating carbon dust that must be cleaned out of a DC motor often to prevent arcing. At longer intervals, the brushes must be replaced. At still longer intervals, the surface of the commutator must be refinished, which takes the motor out of service for a period of time.
- **difficulty of protecting the motor in severe environments.** The need for access to the commutator and brushes for cleaning makes it awkward to seal a DC motor for use in harsh environments. However, DC motors for harsh environments are available.

Reliance Electric

Fig. 18 DC motor application This large DC motor in a paper mill operates a winder, which requires precise control of speed and torque. A tachometer is installed on the near end of the shaft as part of the speed control. Note the external cooling ducts, which provide effective cooling at all motor speeds and loads.

- **larger motor size.** The geometry of the field and armature windings requires a DC motor to be somewhat larger than an AC motor of the same power. External cooling systems are also bulky, but where these are used, they allow the DC motor to serve applications that could not be served by an AC motor.

- **power factor decreases with speed.** Unlike AC drives that use diode rectifiers, the power factor of DC drives declines with motor speed.

- **cannot bypass failed drive.** A DC motor cannot be operated across the line in the event of drive failure, because it would have no speed control. (The speed of an AC motor is determined by the frequency of the input power.)

As with AC drives, the cost of a DC drive system is a combination of equipment and labor costs. Comparing the two types, AC drive installations are typically less expensive in smaller sizes, while DC drive installations may be less expensive in larger sizes.

Waveform-Related Problems and Solutions

Electronic DC drives use switching devices similar to those used in VFD's. Therefore, electronic DC drives may create similar problems in the power supply system. The solutions to these problems are also similar. DC drives have not yet reached the same degree of sophistication in avoiding electrical problems as VFD's,

Coyote Electronics, Inc.

Fig. 19 Eddy current clutch combined with a pulley The inner portion of the clutch is fixed to the motor shaft. The outer portion, including a belt pulley, rotates freely on a ball bearing. The outer portion is driven by an induced magnetic field. The coils that induce the field are energized through a rotating electrical contact.

but they presumably will catch up in time. Refer to the previous discussion of VFD's for details.

The smoothness of the DC voltage produced by DC drives depends on the design of the rectifier and filter. It is possible for a DC drive to produce very smooth motor voltage, but not all models do so. As with AC motors, voltage distortion causes inefficiency and overheating in the DC motor.

(Old-style DC drives had none of these problems. The motor-generator set of the DC drive isolated the DC motor from the power supply, and it provided smooth DC power to the motor.)

Application-Related Selection Considerations

Different applications require different DC drive characteristics. These are the most common selection considerations for DC drives:

- control input provisions
- torque characteristics
- acceleration control
- turndown ratio
- speed precision
- braking and regeneration
- diagnostics and displays
- altitude, temperature, and humidity limits.

You may notice that these selection characteristics are similar to those for VFD's, but that there are fewer of them. Refer to the previous discussion of VFD's for the details of these issues.

VARIABLE-PULLEY DRIVES

Variable-pulley drives are belt drives in which the effective diameter of one of the sheaves can be changed as the equipment is operating. The drives use V-belts. The change in effective diameter is achieved by changing the spacing of the cheeks of the sheave. This squeezes the V-belt farther outward, or allows it to fall farther into the groove. Commercially available models are equipped to accept standard control signals.

Variable-pulley drives are among the most efficient methods of varying motor speed. Typically 3% to 6% of input power is lost to the belt drive at all speeds. This is about the same as the belt loss that occurs with constant-speed belt drives. The motor always operates at its design speed, so it suffers no efficiency loss from speed reduction. The motor does suffer the usual loss in efficiency as load is reduced, if the power requirement falls with the speed of the driven equipment.

The turndown ratio of variable-pulley drives is limited to about 3:1. This is sufficient to achieve most of the energy saving potential in variable-torque applications, such as fans and centrifugal pumps. However, the speed range may not be large enough for many industrial applications.

The maximum horsepower of variable-pulley drives is limited by the fact that power is transmitted through a single belt. At present, the largest commercial size is about 50 horsepower.

The variable-pulley mechanisms of different manufacturers differ substantially in bulk. Some are

Coyote Electronics, Inc.

Fig. 20 Eddy current clutch This direct-drive unit is rigidly mounted to the motor case for driving a pump.

quite small, and fit directly on the shaft of the existing motor. Others requires an intermediate belt drive installed on a separate base with the motor. The need to insert the drive unit between the motor and the driven equipment makes retrofit impractical in many cases.

Variable-pulley drives probably deserve greater attention. They have been eclipsed by variable-frequency drives because of the latter's ease of installation, more aggressive marketing, and the popularity of anything that is electronic. Variable-pulley drives are simple and they have few failure modes. They are free of electrical noise problems. Costs are relatively low. Periodic belt replacement is their only major maintenance requirement. Turndown ratio is their only serious performance limitation.

EDDY CURRENT CLUTCH DRIVES

An eddy current clutch is an electromagnetic slip clutch. Figure 19 shows a cross section of an eddy current clutch, for a unit that is an integral part of a belt drive pulley. The motor drives a rotating electromagnet that induces eddy currents in a metal disk or drum connected to the output shaft. The magnetic field of the driven element interacts with the induced eddy currents

to create torque in the driven element. This is similar to the action of an AC induction motor.

The speed of the driven element is controlled by varying the current that creates the magnetic field. This requires an external electrical connection.

Eddy current drives are less efficient than the types covered previously. They were promoted for energy conservation during the 1970's, primarily as fan drives. Their lower efficiency, compared to the emerging AC variable-frequency drives, caused them to fade away. They may be making a limited comeback, primarily because they are free of the electrical problems that have become notorious with variable-frequency drives.

Eddy current clutches have a fairly high turndown ratio. However, efficiency falls rapidly as speed is reduced, so there is little energy saving below a turndown of approximately 3:1.

The eddy current clutch may be mounted directly to the motor frame, as in Figure 20. This provides a strong, compact mounting. Units are also available that mount directly on the shaft of an existing motor. The clutch assembly has about half the volume of the motor, and it requires a small external controller. Maintenance requirements are low because there are few moving parts, and no parts are subject to frictional contact.

WESINC

Fig. 21 Large wound-rotor motor This air handling unit supply fan serves 150,000 square feet of air conditioned space. The wound-rotor motor was installed to allow an adjustment of the fan speed. The speed is reduced by using the resistor bank in the background to dissipate power that is induced in the rotor windings. In addition to wasting motor power, the resistors heat the cooled air. The building owners have been paying for this energy waste for decades. An ordinary motor with drive belts and pulleys would have been cheaper and much more efficient.

WOUND-ROTOR MOTORS

A wound-rotor motor is a variation of an AC induction motor. As with other induction motors, the magnetic field of the rotor is induced by the magnetic field of the stator. The main physical difference is that the wound-rotor motor has more complex windings embedded in the rotor. The rotor windings are divided into phases to match the number of phases of the stator. The rotor windings have connections that are brought to the outside of the motor through slip rings.

The external rotor connections allow the current that is induced in the rotor windings to be reduced by placing resistors in series with the windings. Reducing the rotor field slows the motor. This method allows motor speed to be reduced to 50-70% of full speed, below which motor operation becomes unstable.

This method of speed control dissipates a large amount of energy in the resistors. Indeed, the presence

of a large external resistor bank is the most obvious clue that a motor is a wound-rotor type. Figure 21 shows an example.

Wound-rotor motors are generally large. They tend to be found in direct-drive applications that lack other means of adjusting speed. However, they could be found in combination with belts or other types of transmissions.

Wound-rotor motors have been rendered obsolete by their poor efficiency and by the availability of better methods of controlling speed. They may get a reprieve from an unusual type of controller that feeds the energy extracted from the rotor back to the power supply system, conserving energy. This is called “slip energy recovery.” This type of controller can be retrofitted to existing wound-rotor motors and is claimed to have high efficiency. It creates harmonic distortion of the input power in a manner similar to that of variable-frequency drives.

Analog and Digital Controls**Open-Loop and Closed-Loop Controls**

This Note covers the basics of automatic controls. To keep the discussion from being too general, and hence confusing, we will focus on temperature controls to provide examples. However, the same principles apply to any condition that you want to control automatically, for example, pressure in boilers, air flow in variable-volume systems, water flow in variable-flow systems, etc. For system conditions other than temperature, replace “temperature” with “pressure,” “flow,” or other relevant variable in the following discussion.

Setpoints

The purpose of thermostatic controls and many other types of automatic controls is to keep a selected variable (e.g., temperature, pressure, etc.) close to a particular value. This selected value is called the “setpoint.” To do this, the control uses a sensor to measure the controlled variable. The sensor produces an output signal that is sent to the equipment that produces the desired condition. The signal tells the equipment whether to increase or decrease its output.

For example, if the controlled variable is space temperature, the control is a thermostat and the desired room temperature is the setpoint. The thermostat responds to the space temperature by sending a signal to the heating or cooling equipment. The equipment operates in response to the thermostat signal in a way that keeps the space temperature close to the setpoint.

The control usually allows a person to change the relationship between the measured variable and the control signal. This allows the person to change the setpoint, or the sensitivity of the control, or other characteristics. For example, all room thermostats allow a person to change the room temperature setting. Some room thermostats, but not all, allow a person to change the sensitivity of the thermostat to temperature changes.

Matching the Controls to the Equipment

The output of the control must be matched to the characteristics of the equipment being controlled. That is, they must “speak the same language.” These characteristics need to be matched:

- **method of transmission.** At present, the most common methods of transmitting control signals are electrical and pneumatic (air pressure). As technology advances, other methods are becoming popular. For example, light beams in fiber optic cables are used for transmitting signals over long distances, and infrared beams are used for transmitting signals over short distances.
- **method of coding information.** The signal may be a simple electrical connection that is turned on or off. For example, this type of control signal is commonly used with small heaters, air conditioners, and water heaters.

The signal may be proportional in strength to the measured condition. This method of coding is called “proportional” or “analog.” For example, pneumatic controls are usually analog.

The signal may be coded as a series of digital pulses. All electronic control systems are digital. Most sensors and actuators are inherently analog devices, so an “analog-to-digital converter” is needed at each end of a digital control system.

- **signal range or protocol.** The range of output from the sensor must match the range of input to the controlled equipment. For example, simple electrical on-off thermostats typically operate at 12 or 24 volts, and the controlled equipment is designed to accept these voltages. Pneumatic controls typically operate in a pressure range of 5 to 15 pounds per square inch. Electrical analog control systems typically operate by varying a current between 4 to 20 milliamperes.

Digital signals can be coded in many ways to carry many different kinds of information. Unfortunately, industry has not yet evolved a common set of standards for digital signals. For more about this problem, see [Reference Note 13](#), Energy Management Control Systems.

- **direct- or reverse-acting.** In a proportional control system, if the sensor output increases as the measured variable increases, the control response is called “direct-acting.” If the sensor output

decreases as the measured variable increases, the response is called “reverse-acting.”

Similarly, if an actuator increases its output as the input signal increases, it is called “direct-acting.” In the opposite case, it is “reverse-acting.”

Combining direct-acting and reverse-acting control components can simplify a control system. For example, a single direct-acting thermostat can simultaneously control cooling with a direct-acting actuator (cooling increases as temperature rises) and heating with a reverse-acting actuator (heating decreases as temperature rises).

- **response curve.** Most analog controls are approximately “linear,” which means that the control signal varies proportionally to the measured variable. The output of equipment in response to the control signal is not always linear. For example, the flow of air through a typical damper is not linearly proportional to the position of the damper actuator.
- **sensitivity.** The sensor is limited in its ability to sense changes in the controlled variable. At the other end of the system, the actuator requires a minimum change in signal to make it respond. For example, a sensitive room thermostat may control temperature within 0.2°C, while a less sensitive thermostat may control temperature within 1.0°C. The sensitivity of some control elements is variable. Sensitivity is a factor in control stability.
- **rate of response.** In many cases, it is not desirable for the equipment to respond instantly to the control signal, as this may cause control instability. For example, water valves and air valves can respond so quickly that they can oscillate under adverse conditions. Some equipment, such as baseboard convectors, respond so slowly that instability is not a problem. (Response rate is only one factor among several that affect system response and stability.) Response rate can be slowed in a variety of ways. One is to select actuators that respond slowly. In pneumatic systems, the signal itself can be delayed by putting a restriction in the air line. Digital systems provide almost unlimited flexibility in tailoring control response. Rate of response is the basis of “derivative” control, which is discussed below.

Two-Position Controls

The simplest type of control turns equipment on and off. Such controls are called “two-position,” “make-break,” and other names. Most two-position thermostats have a bimetallic temperature sensing element that opens and closes an electrical contact as it changes shape in response to temperature. Two-position thermostats are used to control equipment that is on-off in nature, such as electric heating coils, burners in small furnaces and

boilers, and compressors in small air conditioners and refrigerators.

With two-position control, the temperature cycles between two temperature limits, as shown in Figure 1. The difference between the turn-on and turn-off temperatures is called the “differential.” Typical two-position space thermostats have differentials from 1°F to 3°F (0.5°C to 2°C). The need for a substantial temperature differential is a weakness of two-position control. If the differential were too small, the equipment would cycle on and off at an excessive rate.

Note that the temperature shown in Figure 1 is the temperature at the thermostatic element itself. The temperature differential in the space or in the controlled equipment usually is larger than the differential at the thermostat. This is because the thermostat is somewhat isolated, so there is a lag in sensing the space or system temperature. Also, the temperature continues to drift while the heating or cooling equipment starts.

■ Stepped Controls

A stepped, or staged, thermostat consists of several two-position thermostatic elements installed in a single housing, with progressively higher (or lower) temperature settings. Stepped thermostats are used to control multi-stage equipment, such as electric heaters with several elements, boilers with multi-stage burners, and reciprocating cooling compressors with unloading cylinders.

As the load increases and successive thermostatic elements turn on their equipment, the temperature gets further away from the setpoint (the desired temperature). This limits the number of steps that are practical.

Fig. 1 Two-position control This is the response of a heating system. The difference between the “on” and “off” temperatures is the “differential.” In this example, the heating capacity is large, so the temperature rises quickly during the “on” cycle. Also, the heating load is large, so the temperature falls quickly during the “off” cycle.

■ Anticipators

Anticipators are an accessory of two-position thermostats that control space heating equipment that heat space air quickly. The thermostat heats up more slowly than the air in the space. This is because the thermostat is partially enclosed, and because it is mounted on a solid base, which also heats up more slowly than the space air. If no correction were made for this lag in thermostat response, the air in the space would overheat with each heating cycle.

This problem is overcome by installing an “anticipator” in the thermostat. An anticipator is a tiny electric heating element inside the thermostat. It is usually powered by the thermostat control current. Current starts to heat the anticipator when the thermostat circuit is closed by the temperature sensing element, at the same time that the space heating unit starts. The anticipator can be adjusted so that the rate of warming inside the thermostat matches the rate of warming in the space.

Figure 1 in [Measure 5.7.4](#) shows a two-stage heating thermostat that has a separate anticipator for each stage. Each anticipator can be adjusted separately.

Anticipators are used most commonly with forced-air heaters, which heat the air in spaces quickly. Anticipators are used less often in thermostats that control convective and radiant heaters, because these have less tendency to overheat a space. Anticipators are not used in thermostats that are located in the return air stream of fan-forced equipment, because the lag in such thermostats is negligible.

Proportional Controls

A proportional control, as the name implies, provides an increasingly stronger control signal as the temperature gets farther away from the setpoint. Figure 2 shows the response of an ideal proportional control.

Proportional controls are used with equipment that modulates its output, such as hydronic coils, centrifugal and screw chillers, burners in large boilers, pumps in variable-flow systems, etc.

For example, pneumatic thermostats are proportional control devices. Typically, a bimetallic temperature sensing element actuates a tiny valve that bleeds compressed air into a plastic or copper signal line. The air pressure in the line is the output signal of the thermostat.

Instability occurs when the response of a system gets out of phase with actual conditions. Equipment output may increase when it should be decreasing, or vice versa, causing large swings in output. Instability may occur because the system does not respond quickly enough, so the controls continue to require more response when it is not needed. The delay in response may occur because of the travel time of air in ducts, the

Fig. 2 Proportional control The strength of the control signal is proportional to the difference between the system output and the setpoint. The response shown here is ideal. Real proportional control systems rarely behave this well.

travel time of liquid in pipes, time delay in signal travel, heat absorption by the mass of space or equipment, etc. By the same token, the tendency toward instability increases if the control responds to conditions too quickly and too strongly, not allowing the controlled equipment to catch up.

A practical problem of simple proportional controls is friction and play in both the control devices and in the controlled equipment. These cause the equipment not to respond fully to the temperature signal, increasing the offset. For example, a loose linkage or a sticky control valve can seriously degrade control accuracy. The same factors also cause “hysteresis,” which means that the system stabilizes at different temperatures for a given setpoint, depending on whether the temperature was previously rising or falling.

■ Proportional-Integral (PI) Controls

In a proportional control, the difference between the temperature setting and the actual temperature is called the “offset.” (It is sometimes called “drift,” “droop,” or other names.) Figure 3 illustrates offset.

Offset increases as the load increases. It is the main weakness of simple proportional control. Offset can be reduced by making the system more sensitive, i.e., by producing a stronger control signal in response to the temperature offset. However, excessive sensitivity causes control instability, which is the tendency of the control to oscillate or “hunt.”

“Integral” control is a refinement of proportional controls that eliminates the offset error. An older name for this feature is “automatic reset.” A proportional-integral (PI) control has an additional feature that senses the difference between the actual temperature and the setpoint. The control changes its response to eliminate this internal difference. Integral control requires additional hardware in the thermostat or the control system.

Fig. 3 Proportional-integral (PI) control Integral control senses the difference between the setpoint and the actual system output, and responds to close the gap between the two. The response is relatively slow, which is appropriate for many applications.

“Integral” is a term taken from the mathematical method of calculus. An integral is a summation of a variable over some period. In a PI control, the vigor with which the control system acts to return the system to the zero-offset position is proportional to the accumulated offset, or more precisely, the summation of the offset over time.

■ Proportional-Integral-Derivative (PID) Controls

“Derivative” control is a further refinement of proportional controls that is almost always combined with integral control, yielding proportional-integral-derivative (PID) control. Derivative control improves the speed of response, as shown in Figure 4. It is used because integral control alone is rather slow, requiring a summation of the offset over time.

“Derivative” is another calculus term, which means the rate of change of a variable. In derivative control, the rate of change of the control setting is proportional to the offset. If there is a large offset, the control provides a large signal to restore the system to its setpoint.

Derivative control is especially valuable in systems where output is able to change so rapidly that the system response may wander far from the setpoint. Typical applications for PID control are controlling boiler pressure and controlling the flow of air from variable-flow fans.

An unfortunate effect of derivative control is a tendency to overshoot the setpoint, as shown in Figure 4. Instead of proceeding smoothly to the setpoint, the system oscillates around the setpoint. The system is stable if the oscillations damp out quickly. The combination of proportional and integral control provides the desired stability if the controls are adjusted properly.

Derivative control has a further disadvantage in cases where the signal may be noisy, for example, an

Fig. 4 Proportional-integral-derivative (PID) control A “derivative” characteristic increases the speed of response in a proportional control. Overshoot is an inherent aspect of derivative control. Keeping the system response stable requires a proper combination of integral and derivative characteristics.

analog electrical signal in a wire that picks up electrical noise from the environment. A noise spike tells the derivative control that there is a large offset error, which causes the system to respond strongly, although only momentarily. The same problem arises if the signal is subject to small but rapid fluctuations, for example, the return temperature of a chilled water system. Thus, derivative control may be twitchy.

Integral and derivative control are general methods of signal correction, which are not characteristic of any particular type of controls (i.e., pneumatic, electric, or electronic). They are accomplished differently with different types of controls. Integral and derivative control are standard features of electronic digital controls, but they require additional complications in pneumatic and electric analog controls.

■ Limitations of Integral and Derivative Control

Integral and derivative control is not a panacea. It complicates the control system, making it more difficult to diagnose problems. You have to set the rate of response for both the integral and the derivative features of a PID control, based on the speed of response and the lag of the system. For example, the control of a water chiller should take into account the time required for water to circulate through the system, the control characteristics of the equipment that uses chilled water, and the throttling characteristics of the chiller. Improper settings can cause control instability or other problems.

Integral and derivative control can compensate for the effects of play and friction in control linkages, within limits. They cannot compensate for improper thermostat installation, such as placing a space thermostat on an exterior or sun-exposed wall, or installing a chilled water thermostat in the supply line of a reciprocating chiller.

Analog and Digital Controls

All the principles discussed previously apply equally to analog and digital control systems.

Digital controls can provide perfect accuracy in transmitting signals. They also provide perfect accuracy in the internal calculations of the control system. However, the variable being measured (e.g., temperature, pressure, flow, etc.) is usually an analog signal. The sensor technology determines the sensitivity and accuracy of the input signal. Likewise, the output (e.g., a valve setting) is usually an analog variable. The accuracy of the output is determined largely by the controlled device. For example, a sticky valve will not accurately control the flow of water in a coil.

Digital signals are processed with microprocessors, which can be programmed to perform a variety of functions. The response characteristics of a digital control system can be tailored in great detail. These are mixed blessings. See [Reference Note 13](#), Energy Management Control Systems, for more about digital controls.

Open-Loop and Closed-Loop Controls

A closed-loop control system compares the actual system output to the setpoint. The difference between the two creates another signal, called “feedback,” that is used by the control system to reduce the difference. Virtually all control systems used in buildings and plants are closed-loop. This includes all types of thermostatic controls.

An open-loop control simply sends a signal to the controlled equipment. The response of the equipment to the control is determined by the magnitude of the control signal, and by the sensitivity and response speed of the controlled equipment. There is no feedback, except perhaps the response of a human operator. A valve on a garden hose is an open-loop control system. A manual damper on a wood stove is another.

Building Air Leakage**What Causes Air Leakage**

- Unbalanced Fan Systems
- Wind
- Chimney (Stack) Effect

How to Find Air Leaks**How to Estimate Air Leakage****Vapor Barriers and Air Leakage****Maintenance to Reduce Air Leakage**

Air leakage through the skin of a building is a major cause of energy waste in many buildings. This brief Note explains the causes of air leakage, gives methods for finding and estimating leakage, and lays the groundwork for the Measures recommended in [Section 6](#).

We use the term “building air leakage” to mean the passage of air through the outer structural components of the building, including the walls, windows, doors, roof, and floors. The term “infiltration” is often used for air leakage. Strictly speaking, infiltration is air leakage into the building. The less common term “exfiltration” is air leakage out of the building.

The total amount of air entering the building must equal the total amount of air leaving the building, but this does not mean that infiltration equals exfiltration. The most important reason for the difference is the operation of ventilation fans. For example, exhaust fans create a negative pressure in the building that causes infiltration, but no exfiltration. The air exhausted by the fans is not “leakage,” as we define the term, although it may carry away a large amount of energy.

What Causes Air Leakage

Air moves only in response to a pressure differential. The following are the three major causes of pressure differential across the building envelope. The amount of air leakage is proportional to the aggregate effect of these three causes. Air leakage is inversely proportional to the resistance of the envelope to leakage.

■ Unbalanced Fan Systems

A pressure differential is created across the building envelope if fans in one part of the building exhaust more or less air than fans in another part of the system bring into the building. Many air conditioning systems are inherently unbalanced, usually because the system has exhaust fans but no arrangements to force outside air through the conditioning units. In some cases, pressure imbalance in conditioning systems can be eliminated with simple adjustments. In other cases, this would require major modifications. See [Measure 4.2.1](#) about balancing intake and exhaust in air handling systems.

A negative pressure is commonly created inside laboratories, hospital rooms, and other isolated spaces

to prevent contamination of one part of the building by another. This causes a certain amount of infiltration through the outer envelope.

Conversely, a positive pressure is sometimes created in buildings for the sake of comfort. The positive pressure prevents entry of drafts. It also forces warm air through the walls in cold weather, increasing the wall temperature.

■ Wind

The pressure created by wind against a surface is proportional to the square of the wind speed. For example, a wind of 32 miles per hour has a “velocity pressure” of about 0.5 inches water gauge. This means that if all the energy of wind striking a wall is converted to pressure, the pressure on the wall would be 0.5 inches. This is similar in magnitude to the pressure differentials created by the fans of air conditioning systems.

Wind pressure is positive on the upwind side of a building, and is negative on the downwind side, so air leakage caused by wind tends to flow through the building. The magnitude of negative pressure on the downwind side of the building is much less than the magnitude of the positive pressure on the upwind side. This is because the kinetic energy of the wind is dissipated in turbulence on the downwind side.

Not much can be done about wind pressure on the broad face of a building. However, individual outside air intakes can be shielded from velocity pressure in a fairly effective manner. Refer to [Measure 4.2.9](#) for methods.

■ Chimney (Stack) Effect

If it is cold outside a building, the warm air inside the building is less dense than the air outside, and hence lighter. Therefore, the total weight of the atmosphere acting at ground level creates more pressure outside the building than inside the building. The difference in pressure at the base of the building causes air to flow into the building at its lower levels.

The increase in pressure at the bottom of the building is transmitted to the upper levels of the building, which become higher in pressure than the outside. Thus, chimney effect causes air to leak into the bottom of a building, and to leak out the top of the building. The

situation is reversed in a building that is being cooled during warm weather.

The force of chimney effect is proportional to the difference between the inside and outside temperatures. Unfortunately, this makes chimney effect worst when the heating and cooling loads are highest.

Chimney effect is also proportional to the height of the building. In tall buildings, chimney effect can be a strong force, so special methods may be required to limit air leakage. The most visible of these is the revolving door, a hallmark of tall buildings. The revolving door acts as an air lock at ground level.

There is an important fact to apply in minimizing air leakage in tall buildings. If the upper portion of a building is sealed so that air cannot leak out the top, then the force of chimney effect will not induce infiltration at the lower floors. Measures to prevent air leakage from upper floors are recommended in [Subsection 6.4](#). Personnel doors that lead to roofs and penthouses are common paths for leakage. Measures to reduce leakage through these penetrations are recommended in [Subsection 6.1](#).

In principle, chimney effect could be eliminated by isolating each level of the building from the other levels. However, the need for elevators and stairs makes this practically impossible. Also, it might be possible to counteract the negative pressure on lower flows by pressurizing the elevator shafts and other vertical penetrations. However, this approach requires energy to move and condition the outside air that is used for pressurization.

How to Find Air Leaks

Here are some methods of finding air leaks in the building envelope:

- **feel** works well for localized inward leaks, especially during cold weather. Feel is not sensitive enough for outward leaks.
- **small flames** are sensitive to leaks in both directions. Just don't burn the place down. This is how the Three Mile Island nuclear plant meltdown got started. Candles are old fashioned. Use a barbecue lighter.
- **test smoke** is the most effective visual method of finding outward air leakage, but it is poor at detecting inward leakage. Smoke testing has become more practical with the introduction of canisters that can release small puffs. (These are sometimes called "smoke pencils.") Get smoke sources from air conditioning supply houses. Old-fashioned smoke bombs produce far too much smoke, frighten occupants, and set off some smoke alarms.
- **a lightweight cloth** or a **piece of tissue paper** dangled near a suspected leak is sensitive to both

inward and outward flow. This method's only disadvantage is lack of glamor.

- **a lightweight ribbon attached to the end of a stick** works well for finding leaks deep in wall cavities and other places where you cannot reach. Tape a miniature flashlight to the same stick so you can see into the dark hole.
- **infrared thermography** has the unique ability to trace air leakage paths through envelope structures. Scan inside surfaces for incoming leaks, and the outside surfaces for outgoing leaks. Thermography must be done during cold weather, the colder the better. Scans should be done at night, several hours after sunset, to avoid false images caused by solar heating. Thermography is expensive, it cannot get into tight places, and it requires special expertise. For more, see [Reference Note 15](#), Infrared Thermal Scanning.

How to Estimate Air Leakage

It is not possible to estimate the amount of air leakage with precision, even when the locations of leaks are known. The amount of leakage depends on imbalances in the conditioning systems, the average chimney effect, and the average effect of wind, and other factors that cannot be defined accurately. Go ahead and minimize leaks that you find, and forget about making detailed estimates of savings.

ASHRAE has developed formulas and tables for estimating leakage around windows and doors. These methods may be useful if it appears that most leakage occurs at such components. You start by estimating the total opening area of the leakage paths. For example, air leakage around the sash of particular window types can be estimated from ASHRAE tables by measuring the total length of the joints where leakage can occur. These methods are not accurate, but they give you some basis for deciding whether to improve or replace leaky windows or doors.

A significant amount of energy loss can occur from leakage of outside air into the structure of walls and ceilings, rather than into the occupied space. Such leakage bypasses insulation, reducing the effective R-value of the envelope. There is no practical method of measuring the effect of such leakage in the field, but it may be estimated from a thermographic survey. The solution to such leakage is to seal air leakage at the outside surface of the envelope wherever it is practical to do so.

A "blower door" is a device used to test the overall leakage rate in small buildings, such as residential houses. It consists of a panel that fits tightly in a door, window, or other exterior opening. A fan mounted in the panel creates a pressure in the building. A manometer mounted in the panel measures the pressure. If the envelope is tight, the manometer registers a higher

pressure than if the building is leaky. The total amount of leakage is derived from the characteristics of the fan.

Blower doors are difficult to use. In order to find dispersed, small envelope leaks, it is necessary to seal all the intentional openings in the building, including furnace flues, hoods, fireplaces, etc. By the same token, the blower door helps to highlight and quantify such major leaks if the blower door test is repeated as each leakage path is sealed. For example, the blower door test may indicate that it is worthwhile to install a low-leakage damper in a kitchen hood system.

Vapor Barriers and Air Leakage

See [Reference Note 43](#), Vapor Barriers, for an explanation of vapor barriers. In brief, a vapor barrier is an impermeable membrane that blocks the flow of atmospheric water vapor through the building envelope. Vapor barriers can also be an effective means of

preventing air leakage through walls, ceilings, and other large areas where they are installed.

Vapor barriers provide little benefit in the parts of the building envelope that commonly have the worst air leakage, such as windows and door frames. Vapor barriers are broken where wiring must pass through the surface. For example, this accounts for the drafts that you may feel at electrical switches and receptacles that are installed in outside walls.

Maintenance to Reduce Air Leakage

Leakage seals for doors, windows, and other movable envelope components require occasional replacement. Caulking materials used to seal fixed components lose elasticity and shrink with time. Therefore, maintenance is an essential part of deterring air leakage. The effectiveness of sealing depends on good workmanship and selecting appropriate sealing materials and methods.

How Insulation Works

A Quick Review: What is “Heat”?

How Insulation Blocks Heat Flow

- Preventing Heat Conduction
- Blocking Heat Radiation
- Preventing Heat Flow by Mass Transfer
- Preventing Convection

This Reference Note explains how insulation keeps heat from moving. This is the “thermal” part of insulation behavior. With this background as a foundation, [Reference Notes 42](#) through [45](#) continue with the practical aspects of selecting and installing insulation.

A Quick Review: What is “Heat”?

Since the purpose of insulation is to control heat, let’s review what “heat” is. Heat is a form of energy that occurs in two entirely different forms. The first form occurs in any material substance — solid, liquid, or gas. This energy consists of the random vibration of the atoms and molecules that make up the material. The vibration energy increases with temperature. (Conversely, temperature is a measure of the intensity of heat energy. The exact definition of temperature is very theoretical. You don’t need to know it for practical work.)

The second form of heat is electromagnetic energy, which travels in empty space. Heat radiation is the same as light, X-rays, and radio waves. It originates from the vibration of the electric charges in matter. Conversely, any electromagnetic radiation that is absorbed by matter is converted to heat in the material.

The energy of all electromagnetic energy can be considered as heat. However, we usually consider heat radiation as the energy emitted by a hot object, such as the sun or a radiator. Heat is also radiated by objects near room temperature, such as the walls of a building. Most heat radiation falls within a broad range of wavelengths that extends beyond the red end of the visible light spectrum. This broad spectrum is called “infrared.”

How Insulation Blocks Heat Flow

The purpose of insulation is to keep heat from moving. To understand how insulation works, you need to understand how heat moves. There are three fundamental processes of heat movement: “conduction,” “radiation,” and “mass transfer.” A fourth mode of heat movement, “convection,” is driven by the first three. We will summarize how insulation works in relation to each

External Factors that Affect Insulation Performance

Conduction Lag and Heat Storage Effects Heat-Reflecting “Insulation”

of these four modes of heat movement. This will give you enough background to interpret the thermal performance specifications of any type of insulation.

■ Preventing Heat Conduction

Most heat loss through building insulation occurs by conduction. Conductive heat transfer is an exchange of kinetic energy between atoms and molecules as they collide with each other. Therefore, conduction occurs only in matter. You can keep heat from traveling by conduction if you create an empty zone that has no atoms and molecules. Stated differently, heat cannot move by conduction across a vacuum. This is the insulating principle used in thermos bottles. The reason why vacuum is not used for building insulation is that no one has yet devised a reliable, inexpensive vacuum container for large surfaces.

Vacuum is not yet available as a practical form of insulation on a large scale, so insulation uses the next best approach. This is to approximate a vacuum by minimizing the amount of matter through which the heat can move. Gases have much lower density than solids, so insulation works by eliminating as much solid material as possible, and replacing it with a gas. In all porous insulation, the surrounding air is the gas that is used.

An empty air space does not work well as insulation, because air is easily moved by convection and pressure differences. Porous insulation holds the air in place by using small quantities of solid material as a matrix to hold the air still. Air adheres weakly to the solid material, so the air is held stationary. (Even so, the insulation must be enclosed effectively to keep air from moving.) The solid material is distributed so it occupies as much of the space as possible, so that each air molecule is close to an attachment point.

The solid material used in porous insulation may be in the form of fibers or granules. Insulation fiber is usually made of glass or glassy slag. Granules can be made of chopped waste paper (“cellulose”), various minerals in expanded form, foam beads, or other materials. [Reference Note 43](#) covers the common types of insulation materials.

Most heat conduction in porous insulation occurs through the trapped air, much less is through the solid material. However, heat conduction through the solid material is significant. For this reason, manufacturers try to make the solid component as thin as possible.

In the case of fiber insulation, conduction through the fibers can be reduced by orienting them perpendicular to the heat flow, so that heat cannot travel along the fibers. Fiber batt and board insulation is made this way. Loose fiber pouring insulation does not have this advantage.

Many gases have better insulating properties than air. Some of these are used in plastic foam insulation, in less common types of insulation, and in windows. Chlorofluorocarbons (CFC's) have been the primary gases used as alternatives to air. However, concern about the effect of CFC's on the atmosphere is motivating a search for other gases to replace CFC's.

All insulation that uses alternative gases requires closed cells to keep the gas from escaping and being replaced by air. This has proven to be a serious weakness of this kind of insulation. Foam insulation, which dominates the market because it is easy to manufacture, holds the gases in tiny plastic bubbles. Unfortunately, the insulating gas is able to slowly diffuse through the plastic.

Manufacturers of foam insulation use various methods of resisting this leakage, such as increasing the thickness of the bubble walls and bonding metal foil to the faces of insulation boards. The rate of leakage may be low in good insulation, but all contemporary plastic foam insulation will eventually lose its special gases. This has spurred the use of other materials to hold the gases, such as glass foam, but no alternative to plastic foam is presently acceptable for wide application.

■ Blocking Heat Radiation

Radiation heat loss and heat gain is not, by itself, a problem in the opaque parts of the building envelope. All opaque construction materials stop heat radiation completely. However, the energy of heat radiation must go somewhere. Radiation that strikes an opaque material is either absorbed or reflected. Absorbed radiation increases the temperature of the material, and the added heat is transferred by conduction. Since insulation blocks heat conduction, it indirectly blocks heat radiation also.

Radiation heat transfer occurs inside insulation materials at a microscopic level, from one molecule to another. However, this effect is small at normal temperatures. For insulation of typical thickness, this process accounts for less than 10% of heat transfer.

Heat radiation is important in transparent parts of the envelope, namely, windows and skylights. In fact, it is so important that [Section 8](#) is set up to deal with it separately. Refer to there for the Measures that deal with glazing.

■ Preventing Heat Flow by Mass Transfer

If you heat some material, then move it somewhere else and let it cool, you have moved heat by mass transfer. The mass is a carrier for the heat energy. Mass transfer is a powerful method of moving heat. In air conditioning systems, air is moved by fans and water is pumped to transfer heat. Unfortunately, air is also effective in moving heat through the building envelope. If the envelope is leaky, loss of heat carried by air may account for much more energy waste than conduction or convection.

Air leakage in buildings is driven by wind, chimney effect, and unbalanced operation of fans. [Reference Note 40](#), Building Air Leakage, gives the details of these processes.

You can eliminate air leakage by making the envelope airtight. In most cases, the insulation itself plays only a secondary role in minimizing leakage. Air movement is stopped primarily by impermeable structural components and by installing "vapor barriers," which are explained in [Reference Note 42](#).

■ Preventing Convection

Convection is movement of air that occurs when the air is heated or cooled. The air adjacent to a heated surface is warmed by conduction, becomes less dense, and rises. If the air encounters a colder surface, it becomes more dense, and falls. In an enclosed space, such as a wall cavity, this cycle continues as long as one side of the cavity is warmer than the other. If the air inside building envelope cavities is free to move, convection is a powerful mode of heat loss.

Insulation prevents convection by holding the air in a cavity still. To do this, the insulation must entirely fill the space. Even a narrow void can seriously undermine the effectiveness of insulation, especially if it runs vertically. For this reason, the workmanship of the installer has a significant effect on insulation performance. [Reference Note 44](#) covers this aspect.

The density of insulation installed in a cavity is an important factor. The optimum density is a compromise between conduction and convection. In practice, the density of commercial insulation is determined by manufacturing limitations and economics. For example, the mineral structure of vermiculite makes it too dense to have a very good insulation value.

On the other hand, glass fiber blanket insulation typically is less dense than optimum because the manufacturer is minimizing material cost. You can improve the performance of fibrous insulation by packing somewhat more of it into the cavity than is specified by the manufacturer. For example, use an R-19 batt where an R-11 batt is specified. This will also help to fill the cavity. However, you should still be careful to fill the cavity as uniformly as possible.

External Factors that Affect Insulation Performance

The insulation characteristics quoted by the manufacturer are measured under a particular set of conditions. If the insulation is used under a different set of conditions, its performance may differ significantly. Perhaps the most important external factor is the temperature of the insulation. The thermal resistance of all thermal insulation improves as the temperature falls. This is a bonus for building insulation in cold climates. Conversely, if insulation is used for applications at much higher temperatures, such as insulating steam pipe, the insulation value may be lower than expected.

Another factor is the orientation of the insulation. This may affect fibrous insulation, reducing the insulation value somewhat if the fibers are oriented vertically.

In most applications, these variations in characteristics are minor. Usually, they will not create any surprises if you select the type of insulation for the particular application. However, if you use a generic type of insulation, such as vermiculite, which may be used in a wide variety of applications, be sure to obtain its characteristics for the conditions under which you plan to use it.

The thermal resistance of most types of insulation is seriously degraded if moisture can condense inside the insulation, or if air is allowed to move through it. Design the installation and select the insulation to avoid both problems. See [Reference Note 44](#), Insulation Integrity, for the details.

Conduction Lag and Heat Storage Effects

Insulation is inherently light in weight because it must contain little mass. Although insulation obstructs heat flow, it does not delay the heat flow that does occur. However, if insulation is combined with the mass of a heavy structural component, such as a masonry wall or a concrete roof slab, the combination structure may have a significant delaying effect on heat flow. The key factor in the time delay is the heat storage capacity of the massive material. All masonry materials have similar specific heats, so their heat storage effect is proportional to the mass of the insulated component.

The mass effect is important primarily with masonry construction. Masonry buildings may have wall heat conduction delays of several hours or longer. A lag in conduction does not occur with metal structures, because heat travels quickly in metal. Thermal lag is not important in frame structures, because the heat storage capacity of the structure is too low to develop much lag.

The lag effect is significant only if the mass of the structure is exposed to outside conditions, i.e., if the insulation is installed inside the structure. If the weather

alternates on a daily basis between too hot and too cold, the lag effect is beneficial. This is because the lag effect reduces the average temperature differential across the insulation. However, if the insulation is installed outside the mass, the mass is not subjected to large temperature changes, so the lag effect is greatly reduced.

If the mass of the envelope is exposed to the inside of the building, i.e., if the insulation is installed on the outside, there is an adverse interaction with temperature setback (which is described in [Measure 4.3.2](#)). What happens is that a large amount of energy is required to refill the masonry with heat at the end of the setback period. On the other hand, using mass inside the envelope is important with passive solar installations (covered in [Subsection 8.4](#)).

Heat-Reflecting “Insulation”

The warm surfaces inside a building radiate heat energy toward the envelope. Knowing this gave someone the idea of installing reflective surfaces in the building envelope to reflect heat back into the space. It is convenient to piggyback this reflecting surface on batt and board insulation, although their functions are independent. (In the case of foam insulation, foil faces are also intended to retard gas leakage, as we discussed previously.)

Be careful when you read the specifications for insulation with reflective backings. The stated R-value is likely to include the effect of the reflective backing when the insulation is installed in an ideal manner. The benefit of the reflective backing increases strongly at greater temperature differentials. Therefore, manufacturers are likely to specify their insulation performance at a large temperature differential, exaggerating the R-value.

The reflective surface does not work unless there is an air space in front of it. This space needs to be a large fraction of an inch (about two centimeters), at least. For example, if board insulation is attached to an inside wall with battens (furring strips), an adequate gap is created when the interior finish is applied over the battens. Another opportunity to use reflective backing exists where the insulation is exposed to the interior space. This occurs in areas where appearance is not critical and the insulation is not exposed to damage, as in ceiling plenums and the exposed ceilings of industrial buildings.

If the design of the building does not include an air gap that would allow you to use reflective insulation, should you change the installation to create an air gap? Probably not. You will probably get better overall performance by filling the space with insulation. Furthermore, creating a gap in an insulated assembly invites serious convective heat loss.

Reflecting internal heat radiation is an important technique for improving the poor thermal characteristics

of glazing. So-called “low-emissivity” coatings are used on glazing to reflect heat back into the building. See [Section 8](#) for details.

Heat-reflecting insulation can be valuable for reducing heat loss from very hot surfaces, such as high-pressure steam lines. See [Measure 1.11.1](#) for such applications.

What is a Vapor Barrier?
Purposes of Vapor Barriers
Where Should the Vapor Barrier be Installed?

Vapor Barrier Materials
How to Vent the Water Vapor
House Wraps are Not Vapor Barriers

What is a Vapor Barrier?

A vapor barrier is an impermeable membrane that blocks the flow of air through the building envelope. A vapor barrier is an essential part of the building envelope. Because the purpose of a vapor barrier is not obvious, this important component is often omitted or installed incorrectly.

The main purpose of a vapor barrier is preventing the passage of the water vapor that is contained in air. Vapor barriers and the insulation affect each other. They must both be installed so that they interact beneficially rather than harmfully.

Purposes of Vapor Barriers

The specific functions of vapor barriers are:

- **protecting the envelope structure and insulation from condensation damage.** Many wall materials are permeable to the flow of water vapor from inside to outside, or vice versa. As water vapor from the inside of the building moves outward through a wall on a cold day, it encounters progressively lower temperatures. At the point in the wall where the temperature of the air equals the dew point, the vapor starts to condense, and it keeps condensing from that point outward. Figure 1 illustrates this. Condensation damages all types of envelope structures. It rots wood structures, it rusts steel structural members and steel masonry reinforcements, and it causes freeze cracking of masonry. Installing a vapor barrier on the warm side of the envelope prevents water vapor from traveling through the wall, and thereby prevents condensation.
- **preventing air leakage through the envelope.** A well-installed vapor barrier prevents or greatly reduces air leakage through the envelope surfaces, although it does not reduce air currents inside the envelope structure itself. At the same time, the vapor barrier reduces air flow through the

insulation, preserving the R-value. For more about this function, see [Reference Note 40](#), Building Air Leakage. (As a matter of perspective, vapor barriers do nothing to reduce air leakage through the major envelope penetrations, such as doors, windows, roof hatches, and fan openings. These penetrations

Fig. 1 Why building structures need vapor barriers This is a cross section of an insulated stud wall with an outer brick veneer. Below it is a graph of the temperature inside the wall. It is cold outside and warm inside. It is also humid inside. If water vapor can flow through the wall, it will reach a point at which it condenses. From that point outward, the wall is damp. A vapor barrier on the inner surface keeps the water vapor from flowing through the wall.

account for a majority of air leakage in most buildings.)

- ***maintaining interior humidification.*** If humidification is used, a vapor barrier reduces the amount of energy and water required to maintain the desired level of humidity.

Where Should the Vapor Barrier be Installed?

Vapor barriers must be installed on the warm side of the insulation. This is because condensation occurs as water vapor moves from the warm side of the wall to the cold side. If a vapor barrier is installed on the cold side, it traps moisture inside the envelope, making moisture problems worse.

This poses a dilemma in climates where the weather can be hot and humid in summer, but cold in winter. The deciding factor is how cold it gets. Where the winters are seriously cold, as in Minnesota, the best compromise is to install the vapor barrier on the inside. In humid climates where winter temperatures are mild, as in Houston, the best compromise probably is not to use a vapor barrier. If this decision is made, the envelope should be made of materials, such as masonry, glass, and aluminum, that withstand periodic dampening.

It might be tempting to solve this problem by installing a vapor barrier on both sides of the envelope. However, this is the worst approach. Vapor barriers on both sides of the envelope would almost certainly trap harmful amounts of moisture.

Vapor Barrier Materials

In principle, a vapor barrier can be any unbroken surface that is impermeable to water vapor. For example, a common vapor barrier material is polyethylene plastic film, typically installed in thicknesses from .002" to .008" (0.05 mm to 0.2 mm). This material is inexpensive, transparent, easy to handle, and is available in wide widths. It can be attached by stapling, mastic, and other means. Figure 2 shows a properly installed vapor barrier using this material.

Vapor barriers can be attached to permeable insulation, such as glass fiber batts or blankets. The vapor barrier is commonly in the form of impregnated kraft paper, sometimes with a thin foil layer. This type of vapor barrier is unreliable because there is no effective way to close the gap between adjacent lengths of insulation. Fold-over strips intended for overlapping the vapor barrier of adjacent batts are generally ignored by installers.

WESINC

Fig. 2 Perfectly installed insulation and vapor barrier This large room has wood stud walls and a wood rafter cathedral ceiling. Glass fiber batt insulation has been inserted snugly into the stud and rafter spaces, leaving no gaps. The tabs on the paper backing of the insulation are overlapped and closely stapled to the edges of the studs and rafters. A vapor barrier of 0.008" thick polyethylene sheet is stapled over the insulation. The vapor barrier is overlapped several feet at all joints. Plenty of excess plastic material is left in all corners. This slack keeps the plastic from being torn when the wallboard is installed. The vapor barrier is stapled to the window frames, preventing air leakage around the windows.

If the insulation material itself is very impermeable, such as extruded foam board insulation, it may act as its own vapor barrier. This characteristic is useful only if adjacent sheets of insulation are joined to create an unbroken surface. This requires special installation techniques that are difficult to enforce on the job.

Some envelope construction materials, such as asphalt roofing and sheetmetal walls, are impermeable. Therefore, they act as a vapor barrier, whether this is desirable or not. The critical question is whether these impermeable materials are located on the warm side of the insulation. If they are, they can serve as the vapor barrier. If not, they create a moisture venting problem that must be handled properly to prevent damage.

How to Vent the Water Vapor

When installing insulation, create a path for venting water vapor from the insulated cavity. A vapor barrier on the warm side of the envelope must be combined with a venting path on the cold side of the insulation. This is because no vapor barrier is perfect, and because water may get into the structure, typically from rain. In general, the better the vapor barrier and the drier the conditions, the less venting is required.

Effective venting is a challenge with roofs, because they are susceptible to leaks and have an impermeable outer surface. In buildings with attics, a common solution is to vent the attic to the outside. In cathedral ceilings, leave an air space above the insulation to allow

water vapor to travel out to the vents, which should be installed along the full lengths of the ridges and eaves.

Venting walls and soffits is just as important, and the same principles apply. If there is an impermeable surface on the cold side of the insulation, such as a sheetmetal outer wall, leave a gap between the cold side of the insulation and this surface. The gap acts as a path for water vapor. In turn, vent this gap to the outside of the cold surface. Walls that can be wetted by precipitation require thorough venting.

At the other extreme, some wall materials are so porous that moisture may vent directly through the wall. Such material is especially vulnerable to rain soaking. Keep insulation away from direct contact with the wall. Generous roof overhangs are an excellent means of keeping walls dry, if the walls are not too tall.

Portions of the building that are located over soil have the problem of moisture migration into the building, rather than outward. The usual solution is to vent the crawl spaces to the outside, as with attics.

All insulated cavities where water may accumulate should have drains, as discussed in [Reference Note 44](#), Insulation Integrity.

House Wraps are Not Vapor Barriers

“House wraps” are an item that goes through episodes of popularity. House wraps tend to be confused with vapor barriers, although their function is entirely

Fig. 3 This is not a vapor barrier This is a house wrap. It must be made of appropriate permeable material. Using vapor barrier material as a house wrap would cause moisture damage in the walls. The outer sheathing of this house is plywood. If the plywood is well installed, the house wrap is superfluous.

different. Using vapor barrier material as a house wrap can cause serious moisture damage to the structure. Conversely, house wrap material will not work as a vapor barrier.

The purpose of a house wrap is to prevent air infiltration through the building structure. It is always installed on the outer surface of the building. It plays the same role as a wind breaker in human clothing. As we said previously, one of the benefits of a vapor barrier is preventing air leakage. However, in most climates, vapor barriers are installed on the inner surface of the structure. Therefore, they do not protect the structure, or the insulation inside the structure, from heat loss that is induced by wind.

House wrap material must be permeable. Otherwise, it will act as a vapor barrier that is installed on the wrong side of the surface, and cause moisture damage. A common material used for house wrap is a fiber-reinforced paper. The material is stapled to the outer surface of the structure before installing the outer

weather surface (siding, brick, etc.). Figure 3 shows a typical house wrap installation.

The fact that the material is permeable does not significantly interfere with its wind protection. It is like human clothing that protects from wind while allowing moisture to vent from the body.

We should ask whether house wraps are really needed. If a building is constructed properly, house wrap is superfluous. If the exterior sheathing is installed with sufficient care, it will shield the wall structure from wind. Furthermore, a building should not depend on a structural component that has a reliable life that is less than the life of the building. House wraps are fragile, compared to other structural materials. It is unlikely that they will survive for the life of the building, especially if the exterior surface that protects the house wrap will be replaced during the life of the building.

House wraps are not snake oil, but they have a limited range of useful application. They are most valuable when renewing the exterior of a house with leaky walls.

This Note provides specific information about the types of building insulation that are presently available, along with the factors that you should consider in selecting them.

U-Value and R-Value

The thermal effectiveness of insulation is measured by “U-value” and “R-value,” which are two ways of expressing the same information. The formal name for U-value is “thermal conductivity.” In English units, U-value is the number of BTU’s per hour that pass through one square foot of the material for each degree Fahrenheit of temperature differential across the material.

U-value is used in the well known formula for heat transfer by conduction. If Q is the rate of heat flow, expressed in BTU’s per hour, then:

$$Q = U \times (\text{surface area}) \times (\text{temperature differential})$$

Thermal conductivity is also expressed in some tables as “k,” “c,” or “C.” These symbols are not used consistently. “C” usually is the thermal conductivity for a particular thickness that may be specified arbitrarily. “k” is commonly used in two ways, for a thickness of either one inch or one foot. Metric tables use these same symbols with definitions that are expressed in metric units.

The “thermal resistance” of a material is the reciprocal of its thermal conductivity. In English units, thermal resistance is expressed as “R-value.” Mathematically, $R = 1/U$.

R-value is handy because it allows you to calculate the total R-value of an assembly, such as a wall or roof, simply by adding the R-values of all its components.

For example, to calculate the total R-value of a stud wall that is filled with insulation, add the R-values of the outer air layer attached to the exterior siding, the exterior siding itself, the air layer between the siding and the outer wall sheathing, the wall sheathing itself, the insulation inside the stud space, the interior sheathing, and the air layer inside the space.

U-values cannot be added. To calculate the heat transfer through an assembly, first calculate the total thermal resistance by adding the R-values. Then, take the reciprocal of the total R-value and use it in the formula above.

The R-values of most insulation materials are fairly independent of external factors. The R-value of insulation increases at lower temperatures, but this effect is not large enough in envelope insulation to favor one type of insulation over another. (In contrast, the R-values of glazing units are strongly influenced by orientation, temperature, internal drafts, and wind. These insulating characteristics of glazing are covered in [Section 8](#).)

Table 1 lists the typical range of R-values for the common types of building insulation. The R-values of some common construction materials are included for comparison.

Be aware that R-value does not imply resistance to air leakage. It is a common mistake to use insulation as caulking material to plug envelope leaks. All types of fibrous and porous insulation are poor at blocking air flow.

Other Insulation Selection Characteristics

The R-value of insulation is by no means the only important selection consideration. There are many types of insulation, each having advantages and disadvantages as a construction material. You need to consider a

Table 1. R-VALUES OF COMMON INSULATION AND CONSTRUCTION MATERIALS

Material	R-Value per inch
Mineral wool*	2.9 to 3.8
Glass fiber batt & blanket*	2.9 to 3.8
Glass fiber board	3.8 to 4.2
Cellulose, shredded paper, new	approx. 3.3
Extruded polystyrene board**	4.0 to 5.2
Polystyrene bead board**	4.0 to 5.0
Polyurethane foam board**	5.0 to 6.0
Polyisocyanurate foam board	5.5 to 8.0
Perlite	approx. 2.7
Vermiculite	approx. 2.3
Lightweight concrete	0.2 to 2.0
Concrete, sand or gravel mix	0.1
Concrete & cinder blocks	0.15 to 0.3
Brick	0.2
Plywood	1.2
Pine	1.2
Acoustical tile, typical	2.5
Fiberboard sheathing, typical	2.5

* Higher density provides better R-value because commercial batt insulation has less than the optimum density of fibers.

** Assumes CFC fill gas. R-value diminishes with age because of gas loss. The figures assume moderate aging.

surprisingly large number of characteristics for each application. If insulation is mismatched to the application, you may have serious problems. Make your selection using reliable product data.

The following characteristics are important for typical building insulation applications. In specialized applications, there may be other insulation characteristics that are important, such as adhesion or the ability to mold the insulation into shapes. The main point is to recognize all the characteristics that are important for each application.

■ Fire Characteristics

The fire characteristics of construction materials are expressed in a variety of ways. Three of the most common are:

- **fuel value.** If the insulation has no fuel value, it cannot burn. In fact, its presence inhibits the spread of fire. However, be aware that noncombustible insulation materials may be combined with materials that have fuel value, such as binders and backing paper. An example is glass fiber batt insulation, which uses an organic binder, and which may have a flammable backing sheet.
- **flame spread,** roughly speaking, is the rate at which fire moves along the material. This factor is

significant if the insulation itself is the primary fuel for the fire. It is irrelevant if fire spreads outside the insulation.

- **smoke production** indicates the amount of smoke that the insulation material produces when it burns. Unfortunately, this rating does not address the critical issue of the smoke's toxicity.

Fire safety classifications still fail to adequately define another critical factor, which is ease of ignition. This factor may never be defined satisfactorily, because the ignition of material in a fire depends on many factors, such as the manner of installation, the way the fire surrounds the material, changes in the properties of the insulation before it ignites, etc.

The fire resistance of insulation may be improved considerably by adding retardants, which keep the insulation from catching fire. The performance of retardants varies considerably depending on test conditions. The fire retardant rating assigned to a given insulation material may differ radically from one country to another. The basic problem is that fire retardants cease to function effectively if the fire exceeds a certain temperature and duration. *Any material that has fuel value will eventually burn.*

The importance of fire characteristics depends on where the insulation is installed. For example, fire behavior is less important for insulation installed on a concrete roof deck than for insulation installed under interior paneling.

■ Material Cost

There are large cost differences among different types of insulation. The main reason that more expensive types of insulation are on the market is that they are easier to install.

■ Ease of Installation

Labor is a large component of insulating cost, and labor requirements vary widely with different types of insulation. For example, insulation that can be installed by pouring or blowing requires less labor than insulation that is fitted into place by hand. Using foam board insulation is a very quick way of insulating vertical surfaces.

■ Care Required in Installation

This is not the same as ease of installation. The most common example is fiber batt insulation. Even though batts are easy to install, they are commonly installed in a manner that leaves voids and reduces their effectiveness. Similarly, foam board insulation is exceptionally easy to install, but failing to seal the boards properly at the edges can waste most of their insulating value.

■ Ability to Fill Voids

Voids transfer heat because they allow convection. Aside from open areas that are needed for venting, the entire cavity in the envelope structure should be filled.

Most types of insulation have some tendency to leave voids. Each type of insulation requires its own techniques to eliminate or minimize voids.

■ Tendency to Settle

Loose fill insulation tends to settle, which reduces its R-value. If a flat surface is being insulated, the solution is simply to add more material to compensate. However, if the insulation is used to fill a vertical cavity, such as a stud wall, settling causes the upper portion of the cavity to become completely uninsulated. Cellulose insulation has the worst settling among the common insulation types.

Fiber batt and blanket insulation does not settle if laid flat. If installed vertically, it must be installed snugly in cavity, and it must be supported by a backing sheet. If batt insulation is suspended by a backing sheet alone, it will eventually fall away.

■ Resistance to Moisture Damage

Insulation may be wetted occasionally in ways that are not obvious. Insulation installed in a masonry wall is wetted by rain soaking through the wall. Attic insulation is wetted by occasional roof leaks. Lack of an effective vapor barrier causes permeable insulation to be wetted by condensation during cold weather. Most types of insulation tolerate occasional light moisture, but some do not. Some applications, such as exterior foundation insulation, subject the insulation to continuous soaking. This destroys the R-value of most insulation sooner or later, unless the insulation material is exceptionally resistant to moisture.

■ Aging Characteristics

Inorganic insulation generally does not deteriorate with time. At the other extreme, plastic foam insulation suffers a rapid initial lowering of R-value, followed by a slower long-term degradation of R-value. Cellulose insulation is reported to deteriorate somewhat with time.

■ Resistance to Physical Damage

Insulation may encounter various types of hazards. It can be protected by selecting a type that resists the hazard, or by external protection, or by a combination of both. For example, roof insulation must resist people walking on it. The protection can be provided by selecting a plastic foam insulation that is dense enough to resist the pressure, or by distributing the pressure with a covering of ballast, or by installing a walkway over the insulation. Plastic foam insulation is destroyed rapidly by sunlight, so it must be protected with an opaque surface. Pipe insulation in a machinery room is subject to local impact damage, which can be prevented with suitable guards. And so forth.

■ Temperature Range

Temperature tolerance is not often a factor in envelope insulation, but recognize when it may be. For example, do not use polystyrene foam where it may be exposed to temperatures of 170°F or higher. Such

temperatures may occur near flues, ceiling heaters, and incandescent lighting fixtures.

■ Vermin Resistance

Anyone who reads H. P. Lovecraft knows about rats in the walls. Vermin eat cellulose, and they may use other types of loose fill insulation as nesting material. The problem is not primarily loss of insulation value, but proliferation of the vermin.

■ Growth of Microorganisms

Some types of insulation may act as a growth medium for microorganisms, such as mold or fungus. Microorganisms may grow in insulation under some conditions even if the material itself is not organic. These microorganisms may contribute to “sick building syndrome.” This is primarily a problem in duct insulation, not in envelope insulation, but envelope insulation may become a problem if it is wet.

■ Moisture Permeability

Preventing moisture migration through insulated surfaces is important in most applications. If the insulation is impermeable, it may serve as a vapor barrier, but only if it is installed in a manner that leaves no gaps. For more about vapor barriers, see [Reference Note 42](#).

Permeability is not an all-or-nothing characteristic. For example, some people assume that plastic insulation is an absolute vapor barrier. This is not true. All plastic insulation is permeable to some degree, and some types of plastic insulation are much more permeable than others.

■ Emission of Noxious Chemicals

Experience with urea formaldehyde wall insulation during the 1970's and 1980's demonstrated that some types of insulation may emit dangerous chemicals. No similar problem is known with other common types of insulation, but the lesson should be remembered. In particular, be cautious about using insulation that requires mixing noxious components on site, or that emits noxious chemical products.

Contemporary Types of Envelope Insulation

The diversity of insulation applications keeps a variety of insulation types on the market. Each application usually has no more than one or two types of insulation that are best suited to it. The following listing includes the major types worth considering for conventional applications. It omits materials that are now obsolete or unacceptable for building insulation, such as cork, asbestos, and urea formaldehyde.

■ Glass Fiber

Glass fiber insulation has good R-value because the fibers are oriented perpendicular to the direction of heat flow, and have little contact with each other. It is

available in the form of batts, blankets, semi-rigid boards, and loose fill.

Batts are used for wall cavities. They have a stiff paper backing sheet for attachment and handling, and to act as a vapor barrier. Board insulation is attached to the inside surfaces of walls and roofs. Batts, blankets, and loose fill are used for attic insulation. Batts, blankets, and boards use a binder to hold the fibers together. Loose glass fiber insulation can be installed by blowing.

Contrary to what you might expect, the R-value of fiber insulation is higher if the material is compressed more densely than it is supplied, without going to extremes. The cost of material leads manufacturers to produce batts that have less than optimal density. For this reason, when filling a cavity with blankets or batts, consider using thicker insulation to achieve greater density. This also tends to reduce voids. (But, do not do this if it intrudes on an air space needed for moisture venting.) Semi-rigid fiber boards have better R-value than the fluffy blankets and batts, even though they contain more solid matter.

The kraft paper backing sheets of batt insulation is a mediocre vapor barrier at best. To achieve reliable blocking of water vapor, install a separate vapor barrier, such as large sheets of plastic film, over the insulation.

Glass fiber is inert, which makes it generally safe for occupants of the structure. However, the fibers are a safety hazard during installation. They can penetrate eyes and skin, and there is suspicion that they may cause lung disease. Glass fiber may be a hazard to occupants if it can break loose, as from duct linings,

■ Mineral Fiber

Mineral fiber has essentially the same physical properties as glass fiber and it is used the same way. It is made from dirty raw materials, such as boiler slag, so it is not as pretty as glass fiber. It has shorter fibers, so it is more likely to be used in loose form, as “mineral wool,” than in blankets and batts.

■ Plastic Foam Boards

Plastic foam insulation created a revolution in the construction industry because of its high R-value, low moisture permeability, and ease of installation. Most plastic foam is installed in the form of boards, which are used for wall, roof, and subsurface insulation.

Plastic foam has high R-value because the gas is perfectly encapsulated, which prevents gas movement by convection or external pressure differences. The walls of the foam bubbles are thin, which limits conduction through the solid material. The plastic is expanded into a foam by gas injection. CFC's were originally used as the blowing gas, but these are being replaced by other gases because of concern about ozone depletion in the atmosphere.

Unfortunately, the R-value diminishes with age because the insulating gas leaks out and is replaced by

air. Even aged foam insulation has a better R-value than other types of insulation, but the advantage may be substantially reduced.

Foam boards are easy and safe to handle. They have almost no weight, they can be cut easily with a box knife, and they do not irritate eyes or skin. The foam can be bonded to structural and finish materials, such as plywood, chipboard, and gypsum board.

The major disadvantage of all plastic foam insulation is its behavior in a fire. Plastic is made from petroleum, and it burns if it is ignited adequately. A great deal of effort has gone into making plastic insulation fire retardant, and some types can resist small fires. However, once ignited by a surrounding fire, plastics produce large amounts of toxic smoke that kills occupants quickly.

For this reason, it is prudent to avoid using plastic insulation in interior applications. Sheathing plastic insulation in non-flammable material, such as gypsum board, may buy time to evacuate a burning space, but this practice cannot keep the plastic from igniting. In a big fire, plastic insulation melts, runs out into the fire, and then ignites.

There are several types of plastic foam used in board insulation. At present, the main types are:

- **extruded polystyrene foam.** Polystyrene is the cheapest of the foam insulation materials, but it is still about twice as expensive as glass fiber for a given surface area. It is limited to temperatures below about 170°F (77°C).
- **polystyrene beadboard.** Polystyrene foam beads can be fused together to form insulating boards. In fact, the beads can be molded into any shape, such as coffee cups, but boards are the most common shape for insulation purposes. If kept dry, beadboard has about the same thermal properties as extruded polystyrene. It is less resistant to long-term moisture penetration. This is important, for example, in insulation that is installed below grade.
- **extruded polyurethane foam.** Polyurethane foam has better R-value than polystyrene. It is more expensive. It tolerates somewhat higher temperatures, around 250°F. It is less resistant than expanded polystyrene to long-term moisture penetration in wet applications, such as foundation insulation below grade.
- **extruded polyisocyanurate foam.** Polyurethane is combined with isocyanurate plastics to create insulation materials that are usable over a wider range of temperatures, from about -290°F to about +300°F.

■ Plastic Foam Beads

Loose plastic foam beads are used for pouring applications, such as the cavities of masonry walls. Polystyrene is the most common material for making

foam beads. The fire characteristics discussed for foam boards also apply to foam beads. Foam beads are replacing perlite and vermiculite in applications where fire resistance is not important. They have become popular as an aggregate for lightweight concrete.

■ Sprayed Plastic Foam

Sprayed plastic foam typically is applied to flat roof decks. It requires specialized equipment to create the foam on site. It produces a lumpy surface that can puddle water if it is installed on a flat surface. Foam is destroyed rapidly by sunlight, so exposed surfaces need a durable opaque coating. Since the surface is irregular, it is not practical to apply flat sheathing to protect the foam, and the foam is not quite strong enough to support people walking on it. Therefore, you need separate walkways to protect the foam.

■ Loose Dry Cellulose

“Cellulose” insulation consists of shredded old newspapers treated with chemicals. For example, borax may be added to retard fire, and other chemicals may be added to improve vermin resistance. Cellulose insulation was advocated heavily during the 1970’s as a useful way of disposing of waste paper. Its thermal properties are good. Its major weaknesses are settling, fire hazard, degradation if wetted, and the fact that it makes food and nesting material for vermin. Its properties are largely dependent on additives, so quality varies widely among different manufacturers.

Its main advantages are low cost and ease of installation. It typically is blown into place using specialized pneumatic equipment. It is widely used in attics. It can also be blown into walls, but this application is riskier because of its tendency to settle, difficulty in filling voids, vulnerability to moisture, and vulnerability to the skill and honesty of the installer.

Paper burns, so it is important to isolate cellulose insulation from any heat sources, such as flues and incandescent light fixtures.

■ Wet Sprayed Cellulose

Cellulose insulation can also be applied as a slurry of cellulose material mixed with a glue. It can be applied to any orientation, including overhead, although the thickness of each application is limited. When the slush dries, it becomes like papier mache, and it is dimensionally stable.

■ Vermiculite

Vermiculite is a class of minerals consisting primarily of silicates of magnesium, aluminum, and iron that are bound with water. Vermiculite ore has a flat, layered structure that looks like mica, and it has a significant water content. It is converted to insulation by a process called “exfoliation,” which is similar to making popcorn. When exposed quickly to high temperature, the water in the ore bursts into steam,

expanding the layers and creating hollow granules that look like tiny accordions.

The R-value of vermiculite is lower than that of other insulation materials, and it varies depending on the source of the raw material, the particle size, and the manufacturing process. The main advantages of vermiculite are lack of flammability, ability to withstand high temperatures, benign handling characteristics, and easy pouring. Vermiculite is a good aggregate for lightweight concrete. It is also used as a component of sprayed fire retardant insulation.

■ Perlite

Perlite is made from a certain type of volcanic rock that is high in silica. The material contains a small percentage of water. The rock is first crushed. Then, it is heated quickly to a temperature above 1,600°F (870°C). As the rock melts, the water creates a froth of tiny bubbles, expanding the material by a factor of four to twenty. The cooled material retains the sealed bubbles, making it relatively light and providing significant thermal resistance. The individual particles are physically strong, making the material an effective aggregate for lightweight concrete. It can also be used in loose form, typically to fill the holes in concrete block walls.

■ Lightweight Concrete

Concrete can be made with virtually any material as an aggregate. If a lightweight material is used instead of sand or gravel, both the weight and the thermal conductivity of the concrete may be greatly reduced. Lightweight concrete does not have the high R-value of true insulation, but it insulates much better than conventional concrete.

Plastic foam beads make a concrete that is incredibly light. Perlite and vermiculite produce a concrete that is somewhat heavier and stronger. There is a compromise between R-value and strength. The compromise can be adjusted over a wide range by selecting the type and density of the aggregate material.

■ Soil

In the frenzied days of the 1970’s energy crises, “earth sheltered” construction captured the fancy of many, perhaps because the idea of dirt was appealing in its own right. Soil can be considered a very poor grade of expanded mineral insulation. Its only advantage is that it is dirt cheap. However, it costs so much money and energy to modify a building’s structure to accommodate soil that using it for insulation is self-defeating. Using soil adds serious problems, including high pressure on the retaining structure, roof weight, rain and ground water leakage, radon entry, visibility limitations, and the esthetics of a prehistoric burial mound.

Minimize Thermal Conduction Paths
Eliminate Convective Paths
Provide Water Drainage, if Necessary
Install the Vapor Barrier Properly

The effectiveness of insulation depends on the way it is installed. This Note covers the main points of installing insulation in a way that maintains its effectiveness.

Minimize Thermal Conduction Paths

Any solid material that bridges the space between the inner and outer surfaces of the envelope acts as a short circuit for heat. The amount of heat loss is proportional to the R-value and thickness of the conducting material. Wall studs, sill plates, sole plates, window and door framing, floor slabs that extend to the exterior structure, and the edges and supporting structures of curtain wall panels are all conductive short circuits. Metal structural elements have high thermal

conductivity, and their effect is especially severe if they have wide flanges at the inner and outer envelope surfaces.

In the worst cases, conductive short circuits can severely limit the benefit of adding insulation. An example is insulating a concrete block wall by pouring insulation into the holes in the blocks. This provides some benefit, but a large amount of heat will continue to be conducted through the webs in the blocks.

To avoid conduction short circuits, try to use an insulation method that provides an unbroken layer of insulation. For example, covering the interior or exterior surface of a concrete block wall with insulation board is much more effective than filling the holes in the concrete blocks with insulation.

Fig. 1 What is wrong in this picture? The batt thickness is appropriate for the stud widths. However, the insulation is stuffed far inside the cavity, reducing its thickness and creating a large convection path in front. The kraft paper vapor barrier is not effective, because the paper is not joined at the edges. The method of installing the electrical wiring force the insulation installer to stuff the insulation behind the wiring. Fiber insulation is used instead of proper caulking around the window, and under the sole plate. Anything else?

Eliminate Convection Paths

Convection carries heat through voids in the envelope structure. Convection is a powerful mode of heat transfer, so voids should be minimized when installing insulation. This is largely a matter of workmanship and selecting the appropriate type of insulation for the job.

Everyone has seen batt insulation that is stuffed between stud spaces in a manner that leaves large gaps. See Figure 1. A good way to insert tight fitting batt insulation between studs is to use a trowel to tease the edges of the batts past the studs. If electrical wiring is in the way, a large void may be left behind the wiring by sloppy installation. Cut notches or gashes in batts to fit around wiring.

When inserting loose fill insulation into existing walls, there is a risk that the material will snag on obstructions, leaving voids. Preventing voids requires installation methods that are vigorous enough to move the insulation past obstructions. Air blowing, rodding, and vibration are the methods used. Good pouring characteristics may be a major factor in selecting the insulation material.

A major problem with pouring insulation into existing walls is the presence of obstructions that create voids in the insulation. Frame walls may have fire stops, which are horizontal pieces that block the space between studs to retard the spread of fire by convection in the stud space. The gap between the brick and block courses of masonry walls is filled with dried mortar and wall ties. With any wall, it is difficult to get the insulation to fill the space all the way to the top.

If you want to use rigid insulation in a wall cavity, you will have to take special steps to prevent convection. If rigid insulation is placed loosely in a cavity, convection provides a way for heat to bypass the insulation, making

the insulation almost useless. There is little hope of blocking convection unless the insulation boards are firmly attached to one of the wall surfaces and are sealed at the edges.

There are two conditions that make it important to leave a space between the insulation and the outer skin of the building to vent water vapor. One is that the outer skin is impermeable. The other is that the outer skin is permeable and can get wet. (This is discussed further in [Reference Note 42](#), Vapor Barriers.) The vented space allows strong convection. From the standpoint of insulation value, the vent space is effectively outside the insulated portion of the envelope.

Provide Water Drainage, if Needed

Anticipate the possibility that water will occasionally get into the envelope structure. The moisture may come from rain, condensation, piping leaks, etc. If the structure is well vented and is not vulnerable to wetting, it may suffice to allow the water to escape by evaporation through the vents.

If water may accumulate in a cavity, install drain holes. Design the drain holes so they will not be plugged by the insulation. This is a problem especially with insulation materials that can flow, such as foam beads, cellulose, and vermiculite.

Install the Vapor Barrier Properly

Installing the vapor barrier is an integral part of the insulation job. Failing to install the vapor barrier properly can reduce the effectiveness of the insulation and can cause structural damage. For example, in Figure 1, the vapor barrier material that is attached to the insulation has been rendered almost useless by bad installation practice. See [Reference Note 42](#), Vapor Barriers, about installing vapor barriers.

Insulation Economics

This brief Note is intended to clarify the economic aspects of installing insulation. The points are illustrated with a typical example.

Unlike most energy conservation measures, adding insulation is a matter of degree. Furthermore, it is not possible to clearly define a “best” amount of insulation. From the standpoint of energy savings alone, most applications would benefit from installing as much insulation as possible. The total lifetime saving continues to increase as the amount of insulation is increased. However, more is not necessarily better. Beyond a certain amount of insulation, the payback period gets longer.

The economics of adding insulation to an existing building are heavily influenced by the original thermal resistance of the structure. For example, if an attic already has a certain amount of insulation, adding more insulation has a relatively long payback period.

The economically optimum amount of insulation is also affected by the installer’s overhead and labor costs. Both of these cost factors tend to be independent of the R-value of the insulation installed. Therefore, high overhead and labor costs argue in favor of adding more insulation.

These points are illustrated in the following example of adding insulation to an uninsulated masonry wall. These are the conditions:

- the bare, uninsulated wall has an R-value of 3.0
- the annual average temperature differential is 30°F
- energy loss costs \$10 per million BTU
- overhead cost is fixed at \$0.12 per square foot
- base labor cost is \$0.20 per square foot
- additional labor cost is \$0.01 per R-unit per square foot
- material cost is \$0.09 per R-unit per square foot.

From these numbers, the table gives the savings per square foot and the economic return that result from installing different amounts of insulation. The economic return is expressed in two ways, as payback period and as savings-investment ratio. The latter is the inverse of payback period, if no discount factor is included.

In this example, the shortest payback period occurs with an R-value of 6. A wide range of R-values provide payback periods in the same range. However, total savings always increase with additional R-value. An

Total R-Value	Cost, \$	Net 20-Year Saving, \$	Payback Period, yr.	Savings/Investment Ratio
3	---	---	---	---
4	0.42	3.96	1.92	10.42
5	0.52	6.48	1.49	13.46
6	0.62	8.14	1.42	14.13
7	0.72	9.30	1.44	13.92
8	0.82	10.14	1.50	13.37
9	0.92	10.76	1.57	12.70
10	1.02	11.24	1.66	12.02
12	1.22	11.92	1.86	10.77
15	1.52	12.50	2.17	9.22
20	2.02	12.98	2.71	7.37
30	3.02	12.74	3.83	5.22

accountant might select the R-value of 6 for best rate of return, whereas a conservation enthusiast might select an R-value of about 20 to maximize long-term savings. The prudent building owner might select a value somewhere between these two. The range in this example is typical of many insulation jobs.

In many cases, such as insulating wall cavities, there is no need to perform such a detailed analysis because space limitations make it impossible to add enough insulation to achieve the shortest payback. In any case, it is difficult to go seriously wrong by adding too much insulation.

This example does not take the time value of money into consideration, nor does it consider changing energy costs. The time value of money is an important consideration from an economic standpoint, but strictly speaking, it is not relevant to energy conservation. In essence, the time value of money is largely the crux of the argument between energy conservation enthusiasts and those who make choices on a strictly economic basis.

It is tempting to ignore the time value of money and to ignore the possibility of cost changes because these factors are unpredictable over the long term, whereas energy consumption is fairly predictable. However, the fact that the economic factors are not predictable does not mean that they are unimportant.

- How to Visualize the Performance of a Daylighting Installation**
The Key Aspects of Daylighting Design
- Visual Quality
 - Daylight Penetration
 - Avoid Visual Desensitization

- Control Electric Lighting Efficiently
 - Understand Solar Cooling Load
 - Exploit Passive Solar Heating
- A Daylighting Wish List**

The amount of sunlight falling on the surface of almost any building, even on a cloudy day, theoretically is adequate to provide all lighting requirements throughout the building. However, methods of distributing sunlight deep within buildings have not progressed much beyond the conceptual stage.

Most of the successful daylighting installations that you can find today use skylights or translucent roof panels. Figures 1, 2, and 3 are examples. Skylights and translucent roofs can provide daylighting throughout a large space, but they are effective only for the floor level immediately below them.

Just making glazed holes in the roof does not provide satisfactory illumination. Failure of skylight installations is common, as illustrated by Figure 4.

Daylighting through windows has been far less successful. With current techniques, daylighting by windows typically cannot extend into the space much

farther than the height of the window above the floor. However, even this limited benefit is rarely achieved. Ordinary windows do not convert sunlight into useful illumination. Instead, bare windows primarily cause discomfort. Occupants respond to the discomfort they cause by excluding sunlight from the building. Aside from wasting the energy saving of daylighting, this also forfeits the view and ambiance that windows are supposed to provide. Figure 5 illustrates this failure of contemporary architecture.

There is probably no area of energy conservation in which so many fundamental problems have been ignored as in daylighting. Unsuccessful attempts at daylighting not only fail to provide satisfactory illumination, but they typically increase energy consumption for lighting, heating, and cooling. In other words, most daylighting installations waste more energy than they save. In addition, they often create heating and cooling comfort problems.

Kalwall Corporation

Fig. 1 Daylighting for a school cafeteria The entire roof over this space is translucent, so the roof material must have very low light transmission to avoid glare.

Kalwall Corporation

Fig. 2 Daylighting for a swimming pool This is a classic application for daylighting because the illumination levels and lighting geometry are not critical. It also benefits from a large amount of passive solar heating. The surfaces of the translucent panels are warmed by absorption, which keeps them dry in this humid environment.

Despite this dismal record, there is hope for tapping the potential of daylighting. The key insight is that daylighting is complex. To achieve success, you must know where the pitfalls are hidden. Therefore, this brief introduction to daylighting will show you various examples of daylighting failures, and explain why they occurred.

To create effective daylighting, you must master three subject areas. The first is the human factors of illumination requirements and visual comfort. The second is integrating daylighting with artificial lighting. The third is integrating daylighting with the heating and cooling of the building. None of the individual specialties involved in the design of buildings deals with all these factors. Therefore, you will have to go outside your own professional specialty to learn all you need.

How to Visualize the Performance of a Daylighting Installation

Daylighting design faces an especially difficult problem, which is visualizing the conditions that will exist in the finished project, including visual quality, heating and cooling comfort, and ambiance.

Architects' models are a trap for the unwary. Viewing a model from the outside utterly fails to convey how you would feel on the inside of the real space.

Vistawall Architectural Products

Fig. 3 Daylighting for an atrium This kind of grandiose application is often used as an element of ambiance. It can save a significant amount of lighting energy, but only if the architect cooperates with the lighting engineer.

The best school for learning daylighting consists of finding good examples of daylighting, and studying them under all operating conditions. At present, you will have to do a lot of searching to find good examples, unless you are lucky. But, there is no other way. Designers need to spend more time outside their offices, and to develop the skills of critical observation in the field.

Once you have developed this base of experience, you may be able to benefit from various computer models and other computational tools. However, using these tools without extensive observation of real, successful installations will only mislead you.

The Key Aspects of Daylighting Design

Daylighting design is demanding because it requires dealing with a large number of factors, some of which are in conflict. These factors can be grouped in the following subject areas.

■ Visual Quality

To make daylighting satisfactory from a visual standpoint, it must have these characteristics:

- **the right intensity**, neither too dim nor too bright. Nightfall, clouds, and other things interfere with sunlight, as illustrated by Figures 6 and 7. Electric lighting must be available, and it must be controlled to provide just the right amount of supplemental lighting when sunlight is inadequate. On the other hand, daylighting can never be allowed to make any area of the visual field too bright, or occupants will block out the daylighting permanently.
- **absence of excessively bright areas within the visual field**, which causes visual desensitization and discomfort. This problem is called “glare.” (The term has other meanings as well.) Bright areas may be acceptable if they are behind the viewer or are well above the horizontal. Figure 8 shows an example where daylighting through windows was abandoned because it failed this criterion.
- **the right direction**, which basically means eliminating veiling reflections. This is a seriously neglected aspect of lighting design. In general, veiling reflections are avoided by not having lighting originate in the direction that the viewer is facing. This involves space layout as well as lighting.

See [Reference Note 51](#), Factors in Lighting Quality, for a more complete discussion about each of these factors.

■ Daylight Penetration

If daylighting is to be an important energy conservation measure, it must be able to serve as the primary source of lighting for a large area. Not only must the sunlight reach the activity area, but it must arrive from a direction that is visually effective, as discussed above.

WESINC

Fig. 4 Skylights are not the same as daylighting Just making glazed holes in the roof does not create satisfactory daylighting, as this abandoned and covered skylight on a classroom building testifies. The problem was excessive glare.

WESINC

Fig. 5 Windows are not the same as daylighting If direct sunlight can enter a space at any time, the occupants will shut out sunlight entirely, as we see here. The situation is not helped by the vertical blinds, which are an unsatisfactory method of modulating sunlight. There is a nice view, but the occupants can't enjoy it, except on the top floor, which is shaded by a deep overhang. This vast amount of glazing serves little useful purpose, and it increases heating and cooling costs considerably.

WESINC

Fig. 6 Accommodate clouds A thick cloud passing in front of the sun may reduce the available sunlight by a factor of five. Your daylighting application must be able to tolerate this large, abrupt change. Or, you must install devices to regulate the amount of sunlight that enters the space. And, the electric lighting controls must be able to provide just the right amount of supplemental lighting.

WESINC

Fig. 7 Accommodate shading by external features Portions of this large hotel are shaded at different times of day by taller adjacent buildings. Plans for daylighting should expect this, including the possibility of later construction nearby.

WESINC

Fig. 8 Daylighting abandoned because of glare Large windows were installed high in the walls of this gymnasium. They have been blocked completely. Put yourself in the position of a basketball player attempting to follow the ball with direct sunlight coming through the windows. It is difficult to imagine any usage of this space for which the windows would provide acceptable daylighting. On the other hand, well designed skylights might have worked well. This space will remain dependent on electric lighting.

WESINC

Fig. 9 Daylighting abandoned because of visual desensitization This classroom has continuous rows of tall windows at the sides and rear. The room is used to train second lieutenants of the U.S. Marine Corps. Even these perfect physical specimens cannot accommodate the large differences in brightness between the windows and the inside of the space. The windows have been covered with draperies, which are too cumbersome to adapt to changes in daylighting and to the changing lighting needs inside the space. The room will remain dependent on electric lighting.

There are many conceptual methods that have been devised for increasing the penetration of sunlight into a space. They all use some combination of reflection, refraction, and diffusion. The Measures in [Subsection 8.3](#) recommend the techniques that are most practical at the present time.

■ Avoid Visual Desensitization

The human eye is able to adapt to an enormous range of illumination levels, over a ratio of approximately a million to one. However, at any given moment, the eye adapts to the brightest illumination levels within the visual field, and cannot see well within the darker areas of the visual field.

The eye adapts to different light levels by three processes: (1) changes in the size of the pupils, (2) changes in the response of the nerves in the visual system, and (3) changes in the amounts of certain chemicals (photopigments) in the light sensing cells of

WESINC

Fig. 10 An expensive daylighting installation that saves no energy A lot of useful space in this office building was given up to create an atrium illuminated by a large skylight. However, note the electric lights that are turned on everywhere around the perimeter of the atrium. These attempt to equalize the illumination levels of the shaded areas with the sunlit areas. Someone probably won a design award for this.

the retina. At normal indoor brightness levels, only the first two of these processes occur, and both of them respond in a time frame of about one second. At normal indoor lighting levels, the delay in adapting is barely noticeable when looking from a well lit part of a room to a darker part, especially if the range of brightness falls within a ratio of less than 10:1. (This ratio declines with age.)

Electric lighting designed to contemporary standards keeps illumination levels within a narrow range, which allows people to see with little effort of adaptation. In contrast, even the most cleverly designed daylighting applications produce large variations of illumination levels within the space. If daylighting is not well planned, the range of illumination levels within the visual field can far exceed the ability of viewers to adapt to the differences in brightness. Figure 9 shows an example where valuable daylighting was abandoned because windows did not have effective methods of modulating the brightness of daylighting.

People are not forgiving about large variations of brightness within a space. If daylighting causes strong contrasts in illumination, occupants invariably turn on all the electric lights in an attempt to match the illumination levels provided by the daylighting. (The term “fill-in lighting” has been coined by lighting designers to certify this practice, in defiance of the logic of daylighting.) Figure 10 shows an example.

Even worse, unless daylighting is executed very cleverly, the brightness of windows or skylights activates the third adaptation process, depleting the photopigments in the retinal cells, which greatly reduces visual sensitivity. Recovery from this chemical change is slow. Therefore, the eye remains desensitized as long as daylighting is present. This increases the illumination levels needed inside the space, typically to a level several times higher than needed by people whose eyes are adapted to lower lighting levels. This may be acceptable if daylighting is the only source of lighting in the space. However, if a small daylighted perimeter area reduces the visual sensitivity of people farther inside the space, they are likely to turn on all the available lighting equipment.

■ Control Electric Lighting Efficiently

Daylighting saves energy only if it provides a reduction in artificial lighting. Daylighting is useless unless the controls of the lighting fixtures are sophisticated enough and reliable enough to respond to the amount of daylighting that is available from moment to moment. Lack of appropriate lighting controls is a common failing of daylighting installations, as illustrated in Figure 11.

In addition, the electric lighting controls must respond to other variables, such as the occupancy of the spaces, the types of activities being conducted, and individual needs and preferences. For example, the

WESINC

Fig. 11 What's wrong in this picture? This common area of a shopping mall is illuminated effectively by the available daylighting from the skylights. The electric lights, which are all turned on, add virtually nothing on this bright day. There may be a legitimate concern that the HID lighting cannot respond quickly enough to large changes in daylighting caused by clouds. Installing fluorescent lighting instead of HID lighting would have avoided this problem.

WESINC

Fig. 12 The inevitable fate of greenhouse additions to restaurants The restaurant wants a cheap addition that offers daylighting and ambiance. But people are not African violets. The owner must eventually address the discomfort during both hot and cold weather, and covers the greenhouse. This one uses a canvas tarpaulin, which needs replacement every few years. Still, it is better than reflecting films, which are ugly and do not reduce the heat gain and glare sufficiently. Why do architects continue to make this common mistake?

electric lighting in a well designed space may have photoelectric controls for some of the fixtures, time controls for all the fixtures, separate controls for different numbers of lamps within each fixture, override switches for late cleaning crews, and so forth.

People tend to turn lights on, but not to turn them off. This behavior is generally beyond the designer's control. Hoping that occupants will keep unnecessary electric lights turned off is not an acceptable design approach. For specific methods of controlling electric lights to exploit daylighting, see [Subsections 9.5, 9.6, and 9.7](#).

■ Understand Solar Cooling Load

It appears that people who design daylighting installation commonly have no understanding of the amount of solar heat gain that comes along with daylighting. Sooner or later, the cooling load becomes unbearable, in terms of both comfort and energy cost. The result is that all or most of the daylighting installation is abandoned. Figure 12 shows an example.

Some daylighting advocates claim that daylighting reduces cooling load because sunlight is a cooler light source than electric lamps. The basis of this claim is that sunlight has a light-to-heat ratio of about 110 lumens per watt, if the entire solar spectrum enters the space in equal proportions. If all but the visible portion of the sunlight were filtered out, the efficacy exceeds 300 lumens per watt. Currently available glazing can provide daylight that is between these two values. By comparison, the light-to-heat ratio of conventional fluorescent lighting is about 70 lumens per watt.

This theoretical advantage is undermined by the fact that daylighting cannot be distributed as effectively as artificial lighting in real applications. Therefore, an excess of sunlight must be admitted to provide adequate illumination. In a sloppy design, so much extra sunlight may be admitted that the added cooling cost may cancel the saving in lighting cost.

Reflective and absorptive window coatings are widely used as a means of reducing solar cooling load. (These are recommended by [Measures 8.1.3 and 8.1.4](#) for retrofit applications.) These methods have also been used in the vain hope of taming sunlight for illumination purposes. This cannot work, because a direct beam of sunlight is unsatisfactory for illumination, no matter how much it is attenuated. If tinted glass were dark enough to reduce the intensity of a direct beam of sunlight to acceptable levels, it would have to be almost opaque. The illumination provided by direct sunlight is about 6,000 footcandles. Dark tinted glass provides an attenuation of about 80 percent, which still leaves an illumination level of about 1,200 footcandles. Even if the windows are darkly tinted or highly reflective, the response of building occupants is still to close the curtains over all windows that allow direct sunlight.

For maximum efficiency, daylighting should use as little glazing area as possible, which means that the glazing should be clear or translucent. Daylighting forces a compromise between the positive value of free illumination and the penalties of conductive heat loss (while heating) and solar heat gain (while cooling). Any form of window treatment that attenuates the passage of light through the glazing increases the glazed area, along with its undesirable consequences.

Design is complicated by the fact that most climates require both heating and cooling. In such climates, one approach is to base the amount of glazing on the daylighting requirement, and not provide any extra for heating. Another approach is to use shading that can be adjusted continually to provide the best compromise between lighting costs and cooling costs during warm weather. External shading ([Measure 8.1.1](#)) is most effective, while interior shading ([Measure 8.1.2](#)) may be marginally useful for daylighting.

■ Exploit Passive Solar Heating

Once you have a good understanding of the amount of heating energy in sunlight, try to combine daylighting and passive heating wherever possible. Both involve using solar energy through glazing in a controlled manner. However, there are major differences between daylighting and passive heating. Daylighting can be accomplished with relatively small amounts of glazing, whereas passive heating requires large areas of glazing. Daylighting is desirable any time that sunlight is available, but passive heating is desirable only when there is a heating load in the space.

During the dark hours of cold weather, the glazing used for daylighting is a path for considerable heat loss. Furthermore, cold weather brings many more hours of darkness than of sunlight. It has been argued that continuously exposed glazing collects more energy during the day than it loses at night. In northern locations, this is true only if the glazing is oriented toward the sun and has exceptionally high thermal resistance.

See [Reference Note 47](#), Passive Solar Heating Design, for details.

A Daylighting Wish List

We can make a “wish list” of developments that would make daylighting a powerful and widely applicable energy saving technique. These developments would create a breakthrough, if they were economical and free of serious practical problems:

- light pipes and other devices to move light into the interior of the building in a visually effective manner
- glazing materials with high thermal resistance, for applications where heating is a major cost

- glazing materials with opacity that is variable over a wide range, for applications where daylighting is combined with passive solar
- glazing that filters out the infrared component of sunlight in a non-absorptive manner, for applications in warm climates.

Development continues in all these areas. Check their current status when you have an opportunity to use daylighting.

Passive solar heating is the direct use of sunlight for space heating. The concept is simple, but creating a successful installation may be complex. Passive solar heating is not a concept for casual experimentation, because failure is almost certain to leave a big mess. In general, the larger the fraction of the building's heating that is provided by passive solar, the more complex the design must be to avoid adverse effects.

Passive heating should include daylighting wherever possible, since both involve the controlled intake of solar energy through glazing. However, combining the two is not easy.

Passive solar heating is a broad concept. The following discussion presents the general principles. Use them as a basis for developing specific applications.

System Components

Figure 1 shows the basic conceptual scheme of a passive solar installation, which includes these components:

- large glazing units, to collect the thin concentrated energy of sunlight
- variable shading devices, to control solar input
- removable glazing insulation, to limit heat loss during darkness
- devices to absorb sunlight and emit heat at desired locations within the space
- thermal storage mass, to provide heating during periods of darkness
- shading devices to control the flow of sunlight into the storage mass
- adjustable insulation, to control the flow of heat from the storage mass
- light diffusion and distribution devices, to make the incoming sunlight suitable for illumination as well as for heating.

This description is conceptual. Probably no real system would have all these elements. For example, it is simpler to control the release of heat from the thermal storage mass by exploiting the inherent time lag of the material, rather than by using adjustable insulation.

The term “passive” implies the absence of moving parts. However, Figure 1 shows that a passive system may require moving parts. These are potentially the most troublesome part of the system. These components are not presently available as standard equipment, and it may be difficult to fabricate them for many installations. The future evolution of passive solar depends largely on eliminating custom components. This will reduce cost, simplify design, and improve reliability.

Figure 2 shows a rationally designed passive solar installation for a house. It makes an interesting contrast with the comprehensive system depicted in Figure 1.

Comparison between Active and Passive Solar

Active and passive solar systems have almost nothing in common, except for the advantage of collecting free solar energy. Active solar systems are primarily mechanical systems, which have architectural ramifications. Passive solar is primarily an architectural feature, which must be tightly integrated with the building's mechanical systems. Table 1 summarizes the main areas of difference between the two.

Where to Consider Passive Solar Heating

In terms of geography, there is sufficient sunlight for passive solar heating throughout the middle latitudes. The coldest weather in these latitudes is associated with the passage of cold fronts, which are followed by clear skies. So, passive heating is often available when it is needed the most. The value of passive solar is greatly

reduced in locations that tend to be cloudy or foggy in winter.

Of course, solar energy is available only during the daytime. Winter days become shorter at higher latitudes. More northerly latitudes tend to be ineligible because they have few hours of sunlight in winter, and because their lower average temperatures cause greater heat loss through the glazing.

In terms of building configuration, passive heating requires exposure to the sun. Therefore, passive solar requires an orientation that is generally toward the south, or facing upward. The acceptable range of orientation is fairly narrow. In winter, the sun rises well to the south of due east, and sets well to the south of due west. Also, the sun remains low in the sky all day. (Reference Note, 24, Characteristics of Sunlight, covers the geometry of solar motion in greater detail.)

Reference Note 46, Daylighting Design, points out that it is difficult to get sunlight to penetrate far into the building interior. This is generally not a limitation for passive heating, because building heat loss occurs through the envelope. Passive heating can be quite effective as a perimeter heating system. However, passive heating is limited to sides of the building (including the roof) that face the sun.

In a building that consists of tall, open space, such as a warehouse, the geometry of the space may allow passive solar to heat the entire building. If sunlight can be delivered from overhead, it is possible to provide widespread daylighting along with heating.

Advocates of passive solar heating tend to promote it for residential and small commercial applications. However, passive solar heating is especially well adapted to many industrial activities, for these reasons:

Fig. 1 Complete passive solar heating system This conceptual drawing symbolizes all the functions that any passive heating system should have. Bear in mind that any passive heating system is also a daylighting system, and it must perform well in both roles. In real installations, the clever designer will combine these functions wherever possible, and will exploit the inherent features of the building, such as heat storage mass.

- they are less sensitive to passive solar's lack of precise control of heat gain and illumination. Industrial work involves physical exertion, which makes people less sensitive to small temperature changes that would annoy sedentary workers.
- most industrial tasks are tolerant of a greater range of illumination levels than is office work
- in industrial-type structures, it is often practical to substitute glazing elements for conventional roof and wall materials
- unconventional sunlight control devices are less likely to create an appearance problem in the industrial environment
- industrial facilities tend to have high inherent thermal storage because of the mass of equipment and exposed floor slabs
- availability of skilled maintenance personnel is an important advantage for passive solar installations that have unusual mechanisms.

The need to integrate passive solar heating with both the external and internal design of the structure tends to limit passive solar heating to new buildings, where

passive heating is an integral part of the design. This being said, do not overlook the possibility of exploiting passive solar in existing buildings, especially if conditions, such as climate, glazing exposure, and internal layout, are favorable.

Energy Saving Potential

■ Heating

The heating capability of sunlight is weak in comparison with the heat losses that can occur from a poorly insulated building in cold weather. (See [Reference Note, 24](#), Characteristics of Sunlight, for the heat content of sunlight.) Therefore, the effectiveness of solar heating is dominated by the quality of the building envelope. If a building has good envelope insulation and little air leakage, passive solar may provide over half of the heating requirement in most eligible climates. This assumes that the building does not have a large ventilation requirement.

Passive heating does not necessarily have to provide a large part of total heat input to be worthwhile. In fact, passive solar is most economical as a supplemental heat

WESINC

Fig. 2 Rationally designed passive solar installation Two large sunlight collectors are installed in the cathedral ceiling of the living room of this house. Each has an insulated cover, one shown fully open, and the other fully closed. Actuators to control the position of the covers are not yet installed. Before the covers were installed, the surface area proved adequate to maintain the temperature of the space during most winter weather, without other heat. Satisfactory temperature was maintained throughout the night, probably because of heat absorption in the gypsum wallboard. However, the uninsulated glazing sweated profusely at night, causing damage to the frame and floor. The lighting level is bright, but not oppressive, except when reading. Placing the reading chairs in the shaded portion of the room solved this problem. During warm weather, holding the covers in a slightly open position provides very pleasant daylighting with minimal cooling load. The slope of the roof faces southeast, which is not optimum for collecting sunlight in winter. Therefore, the covers are hinged on the right side. They are intended to track the sun so that sunlight will reflect into the space from the white underside of the covers. The actuators, not yet installed here, are the only serious challenge. They must hold the covers rigidly against strong wind in both directions, and they must not be too ugly for the neighborhood. Sliding covers would have been a much easier solution if the roof had faced toward the south.

Table 1. COMPARATIVE CHARACTERISTICS OF ACTIVE AND PASSIVE SOLAR SYSTEMS

	Active Solar	Passive Solar
Heating Capacity	Can be increased indefinitely by adding collector area and storage capacity. In practice, limited by economics and weather patterns.	Limited to faces of the building that have a generally southern orientation, and to adjacent spaces.
Daylighting	Does not provide daylighting.	Inherently provides daylighting in heated spaces. Requires specialized techniques, separate from the control of heating, to make it satisfactory.
Heat Distribution	Heat is distributed with conventional equipment. Space temperature can be controlled precisely.	Heat distribution is dependent on interior space layout and exterior orientation of building. Heat release is subject to relatively wide temperature fluctuations, unless highly unusual features are included.
Dependence of Heat Collection on Temperatures	Cannot absorb solar heat until the temperature of the fluid in the collector rises above the distribution and/or storage temperature of the heating application. Collector performance declines with ambient temperature.	Outside and inside temperatures have virtually no effect on the amount of energy collected. Heat gain through glazing is almost always higher than heat loss during hours of sunlight. Low ambient temperature during dark hours creates major heat loss, unless system has insulating components.
Heat Loss from Spaces	Does not increase heat loss.	Large glazing areas create a serious heat loss path during hours of darkness. Requires troublesome insulating components, especially in colder climates.
Controlling Excess Solar Gain	Excess solar input is easily isolated from the spaces. Protecting collectors from excess temperatures may be troublesome.	Tends to create extreme space cooling load. May require troublesome components to prevent this.
Integration with Building Structure	Collectors are distinct from the building structure. Attaching the collectors to the structure may require strengthening. Cost cannot be reduced by substituting for other building components.	Integral with building structure. Likely to require radical change to structural design. Collectors may substitute for conventional windows and skylights. Other components are extra. Designing external movable components to resist wind and precipitation is a challenge.
Space Requirements	Heat distribution systems are the same as for conventional heat sources. In addition, a large storage tank is needed. Collectors require a large exterior area.	No internal space is needed for equipment. The layout for distributing sunlight and heat within the building may require additional space, and may require unconventional features, such as multi-story spaces adjacent to the walls.
Long-Term Survival	Collector components are subjected to ultraviolet degradation, oxidation, and daily cycles of thermal expansion over a large temperature range. Metal and glass components are durable, but soft components require periodic replacement.	Metal and glass components are durable, but soft components are a potential source of leakage from precipitation. Plastic glazing has limited life. Systems are likely to have unusual moving components requiring maintenance. Movable components can be designed to shield vulnerable components at night and during warm weather.
Appearance	Solar collectors are ugly, but they can be separated visually from the structure. Supporting structures can be hidden.	Components are large and unusual, a major visual element of the structure. Can make the entire building irreparably ugly if the designer is not clever.
Component Availability	Collectors and controls are the only specialized components, and are widely available.	Large glazing elements are the only specialized components available as common items, and these are not entirely satisfactory. Other specialized components must be fabricated on an experimental basis, which makes them expensive and unpredictable.
Maturity of Design Doctrine	Extensive experience has been accumulated with many designs. Extensive documentation exists. Best designs are not yet clearly distinguished. Methods of rejecting excess collector heat are not entirely resolved. Design of active system can evolve largely in isolation from other aspects of building design.	Design doctrine has not yet started to evolve in a serious way. Most design issues are not yet generally recognized. There have been few successful installations, if any, to serve as models for various building types. Evolution of passive design requires difficult interactions with conventional practices of architecture, interior design, lighting design, and HVAC design. Design of custom components requires creativity, along with engineering skills outside the conventional realm of building design.
Economics	Costs are well known. Prices have leveled out. Payback period is long, and will remain so. Variations in design result in relatively small cost differences.	Costs can vary widely. Component costs are high because they are still custom items. Major opportunity for cost reduction remains. Payback period remains to be demonstrated.

source. Probably the best approach is to add as much passive solar capacity as possible without requiring elaborate and expensive features.

■ Lighting

See [Reference Note 46](#) about the energy saving potential of daylighting. If cleverly designed, a passive heating system can provide as much illumination as a system designed primarily for daylighting.

Primary Design Issues

Success with passive solar requires attention to an array of considerations that initially appears bewildering. As with any complex matter, the best approach is to identify all the elements, attack them individually, and then figure out a clever way to combine them. The following are the major issues of passive solar design.

■ Glazing Area

Because of the low energy density of sunlight, passive heating requires large glazing areas, unless the climate is mild. There is a trend of diminishing returns as glazing area is increased. That is, adding more glazing results in a greater number of hours per year when heating capacity exceeds need.

Daylighting requires much less glazing area than passive heating. To avoid excessive brightness, convert most of the sunlight to heat before it is seen by the occupants.

■ Glazing Location

Heat is released into the space at points where the sunlight is absorbed, rather than where it enters. Therefore, consider the location of glazing in relation to the locations of the heat absorbers and the heat storage masses. You may have a great deal of flexibility in making these arrangements. Furthermore, as with conventional heaters, convection can be exploited to distribute heat through the space. You need to tailor the location of glazing more carefully for daylighting than for heating.

Sunlight absorbers, which may consist of nothing more than dark pieces of cloth, can easily be moved to accommodate the glazing. However, the geometrical relationship between the glazing and the heat storage masses is fixed. For example, if you use a masonry wall as a heat storage element, locate the glazing so that sunlight falls primarily on the wall.

■ Absorption, Distribution, and Control of Sunlight Within the Building

Many attempts at passive solar failed because they simply dumped sunlight into the space without regard to consequences. Each location in the space where sunlight is absorbed acts as a heating unit, so these locations must be planned. For example, painting a sunlit wall in a dark color causes heat and light to be absorbed there, whereas painting the wall in a light color causes heat and light to reflect throughout the space.

People cannot work at most indoor tasks in full sunlight. Also, strong sunlight eventually destroys organic materials, such as upholstery, wallpaper, etc. Therefore, provide shading for sensitive areas. For example, install diffusing screens over individual work areas.

Activities within the building may move repeatedly, so design the passive heating system to adapt easily to changing activities.

■ Regulating Heat Input

One of the crippling flaws of passive solar has been failure to provide effective methods of blocking excess sunlight. The most efficient approach is to stop the sunlight outside the building with exterior shading. This may be difficult. External shading devices are large, they must be monumentally strong to resist wind forces and snow loads, and they require mechanisms that are cumbersome and unattractive. In addition to being an engineering challenge, they radically change the appearance of the building.

A less efficient method of controlling excess heat gain is to vent warm air from the space. This method generally is limited to spaces with tall or sloped ceilings. Relying on vents poses the risk of serious heat loss through convective leakage. Vent dampers are the kind of equipment that tends to be forgotten, so they are not operated or maintained properly.

Glazing with controllable opacity may come to market at an acceptable price. This would be a major advance for passive solar, because it would allow control of heat input without the external apparatus.

■ Limiting Heat Loss

Another major problem with passive heating is the high conductive heat loss of glazing, especially during hours of darkness, when there is no heat input and outside temperatures are lowest.

With skylights and other glazing that is slanted, the problem is especially severe. ASHRAE data indicate that multiple-glazed units have two to three times more conductive heat loss when they are installed in a heavily slanted orientation than when they are installed in a vertical orientation. In addition, slanted glazing requires more frame structure and stiffeners to resist sagging, and these components conduct heat.

The low thermal resistance of glazing, especially of skylights, allows the inside surfaces to get cold at night, causing condensation problems. In facilities that have humidification or other moisture sources, skylights may sweat prodigiously. The sweating is unsightly, it grows mildew, and it destroys wooden or steel framing. The condensation may be copious enough to drip on the space below, causing moisture damage inside the space. Condensation usually is not serious during daylight hours, because enough solar heat is absorbed

by the glazing to keep it above the dew point of the inside air.

The large, cold surfaces of bare glazing may create discomfort at night, especially if people are close to the glazing.

The heat loss problem was recognized early in the history of passive solar, although it probably was underestimated. Many concepts were devised to add insulation to the glazing during hours of darkness. This conceptual class of insulation has been given a variety of names, including “movable insulation” and “thermal shutters.” Unfortunately, all the methods that have been popularized so far have serious practical problems.

At first glance, the easy approach seems to be installing movable insulation inside the glazing. In fact, many types of internal insulation have been tried. These included various types of quilted shades, movable panels of various designs, and insulating shutters. Unfortunately, all these methods fall afoul of condensation problems. Interior insulation keeps the glazing at outside temperature. Moisture infiltrates past the insulation and condenses on the glazing. The insulation traps the moisture against the glazing and its surrounding structure, promoting mildew, rot, and rust.

Another approach is installing movable insulation on the outside of the building. This approach avoids condensation problems. It also protects the glazing from hail, snow, etc. However, the insulating panels must be as large as the glazing. Large external movable panels are an engineering headache. They must be able to withstand wind, they must be designed to prevent air leakage between the panels and the glazing, and they must not look too bizarre for the neighborhood.

A third approach is installing movable insulation inside the glazing, between the panes. For example, one briefly popular concept was blowing foam beads into the space between the panes overnight. This method fell out of favor because the beads stick to the glazing from electrostatic attraction. It is a pity that this did not work. Installing movable insulation between the panes avoids condensation problems, provided that the space is vented to the outside. Adjustable insulation inside glazing units merits more development effort.

Since you need adjustable shading to control heat gains, try to design the exterior movable insulation to act as an adjustable shading device. Needless to say, this involves additional complications.

The oppressive need for movable insulation would disappear entirely if glazing were available for skylights that has a high thermal resistance. Depending on climate, a minimum R-value between 6 and 15 would be sufficient to eliminate the need for movable insulation. For passive heating and daylighting, the glazing would not have to be transparent, only translucent, with a reasonably high light transmission. Such glazing may become available within the foreseeable future.

■ Amount of Heat Storage Mass

Heat storage is a necessary part of almost any passive heating system, because the sun does not shine continuously. With passive systems, storage occurs by the absorption of sunlight in mass. Storage capacity is determined primarily by the amount of mass that is exposed to direct sunlight. Ideally, enough solar energy should be absorbed in the storage mass during the daytime to carry through the hours of darkness.

Buildings are heavy, so a large heat storage potential exists in the building structure. For example, a typical office space may contain several tons of gypsum board that can serve as an effective thermal storage medium if it receives sufficient exposure to sunlight. Concrete floors and masonry walls often have enough mass to provide all the thermal storage mass that may be desired, provided that it is exposed to sunlight. Heavy machinery has a significant amount of heat storage capacity. The clever designer will exploit the mass of the building and its contents as much as possible.

The storage effectiveness of mass is reduced if it is covered by insulating materials, such as carpets, and wall finishes installed over furring strips.

In new construction, the heat absorbing capacity of massive components, such as floor slabs, often can be increased inexpensively by adding more material.

The usual candidate material for thermal storage mass is some type of masonry, such as concrete, brick, stone, tile, etc. Water also has been used. The weight of material required for storage is depends on the material's specific heat. (Specific heat is the heat capacity per unit of weight, in comparison with the heat capacity of water.) The specific heat of water is 1.0, of concrete and most masonry products is between 0.20 and 0.27, of steel is about 0.12.

The volume of the thermal storage mass depends on both the specific heat and the specific gravity of the material. (Specific gravity is the density of a material in comparison with the density of water.) The specific gravity of water is 1.0, of concrete and most construction stone is between 2.0 and 3.0, of steel is about 7.7.

If you multiply the specific gravity of each of these materials by its specific heat, you get the heat storage capacity per unit of volume. By coincidence, water and most bulk construction materials have about the same heat storage capacity on a volumetric basis.

■ Mechanical Properties of the Storage Medium

The heat storage mass is subject to thermal expansion and contraction. Centuries of experience have taught designers how to deal with this in common structural materials.

Masonry tolerates expansion well, but it must be kept loaded in compression, like the bricks in a wall. Tiles cemented to a surface are likely to break loose because of differences in thermal expansion between the tile and the masonry behind it.

Water is cheap. It has exceptionally high specific heat, which reduces structural loading, but it cannot serve as a structural element itself. It has no thermal lag. Convective currents in water prevent thermal lag, and also cause vertical temperature stratification. If water is stored in a transparent container, a dye should be added to it to absorb sunlight.

■ Location of Heat Storage Mass

When masses are releasing heat, they act as huge, low-temperature radiators, which provide comfortable heating throughout a large area. Their location tends not to be critical.

As with any heating system, it is desirable to release the heat near the envelope, to offset the envelope heat losses. From this standpoint, for example, it is better to absorb sunlight in a floor slab close to the exterior wall than to absorb sunlight in an interior wall.

■ Control of Heat Storage Input and Output

Using heat storage efficiently involves three factors: the rate of heat absorption, the rate of heat release, and the timing of heat storage and release. Fortunately, in keeping with the concept of a “passive” system, it is often possible to design these factors into the system without resorting to devices that need to be controlled.

The rate of heat absorption is determined by the surface area exposed to sunlight and by the absorptance of the surface. Mass is effective for heat storage only if it is directly illuminated by sunlight. Therefore, the relative placement of the glazing and storage mass is critical. The motion of the sun causes different parts of the interior to be illuminated throughout the day, which may be advantageous. Warming the space in the morning can be accelerated, at the expense of delaying heat storage, by using internal heat absorbing screens to shade the mass.

The absorptance of the storage mass is determined entirely by its surface. In general, dark colors absorb the most sunlight. “Color” indicates absorptance only in the visible portion of the solar spectrum, which accounts for only about 35% of total solar energy. Absorptance in the infrared portion of sunlight is more difficult to determine. Refer to [Measure 8.2.2](#) for methods of determining the absorptance of particular materials.

The rate of heat output from the storage mass is determined by the surface area and by the emittance of the surface. The emittance of most solid materials used for heat storage is about 0.8, which is satisfactory for the purpose. There is generally no need to tinker with emittance. (Refer to [Measure 8.2.2](#) if you want to learn more about it.)

The timing of heat release in most passive solar systems depends on the thermal lag of the storage mass. Thermal lag is a delay in the release of heat from a mass after the heat has been absorbed. Using thermal lag to

control the timing of heat release is usually the preferred method. It is not precise, but it minimizes the need for maintenance or active control.

Thermal lag in a material results from the interplay of its thermal conductivity, heat capacity, and geometry. As heat is absorbed by the sunlit surface of a material, the temperature of the surface is raised, and the rise in temperature forces the heat deeper into the material. When the surface is no longer illuminated, the process reverses. The surface emits heat and becomes cooler, which creates a flow of heat toward the surface. Of course, this is not an on-and-off process. Heat is continuously emitted from the surface, whether it is sunlit or not. As the space cools at night, the increased temperature differential across the surface draws more heat out of the mass.

The thermal lag is much longer and more distinct if the storage mass is heated by the sun on one side and the space being heated is located on the other side. In such cases, there is a distinct peak in heat emission into the space that may occur many hours after sunset.

Calculating thermal lag is somewhat complex. It can be done using some of the more sophisticated energy analysis computer programs. The U.S. National Institute of Standards and Technology has done much of the work in calculating thermal lag in buildings. They offer guidance in this subject.

Water has virtually no thermal lag, because convection keeps transferring heat to the outer surface of the container. The thermal lag of metals is minimal because of their high thermal conductivity.

In some cases, it may be desirable to use adjustable insulation to bottle up heat within the storage mass until needed.

■ Coordinate with Daylighting

Try to exploit daylighting if you use passive heating, since the sunlight is coming into the space anyway. By the same token, you need to consider lighting conditions in a passive solar installation to avoid intolerable brightness and glare.

The methods you use to control sunlight for illumination are quite different from the methods you use for passive heating. Daylighting is desirable any time that sunlight is available, but passive heating is desirable only when there is a heating load in the building. Illumination requires much less glazing area than passive heating, but more careful distribution of sunlight. Daylighting requires still more auxiliary devices, such as light diffusers.

■ Coordinate with Electric Lighting

Refer to [Subsection 9.5](#) for methods of controlling electric lighting to exploit daylighting.

■ Coordinate with Heating and Cooling Equipment

To avoid wasting heating and cooling energy, be sure to design the thermostatic controls of the

conditioning equipment so that they do not fight the passive heating system. Passive heating results in swings of temperature. If the passive system is designed properly, the temperature swings remain small enough to avoid discomfort. Design the thermostatic controls to keep heating and cooling equipment turned off as long as temperatures remain within acceptable limits. This is called “deadband.” See [Measure 4.3.4.2](#) for details.

■ Longevity of Materials and Installation Methods

Your choice of the materials and installation methods has a major effect on longevity and maintenance requirements. There is a strong temptation, when buying large expanses of glazing, to use short-lived materials to reduce cost. Your successors will curse you for this if you succumb. If you cannot afford the right materials, forget about passive solar. See [Measure 8.3.2](#) about selecting materials for longevity.

■ Water Leakage

Large expanses of glazing tend to be vulnerable to water leakage, especially if the glazing is non-vertical. See [Measure 8.3.2](#).

■ Wind

Shading devices and movable insulation for passive solar systems have a large amount of surface area, which makes it important to design them strongly. In many applications, wind is the greatest impediment to using external devices.

■ Snow

Fortunately, skylights tend to shed snow, provided that they have even a modest slope. Heat loss through the glazing, combined with the insulating property of snow itself, causes the bottom layer of snow to melt and slide off the smooth surface of the glazing. Also, sunlight penetrates snow and warms the surface underneath.

Nonetheless, snow can be very heavy. Skylights should be designed to resist the weight of an overnight wet snowfall. If insulating covers are used, they can be designed to carry the snow load. This requires reliable controls that respond automatically to snowfall. Snow melts and turns to ice, so external mechanisms must be designed to avoid jamming by ice.

■ Maintenance

In theory, passive solar systems should require minimal maintenance. Good design places priority on achieving this ideal. If mechanisms are necessary, such as movable shading devices and thermal shutters, design these for ruggedness and easy maintenance.

■ Esthetics

Daylighting and passive solar heating have a major effect on both the exterior appearance and internal layout. Blending these elements into the design of a building requires imagination and a fine esthetic sense. These qualities are not prevalent in contemporary architecture, and many buildings heated by passive solar are lovely only to their designers. Sadly, many attempts at passive solar design have been so ugly that they degrade the value of the building. The only solution is for owners to be aware of this potential problem, and to cast a critical eye on the esthetic aspects of the design.

■ Cost Efficiency

The clever designer will attempt to satisfy all the functions symbolized in Figure 1, while minimizing the hardware and complexity required. For example, it may be possible to dispense with specific thermal storage devices if the mass of the building is exploited effectively for thermal storage. Considerable thermal storage may be added cheaply by increasing the quantities of inexpensive masonry materials in floor slabs and walls.

In new construction, it may be possible to minimize materials costs by substituting glazing for other roof and wall surfaces.

Measuring Light Intensity**Lumens
Footcandles and Lux
Candlepower**

In doing lighting efficiency work, you need to measure light intensity. You also need to know how to express light intensity for selecting lamps and for laying out the overall lighting configuration. Unfortunately, lighting terminology tends to be confusing and somewhat inconsistent. This brief Note introduces you to the terms that the lighting trade uses to communicate about light intensity, and it points out which of these terms are important to know.

Lumens

“Lumen” is the unit of total light output from a light source. If a lamp or fixture were surrounded by a transparent bubble, the total rate of light flow through the bubble is measured in lumens. Lumens indicate a rate of energy flow. Thus, it is a power unit, like the watt or horsepower.

Typical indoor lamps have light outputs ranging from 50 to 10,000 lumens. You use lumens to order most types of lamps, to compare lamp outputs, and to calculate lamp energy efficiencies (which are expressed as lumens per watt).

Note that lumen output is not related to the light distribution pattern of the lamp. A large fraction of a lamp’s lumen output may be useless if it goes in the wrong directions.

Footcandles and Lux

“Footcandles” and “lux” are units that indicate the density of light that falls on a surface. This is what light meters measure. For example, average indoor lighting ranges from 100 to 1,000 lux, and average outdoor sunlight is about 50,000 lux.

The footcandle is an older unit based on English measurements. It is equal to one lumen per square foot. It is being replaced by lux, a metric unit equal to one lumen per square meter. One footcandle is 10.76 lux. Although footcandles are now officially obsolete, they probably will continue to be used because many existing light meters are calibrated in footcandles.

The general term for lux or footcandles is “illuminance.” The general term is sometimes used by lighting engineers, but the units of lux or footcandles are more commonly used.

**Brightness
In Summary ...**

You use footcandles or lux to measure the adequacy of lighting on the task. Footcandles and lux relate only to the task area, not to the lighting equipment or to the geometry of the space. For example, you could create an illumination level of 100 lux on a surface by using a single spotlight located far away, or by using many cove lights nearby.

For energy conservation work in existing facilities, you need a light meter that measures illuminance in footcandles or lux. You will use it continually as you lay out lighting, select fixtures to be delamped, etc. Light meters have become inexpensive, so you can afford to spend the money to get a rugged electronic unit of good quality, rather than the older type that uses a fragile meter movement. Figure 1 shows a footcandle meter.

Candlepower

“Candlepower” is a measure of lighting concentration in a light beam. It is used primarily with lamps that focus, such as spotlights and PAR lamps. In lamps where candlepower is specified, the candlepower rating usually applies only to a small spot in the center of the beam.

WESINC

Fig. 1 Footcandle meter The meter is used to measure “illuminance.” It is the only measuring instrument that you need for most applied lighting efficiency work. Being an older model, this meter indicates in units of footcandles. Newer models indicate in units of lux.

The official unit of candlepower is the “candela,” which is equal to one lumen per steradian. (A steradian is a fraction of the surface area of a sphere that is equal to the square of the radius divided by the total surface area. This is approximately 8% of the total surface area.) This term is rarely used in practical work. Lamp catalogs usually list “candlepower” rather than candelas. This is like using “horsepower” as both a general term and a specific unit. To confuse matters further, candelas were earlier called “candles.”

Brightness

In general, “brightness” is an expression of the amount of light emitted from a surface per unit of area. “Brightness” is not an official term of the lighting trade, and lighting designers may become huffy when you use it. However, the concept is essential for understanding visual quality, especially in relation to contrast and glare.

Brightness does not inherently relate to lamps, or even to light sources. The light could be reflected or transmitted. For example, the bright surface could be the surface of a fluorescent tube, a page of a book, a window with a view of the sky, or a store window with reflections.

The closest official term is “luminance,” which is expressed as candelas per square meter of light emitting surface. (Luminance used to be measured in “footlamberts,” which is now an obsolete term.) For example, the luminance of a heavily overcast sky is about 1,000 candelas per square meter, and the luminance of a typical frosted light bulb is about 100,000 candelas per square meter.

Luminance is defined in terms of the direction of light emission. The details get technical, and you probably will not need to deal with them. In brief, the brightness of an object usually depends on the direction from which you look at it.

Note that luminance has nothing to do with size of the light emitting surface. The light source could be as

small as a lamp filament, or it could be as large as the whole sky, or it could be a task area, such as a desk top.

Measuring brightness (“luminance”) is tricky and requires specialized equipment. For practical work, learn how to avoid excessive brightness, so you won’t need to measure it. If you do a good job of laying out lighting, people within the space will not be subjected to brightness that is severe enough to cause glare.

Luminance is the converse of illuminance. The former describes the intensity of light that is leaving a surface, whereas the latter describes the intensity of light that is falling on a surface. For light reflected from a surface, luminance equals illuminance multiplied by the percentage of reflectance.

“Brightness” also is used to describe the subjective sensation of light intensity. This sensation largely depends on the overall layout of the scene surrounding the viewer. An uncomfortable level of brightness is described as “glare.” (The term “glare” is used in several ways. It is an important concept, but is not precisely defined by the lighting trade. Various types of glare are explained in [Reference Note 51](#), Factors in Lighting Quality.)

In Summary ...

So, here is the overall picture. A lamp produces a certain amount of light, measured in lumens. This light falls on surfaces with a density that is measured in footcandles or lux. A person looking at the scene sees different areas of his visual field in terms of levels of brightness, or luminance, measured in candelas per square meter.

Many characteristics other than light intensity are important in selecting light sources. These include color, operating temperature, starting time, etc. To learn about all of them, see [Reference Note 52](#), Comparative Light Source Characteristics.

- Color Rendering Affects the Required Illumination Level
- How to Accommodate Color Vision Deficiencies
- Loss of Color Vision in Low Light

The most important aspect of lighting is visual quality. As you seek to make lighting more efficient, do it with an understanding of the factors that contribute to visual quality. When you change lighting for the sake of energy conservation, you assume all the responsibilities of lighting design, an activity that even specialists find difficult. You are likely to create bad lighting if you do not understand the factors that affect visual quality. On the other hand, if you deal with each of these factors properly, you can be sure that the lighting will be good.

Visual Quality = Visual Efficiency + Visual Comfort

Good visual quality consists of high visual efficiency combined with visual comfort. Visual efficiency is a measure of a person's ability to perform tasks involving vision. For example, persons can be tested to measure their rate of making proofreading errors under various lighting conditions. Visual efficiency can be measured with objective tests, although it is difficult to make test conditions relevant to typical environments.

Visual efficiency depends both on the nature of objects being viewed and on the nature of the illumination. With respect to the objects themselves, the most important factor is the size of details. For example, large type is easier to read than small type.

With respect to illumination alone, the most important factor in visual efficiency is the illumination level. In brief, higher illumination levels produce greater visual efficiency, up to a point. Illumination levels are determined by lamp output and light distribution, fixture light distribution, and lighting layout.

A third major factor that increases visual efficiency is the contrast within the subject being viewed. Contrast depends on both the nature of the task and the nature of the lighting. You can achieve the best possible contrast

by carefully selecting the fixtures and their locations. In the case of colored subjects, you can also improve contrast by selecting lamps for good color rendering.

Less important to visual efficiency is the relative brightness of the task and surroundings, and other factors.

Visual comfort is a matter of feelings and perceptions. These may range from subtle moods to overt discomfort. Visual comfort is related to the ease of seeing the task, which involves the same factors as visual efficiency. In addition, visual comfort is affected by the brightness of the task, the presence of extreme brightness in the visual field, the contrast in brightness between the task and the background, and other factors.

Visual comfort is very subjective. For example, the amount of background lighting may not matter to a person who is concentrating on a task, but it is significant to a person who gazes at the surroundings. Even objective irritations, such as glare, are difficult or impossible to quantify. Attempts to quantify visual comfort have been devised, for example, by measuring "visual comfort probability," but such measurements are imprecise.

Visual efficiency and visual comfort sometimes conflict. For example, intense illumination improves visual efficiency, but it is uncomfortable over an extended period of time.

Illumination Intensity

Illumination intensity, or illumination level, is expressed in footcandles or lux. It is usually the first criterion used in lighting design. Illumination levels usually are selected according to the anticipated types of tasks. Other factors, such as the age of viewers, may also be considered in selecting illumination levels.

The *IESNA Lighting Handbook* is a primary source for recommended illumination levels. Some typical ranges of illumination levels from the *IESNA Lighting Handbook* (1993 edition) are, in footcandles (multiply by 10 for lux):

corridors and stairs	10 - 20
office reception areas	10 - 20
locker rooms	10 - 20
loading docks	20
exterior walkways	5
reading, books	20 - 50
reading, photographs	50 - 100
reading, poor quality copies	50 - 200
proofreading	100 - 200
drafting, high contrast	50 - 100
cartography	100 - 200
work at video monitors (if shielded from glare)	5 - 10
dairy barns	10 - 50
meat packing	20 - 50
bakeries	20 - 50
kitchens, commercial	50 - 100
kitchens, residential	20 - 100
automotive repair	50 - 100
autopsy	200 - 500
cloth inspection	1,000 - 2,000

To select within these ranges, the *IESNA Lighting Handbook* provides factors for the age of viewers, the reflectances of the room surfaces, and the speed and accuracy required in the tasks. Typical of contemporary American lighting practice, these lighting levels range between generous and extravagant.

Selecting illumination levels is highly subjective. Recommended levels have changed radically over time. In the years that followed Edison's invention of the light bulb, the emphasis was primarily on increasing lighting levels. The early development of lighting was driven explicitly by the electric utility industry's desire to sell more electricity. In the United States, recommended illumination levels soared between the 1950's and the 1970's. For example, the Illuminating Engineering Society of North America (IESNA) recommended office lighting of 30 to 50 footcandles in the year 1952. Twenty years later, on the eve of the first modern "energy crisis," the same organization recommended lighting levels three times higher.

Research on the effects of lighting on human performance first concentrated on the effect of illumination level. Illumination level interested researchers because it can be measured objectively, it is easy to define, and it can be controlled easily as an experimental variable. Also, illumination level had been the limiting factor in lighting throughout the previous

history of humanity, and electric lighting now made it possible to increase illumination level at will. As late as the 1970's, the main thrust of lighting research was to demonstrate that ever higher illumination levels would produce ever better performance on detailed tasks. This research tended to elevate "more is better" to the level of dogma.

Most of the early research was conducted in laboratory settings, for short durations, and typically with young subjects. Long-term visual comfort, esthetics, and energy efficiency were largely ignored. The latter considerations began to receive more attention during the 1970's. Since then, research has suggested that excessive lighting levels and poor placement of fixtures might also be a problem. The combined concerns of energy efficiency and visual comfort halted the rapid escalation of lighting levels, and in some cases, reversed it.

After the energy crises began in 1973, lighting level recommendations in the United States came tumbling back down. Even so, U.S. lighting recommendations today may be several times higher than in other countries. This range of experience demonstrates that human vision does not have narrowly definable requirements for illumination intensity.

■ The Effect of Illumination Level on Task Efficiency

To summarize a rather complex and incomplete field of research, the illumination intensity required to provide good visual efficiency (without regard to comfort) depends strongly on three interrelated factors:

- **the size of details in the task.** For example, less light is needed to read large print efficiently than to read small print.
- **task contrast.** For tasks of high contrast (e.g., black ink on white paper), performance quickly reaches a plateau, above which increased illumination adds little to performance. However, for tasks of low contrast (e.g., machine work, fabric inspection, surgery), visual efficiency continues to improve significantly up to illumination levels that are extremely high. For such tasks, the illumination levels needed to achieve best perception are much too high for long-term comfort.
- **the age of the viewer.** Starting at about the age of 40, visual sensitivity starts to decline significantly. By age 60, visual sensitivity is declining rapidly. In some tests of visual performance, older subjects had substantially lower performance scores than young subjects at all illumination levels. Also, older viewers suffer more serious degradation of performance at lower illumination levels. The extent of this degradation with age varies greatly with the visual quality of tasks. One experiment with tasks of high visual quality showed that viewers of all ages do not suffer much degradation

of performance within the range of 10 to 1,000 footcandles.

Higher illumination levels reduce the effect of vision problems that arise commonly in old age, including farsightedness, astigmatism, and cataracts. For example, a person who is becoming farsighted can see closer in brighter light than in dim light. Most of this benefit probably arises from contraction of the pupil, which minimizes the effect of defects in the lens.

It seems clear that these are the three main factors that determine illumination level, but different tests seem to suggest wildly different lighting levels. The reason seems to be that there are factors other than lighting that have a major effect on the performance of visual tasks.

For example, during the 1970's, the Illuminating Engineering Research Institute (IERI) conducted tests that consisted of proofreading mimeographed sheets of good and poor quality. The tests were scored in terms of accuracy and speed. The tests showed little difference in performance in the range between 10 footcandles and 1,000 footcandles, except for older persons reading poor quality material. On the other hand, other tests reported that increased lighting levels significantly increased speed and accuracy, even beyond 1,000 footcandles (10,000 lux).

Office work is an important exception to the findings that higher illumination levels improve work efficiency. There may be several reasons. One is that office work has very high contrast, namely, black type on white paper. Another is that office tasks offer redundant cues to meaning. (For the same reason, the speed of reading ordinary text is not significantly reduced if a few words are misspelled.) Another theory is that perception in office work requires a certain amount of thought, and the eye is quicker than the mind, even in poor light.

Thus, the present practice of specifying illumination levels by generic type of activity is painting with a brush that is too broad. Within a given type of activity, there may be great variability in the visual quality of the subject matter. For example, graphics work involving large, colorful posters requires good color rendering but not high illumination intensity, whereas line engravings require high illumination levels and careful fixture placement, but only modest color rendering.

With tasks that have variable lighting requirements, the key to energy efficiency is supplementary lighting. For example, a dentist uses an intense, narrowly focussed lamp to work inside the patient's mouth, while the rest of the office is illuminated at typical indoor levels.

■ The Effect of Illumination Level on Comfort

Within a normal range, the exact illumination level does not appear to be a major factor in visual comfort. Complaints about visual comfort are usually associated with specific lighting defects, such as glare and excessive

task contrast. Experiments and field observations over the years yield these relationships between illumination level and visual comfort:

- There is a broad range of illumination levels that people consider comfortable, for a given activity.
- People prefer higher illumination levels for tasks that are more visually demanding, i.e., that have finer detail or poorer contrast.
- Persons prefer higher illumination when concentrating narrowly on a task.
- Older people prefer higher illumination levels.

It seems that most formal experiments do not make an adequate distinction between the average illumination of the task area and illumination of a narrow area of concentration. For example, a person may prefer an illumination level of 30 footcandles (300 lux) over his desk, but he may want twice this illumination on a piece of paper with poor quality text.

A newer finding, not yet adequately covered by research, is that higher illumination levels become uncomfortable over the long term. Extensive field observations by Wulfinghoff Energy Services, Inc. indicate that 100 to 200 footcandles (1,000 to 2,000 lux) is an upper limit for long-term comfort in office work for most people.

This same experience revealed that people do not appear to recognize when high illumination level is the source of their discomfort. Where excessive artificial lighting is available on an elective basis (usually, with multiple switching), workers tend to keep artificial lighting turned up to a level that causes long-term discomfort, usually in the form of fatigue and headache. When an outside party turns down the lighting, the response of the occupants typically is gratified relief. But also typically, occupants eventually restore the excessive illumination level. (Part of this may be a social response. I.e., people may feel that all available lights are meant to be turned on, regardless of illumination level.)

Low lighting levels do not appear to cause discomfort, provided that the viewer is able to control the lighting level. For example, if a person can read well at 10 footcandles, he may choose to do so for hours on end. Early lighting dogma highlighted low lighting levels as a source of visual discomfort, typically described as "eye strain." However, this problem does not arise unless the illumination level is a fraction of contemporary standards, and only in cases where higher lighting levels are not available at the option of the viewer.

Uniformity of Task Illumination

Illumination within the task area should be as uniform as possible, and differences from one part of the task area to another should be gradual. In other words, lighting should not be spotty.

For purposes of this discussion, the “task area” is defined as the working area within the field of vision. Differences in illumination between the task area and the surroundings may be much greater, as discussed below.

This is not to say that the task area should be uniformly bright overall. The task itself should be brighter than the immediate background in the task area. For example, a desk top should be significantly darker than the paperwork. (Illumination level is determined by the light fixtures, but task brightness is determined by the reflectance of the task surfaces.)

In one test of task lighting conducted by Wulfinghoff Energy Services, Inc., efficient and pleasing illumination was achieved using 30 footcandles on one side of a brown desk where papers were read, with 20 footcandles illuminating a keyboard in the middle, and with 15 footcandles illuminating the side of the desk where a coffee cup and pencil holder resided. (Care was taken to avoid glare and veiling reflections, which are discussed below.)

It may not be possible to achieve reasonably uniform illumination over the task area by using a single fixture. A single fixture would need to be several times farther from the task area than the width of the task area. This condition cannot be met with typical modern ceiling heights. With low fixture heights, it is usually necessary to install two fixtures, on opposite sides of the viewer and with partially overlapping illumination patterns.

Self-Shadowing Within the Task

Tasks that are perfectly flat, such as a drafting table, are rare. Most tasks are three-dimensional to varying degrees. The higher areas of the task tend to cast shadows on the lower areas. This shadowing may be important for creating contrast. An extreme example is metal engraving, where the differences in height in the metal surface are tiny, but the shadows in the surface account for most of the viewer’s ability to see the engraving.

On the other hand, too much self-shadowing is unpleasant. For example, one of the most important aspects of lighting in glamor photography is minimizing self-shadowing at surfaces. Almost any type of lighting produces enough shadowing for satisfactory contrast, provided that the fixtures are arranged to avoid glare and veiling reflections. The problem usually is too much shadowing, rather than too little.

Professional photographers describe lighting that produces surface shadowing as “harsh.” Generally, the cause of harsh lighting is a light source that has a small surface area in relation to its distance from the task. In other words, as the light source approaches a point source, it has a greater tendency to create shadows within the task surfaces, and the shadows are sharper. If the

task is not flat, shadows cast by one part of the task may mask adjacent areas of the task surface, which reduces visual efficiency.

Even in office work, where most material is flat, concentrated light sources create annoying shadows. For example, turning the pages of a book results in large changes in illumination as each page turns parallel to the light beam. With work that is very three-dimensional, such as most industrial work, the shadows caused by small light sources may seriously hamper performance.

Point-source lighting may be employed to provide a dramatic highlight for some activities, such as displays. However, people should not have to work within the area illuminated in this manner. A prime example is theater stage lighting, which is effective for the audience but is notoriously uncomfortable for the actors. (Even in these cases, a number of distributed point sources are used, rather than a single point source.)

Not only point sources create sharp shadows. Light sources that are small in one dimension create them also. For example, a row of single-tube fluorescent strip fixtures suspended over a work area creates shadows that are strong and sharp-edged in a direction parallel to the lamps.

Photographers long ago discovered the solution to the problems caused by this kind of shadowing, which is to radically increase the surface area of their light sources. If you visit a commercial photographic supply store, you will see many types of large focussing reflectors, and even larger reflecting screens, whose purpose is to increase the effective area of the light source.

Experiments with office task lighting conducted by Wulfinghoff Energy Services, Inc. suggest that the average width of the fixture’s radiating surface should be at least one fifth of the distance of the fixture from the task. For example, a round reflector fixture installed five feet above a desk should have a diameter of at least one foot. The surface area required to avoid excessive shadowing varies with the type of task. Generally, it is desirable to make the light source area as large as practical without introducing glare or veiling reflections.

(The extreme of large light source surface area is “equivalent sphere illumination,” a theoretical concept that captured the fancy of the lighting trade for a while. In this concept, light is produced uniformly by a hemisphere surrounding the viewer. This geometry effectively eliminates shadowing. However, it is far from ideal, because the part of the hemisphere within the viewer’s visual field produces source glare and veiling reflections.)

Contemporary area lighting, which uses closely spaced fluorescent fixtures of large surface area, almost eliminates troublesome shadowing. In moving away

from this inefficient type of lighting toward more efficient task lighting, be careful to avoid excessive shadowing. Here again, the main points are effective fixture placement and making the light source area as large as possible.

Light reflected from large surfaces, such as an adjacent wall, also reduces the intensity of shadows. Exploit this fact by making walls and ceilings as reflective as possible, using a diffusing surface finish. In other words, use flat white paint liberally.

Shadowing by the Viewer and Adjacent Objects

Another type of shadowing that diminishes visual quality is shadowing of the task by the viewer's own body or by surrounding objects. The problem is caused by light sources that are located too far behind the viewer, or in the wrong position with respect to other shadowing objects.

To avoid excessive shadowing by the viewer's hands, as when writing, it is necessary to install more than one fixture. The fixtures are located on opposite sides of the task. This positioning reduces the shadows by the crossfire of light, and it avoids source glare and veiling reflections. However, the remaining shadows of the viewer's hands slant inward toward the center of the visual field. Light sources need large surface areas to diffuse these shadows.

Using a number of point sources, such as reflector lamps, is not a satisfactory substitute for a large light source area. Each point source creates a shadow that is sharply defined, although less intense than with a single lamp.

Background Lighting

Background lighting is lighting outside the immediate area of the task, i.e., what you see out of the corner of your eye or what you see when you look up from the task. The issue of concern is how much difference is acceptable between the brightness ("luminance," to purists) of the task and the background. The concept is most relevant to environments where there is a clear separation between an immediate task area, such as a desk or machine tool, and the rest of the space. The distinction blurs in environments where looking around is part of the primary visual activity, as in retail stores and meeting rooms.

The need for brightly lighted surroundings is largely an assumption of current lighting dogma, rather than a firm conclusion based on research. Formal laboratory studies show little agreement about people's preferences for background brightness. However, the inconsistency of the research does not mean that the need for background lighting is fanciful. Many real human needs have not been described or explained scientifically.

■ Effect of Background Lighting on Visual Efficiency

The human eye adapts to different lighting levels by three processes: (1) change in the size of the pupils, (2) change in the response of the nerves in the visual system, and (3) change in the amounts of certain chemicals in the light sensing cells of the retina ("rods" and "cones").

Only the first two of these processes occur at normal indoor brightness levels. Both types of adaptation occur in a time frame of about one second. When looking from a well lighted part of a room to a dark part of a room, the delay in adapting is barely noticeable. This is especially true if the viewer is looking around casually. Therefore, it appears that the intensity of background illumination has little effect on task efficiency as long as it is limited to indoor lighting levels.

Excessive brightness activates the third adaptation process, depleting the light sensitive chemicals in the retinal cells. It may take many minutes after exposure for the chemicals to be replaced, restoring full sensitivity.

The two major sources of excessive brightness in the visual field are daylight and poorly shielded light fixtures. If windows or unshielded fixtures are part of the background, they increase the overall lighting level required to maintain a given level of visual efficiency. At the same time, these bright light sources make the rest of the surroundings appear darker. This may create the false impression that the (apparently) dark background is reducing visual efficiency, leading to the wasteful response of increasing background lighting.

■ Effect of Background Lighting on Visual Comfort and Esthetics

Dark surroundings generally do not cause headaches, sore eyes, or other physical symptoms commonly associated with bad lighting. Physical symptoms of visual discomfort arise only in unusual cases where the surroundings are brighter than the task.

This leaves esthetic preference as the main factor of concern with background illumination. Approach lighting efficiency in a manner that is consistent with the importance of esthetics to the activity. For example, lighting esthetics is important in the lobby of luxury hotel, but it is fairly unimportant in a boiler factory.

For environments where lighting esthetics is important, the *IESNA Lighting Handbook* offers background lighting recommendations related to considerations including "visual clarity," "spaciousness," "relaxation," "privacy," and "pleasantness." These recommendations appear to be bald assertions, which does not mean that they are invalid. In a nutshell, the *IESNA Handbook* recommends high background illumination to convey spaciousness, and low background illumination to convey privacy. No surprises there!

The esthetic importance of background lighting depends on the extent of the viewer's concentration on the task area. For example, if a person is concentrating on a crossword puzzle, he is oblivious to lighting more than a few feet away. However, as soon as the puzzle solver looks up, he becomes conscious of the lighting in all the surroundings that he can see. This suggests, for example, that background lighting is relatively unimportant for detailed assembly work and may be more important for typical office work.

In environments where lighting does not play an explicitly decorative role, the main problem to be avoided is leaving people with the sensation of being stranded in an island of light. The seriousness of this issue is a matter of opinion, as is the amount of background lighting that is considered necessary to avoid it.

Depending on the environment, the minimum acceptable background brightness may range from 5% to 30% of the task brightness. Current lighting dogma in the United States says that background brightness should be between 30% to 100% of the brightness of the task. However, observation of the real world reveals that such extravagance is not necessary for most activities.

■ Minimizing Energy Consumption for Background Lighting

Efficient background lighting is primarily a matter of increasing the brightness of background surfaces, rather than flooding the entire environment with light. The way to maximize the brightness of distant surfaces with minimum energy consumption is to use surface colors that are highly reflective and diffuse. (See [Measure 9.7.1](#) for details.)

If you need background lighting, put it on ceilings and walls, because these fill most of the visual field. In turn, these surfaces should sufficiently illuminate adjacent furnishings. For example, if a person is working alone in a large area, it is most important to put some light on the walls, rather than turning on all the lights between the person and the walls.

The size of the surrounding visible space largely determines whether an "island of light" sensation occurs. In a small room, or in an office cubicle of limited dimensions, the sensation may not arise. On the other hand, a mechanic working at a lighted bench in the middle of a darkened aircraft hangar will certainly experience the sensation. An efficient way to deal with this problem is to visually isolate the activity area. Partitions that extend above head level are very effective. In addition, architects and interior decorators have a variety of tricks to create visual boundaries without solid partitions, such as foliage, changes in decor, etc.

Light Source Glare

"Glare" is an important issue for visual efficiency and comfort. The term is somewhat vague, because it has been used to describe a variety of lighting problems. Glare is perhaps best described as discomfort caused by areas of excessive brightness within the field of view. It is usually not a matter of brightness alone, but also to substantial differences in brightness within the visual field. The eye can adapt to an enormous range of brightness, but when the eye is confronted simultaneously with differing brightness levels, it cannot adapt to them all.

The discomfort may be caused by the excessive brightness itself, or by strain resulting from attempting to see detail in the darker areas, or perhaps by other causes. Glare usually involves sources bright enough to deplete the light sensitive chemicals in the retinal cells, which prevents rapid adaptation from bright to dark.

All conventional light sources have the potential to be major sources of glare if they are not shielded from view. To illustrate this point, here is a comparison of the typical brightness of light sources compared to the brightness of typical office work (in candelas per square meter):

the sun, at high elevations	1,000,000,000
incandescent lamp filament	2,000,000
frosted light bulb	100,000
fluorescent tube	10,000
fluorescent fixture, prismatic diffuser	4,000
overcast sky	2,000
window facing north, viewing clear sky	500
office desk, covered with paperwork, etc.	150

Thus, any light source is much brighter than a typical task area. It is well known that visual efficiency and comfort suffer if there are areas in the background that are brighter than the task. The extent of discomfort and desensitization depends of these characteristics of the background brightness:

- ***the size of the light source within the visual field.***
For example, the table above shows that incandescent lamp filaments are 10,000 times brighter than typical indoor scenes. Yet clear bulbs that expose their filaments to vision are widely used in chandeliers and other lamps. This is tolerable because the size of the filaments in the visual field, at typical distances, is minuscule. A frosted bulb with the same filament may be just as annoying because it appears larger, even though its surface brightness is less by a factor of 20.
- ***the position of the light source in the visual field.***
Light sources produce less discomfort the farther they are from the line of sight. Higher positions

are less annoying, probably because humans evolved to see by the overhead sun.

- **the duration of exposure.** For example, brief exposure to clear chandelier lamps in a hotel lobby is not annoying, but longer exposure would be.
- **the brightness surrounding the light source.** For example, a light fixture mounted on a white ceiling is perceived as having less glare than the same fixture mounted on a dark ceiling.
- **the age of the viewer.** Sensitivity to glare increases radically with age, mostly beyond mid-life. A variety of changes occur to the eye as it ages, all of which conspire to decrease tolerance to glare.

In general, avoid light source glare by keeping the source out of the visual field of the viewer. This includes any localized bright spots that may be caused by reflection. In spaces that have only a single occupant, such as one-person offices, this may be fairly simple to accomplish.

Difficulty arises in spaces that have more than one viewer, because the fixtures serving one task area may be visible from other task areas. With contemporary lighting, a great deal of effort has been devoted to making fixtures appear less bright to viewers outside the task area. This is generally done by designing the fixture to limit light emission outside the desired area of coverage. Many fixtures designed this way, including downlights with internal baffles, are extremely wasteful of energy. On the other hand, some modern fluorescent fixtures have achieved a much better compromise between light output efficiency and control of light spread.

Another approach, as yet rarely used in contemporary lighting, is shielding the entire fixture from the view of adjacent areas by installing blinders in the line of sight with the fixture. This approach is discussed in [Measure 9.7.6](#), which deals with task lighting. Glare shielding appears to be almost mandatory with task lighting. This method deserves more attention than it presently receives.

The glare of light sources may be reflected from surfaces. If reflection brings the image of a light source more within the line of sight, the reflected glare may be worse than the direct glare from the light source itself. Generally, reflected glare from light sources is not a problem if the lighting is laid out to avoid veiling reflections, as discussed next.

Veiling Reflections

To understand veiling reflections, recall that you are able to see details in an object because they absorb light differently than the areas that surround them. For example, you can read the words on this page because the ink absorbs more light than the paper. If you were looking at a colored picture, you would distinguish the colors because the different dyes absorb different wavelengths from the incoming light.

WESINC

Fig. 1 A work station with serious veiling reflections A person working at this desk is subject to severe veiling reflections from the large light fixture, and from the illuminated area of wall under the light fixture. When the person turns around to work at the computer, he sees strong reflections from the surface of the monitor.

By the same token, if all the light striking a surface were reflected unchanged, you could see no details in the surface. Most surfaces reflect a fraction of the incoming light in this manner. In other words, for a certain fraction of the incoming light, the surface acts like a mirror. The light reflected in this manner is called a “veiling reflection,” because it acts as a veil that masks the light that carries information about the task.

For example, veiling reflections in store windows keep you from seeing the merchandise, veiling reflections from the surface of water keep you from seeing the fish, and veiling reflections from glossy paper keep you from seeing the text or pictures.

Veiling reflections reduce visual efficiency by reducing contrast. For example, dull black ink absorbs almost all light, while white paper reflects over 80%. In this example, the reflectance ratio is very high. On the other hand, if ink and paper are glossy, 50% of the incoming light may be reflected as a veiling reflection. This reduces the contrast between the ink and the white background to a ratio of about 2:1. If the inks are light colored, the contrast is degraded by an even greater amount.

Veiling reflections also cause discomfort by making it more difficult to see. This discomfort typically occurs over a long term, and the viewer typically is unaware of the cause.

Veiling reflections waste energy in two ways. First, the light contained in the veiling reflection is entirely wasted. Second, by reducing contrast, veiling reflections

increase the overall illumination level that is needed for a viewer to function at a given level of visual efficiency.

Veiling reflections are perhaps the most underestimated problem in lighting design. They tend to be ignored by lighting designers because the locations and orientations of tasks usually are not known at the time the light fixtures are installed. Even if the task locations and orientations are known, it takes a lot of additional effort to lay out the fixtures to avoid veiling reflections.

■ Where Veiling Reflections Cause Trouble

Veiling reflections are limited by the law of reflection, which states the angle of reflection must equal the angle of incidence (arrival). Veiling reflections can cause trouble only if the surfaces in the task area are oriented so that the reflections from a light source are in the viewer's line of sight. Figure 1 shows a task geometry that has serious veiling reflections.

If veiling reflections can occur from a surface within the task area, they are a potentially serious problem if people must look at the surface for extended periods. Examples are office work, drafting, and sheetmetal work. Veiling reflections are less likely to be a problem if the eyes are continually scanning in different directions, as in work behind a sales counter.

Veiling reflections are usually not a major consideration where activities involve irregularly shaped or moving objects, because the objects reflect light in all directions. However, veiling reflections may be a problem if there are flat surfaces behind the object, as in assembly operations on top of a flat table.

Veiling reflections are almost certain to occur where light fixtures are installed in a blanket manner, without regard to the task location or orientation. In a space with many fixtures, there is a large probability that a viewer will encounter veiling reflections from some fixture in the vicinity. The general solution is to customize the lighting to each task. Task lighting ([Measure 9.7.6](#)), which extends this concept to its limits, holds considerable promise for eliminating veiling reflections in the future.

Metals reflect strongly and in a specular (mirror-like) manner, so it is especially important to avoid veiling reflections in industrial operations involving metal surfaces.

Strong veiling reflections can occur with daylighting, whether you are trying to exploit daylighting deliberately or whether it is merely incidental to the presence of windows and skylights. (See [Subsection 8.3](#) about daylighting.) If there is

WESINC

Fig. 2 Some lessons about glare and veiling reflections This hotel kitchen requires a high illumination level throughout the space for food preparation and sanitation. At first glance, the metal surfaces everywhere appear to cause serious glare and veiling reflections. However, the shelves at the rear of the counters shield the work area from most veiling reflections. The work involves a large amount of movement and shifting gaze, which limits the duration of exposure to veiling reflections. The uniformity of the lighting reduces glare by not requiring the cooks' eyes to adapt to different brightness levels as they work. This lighting environment is at the opposite end of the spectrum from those where task lighting is appropriate. With task lighting, each work area must be arranged individually to avoid glare and veiling reflections.

daylighting in a space, you have to arrange activities with respect to the windows and skylights first, because their locations are fixed. Then, arrange the light fixtures.

■ The Strength of Veiling Reflections

Veiling reflections are a surface phenomenon. Their intensity depends primarily on the smoothness of the surface. All fairly smooth surfaces can produce strong veiling reflections. For example, polished wood produces veiling reflections from the very top surface of the lacquer. The grain of the wood is rendered visible by light that penetrates the lacquer deeply enough for the light to be selectively absorbed and reflected by the wood's structural details.

If the surface is very smooth, such as a glass desk top, the veiling reflection is actually an image of the light source. Such images are bright and limited in size. For a surface to produce mirror-like reflection, its surface irregularities need to be smaller than about one wavelength of light (about 0.0005 millimeter).

Even surfaces that are not considered to be optically smooth, such as uncoated paper, can produce significant veiling reflections. The brightness of the veiling reflections is reduced because the incoming light is scattered somewhat. For the same reason, the veiling reflections cover more of the surface than a reflected image of the light source would cover.

Veiling reflections are not formed if the surface is rough enough to break up the incoming light beam completely. This requires the surface to be composed entirely of irregularities much larger than the wavelengths of light. For example, clay brick, blotter paper, and fabrics made from natural fibers produce little veiling reflections.

Surfaces that conduct electricity, such as metals, tend to reflect strongly at all angles of incidence. (This is why glass mirrors depend on a thin metal coating to provide most of their reflective property.) As a result veiling reflections can be very strong in environments where bare metal is within the field of view, as in sheetmetal shops and commercial kitchens (see Figure 2).

With smooth surfaces that do not conduct electricity, such as paper, plastics, and wood, the strength of veiling reflection depends on two factors: the index of refraction of the material, and the angle of incidence. The index of refraction is a physical property of the material related to its density. Veiling reflections are very strong if the light strikes the material within about 30° of the surface. Reflections are weakest if light strikes a surface at an angle near the perpendicular. However, veiling reflections are usually objectionable even in the latter case, because the fixture is then close to the viewer. For example, a light fixture located directly over a desk produces severe veiling reflections.

The strength of veiling reflections does not depend on the color of the material. For example, the veiling reflections from polished black marble and polished white marble are approximately equal, for a given angle of incidence. Therefore, a larger fraction of the light reflected from black marble is in the form of veiling reflections.

■ How to Avoid Veiling Reflections

One foolproof way to avoid veiling reflections is to arrange the layout of the task area so that no smooth surface within the field of view can reflect light from a light source into the eyes of the viewer. In general, install light fixtures off to the side of the viewer's line of sight. At the same time, select the fixture locations to avoid glare and self shadowing, and to provide a uniform illumination level. (These considerations were discussed previously.) Installing the fixtures to the side and slightly behind the viewer is usually best.

If you have a task area where veiling reflections occur, either move the light source, or the task, or the viewer. Or, change the angle of the reflecting surface.

Do not assume that all working surfaces are horizontal. For example, computer monitor screens are approximately vertical, allowing veiling reflections from light fixtures far behind the user. Paper in a typewriter or printer lies at some angle between vertical and horizontal, allowing veiling reflections from a fixture that is overhead or to the rear of the viewer. Locating the fixtures to the side usually avoids veiling reflections from non-horizontal surfaces.

Another way of eliminating veiling reflections is to shield from view the fixtures that create veiling reflections, as discussed previously under "Light Source Glare." This method may be much less cumbersome than rearranging fixtures, especially in a space where task areas are spread out in all directions.

■ Relationship to Reflected Glare

The same layout that makes veiling reflections a problem also invites glare that is caused by reflection of the light source from surfaces in the task area. Glare is a matter of excessive brightness. Whether reflections can cause unacceptable glare depends mainly on the degree of smoothness of the surface. If the task surface is smooth enough to preserve an image of the light source, the reflection will be bright enough to cause desensitization and discomfort. With surfaces that are moderately rough, such as uncoated paper, the reflection of the light source may be scattered enough to reduce its brightness to a tolerable level, even though the veiling reflection is strong enough to reduce contrast seriously.

In general, arranging the lighting to eliminate veiling reflections also eliminates reflected glare, and vice versa.

Figure 2 is an environment that illustrates several points about glare and veiling reflections.

■ Polarization

To be complete, we should mention the polarization of light in veiling reflections. Light waves consist of electric and magnetic fields vibrating perpendicular to the direction of travel. Most light is randomly polarized, which means that the electric fields in the photons of a light beam are oriented randomly around the direction of travel. When light is reflected from a non-conducting surface, the vertical component of the reflected electric field partially cancels the vertical component of the incoming electric field. Such interference cannot occur in the horizontal component. As a result, veiling reflections are polarized parallel to the reflecting surface.

Polarized sunglasses are designed to pass only light that is vertically polarized, and thus they block horizontally polarized veiling reflections from asphalt roads, the surfaces of swimming pools, etc. Therefore, a viewer could avoid most veiling reflections from his desk by wearing polarized sunglasses. This is not practical, so some people have tried the opposite tack, installing vertical polarizers on light sources. This approach has a large energy cost because available polarizing materials absorb a large fraction of the light that passes through them.

Even in principle, trying to use polarization to eliminate veiling reflections is a dead end. If a fixture is located where it can produce veiling reflections, it will also create reflected glare, which is not eliminated by polarization. The only correct way to prevent veiling reflections is by correct fixture placement, perhaps combined with effective shielding.

Color Rendering

A large part of the information and pleasure that people derive from vision is the result of their ability to distinguish colors. Colors are wavelengths of light. The color of an object is the result of selective absorption and reflection of different wavelengths of light by that object. When we design lighting, we want to bring out all the colors in the objects that we see. The ability of lighting to do this is called “color rendering.”

Color rendering is determined primarily by the type of lamp or other light source. Selecting lamps is a compromise between color rendering and other factors, especially energy efficiency and cost. To achieve appropriate color rendering, match the color characteristics of the lamp to the color rendering needs of the task and to the physiology of human vision. The penalties for inadequate color rendering are reduced contrast, missing detail, higher illumination requirements, and discomfort.

The quality of color rendering that is required in lighting varies enormously among different activities. In some applications, such as clothing merchandising and medical treatment, color rendering is critical. Other activities, such as paperwork, may involve little or no

color vision because there is no color in the task. However, even such activities may require good color rendering in the surroundings for visual comfort. Activities such as warehousing require only mediocre color rendering, even though the articles being handled may be colorful.

■ How Human Beings See Color

There are two types of light receptor cells in the retina of the human eye, called rod cells and cone cells. Only the cone cells can distinguish color. We see color because there are actually three different types of cone cells, each of which has a peak sensitivity at a different wavelength of light. The sensitivity peaks are around 600 nanometers (“red”), 530 nanometers (“green”), and 450 nanometers (“blue”). The red-peaking and green-peaking cone cells are more sensitive than the blue-peaking cells, and they respond to broader ranges of wavelengths.

When light of a particular color enters the eye, the visual portion of the nervous system senses the differences in the responses of the three types of cone cells, and this unique combination of responses is sensed as the color being viewed.

Because vision works this way, the eye may “see” a particular color in two entirely different ways. One way is to receive light of the actual wavelength corresponding to that color. For example, grass looks green because chlorophyll reflects light in the green part of the spectrum. However, the eye may also see “green” as a combination of blue light and yellow light, even though no actual green light enters the eye.

Color printing and color television mimic the eye’s method of seeing color. They reproduce all colors by mixing three standard colors. (One system uses red, green, and blue as the primary colors. Another uses cyan, magenta, and yellow.) Color reproduction would be a severe technical challenge if it were necessary to replicate all the actual colors in nature.

Similarly, a lamp can produce a sensation of “white” light in two ways. One is to reproduce the continuous color spectrum of sunlight. The other is to mix a limited number of colors. Only the first method can provide good color rendering of all colors and combinations of colors. In the second case, the quality of color rendering also depends on how colors are mixed in the objects being viewed. If a color in an object being viewed is absent in the light source, that color is not revealed.

Color perception is very subjective, and in most cases, it is very forgiving. The eye compensates considerably for differences in the color distribution of the light source. To a large extent, people see what they expect to see. Thus, for example, incandescent and fluorescent lamps appear to give good color rendering, even though their light output has a very non-uniform distribution of wavelengths. Only when the lamp lacks

light output in broad bands of wavelengths, as for example with clear mercury vapor lamps, does the rendering of colors appear distinctly “muddy.”

■ Sunlight and Vision

About 35% of solar energy that penetrates to sea level consists of visible wavelengths. This energy is radiated in a continuous spectrum that is strong across the entire wavelength range of human color sensitivity. The eye is most sensitive at the wavelength at which sunlight is strongest, probably because human vision evolved to make the best use of sunlight.

Sunlight is the *de facto* standard against which the color rendering of all lamps is compared. Sunlight is almost ideal as a light source because human color vision is closely matched to the characteristics of sunlight, and because the continuous spectrum of sunlight is able to illuminate all the colors in visible objects.

■ Lamp Spectra and Vision

When we see an object under artificial light, we are seeing the light of the lamp as it is reflected by the object. When we see colors, we are seeing the wavelengths corresponding to those colors reflected strongly, while the other wavelengths of light are absorbed. Therefore, if we are to see the colors in objects, the light source must emit wavelengths corresponding to those colors. Good color rendering requires that the light source should contain colors in roughly the same proportions that they occur in sunlight.

At the present time, there is no type of lamp that closely mimics the visible wavelength characteristics of sunlight. There are several types of lamps that have a high “color rendering index” (described in [Reference Note 52](#)), but all these have light output spectra that are very different from the spectrum of the sun.

Incandescent lamps produce a continuous spectrum of wavelengths, so they reveal all colors. This is why incandescent lighting is preferred for surgery, fabric display, graphics work, and other activities where it is critical to see subtle distinctions in color. However, the light output of incandescent lamps is skewed heavily toward the red end of the spectrum, so colors in the blue end of the visible spectrum are revealed relatively weakly.

In contrast, high intensity discharge (HID) lighting produces narrow wavelengths of light, which poses a serious problem for coloring rendering. One type of HID lamp, metal halide, attempts to emulate the solar spectrum by emitting a large number of discrete wavelengths across the visible spectrum. This method works fairly well. However, if an object being viewed has a discrete color component that is absent in the lamp spectrum, that color will not be visible. Thus, a given

HID lamp may produce good color rendering for some objects and not for others.

For most general lighting, the best compromise between efficiency and color rendering is achieved with fluorescent lighting. Fluorescent lighting is a two-step process. Light is emitted inside the tube at invisible ultraviolet wavelengths. The ultraviolet light stimulates phosphors to emit light in a continuous band of visible wavelengths. Different phosphors are selected to emit light in different bands. Many different color characteristics are available with fluorescent lamps.

For more detail about the spectra of individual lamp types, see [Reference Notes 54](#) (incandescent lighting), [55](#) (fluorescent lighting), and [56](#) (HID and LPS lighting).

■ Color Rendering Affects the Required Illumination Level

A basic limitation of the lumens-per-watt method of rating lamp energy efficiency is that it fails to recognize the role of color in visual efficiency. The extreme example of this weakness is low-pressure sodium lamps, which initially proliferated for many applications because of their high lumen-per-watt ratings. These lamps emit light at only one wavelength, so they fail to provide visual cues that are based on color differences. This is a poor way of revealing robbers in parking lots, for example. A lamp of the same wattage with good color rendering might be much more visually effective, although it produces fewer lumens.

The same principle extends to lamps with mediocre color rendering. For example, one study reported that if lamps having a color rendering index (CRI) of 60 are replaced with lamps having a CRI of 85, the same overall visual quality can be maintained while reducing the lumen level by 25%. However, this would be true only for a scene that depends on color discrimination.

The relationship between lumen levels and color rendering applies even to viewers who are colorblind. This is because objects reflect light only at the wavelengths emitted by the lamp. If the lamp spectrum has serious gaps, the non-illuminated colors in the object cannot be distinguished from the dark background.

■ How to Accommodate Color Vision Deficiencies

Approximately 8% of men and 0.5% of women have reduced ability to distinguish colors. Total color blindness is rare. It is believed that most color blindness is caused by defects in one or more of the three types of cone cells.

For people with partial color vision deficiencies, color vision can be improved by higher illumination levels and better lamp color rendering. In cases of extreme color blindness, nothing can be done with the lighting to improve color vision.

■ Loss of Color Vision in Low Light

The cone cells of the eye are much less sensitive than the rod cells. Therefore, color vision disappears in low light. You can observe this at night. With bright moonlight, you can see outdoor objects fairly well as

shades of gray, but you can see colors only under street lights or in a flashlight beam.

This loss of color vision in dim light is not a factor at normal indoor lighting levels.

The energy needed for lighting goes into lamps. Lamps almost exclusively determine the color characteristics of lighting. Lamps are also the limiting factor in lighting efficiency, and they determine all the electrical characteristics of the lighting system. So, selecting the lamps should be your starting point when deciding how to illuminate an activity efficiently. When a lamp is coupled with its auxiliary equipment (e.g., a ballast or ignitor) and installed in a fixture, it becomes the complete light source that is the basic element of the lighting design. Much of energy conservation consists of replacing one light source with another that is more efficient.

Table 1 provides an overview of the major characteristics that distinguish one light source from another. The rest of this Note explains the light source characteristics that are listed in Table 1.

For greater detail about individual lamp types, see [Reference Note 54](#) for incandescent lamps, [Note 55](#) for fluorescent lamps and their accessories, and [Note 56](#) for high-intensity discharge and low-pressure sodium lamps and their accessories. [Reference Note 50](#), *Measuring Light Intensity*, explains the units that are used to measure the output of light sources.

Lumen Output

Incandescent lamps cover the entire range of capacities that are needed for general lighting. There are no limits on size, except for market demand.

With fluorescent lamps, the power density of the lamp must be kept low to maintain efficiency. Therefore, the size of the lamp must increase with output, and size itself imposes the upper limit on output. The lower size limit is imposed by efficiency and cost, since smaller fluorescent lamps are less efficient but not less expensive. Similar constraints exist with low-pressure sodium lamps.

With HID lamps, there is no hard upper limit except market demand. The lower size limit is efficiency and cost, since smaller lamps are less efficient but not much less expensive.

Lumen Degradation

With all lamp types, output declines with age. Most types of lamps lose output most rapidly at the beginning of their lives. High-pressure sodium lamps are an exception, maintaining output well in the first half of life, but losing output rapidly thereafter. The factors that cause light output to decline are discussed in [Reference Notes 54](#) through [56](#), respectively, for the different types of lamps.

One way to maintain a higher average light output is to replace lamps before they fail. This is probably not economical with lamps whose light output drops early in life. It may be practical with high-pressure sodium lamps. Consider this as a possibility if you do group relamping.

Service Life

The lighting industry defines service life as the time period during which 50% of lamps fail. For most lamp types, there is a fairly broad distribution, so some lamps fail well before the average. If lamps are replaced on a group basis, this may substantially shorten the replacement interval.

With all lamp types, service life is reduced by increasing the number of starts. Good information does not appear to be available on the effect of frequent cycling. For example, available data on the effect of cycling on fluorescent lamps generally starts with a minimum of 3-hour cycles.

With incandescent lamps, there is a severe compromise between service life and efficiency, since both depend primarily on filament temperature.

Table 1. COMPARATIVE LIGHT SOURCE CHARACTERISTICS

	Conventional Incandescent	Halogen Incandescent	Conventional Fluorescent
Lumen Output (lumens)	10 to 50,000	300 to 40,000	900 to 12,000
Lumen Degradation (percent of initial lumens)	15 to 40	8 to 15	8 to 25
Service Life (hours)	750 to 4,000	2,000 to 6,000	7,000 to 20,000
Efficacy (lumens per watt)	7 to 22	14 to 22	30 to 90
Ballast Energy Consumption (percent of lamp wattage)	none	none	5 (high quality electronic ballasts) to 20 (cheap magnetic ballasts)
Potential for Lamp Substitution and Mismatch	Unlimited substitution wherever the lamp fits the fixture, provided that fixture heat capacity is adequate.	Unlimited substitution wherever the lamp fits the fixture, provided that fixture heat capacity is adequate.	Limited within narrow ranges of wattage by lamp size, socket style, and ballast compatibility.
Dimming Ability	Unlimited.	Unlimited, except that units with diodes cannot be dimmed.	Requires special dimming ballasts.
Color Rendering Index (CRI)	100	100	50 to 95
Lamp Color	Perceived as white, but actually reddish yellow. Continuous spectrum, but concentrated very heavily toward the red end, with little energy at the blue end.	Perceived as white, but actually reddish yellow. Continuous spectrum, somewhat more balanced in color than conventional incandescent.	Almost unlimited color choice by selection of phosphors. Spectra range from very spiky to fair approximation of continuous solar spectrum. All emit strong mercury spectra.
Starting Temperature	no limit	no limit	60°F (15°C) for high efficiency lamps, 50°F (10°C) for conventional lamps. Special ballasts can be installed to provide much lower starting temperatures.
Effect of Temperature on Light Output	Minimal.	Minimal.	Serious loss of light output above and below optimum lamp temperature (about 100°F).
Starting Interval	Instantaneous.	Instantaneous.	Instantaneous for lamps with instant-start ballasts. About one second for rapid-start ballasts. One to several seconds for preheat ballasts.
Restarting Time	Instantaneous.	Instantaneous.	Shorter than cold start.
Control of Light Distribution	Some styles allow very tight focussing.	Some styles allow very tight focussing.	Allows only loose focussing. Most control perpendicular to lamp axis.
Decorative Lamp Options	Wide variety of decorative styles.	Mini-reflectors are often used as decor.	None.
Mounting Position Limitations	None. Some lamps are designed to exploit base-up fixtures.	None.	Long lamps should be mounted nearly horizontal.
Acoustical Noise	Minimal.	Minimal.	All magnetic ballasts produce some noise, and defective noisy units are fairly common. Some electronic ballasts have noticeable noise.
Power Factor	No problem.	No problem.	Ballasts with high power factor are available. Some ballasts have low power factor.
Harmonic Distortion	None.	None.	High distortion occurs primarily in cheaper electronic ballasts.
Electromagnetic Interference	None.	None.	Some problems may occur with any electronic ballast. Problems are more severe with cheaper units.

Compact Fluorescent	Mercury Vapor	Metal Halide	High-Pressure Sodium	Low-Pressure Sodium
250 to 1,800	1,200 to 60,000	4,000 to 160,000	2,000 to 50,000	1,800 to 35,000
15 to 20	35 to 45	30 to 45	25 to 35	
10,000	24,000	5,000 to 20,000	10,000 to 24,000	18,000
25 to 70, including ballast losses	35 to 65	70 to 130	50 to 150	100 to 190
10 (electronic ballasts) to 20 (magnetic ballasts)	8 (large lamps) to 50 (small lamps)	7 (large lamps) to 30 (small lamps)	10 (large lamps) to 35 (small lamps)	ca. 20
Screw-in lamps substitute for each other and for most incandescent lamps, except where they are too large to fit. Cannot be used in dimming fixtures. Other compact lamps have specialized bases that limit substitution.	Substitutions within type highly limited by ballast compatibility. Some mercury vapor lamps substitute for incandescent lamps without external ballasts, but these offer minimal efficacy advantage.	Substitutions within type highly limited by ballast compatibility.	Substitutions within type highly limited by ballast compatibility. Some HPS lamps are designed as direct substitutes for mercury vapor lamps, offering major efficacy improvement but worse color rendering than other HPS lamps.	Substitutions within type highly limited by ballast compatibility and specialized sockets.
Units with integral ballasts cannot be dimmed.	Single-stage dimming to 50% output, only with transformer ballasts.	Single-stage dimming to 50% output, only with transformer ballasts. Major lamp color change.	Single-stage dimming to 30% output, only with transformer ballasts. Major lamp color change.	None presently available.
60 to 85	40 to 50	60 to 70	20 to 85	0 to 20
Similar to conventional fluorescent. Wide color choice, 2,700K to 5,000K.	Distinctly blue-green. Clear lamps concentrate most energy in a few narrow mercury emission lines. Phosphor lamps add additional broader color lines and some continuous spectrum.	Bluish white. Clear lamps emit a large number of narrow lines across the visible spectrum. Phosphor lamps add more continuous spectrum.	Yellowish white. Narrow continuous spectrum centered around 600 nanometers. Units with enhanced color increase output at red end of spectrum. All are deficient in blue half of spectrum.	Monochromatic yellow.
-20°F (-29°C) to 32°F (0°C)	typically -20°F (-29°C)	typically -20°F (-29°C)	typically -20°F (-29°C)	typically -20°F (-29°C)
Serious loss of light output above and below optimum lamp temperature (about 100°F). Lamps that use mercury amalgam maintain light output much better at low temperatures.	Minimal loss of output above -20°F (-29°C).	Minimal loss of output above -20°F (-29°C).	Minimal loss of output above -20°F (-29°C).	Minimal loss of output above -20°F (-29°C).
One to several seconds. Units with mercury amalgam require about one minute to reach full brightness.	4 to 8 minutes	3 to 10 minutes	5 to 10 minutes	7 to 15 minutes
Shorter than cold start.	Similar to cold start.	5 to 10 minutes longer than cold start.	Substantially shorter than cold start.	Immediate.
Allows moderately tight focussing, especially with unconventionally large fixtures.	Allows moderately tight focussing.	Allows moderately tight focussing.	Allows moderately tight focussing.	Allows only loose focussing. Most control perpendicular to lamp axis.
Globes, some specialized diffusers.	None.	None.	None.	None.
None.	Some models have designated mounting positions.	Most models have designated mounting positions.	Not sensitive to mounting position.	
Good units are quiet, cheap units may be noisy.	Ballasts are magnetic, and produce some noise.	Ballasts are magnetic, and produce some noise.	Ballasts are magnetic, and produce some noise.	Ballasts are magnetic, and produce some noise.
Units with high power factor are available. Some have low power factor.	Ballasts with high power factor are available. Some ballasts have low power factor.	Ballasts with high power factor are available. Some ballasts have low power factor.	Ballasts with high power factor are available. Some ballasts have low power factor.	Ballasts with high power factor are available. Some ballasts have low power factor.
All units with electronic ballasts have significant harmonic distortion. Cheaper units have much more than others.	Minor, assuming that the ballasts are magnetic.	Minor, assuming that the ballasts are magnetic.	Minor, assuming that the ballasts are magnetic.	Minor, assuming that the ballasts are magnetic.
Some problems may occur with any models having electronic ballasts, but are likely to be less severe than with conventional fluorescent fixtures. Problems are more severe with cheaper units.	None, assuming that the ballasts are magnetic. No experience with electronic ballasts.	None, assuming that the ballasts are magnetic. No experience with electronic ballasts.	None, assuming that the ballasts are magnetic. No experience with electronic ballasts.	None, assuming that the ballasts are magnetic. No experience with electronic ballasts.

Efficiency/Efficacy

The ability of a light source to turn electricity into light is almost always expressed in terms of “luminous efficacy,” or simply, “efficacy.” The units of efficacy are lumens per watt. Except for the units, the concept of efficacy is the same as the concept of efficiency. (With efficiency, the input and output units are the same, so that efficiency is expressed as a simple percentage.)

Efficiency, or efficacy, varies widely within each lamp type. The theoretical maximum efficacy of a white light source is about 220 lumens per watt. Table 1 shows that the best modern light sources are approaching this target figure.

For all lamp types, there is a strong correlation between efficacy and size. In Table 1, the higher numbers are for the largest lamps, and the lower numbers for the smallest lamps.

With incandescent lamps, there is a serious compromise between efficacy and lamp life.

With fluorescent and HID lamps, efficacy relates strongly to color rendering. With fluorescent lamps, the most efficient lamps have the best color rendering. Conversely, with HID lamps, good color rendering imposes a severe efficacy penalty.

The rated efficacy of lamps generally is measured under optimum conditions. Efficacy declines with age for all lamp types. Most of the loss consists of a decline in light output without a corresponding drop in energy input. The relationship between the output and efficacy varies with lamp type.

With all lamp types except incandescent, efficacy drops with non-standard ambient temperature and with low supply voltage.

These figures do not include ballast losses, which vary considerably with lamp size and type. One exception is the compact fluorescent fixtures, which include the losses of their integral ballasts.

Ballast Energy Consumption

All conventional fluorescent and HID lamps require ballasts, and some HID lamps require an additional starting device called an “igniter.” The purposes of these devices are described in [Reference Notes 55](#) and [56](#), respectively. Ballasts dissipate a significant amount of energy, which detracts from the overall efficiency of the lamp and fixture.

With fluorescent lighting, ballast energy consumption depends mainly on whether the ballast is magnetic or electronic, the latter being more efficient. There are large efficiency variations within each type. Other features, such as the ability of a ballast to turn off lamp filaments once the lamp has started, also affect energy consumption.

Compact fluorescent fixtures include an integral ballast. With some compact fluorescent fixtures, the tube is detachable from the ballast and can be replaced separately.

With HID lamps, ballast technology is still old and magnetic, and progress toward higher ballast efficiency is slow. Magnetic ballast losses do not increase rapidly with increasing lamp capacity, so the relative losses are much greater with smaller lamps.

Some types of HID lamps have been developed that do not need ballasts, but these lamps are very inefficient.

Potential for Lamp Substitution and Mismatch

Substituting one light source for another is a common step in improving lighting efficiency. You may wish to substitute lamps of a particular type to reduce output, or to increase efficiency, or both. Or, you may wish to substitute a more efficient type of lamp.

Lamp substitution is much easier and more economical if you can switch lamps without the need to replace the fixture or the auxiliary equipment. This is possible with some types of lamps, but not with others.

On the negative side, it is often possible to substitute lamps in a way that wastes energy. Improper substitutions may also shorten lamp life and do other damage to equipment. Similarity of lampholders, or sockets, allows the wrong size, type, or model of lamp to be installed in a fixture. [Measure 9.8.2](#) recommends fixture marking to minimize this problem.

With incandescent lamps, lamp substitution is limited only by the socket configuration and the maximum safe fixture wattage. This is a problem for energy conservation because it allows lamps of higher wattage than needed to be installed in the fixture.

With fluorescent lamps, substitution is confined to a narrow range of wattage by the physical dimensions of the lamp. Also, substitutions are limited by ballast compatibility. Unfortunately, improper substitutions are easy to make because of common socket types.

Substituting compact fluorescent fixtures for incandescent lamps is an important energy conservation measure. Unfortunately, the relative bulkiness of the compact fluorescent units often makes it impossible to install them in existing fixtures.

Most HID lamps for general lighting use medium and mogul bases, but lamp substitutions are limited by the need for ballast compatibility. Some high-pressure sodium lamps are designed as direct substitutes for mercury vapor lamps, providing a significant increase in efficiency, but worse color rendering, than other types of high-pressure sodium lamps.

Some mercury vapor lamps are designed as direct substitutes for incandescent lamps, without external ballasts, but these offer little improvement in efficiency.

Dimming Ability

Dimming is a well established technique for incandescent lighting, but it has only recently become practical for fluorescent lighting. Dimming of HID types is still in its infancy.

Dimming radically reduces the efficiency of incandescent lamps, but modern fluorescent dimming equipment incurs only a modest efficiency penalty.

Dimming incandescent and HID lamps changes their color radically. Dimming fluorescent fixtures does not cause much color change.

Color Rendering Index (CRI)

The relationship between human color vision and the color output of lamps is discussed in [Reference Note 51](#), Factors in Lighting Quality. At present, the “color rendering index” (CRI) is the only selection criterion generally available to indicate how well particular lamps render the colors of illuminated objects. CRI figures are becoming increasingly common in lamp catalogs.

The CRI scale consists of numbers from 0 to 100. The CRI of a particular lamp indicates the amount that it changes color perception of standard colored patterns in comparison with the color perception of these patterns when they are illuminated by incandescent test lamps.

CRI does not tell the whole story about a lamp’s color rendering. Roughly speaking, the CRI indicates the ability of a lamp to allow individual colors to be seen and to distinguish between colors. However, two lamps having the same CRI may bring out colors differently. If the CRI is high, the differences may be too subtle to notice in direct vision. However, color photography is sensitive to color differences, so CRI alone is not adequate for selecting lamps for photography.

A high CRI does not imply a smooth distribution of colors, as occurs in incandescent light. In fact, a lamp with a high CRI may have a spiky light distribution curve. (For example, this is true of metal halide lamps that have high CRI’s.) This may be satisfactory for general color rendering, but such lamps may not accurately represent pure colors, such as those used in graphics work.

The types of lamps presently being used for general lighting differ radically in their ability to render colors well. At one extreme, incandescent lamps have a continuous color spectrum that brings out all colors well, although their color distribution is skewed toward the red end of the visible spectrum.

At the other extreme are lamps that emit only a few narrow bands of wavelengths, such as mercury vapor lamps. The most extreme case is low-pressure sodium lamps, which emit only one pure color. Low-pressure sodium lighting stands apart from the other types because it has virtually no ability to bring out colors.

In the middle are fluorescent lamps and some types of HID lamps that have been modified for improved color rendering. These lamps have a continuous (but uneven) distribution of wavelengths, upon which is superimposed tall emission spikes at wavelengths that are characteristic of the gases in the lamps.

With HID lamps, there is a severe compromise between color rendering and efficiency. For this reason, HID lamps are available with a large range of CRI’s. With fluorescent lamps, there is a compromise between color rendering and cost, also resulting in a wide range of CRI’s.

A lamp’s own color appearance does not provide reliable guidance to its color rendering ability. The eye cannot judge this characteristic of a lamp. For example, a lamp could appear “white” either by having a continuous output spectrum or by mixing a few colors. The Color Rendering Index is necessary to tell how well the lamp brings out colors in other objects.

Lamp Color

Odd as it may seem, the ability of a lamp to display colors well is not strongly related to the lamp’s own average color. A lamp produces good color rendering by emitting light throughout the visible spectrum. The eye tends not to notice variations in the appearance of illuminated objects due to an uneven or skewed wavelength distribution from the lamp. For example, large differences in average lamp color, such as the difference between “cool white” and “warm white” fluorescent lamps, do not strongly affect perceived color rendering.

Lamp color is discussed in the lighting trade mostly in the context of theories about how light affects mood. Specifically, reddish colors are supposed to be “warm” and uplifting, while bluish colors are “cold” and severe. The scientific support for such notions is flimsy, but they provide plenty of advertising copy for lamp manufacturers.

On the other hand, lamp color is critical for photography. Color film is sensitive to lamp color, so good color photographs require careful matching of lamp color to film characteristics. For example, you might not notice the difference between lighting a room with a metal halide or a high-pressure sodium lamp, especially if both lamps have a high CRI. However, color photographs of the room would reveal a stark difference.

A common color specification for lamps is the “correlated color temperature,” which is becoming increasingly common in lamp catalogs, especially for incandescent and fluorescent lamps. Roughly speaking, this is the temperature of an ideal incandescent source that is closest in color to the lamp.

With incandescent lamps, the color temperature is fairly close to the actual temperature of the filament. With fluorescent and HID lamps, color temperature

bears no relationship to the temperature of the lamp because these lamp types do not produce light primarily by a thermal process. In fluorescent lamps, the color temperature represents the average color of all the phosphors in the lamp. In HID lamps, color temperature is a weighted average of the temperatures corresponding to the different wavelengths emitted by the gases in the lamp.

Low color temperatures tend to be reddish, and high color temperatures tend to be bluish. However, this is not a reliable guideline. A fluorescent or HID lamp may have a prominent tint that is quite different from the color that corresponds to the color temperature of the lamp.

Color temperature is expressed in degrees Kelvin, or kelvins, rather than degrees Celsius, so it is sometimes called “Kelvin temperature.” (The Kelvin scale uses degrees of the same size as the Celsius scale, but the zero point is absolute zero instead of the freezing temperature of water.)

A more precise description of color is the CIE Chromaticity scale. (CIE are the initials in French of the International Commission on Illumination). This is a two-dimensional color chart that includes all visible colors. A color is specified by two position coordinates on the chart, “x” and “y.” The Chromaticity Diagram is much more accurate in describing a particular color than the color temperature can be. Unless you have a lot of experience using the chart, you need to have a copy on hand when reading lamp chromaticity specifications in a catalog.

Neither color temperature nor the Chromaticity Chart can distinguish between a pure color and a color that is the result of mixing other colors. Therefore, neither provides an indication of the color rendering ability of a lamp. On the other hand, the Color Rendering Index (CRI) does not provide information about average lamp color. For example, a high-pressure sodium lamp having a CRI of 60 may produce an overall reddish cast, while a metal halide lamp with the same CRI may produce an overall bluish cast.

Starting Temperature

All lamp types, except incandescent, have minimum starting temperatures that limit the environments in which they can be used. Conventional fluorescent fixtures are not rated to start much below room temperature, a fact that is commonly overlooked. Starting temperatures can be lowered by using special low temperature ballasts, but this does not solve the problem of reduced efficiency at low temperature, discussed next. Compact fluorescent lamps have lower design starting temperatures. HID lamps have even lower starting temperatures, which makes them suitable for outdoor use.

Effect of Temperature on Light Output

The fact that a lamp will start at a low temperature does not imply that the lamp will operate efficiently at that temperature. The light output of fluorescent lamps drops severely with reduced ambient temperature, for reasons covered in [Reference Note 55](#). Compact fluorescent lamps that use a mercury amalgam maintain light output at much lower temperatures than lamps without this feature.

The light output of HID lamps is relatively insensitive to ambient temperature because most have double glass envelopes.

Lamps can operate at lower ambient temperatures if they are installed in enclosed fixtures that retain heat. However, this is a two-edged sword for fluorescent fixtures. When the environment is warm, the lamp will become warmer than its optimum temperature, and its efficiency and life will decline.

The efficiency of fluorescent and HID lamps declines roughly in parallel with the fall in light output.

Starting Interval

Incandescent lamps reach full brightness virtually instantly.

Fluorescent lamps may start almost instantly, or they may need a second or two, depending on the type of starter. They require a few seconds to reach full brightness, but this may not be noticeable. An exception is compact fluorescent lamps that use a mercury amalgam. The mercury evaporates from the amalgam slowly, so brightness grows perceptibly, requiring perhaps a minute to reach maximum.

HID lamps are notorious for long starting times, which limits them to applications that can tolerate a delay of several minutes in reaching full output. Some new types of HID lamps are being introduced that allow rapid starting, but so far these suffer a serious efficiency penalty.

Restarting Time

HID lamps cannot restart until they have cooled somewhat. Mercury vapor and metal halide lamps may take longer to restart than to start from a cold state. As a result, HID lighting is limited to long-duration applications where the need for light is predictable.

Some specialized HID lamps are designed for quicker restarting, but these carry a cost penalty, and possibly an efficiency penalty as well. For example, one type contains two separate arc tubes. If the warm arc tube is turned off, power is transferred to the cold arc tube.

Control of Light Distribution

Control of the light distribution pattern is an essential aspect of lighting efficiency. The lamp and the fixture together form a system that determines the distribution pattern. The geometry of the lamp may limit the ability of the fixture to exercise precise control. In general, the smaller the light source, the better the control. Light from a point source can be focussed precisely, but light from a large source, such as a conventional fluorescent lamp, cannot be focussed except in a broad pattern.

Some incandescent lamps have filaments that are designed for small size to maximize focussing ability. These are not needed for general lighting. For most purposes, ordinary incandescent bulbs can be treated as a point source, with the fixture controlling the distribution pattern. However, details of the lamp matter even for general lighting. For example, the shape of the filament determines the light distribution pattern from the lamp, especially if the lamp envelope is clear.

There are many types of incandescent reflector lamps that provide accurate control of the distribution pattern. Compact fluorescent lamps are also available in reflector fixtures.

Conventional fluorescent tubes have a broad distribution pattern. A bare tube has a pattern that is shaped like a doughnut surrounding the tube. In fluorescent lighting, the fixture plays an important role in controlling the distribution pattern.

HID lamps have relatively small arcs that behave approximately as point sources when the lamps are installed in large fixtures. Low-pressure sodium lamps have a relatively long arc that is similar in dimensions to a short fluorescent tube.

Decorative Lamp Options

Some incandescent lamps are meant to be seen for decorative purposes, and these are available in a large variety of shapes, in clear or coated glass, and with various filament configurations. Fluorescent and HID lamps are not meant to be viewed directly, so they do not offer such options. Compact fluorescent fixtures offer a limited range of decorative configurations, such as globes.

Even with decorative lamps, careful selection of wattage, filament configuration, and other features can reduce energy waste.

Mounting Position Limitations

In most cases, incandescent lamps are not sensitive to mounting position. There are exceptions. For example, some bulbs are designed with straight filaments aligned with the bulb axis to minimize darkening when the lamps are mounted in base-up fixtures.

Conventional long fluorescent tubes should be installed horizontally, or nearly so. If the tubes are tilted and are operated only for short periods, the mercury in the tubes may accumulate at one end, making them hard to start.

Some HID lamps can be operated only in a limited range of mounting positions, for reasons covered in [Reference Note 56](#).

Acoustical Noise

Most acoustical noise in lighting emanates from magnetic ballasts, although electronic ballasts may produce some noise. Selecting your ballasts carefully is the way to avoid this problem.

Power Factor

Low power factor is a problem related primarily to cheaper magnetic ballasts used with fluorescent and HID lighting. Refer to [Subsection 9.2](#) for details.

Harmonic Distortion

Harmonic distortion is a distortion of the waveform in the facility's electrical power system that may cause trouble with other electrical equipment. The problem is related to ballasts, primarily cheaper electronic ballasts. Refer to [Subsection 9.2](#) for details.

Electromagnetic Interference

Electronic ballasts operate at high frequency. The high frequency current in the lighting system may radiate interference into space, and the interference may also propagate in the electrical power system. Refer to [Subsection 9.2](#) for details.

Lighting Efficiency Standards

Construction Efficiency Codes Equipment Efficiency Standards for Manufacturers

In response to the energy shortages of the 1970's, many versions of engineering and legal guidelines for lighting efficiency were put forward. A hodgepodge drawn from these were enacted into law. At this time, lighting efficiency standards are diverse and still evolving. Individual standards are incomplete, unbalanced in emphasis, and sometimes quirky in logical structure. The reason is apparent if you consider how difficult it would be to mandate all the aspects of lighting efficiency that are covered in [Section 9](#).

Construction Efficiency Codes

In the United States, Federal law requires each state to include efficiency standards for lighting and other aspects of construction in its building codes. The underlying source for most of the efficiency standards in the United States, and in some other countries, is ASHRAE Standard 90. The ASHRAE standard may be referenced directly by the state codes, or it may be referenced through model energy codes developed by interstate code organizations, including Building Officials and Code Administrators International (BOCA) and the Council of American Building Officials (CABO).

Alternatively, some states that are particularly aggressive about energy conservation have developed energy conservation codes independently of ASHRAE. U.S. federal law mandates that any State or local codes must meet the minimum requirements of the ASHRAE-derived codes.

Because of practical difficulties, there are no lighting efficiency codes based on a comprehensive approach to lighting efficiency. The leading lighting conservation standards, including ASHRAE Standard 90, are a grab bag of different pragmatic approaches, including the following:

- **illumination level standards.** The first widespread approach to mandating lighting efficiency was defining tables of illumination levels for different types of activities. This method has the serious weakness of failing to account for the efficiency of lamps and fixtures, or for the efficiency of light distribution. Furthermore, specific lighting levels are subject to continuing dispute. Illumination level standards have been almost completely abandoned.
- **lighting power budget.** A newer method of mandating lighting efficiency that goes directly to the question of energy input is the "lighting power

budget." This approach specifies the lighting wattage that is allowed for different types of activities. This approach is the major element of ASHRAE Standard 90 and its derivatives. Lighting power budgets have several major weaknesses. They apply only to permanently installed lighting, which ignores the possibility that the efficient lighting fixtures of the future will be easily movable. (For more about movable fixtures, refer to [Measure 9.6.2](#), which deals with task lighting.) Lighting power budgets are virtually impossible to police as lighting is changed in response to changing activities. Also, they do not account for light fixtures that are plugged into receptacles.

- **component efficiency standards.** Some construction codes include efficiency standards for certain components. For example, ASHRAE Standard 90 requires that all ballasts should have a power factor of at least 90%. Some state codes specify lamp and ballast efficiencies, usually following Federal law.
- **control requirements.** The newest development in efficiency codes is requirements for efficient controls. For example, ASHRAE Standard 90 has a rather weak and general section related to manual lighting controls. It also has an oddly illogical provision that allows the installed lighting power to be increased if automatic controls are installed.

Equipment Efficiency Standards for Manufacturers

In the United States, Federal law mandates minimum efficiencies in the manufacture and importation of a limited number of common types of lighting equipment. At present, there are two such Federal laws:

- The National Appliance Energy Conservation Act of 1988 specifies minimum ballast efficacy factors (described in [Subsection 9.2](#)) for certain common classes of fluorescent ballasts.
- The National Energy Policy Act of 1992 specifies efficiency standards for the more common types of fluorescent lamps, for compact fluorescent lamps, and for the more common types of incandescent lamps. The same law pushes for vaguely stated improvements in HID lamps and in light fixtures, although specific action in these areas will require enactments at later dates.

Filament Configuration Options**Service Life and Lumen Degradation****A Comparison of Incandescent Lamps****How Incandescent Lamps are Named**

The simple looking incandescent light bulb is one of the marvels of civilization. Perfecting it was the achievement that made Thomas Edison famous, after many others had failed. This Note will give you a thorough understanding of this wonderful device, along with its inherent efficiency limitations. With this background, you will know where to use incandescent lighting, and where to avoid it. In addition, this Note provides practical information that you need to select the right lamps for applications where incandescent lighting is appropriate.

Mother Nature's Basic Light Source

All light that human beings see is created when electrons lose energy by falling from one energy level to a lower energy level. To get rid of the difference in energy, the electron emits a photon, which is a small package or particle of light. This is the basic process of any kind of light source, whether it is a light bulb, a fluorescent tube, an LED, an electroluminescent night light, a firefly, or a camp fire. In brief, to make a useful light source, we have to get a lot of electrons in one place, excite them to a higher energy level, and let them drop to a lower energy level.

Electrons are a part of every atom, so we have no trouble finding enough electrons to create a light source. Also, there are many ways to excite the electrons. In the three main types of light sources — incandescent, fluorescent, and HID — the electrons are excited by physical collisions. Most of these collisions are with other electrons.

When an electron drops from one energy level to a lower energy level, it has to get rid of the difference in energy. It can do this in several ways, but the most common is to emit a photon. The wavelength of the photon is determined only by its energy. As we said before, the energy of the photon equals the change in energy of the electron as it falls from one level to another.

If the photon has a wavelength that falls within a particular range, our eyes can see the photon. A good light source emits many photons within this visible range. Some light sources (such as low-pressure sodium lamps) emit most of their photons in the visible range. Others (such as candles and incandescent lamps) emit only a small fraction in the visible range. For a light source to be efficient, a large fraction of the energy that we put into the light source should produce photons in the visible range.

We have not yet explained what an electron's "energy level" means, so let's explain it now. An electron is a material particle. Like any moving particle, it has kinetic energy. If the electron is traveling in empty space, all its energy is kinetic. However, electrons in light sources spend a lot of time traveling under the influence of nearby atoms. The electron has a negative charge, and atoms have a positive nucleus, so an electron is attracted to the atom by electrostatic force. The energy stored up in this attraction is called potential energy. An electron's total energy is the sum of its kinetic and potential energies. This total energy is what we mean by the "energy level."

(The energy level actually applies to the system consisting of the electron and the atom or atoms with which it interacts. However, the electron is the main player, and it undergoes most of the change in energy. Therefore, it is common to describe the energy level as belonging to the electron.)

If an electron is attached to a single isolated atom, it moves in a precise standing-wave pattern. Each vibration pattern has a different combination of kinetic and potential energy, with a different total energy. If the atom is isolated, as it is in a low-pressure gas, the electron energy levels are stable and sharply defined. Therefore, when an electron changes its energy level, the photons are emitted at a limited number of precise wavelengths. The light from a low-pressure sodium lamp is an example of this.

If atoms are packed together, as in a solid lamp filament, the electrons of one atom feel the influence of the surrounding atoms, and they collide with other electrons. This interference distorts the vibration patterns of the electrons, changing their energy levels in a random way. Thermal agitation also randomly changes the distance between atoms. As a result, the wavelengths of light emitted by electrons in a hot solid are distributed in a broad, continuous statistical pattern. When light is emitted in this manner, it is called “incandescent.”

Now, we have all the ingredients of any light source. In modern lamps, we put energy into the lamp in the form of electricity, which is a stream of electrons. The electrons collide with the electrons in atoms of specially selected materials in the lamp, exciting the latter electrons to higher energy states. The excited electrons fall back to lower energy states, and emit light in the process.

BULB

Soft glass is generally used. Hard glass is used for some lamps to withstand higher bulb temperatures and for added protection against bulb breakage due to moisture. Bulbs are made in various shapes and finishes.

FILAMENT

The filament material generally used is tungsten. The filament may be a straight wire, a coil or a coiled-coil.

LEAD-IN WIRES

Made of copper from base to stem press and nickel-plated copper or nickel from stem press to filament, they carry the current to and from the filament.

TIE WIRES

Molybdenum wires support lead-in wires.

STEM PRESS

The lead-in wires in the glass have an air-tight seal here and are made of a nickel-iron alloy core and a copper sleeve (Dumet wire) to assure about the same coefficient of expansion as the glass.

Fig. 1 How a conventional incandescent lamp is made

Osram Sylvania Inc.

important incandescent light source, is a gas in which the atoms are tightly packed by the sun's gravity. The intense thermal agitation prevents the atomic energy levels involved in light emission from settling down in stable states. This causes light to be emitted in the random, "incandescent" manner. The same is true of electric arc lighting.

Virtually all incandescent lighting today is done with electric lamps. Figure 1 shows how the basic type of incandescent lamp is constructed. The light emitting element is a tungsten wire, or filament, which acts as a resistor. Passing electricity through the filament heats it enough to make it a useful source of light.

The Spectrum of Incandescent Lamps

The light emitted by any light source has a characteristic pattern of wavelengths, which is called its "spectrum." The spectrum of any incandescent lamp is a lopsided bell curve. At the long-wavelength (low energy) end of the spectrum, light emission rises slowly, and then levels off at a peak. On the short-wavelength (high energy) side of the peak, emission falls off steeply.

The amount of heat in a material is expressed by its temperature. If the temperature of the source increases, the additional kinetic energy increases both the number and the intensity of the electron excitations. This has two dramatic effects on the energy output pattern:

- the amount of light energy that is emitted increases very rapidly. In fact, the rate of emission is proportional to the fourth power of the temperature. (This fourth-power relationship is called the Stefan-Boltzmann Law.)
- the average wavelength of the light becomes shorter. More specifically, the peak wavelength is inversely proportional to the absolute temperature. (This inverse relationship is called Wien's Displacement Law.)

If an object becomes hot enough, it emits a significant amount of energy at wavelengths that can be seen by human beings. At a temperature of 1,000°F (540°C), a solid emits a dull red glow. Continuing to raise the temperature eventually yields a useful amount of light. The filament temperature of ordinary incandescent bulbs ranges from about 3,800°F (2,100°C) to about 5,000°F (2,800°C). Figure 2 shows the spectrum of incandescent lamps.

The Color Rendering of Incandescent Lamps

An important characteristic of any light source is its ability to reveal the colors in the material that is being illuminated. When you look at a colored object, the colors that you see come from the light source, not from the object itself. Therefore, a light source must emit all colors if it is to have good color rendering. The broad, continuous spectrum of incandescent light emission does provide good color rendering. In fact, the Color

Rendering Index (CRI) of incandescent lamps is defined as 100, or near 100, because it includes all the colors of the visible spectrum. (For more about CRI, see [Reference Note 52](#), Comparative Light Source Characteristics.)

This fact seems to mislead many into believing that incandescent lamps are "ideal" in terms of color rendering. This is far from true. In fact, sunlight is closest to being the ideal light source. This is because sunlight contains a large amount of energy at all wavelengths within the visible spectrum. The same is not true of incandescent lamps. Figure 3 compares the spectrum of sunlight at visible wavelengths to the spectrum of incandescent lamps.

The difference results from the fact that the surface temperature of the sun is about 10,000°F (6,000°C), while the temperature of an incandescent lamp filament is half of this, or less. As Figure 2 shows, visible light emission by an incandescent lamp lies at one edge of its wavelength spectrum. The result is that the wavelength distribution across the visible spectrum is very unbalanced, dropping nearly to zero at the blue end of the spectrum.

Thus, incandescent lamps have very good color rendering from the standpoint of having a continuous spectrum of visible wavelengths, but the color rendering is very poor in terms of the relative strengths of the different wavelengths. Human vision compensates for the latter defect, so we barely notice it when we are looking at colors in person. However, photographic processes reveal the unbalance of wavelengths very strongly.

Osram Sylvania Inc.

Fig. 2 The spectrum of incandescent lamps Most of the energy output is invisible, lying in the infrared region. Only the shortest wavelengths are visible to the human eye. Higher filament temperatures push more of the radiation into the visible region.

Why Incandescent Lighting is Not Efficient

If human beings could see all wavelengths, incandescent lighting would be highly efficient, because all the energy input to an incandescent lamp is converted to radiation. However, incandescent sources emit over a much broader range of wavelengths than the human eye can see, as shown by Figure 2.

The sun is about the most efficient incandescent light source from the standpoint of human vision, because the peak of the sun's light distribution pattern occurs near the center of the human vision spectrum. Even so, only about 35% of the sun's energy is visible.

Noontime Sunlight

Incandescent

Osram Sylvania Inc.

Fig. 3 The visible spectrum of the sun and the visible spectrum of incandescent lamps The high temperature of the sun causes sunlight to have a fairly uniform distribution of wavelengths across the visible spectrum. In contrast, incandescent lamps barely have a temperature high enough to get into the blue end of the visible spectrum. The distribution of colors is very skewed. The renowned color rendering of incandescent lamps results from their continuous spectrum, not from a good balance of colors.

Incandescent lamps, which have filament temperatures much lower than the surface temperature of the sun, waste most of their energy at infrared wavelengths. These wavelengths are too long for humans to see. Carbon arc lamps operate at temperatures approaching the sun's, so they have correspondingly higher efficiency.

In principle, it is possible to make incandescent lighting efficient by capturing the infrared radiation before it leaves the lamp and using this energy to heat the filament. In this way, the visible light output remains and the input energy is reduced. Some contemporary incandescent lamps employ this technique, but they recover only a small fraction of the heat radiation.

Practical Effects of Filament Temperature

As we have seen, the light emission characteristics of incandescent lamps depend on the filament temperature. The filament temperature also has a strong effect on other aspects of incandescent lighting, which we will cover now.

■ Limitations in Filament Materials

Almost all modern incandescent lighting uses a solid, electrically heated filament as the light source. The development of incandescent light has largely been a search for filament materials that can produce light more efficiently. Primarily, this means finding materials that can survive the high temperatures needed to produce strong light emission. Thomas Edison's main contribution to the invention of the light bulb was finding filament materials that could survive long enough to be useful. His first successful lamps used filaments of carbon, in the form of charred bamboo fiber, charred cotton threads, and other materials. He and his collaborators also experimented with wire filaments made of platinum, osmium, and tantalum.

The breakthrough to modern incandescent lighting occurred in 1908, when Edison's General Electric Company developed a process for making filaments from tungsten, an extremely brittle metal. This improved lamp efficiency by about 250%. Most of this increase resulted from the high melting point of tungsten, along with its low rate of evaporation at high temperature. Also, the light emission pattern of tungsten is skewed toward shorter wavelengths compared to an ideal incandescent source, so more of its emission occurs at visible wavelengths. Tungsten is now used as the filament material for virtually all incandescent lamps.

Unfortunately, the temperature of a tungsten filament is still much too low to provide a wavelength spectrum that matches the sensitivity pattern of the human eye. No materials exist that can survive in a solid state near the high temperature needed to produce maximum incandescent light emitting efficiency.

(It is worth mentioning that arc lighting, the oldest practical form of electric light, operates at a much higher temperature than incandescent lamps that use solid

filaments. Arc lighting failed to become popular because the carbon electrodes have short life, and because no one figured out how to make arc lights in small sizes.)

■ Effect of Filament Temperature on Color

Because the filament temperature determines the wavelength distribution of the light, the color characteristics of an incandescent lamp are described by its “color temperature.” This is defined as the temperature of an ideal incandescent source that emits at the same peak wavelength. The color temperature is fairly close to the actual filament temperature. Color temperature is explained further in [Reference Note 52](#), Comparative Light Source Characteristics.

■ Effect of Filament Temperature on Service Life

Tungsten melts at about 6,100°F (3,370°C). A tungsten filament heated just below its melting point emits light at an efficacy of about 50 lumens/watt, but a filament survives only briefly at this temperature. (“Efficacy” is lamp efficiency when expressed in terms of lumens per watt.) Metal evaporates from the filament surface at an increasing rate as the temperature approaches the melting point. The loss of metal weakens the filament, and it also blackens the surface of the bulb. Thus, filament temperature is a compromise between efficiency and service life.

The desire for longer service life has created a market for incandescent lamps that operate at reduced voltage in relation to their ratings. For example, “130-volt” lamps are commonly used on 120 volt circuits to achieve long life. Unfortunately, there is no magic in doing this. If a lamp is operated at reduced voltage, light output declines sharply. Also, the color temperature

drops, further crippling color rendering at the blue end of the spectrum. Figure 4 shows these effects.

■ Ultraviolet Emission

Because filament temperature is limited, the light distribution of incandescent lamps is heavily skewed toward the infrared. An accidental bonus of this characteristic is that most incandescent lamps do not emit enough ultraviolet light to cause trouble. However, incandescent lamps that operate at the high end of the temperature range may emit enough ultraviolet to be damaging in some applications. For example, display lighting may cause fading of fabrics. For such applications, lamps are available with bulbs that block ultraviolet light.

Methods of Improving Incandescent Lamp Efficiency

Filament temperature affects the efficiency of incandescent lamps to an extent that dwarfs all other factors. Virtually all significant improvements to incandescent lamp efficiency, with one exception, are intended to sustain higher filament temperatures. The “high efficiency” incandescent lamps presently on the market use one or more of the following techniques.

■ Heavy Fill Gases

Evaporation of tungsten from the filament can be retarded by filling the lamp with inert gas. Tungsten atoms attempting to leave the metal surface are reflected back by collisions with the gas atoms. The amount of fill gas must be limited, because the gas conducts heat away from the filament. In ordinary lamps, the optimum pressure is near atmospheric. This has the fortunate side effect of reducing the hazard of bulb breakage.

If the fill gas has higher atomic weight, it is more effective in reducing tungsten evaporation, and it conducts less heat away from the filament. Ordinary lamps are filled with nitrogen, which has an atomic weight of 14. Argon, which has an atomic weight of 40, may also be used. Krypton is best of all, with an atomic weight of 84, but it is expensive.

Using krypton increases the cost of an ordinary bulb by about 50%, while providing an efficiency improvement of 5% to 15%. Krypton is more economical to use in halogen lamps. Halogen lamps contain the filament in a small capsule that requires little gas, and their higher filament temperatures allow the krypton to make a bigger difference.

■ Tungsten Halogen Lamps

If the filament is surrounded by a hot gas that is a member of the halogen family (i.e., fluorine, chlorine, bromine, or iodine), tungsten that evaporates from the filament forms a compound with the halogen gas. When the halide compound contacts the filament, the high filament temperature breaks down the compound and the tungsten is returned to the filament. Figure 5 diagrams the halogen lamp cycle.

Osram Sylvania Inc.

Fig. 4 Effects of reducing lamp voltage Lamp voltage has a strong effect on filament temperature, which affects light output, service life, color temperature, and efficiency.

The regeneration of the filament allows it to run hotter and last longer. Tungsten filaments tend to burn out locally. However, when a part of the filament becomes thinned, the added resistance of that part causes it to become hotter than the rest of the filament. In turn, the higher temperature enhances the breakdown of the tungsten halide gas, tending to repair that part of the filament preferentially.

The halogen gas also combines with tungsten that deposits on the lamp envelope, keeping the lamp clean. The envelope must be very hot to make this process work. This is one reason why halogen lamps should not be operated with dimmers.

In order to keep the gas hot enough, the filament is enclosed by a small transparent capsule made of heat resistant material. The material may be quartz (but is not always), so halogen lamps are often called “quartz” lamps. The material must be durable because the gases inside the capsule, which include the halogen gas, krypton, and perhaps other gases, operate at a pressure of several atmospheres.

The high temperature and pressure inside the quartz capsule are a safety hazard. For this reason, halogen lamps require either an outer glass envelope or special enclosed fixtures. Halogen reflector lamps are made in the PAR configuration because of its ruggedness. Halogen lamps intended as direct replacements for ordinary incandescent bulbs may be exposed, so they have an outer glass shell that is heavier than ordinary bulbs. These features make halogen lamps more expensive to manufacture.

As with other incandescent lamps, halogen lamps must compromise efficiency with service life. If all the

advantage goes to efficiency, an efficiency improvement averaging 30% can be achieved. If all the advantage goes to service life, service life is increased by a factor of three to five.

■ Infrared Reflecting Coatings

The inside of the lamp envelope can be coated with a film that selectively reflects light of infrared wavelengths back to the filament, reducing the amount of electrical energy needed to heat the filament. This is the only major improvement in incandescent lamp efficiency that works by a method other than increasing filament temperature.

Figure 6 shows a halogen lamp that uses this efficiency improvement. To date, infrared reflecting coatings are used only with halogen lamps. The small quartz capsule of halogen lamps is ideal as a carrier for the reflective coating because it can accurately focus the heat radiation back on the filament, and because its small size reduces the cost of the coating.

Do not confuse these coatings with similar coatings that are applied to the rear shell of some reflector lamps. Such lamps are used to reduce the amount of heat in the light beam. Infrared radiation from the filament is selectively released through the back of the lamp. To work, these lamps must be installed in a vented fixture. They do not save energy, and they are an invitation to fires because of the additional heat released in the vicinity of the lamp.

■ Low-Voltage Filaments

For a given wattage, low-voltage lamps have thicker filaments, which allows them to run hotter and reduces the need for heat-robbing support wires. As an extreme example, a 12-volt, 25-watt lamp with a rated life of

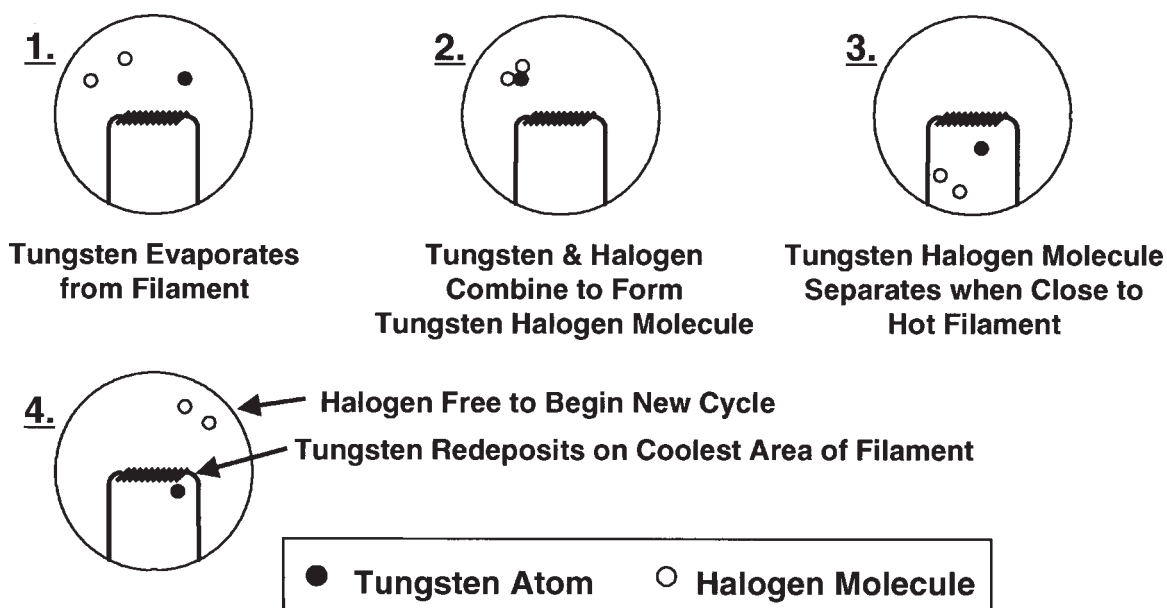

Fig. 5 The tungsten halogen lamp cycle

Osram Sylvania Inc.

Osram Sylvania Inc.

Fig. 6 Tungsten halogen lamp The inside surface of the spherical inner capsule can be coated to reflect infrared radiation back to the filament. The reflected heat reduces the amount of electricity needed to heat the filament, improving lamp efficiency.

1,000 hours is about 70% more efficient than a comparable 240-volt lamp. The efficiency advantage declines at higher wattages. For example, a 12-volt, 100-watt lamp is about 25% more efficient than a comparable 240-volt lamp. A major disadvantage of this method is the need for a low-voltage power system, which adds cost and its own energy losses.

Filament Configuration Options

The lamp buyer has a choice of filament configurations. This choice affects the following lamp characteristics:

- the **light distribution pattern**, especially in clear bulbs. This can have a major effect on light trapping inside the fixture, as well as the efficiency of light distribution to the activities. See [Measure 9.1.3](#) about how to select lamps for efficient light distribution.
- the **pattern of tungsten deposition on the glass bulb**, as discussed below
- **resistance to shock or vibration** (different designs for each). Filaments designed to be more durable require more support structure for the filament. Unfortunately, the supports conduct heat away from the filament and reduce efficiency.
- **efficiency**. Low-voltage filaments are inherently more efficient, as previously discussed. This is true of thicker filaments in general.

- **tightness of focus**. Smaller filaments are closer to being point sources, so they allow the light to be focussed more tightly.

Service Life and Lumen Degradation

The life of an incandescent lamp is limited by evaporation of material from the filament. The same factor causes a loss of light output as the lamp ages, which is called “lumen degradation” or “lumen depreciation” in the lighting trade.

Tungsten does not evaporate from the filament uniformly. If it did, the life of an individual lamp would be predictable within narrow limits. However, in a batch of similar incandescent lamps, a significant number may fail at half the average life. The reason is that small imperfections in the filament increase resistance and cause the filament to be hotter at those points. Evaporation increases rapidly with temperature, so the metal evaporates faster at the imperfections, further increasing the resistance and the rate of loss. The filament may break at one these points long before there is much tungsten loss overall. These processes are unstable and unpredictable, so the life of any individual lamp is unpredictable.

The resistance of the filament increases from the tungsten loss, which reduces energy input and light output. In addition, the tungsten that evaporates from the filament comes to rest on the inside of the lamp shell, where it absorbs light. Metals are very opaque, so even very thin deposits absorb a significant amount of light.

The absorption loss varies widely. In lamps that have no fill gas (“Class B”), tungsten atoms proceed from the filament to the glass shell with little interference. Therefore, the distribution of metal on the glass is fairly uniform.

Osram Sylvania

Fig. 7 Lumen depreciation of incandescent lamps Tungsten halogen lamps have longer life, and they also lose much less light output during their life. This is because the filaments do not become as thinned by evaporation, and less tungsten darkens the bulb.

In gas-filled lamps (“Class C”), evaporated tungsten is caught by the fill gas. The heat of the filament causes strong convection currents inside the lamp, which carries the tungsten to the top of the lamp. As a result, the darkening is localized and the effect on light distribution depends on the lamp’s mounting position. For example, in a torchere fixture, which projects light out the top, absorption becomes severe toward the end of lamp life. Conversely, the absorption loss is minor in a downlight. One type of lamp filament, the straight axial filament, is specifically for bulbs mounted base-up because most of the lost tungsten is deposited harmlessly in the base of the lamp.

Halogen lamps have longer service lives and lower lumen degradation because they return the evaporated tungsten to the filament. Unfortunately, the halogen

process does not return all the tungsten to the thinned spots. Otherwise, these lamps would last virtually forever.

Figure 7 compares the lumen degradation of conventional and halogen incandescent lamps.

A Comparison of Incandescent Lamps

Table 1 lists efficacies and service lives for typical incandescent lamps used in general lighting. Note the trends in the table that illustrate the relationships between efficacy (the lamp efficiency expressed as lumens per watt), wattage, service life, and lamp type.

For a comparison of incandescent lamps with other lamp types, see [Reference Note 52](#), Comparative Light Source Characteristics.

How Incandescent Lamps are Named

There is an extraordinary variety of incandescent lamps available, even for general lighting. Special lamps for locomotives, ovens, refrigerators, traffic signals, swimming pools, etc., swell the catalogs. Lamps are available from 3 watts to 1,500 watts in small increments, with extensions in wattage at each end of the range for special applications. Aside from wattage, lamps are identified in these ways:

- **bulb shape and size.** Lamps have dimension codes that consists of letters and a number, such as A-19, PAR-30, G-25, etc. The letter or letters indicate the shape. The number is the approximate maximum diameter in eighths of an inch. For example, an A-19 lamp is a round bulb of approximately 2-3/8" diameter.

Figure 8 is a chart of the most common lamp shapes. Ordinary incandescent bulbs are "A" shape, except that larger wattages are commonly "PS" (pear-shaped with straight neck) shapes. These typically have higher efficiency than other shapes. Reflector types include "R" (typically, indoor flood), "PAR" (parabolic reflector), "ER" (ellipsoidal reflector), and others. A trip to the hardware store shows that

there are many other shapes, including tubular, globes, flame, etc.

- **filament type.** Filament codes consist of one or two letters and a number. The letters usually are "C" (coiled), "CC" (coiled coil), or "S" (straight). The numbers describe different suspension arrangements. Various filament configurations are shown in Figure 9. The shape of the filament and the way it is suspended in the bulb affects the light distribution pattern, resistance to vibration and shock, efficiency, and the pattern of bulb blackening from evaporated filament material.
- **base or socket type.** Most lamps for general lighting have "medium" screw bases, except that larger wattages use "Mogul" screw bases. There are many types of specialty bases, including an entire family just for halogen lamps. Incandescent base types are pictured in Figure 10.
- **class** is either "B" (vacuum) or "C" (gas filled). Smaller lamps usually are class B, and lamps larger than 25 watts usually are class C. This rating does not tell you anything about the type of gas filling.
- **special characteristics**, which could be anything relevant, such as "halogen," "green," "vibration service," "traffic signal," etc.

Methods of Starting Fluorescent Lamps**Environmental Problems**

This Note covers the theory and design of fluorescent lighting equipment. It will help you select fluorescent lighting equipment with assurance, and it explains the changes that are occurring in fluorescent lighting technology.

How Fluorescent Lighting Works

A fluorescent lamp consists of a glass tube with electrodes at each end. The inside surface of the tube is coated with one or more types of phosphors. Mercury vapor fills the tube at very low pressure, along with one or more “buffer” gases. Figure 1 shows how a conventional fluorescent tube is made.

Fluorescent lamps produce light through a sequence of physical processes, each of which is related to one or more of the tube’s components. The design of the components has been refined over the years to improve efficiency, color rendering, service life, and other properties. You need to understand the purpose of each component to sort through the numerous choices that are available in fluorescent lighting today. Let’s examine each one.

■ The Mercury Vapor

Go to [Reference Note 54](#) and read “Mother Nature’s Basic Light Source.” Then, come back to here.

Light is generated in a fluorescent lamp in two stages. The first stage is an “arc” discharge. The purpose of the mercury vapor is to form the arc.

An arc is a gas or vapor that is carrying an electric current. Free electrons traveling through space are accelerated by an electric field to high speeds. The electrons slam into the mercury vapor atoms, knocking loose more electrons, which then contribute to the electric current. The heavy, ionized mercury atoms are also moved by the electric field, but much more slowly. The electrons are negative and the ions are positive, so they move in opposite directions.

At the extremely low pressure of the mercury vapor, each mercury atom is isolated from the effect of other atoms. Therefore, the energy levels of its electrons are sharply defined. The electrons are excited to higher levels by collisions with electrons that travel freely in the space between the atoms.

To make a fluorescent lamp efficient, it is designed to excite the mercury atoms to their first excited level, and to minimize exciting the atoms to other levels. This concentrates the emitted light energy at a particular wavelength. Having one dominant wavelength makes it possible to design the phosphors for efficient light conversion and accurate control of color.

The light that is emitted when mercury atoms relax from their first excited energy level has a wavelength of 254 nanometers. This wavelength is outside the visible spectrum, far into the ultraviolet. The job of the phosphors is to convert this ultraviolet light to a broad spectrum of visible light, as discussed below.

It is not possible to concentrate all the light emission at 254 nanometers. In typical fluorescent lamps, about 50% of the input energy becomes radiation at this wavelength, and about 10% becomes radiation from the next higher energy level, which produces light at 185 nanometers, even further into the ultraviolet.

Some collisions in the arc stimulate even higher energy levels in the mercury vapor. Ironically, these mostly produce light at longer wavelengths. The reason is that many of the higher states decay in steps, each step emitting a photon of relatively long wavelength. (About 2% of the light emitted by the mercury vapor is in the visible spectrum. This is the light that you see in school laboratory demonstration lamps.) The higher energy states are stimulated by electrons that accumulate too much energy before hitting a mercury atom. Also, a relatively weak electron can raise an already excited atom to a higher energy level.

Electrons are first emitted by the electrodes at both ends of the tube. Fluorescent lamps usually operate from alternating current, so the electrons flow half the time in one direction, and half the time in the other direction. Most of these original electrons are lost to the tube wall before they reach the other end. If current is to keep flowing, the original electrons must be replaced by knocking electrons loose from the mercury atoms.

The process of knocking an electron loose is called "ionization." The energy needed to create the free electrons is mostly wasted because only part of the ionization energy is ever recovered as light.

The mercury atom that is missing one electron is called an "ion." It has a single positive charge, because it is missing the negative charge of the electron. Even though ions are charged particles, they carry little current because they are heavy and slow. However, the heavy ions are important because they heat the electrodes by impact. The impact and heat help to release the electrons from the electrodes. The same impacts also eventually destroy the electrodes.

Ions may re-combine with electrons while they are wandering in the arc, but this is unlikely. If an ion does not reach the negative electrode, it usually hits the tube wall and combines with an electron there.

Fluorescent lighting is limited to low intensity, typically about 10 watts per foot (30 watts per meter) of tube length. This is because the current in the lamp must be limited. If the flow of electrons is too high, the

probability increases that an electron will further excite mercury atoms that are already excited. This excites a cascade of light emission at many wavelengths, most of which are too long to be useful.

Mercury is the only light emitting vapor used in fluorescent lighting. It is the only substance yet discovered that has the combination of characteristics needed for efficient generation of light by the fluorescent process. The favorable characteristics of mercury are:

- The density of the vapor is optimum for efficient lamp operation near room temperature. The optimum density for mercury vapor occurs at about 104°F (40°C). Indoor fluorescent lamps operate near this temperature.
- Mercury emits light strongly from its first excited energy level. Concentration of light from the first energy level avoids wasting energy produced at unusable wavelengths. It also allows the lamp design to be optimized to deal with the single primary wavelength.
- The wavelength of mercury's first excited level can be converted to visible light fairly efficiently by phosphors that have other desirable characteristics. These other characteristics include good color rendering, long life, reasonable cost, etc.
- Mercury has a critical interaction with argon, discussed below, that greatly improves the efficiency of ionizing mercury atoms to carry the lamp current.

Fig. 1 How a conventional fluorescent lamp is made

Osram Sylvania Inc.

■ Phosphors

Phosphors convert the ultraviolet light emitted by the mercury vapor into visible light. Phosphors are crystals, which are regular arrays of atoms. Crystals are literally huge molecules. Like all molecules, they have characteristic energy levels. Instead of having discrete energy levels like individual atoms, crystals have broad energy bands that are created from the energy levels of the closely packed atoms. When the phosphor crystals are excited by the ultraviolet radiation from the mercury vapor, they emit light over a broad spectrum of wavelengths. Energy is lost in this process, so the wavelengths emitted by the phosphors are longer than the wavelength of mercury emission. Phosphors are selected to emit most of their radiation in the visible spectrum.

Some of the mercury radiation is dissipated by generating vibrations in the crystal structure, which is heat. The efficiency of the phosphors in converting the ultraviolet to visible light ranges from 35% to 50%.

Phosphor crystals have additives called “activators” that modify their absorption and emission characteristics. The phosphors and activators are selected to maximize absorption at the 254-nanometer wavelength of mercury emission, and to emit light within the visible spectrum.

The makeup of the phosphors determines the color of a fluorescent lamp. To a large extent, the phosphors also determine the efficacy and cost of the lamp. Selecting a particular model of fluorescent lamp is largely a matter of selecting particular phosphors.

Older fluorescent lamps use a single type of phosphor. The newest phosphor systems combine three different types of phosphors, each of which produces a color distribution with a different peak. The three-phosphor system improves maximum lamp efficacy from its previous maximum of about 75 lumens/watt to about 90 lumens/watt. The color rendering index (CRI) is increased from around 60 to as high as 90. Loss of light output during the life of the lamp is reduced from about 20% to about 7%. The disadvantage of the triple phosphor systems is that are considerably more expensive than the older types.

Figure 2 shows the output spectra of fluorescent lamps with several different types of phosphors. It shows that some lamps emit most of their light at discrete wavelengths, while others emit much of their light as a continuous spectrum. Among both types, light output can be tailored somewhat to emphasize the red or blue end of the spectrum.

■ Buffer Gases Increase Lamp Efficiency and Output

Fluorescent lamps contain one or more “buffer gases” in addition to the mercury vapor. In fact, fluorescent lamps contain much more buffer gas than mercury vapor, typically at several hundred times higher pressure than the pressure of the mercury vapor (but

still only a small fraction of atmospheric pressure). Argon is always the primary buffer gas that is used in fluorescent lighting. Argon is needed to work with the mercury vapor in the lamp, as we shall see.

The buffer gas is sometimes called the “inert gas” or “rare gas,” because the gases that are used in fluorescent lamps have these chemical classifications. Their essential characteristic is that they resist excitation. This is because their first energy level is exceptionally high. (This is the main reason why these gases are chemically inert.)

Buffer gases perform several functions. One of these is reducing the loss of the electrons that transmit energy to the mercury atoms. Stated differently, the buffer gas increases the probability that any one electron will stimulate mercury atoms to emit light.

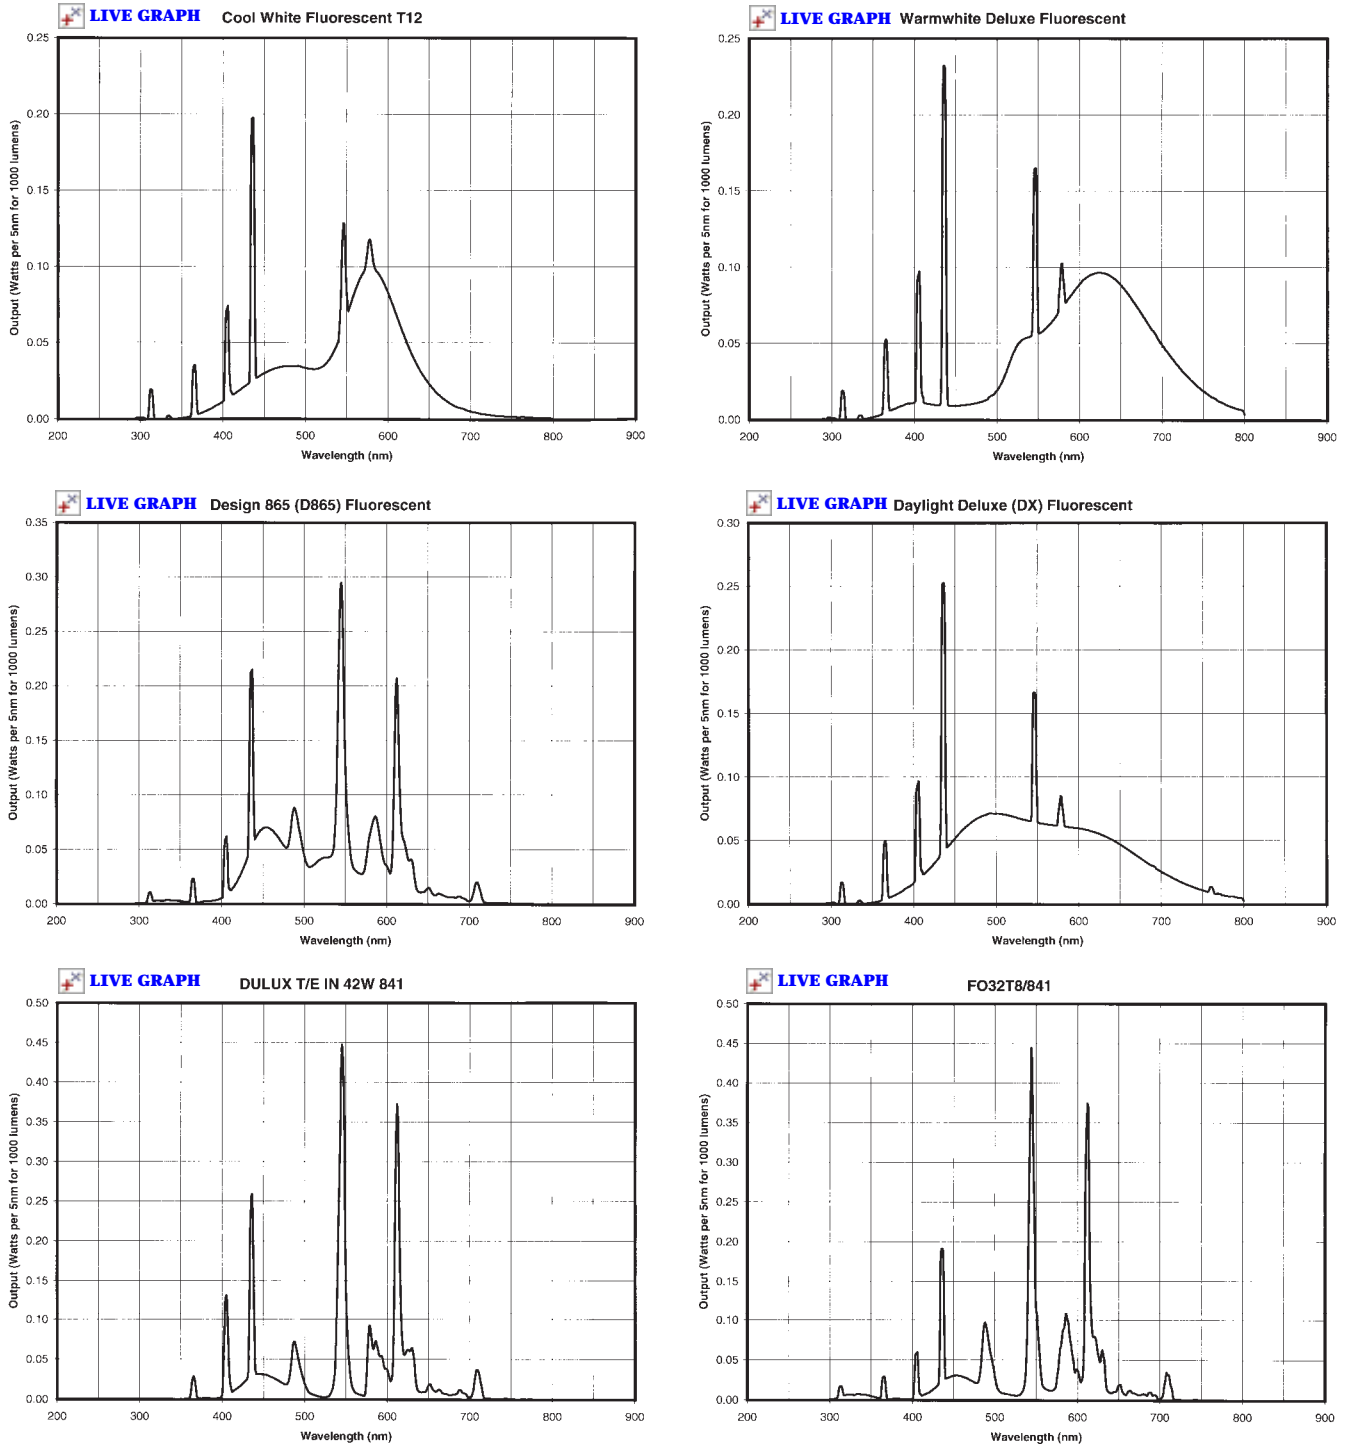

Buffer gases are needed for this purpose because the density of the mercury vapor in the lamp is very low. If the tube contained only mercury vapor, an average electron would travel about two inches (50 mm) before hitting a mercury atom. This distance is so long that the electron would be more likely to hit the tube wall or the positive electrode than to hit a mercury atom. By the same token, few mercury atoms would be stimulated, and light output would be feeble.

Furthermore, the lamp would not work at all with normal voltage, because the loss of electrons would exceed the number of new electrons created by ionization. The only way to make the lamp work would be to use a much higher voltage to create more ionization. This would make fluorescent lighting expensive and dangerous. The lamp would be inefficient because of the high electron loss. Also, it would be inefficient because the high voltage would accelerate the electrons to excessive energies. In turn, the electrons would stimulate the mercury to energy levels that are too high for efficient light emission.

The solution to the problem of low mercury vapor density is to add another gas, called a buffer gas, in sufficient quantity to shorten the distance that an electron travels between collisions. In a fluorescent lamp, the presence of the buffer gas reduces the average distance between collisions to about 0.004 inches (0.1 mm).

(Mercury itself cannot be added at higher pressure, because it exists as a vapor in equilibrium with liquid at room temperature. Attempting to add more mercury vapor would simply cause more of it to condense into the liquid state. Also, in a dense mercury vapor, the light emitted by excited atoms would be absorbed by the surrounding unexcited atoms. This is because an atom absorbs strongly at the same wavelengths it emits.)

The free electrons that carry current through the tube gain energy progressively as they bounce between atoms, accelerated by the electric field of the electrodes. A free electron cannot stimulate an atom to a higher energy level until it gains an amount of energy equal to the

Osram Sylvania Inc.

Fig. 2 Visible light spectra of fluorescent lamps The upper four are from T12 lamps. These emit a large fraction of their light as a continuous spectrum, providing good color rendering. The bottom left spectrum is from a compact fluorescent lamp. The bottom right is from a T8 lamp. These two emit much more of their light at discrete wavelengths.

lowest energy level of any atom it encounters. The buffer gases have high energy levels, whereas mercury does not. This makes it likely that a mercury atom will be the first type of atom stimulated. This is also why the first energy level of mercury is stimulated more than its other energy levels.

To improve efficiency, krypton is added to the argon in some lamps. This reduces the energy loss that occurs from the heating of the buffer gas by electron collisions. Even though most collisions between free electrons and the buffer atoms are elastic (which means that no energy is lost in the collisions), there is a transfer of kinetic energy from the electrons to the atoms. This kinetic energy is not useful, and the atoms eventually dissipate their kinetic energy as heat in collisions with other atoms, the wall of the tube, or an electrode. Krypton is heavier than argon, so it absorbs less energy in collisions.

Krypton is more expensive than argon, so it is used only in premium lamps. Krypton cannot substitute entirely for argon, because it does not have the fortunate matching of energy levels that aids starting. This is discussed next.

■ The Role of Argon in Ionizing Mercury

Argon is always selected as the primary buffer gas because it must perform an entirely different function from the one discussed previously. This function is helping to create enough free electrons to maintain the current within the lamp.

The action of buffer gas discussed previously greatly reduces the loss of the free electrons emitted by the electrodes. Still, most of these electrons do not survive the entire trip through the tube. The lost electrons are replaced by knocking additional electrons loose from the mercury vapor. The difference here is that the electrons are not merely excited, but are knocked completely free of the atom. In other words, the mercury is “ionized.”

Electrons are unlikely to ionize mercury directly, because they tend to give up their energy exciting lower mercury energy levels. Instead, a free electron excites an argon atom, which then ionizes a mercury atom. Bear in mind that a free electron is about 100 times more likely to hit an argon atom than a mercury atom, so the electron may accumulate enough energy to ionize a mercury atom before it actually hits one.

Argon is special for this purpose because it has an energy level that is slightly higher (11.6 electron volts) than the ionization energy of mercury (10.4 electron volts). Equally important, the argon atom does not relax quickly from this excited state, so it is likely to collide with a mercury atom first. When the collision occurs, the excitation energy of the argon is immediately transferred to the mercury atom, ionizing the mercury atom. This fortunate interaction between mercury and argon is one of the factors that has made fluorescent lighting practical.

This process is especially important to help the fluorescent tube get started without needing higher voltage. For this reason, the argon in a fluorescent lamp is often called the “starting gas.”

■ Buffer Gases Protect the Electrodes and Phosphors

The buffer gas also protects the electrodes and phosphor crystals. The heavy ions are kept at low speed by repeated collisions with the buffer atoms. If this did not happen, the electric field would accelerate the ions to energies that would quickly destroy the electrodes. By the same token, the cloud of buffer gas around the electrodes rebounds evaporated electrode material back to the electrodes.

In much the same way, the buffer gas shields the phosphor crystals from damage by mercury ion bombardment.

■ Electrodes

The electrodes in a fluorescent tube are the gateways through which the current from the ballast enters the arc. The electrons in the metal electrodes don't want to jump out into the vacuum of the tube. They have to be forced to do so. Two methods are used in fluorescent lighting to get the electrons to leave the electrodes. One is to wrench the electrons loose with a strong electric field. This method is used in “instant-start” lamps.

The other method is to heat the electrodes so that the electrons are knocked out of the electrode surface by thermal agitation. (This process is called “thermionic emission.”) “Rapid-start” and “preheat” fluorescent lamps use this method. Once the lamp is operating, bombardment of the electrodes by ions and electrons may keep the electrodes hot enough to continue electron emission, so the electric current that heats the filaments can be turned off.

Both methods require energy that produces no light, so they reduce lamp efficiency. To minimize the amount of energy needed to extract electrons from the electrodes, the electrodes are coated with a material that reduces the amount of energy needed to evict the electrons. This material is gradually depleted from the electrode surface during operation, especially when the lamp starts from a cold state. The original amount of the material, and its rate of loss, determine lamp life. The amount of emissive material is limited by the fact that the lost material contaminates the phosphors and darkens the interior of the lamp. This forces a compromise between lamp life and preservation of lumen output.

The loss of energy at the electrodes can be reduced by increasing the frequency of the alternating current from the ballast. Part of the loss in a fluorescent lamp occurs because the arc dissipates with each half cycle of the applied voltage, so it must be continually restarted. Also, during the relatively long time between cycles in 60 Hz current, some of positive mercury ions are attracted to the negative electrode, where they give up

their energy without producing light. If the frequency of the input current is greatly increased, the mercury ions do not have time to wander between cycles, and the column of ions does not have time to dissipate completely, so the arc is easier to restart.

The development of electronic ballasts made it possible to supply current to lamps at high frequency. Lamp efficacy rises to a plateau at about 20 KHz, with an improvement of about 10%. By a fortunate coincidence, 20 KHz is the top of the frequency range for human hearing, so electronic ballasts are designed to operate at this frequency or higher. Fortunately, the lamps do not have to be modified to exploit high-frequency power.

The Effect of Temperature on Efficiency and Light Output

Unlike incandescent and HID lighting, the efficiency and the output of fluorescent lighting is sensitive to the temperature surrounding the lamp. The primary reason is that the surface temperature of the lamp determines the vapor pressure of the mercury, which is the primary source of light.

As mentioned previously, the optimum density for mercury vapor occurs at about 104°F (40°C). Accounting for some insulation effect by the glass bulb and phosphors, this means that the exterior surface of the lamp should be at a temperature of about 85°F (30°C). Figure 3 shows that efficiency declines seriously at higher and lower temperatures.

Since the vapor pressure of mercury declines with temperature, the light output declines also.

It is possible to use fluorescent lamps in cooler environments by installing them in sealed fixtures that

Osram Sylvania Inc.

Fig. 3 The effect of ambient temperature on lamp efficiency. The surface temperature of the lamp controls the vapor pressure of the mercury, which determines light output and efficiency.

retain heat better. However, this simply shifts the optimum temperature. Light loss in the enclosure also reduces the effective maximum efficiency of the lamp.

Compact fluorescent lamps operate at higher temperature because they have higher current densities. As a result, these lamps can be used in cooler environments. However, deviating from the optimum temperature for these lamps also reduces efficiency.

The Effect of Lamp Shape on Efficiency

The length of the tube is a factor in efficiency. The electrodes consume energy without producing light, and light emission in the vicinity of the electrodes is inefficient. These losses are essentially constant, regardless of the length of the tube. Also, the ends of the tube become darkened by evaporated filament material. Therefore, longer tubes tend to be more efficient than shorter tubes. For example, a typical 8-foot tube is about 10% more efficient than a comparable 4-foot tube, which in turn is about 20% more efficient than a comparable 2-foot tube.

Curvature of the tube contributes to inefficiency. Light emission in a given lamp type is less efficient close to the wall of the tube. Bends in the tube force the arc closer to the tube wall, so U-tube and circular configurations tend to be less efficient than straight tubes. For example, a straight 4-foot tube is about 10% more efficient than a comparable U-tube.

The diameter of the tube is a compromise between competing efficiency factors. If the tube is fat, too much radiation from the center of the tube is re-absorbed by the mercury vapor. If the tube is slender, it has more surface area in relation to its gas volume, which increases quenching of the mercury arc at the tube surface. Also, smaller diameter increases the current density for a given wattage, which may reduce efficiency. Since the diameter of a fluorescent lamp affects efficiency in several ways, you cannot judge the efficiency of a fluorescent lamp from the diameter alone.

The high cost of high-efficiency phosphors motivates smaller tube diameters. This factor is largely responsible for the introduction of T8 (1" diameter) tubes for applications that previous used T12 (1.5" diameter) tubes.

Service Life and Number of Starting Cycles

The nominal service life of conventional fluorescent lamps averages about 20,000 hours. The actual service life is affected strongly by the number starting cycles during the life of the lamp. The reason is that starting the lamp causes the electrodes to lose a part of their emissive material.

The nominal service life is usually based on three hours of operation per start. Lamp manufacturers are coy about stating the service life for shorter periods of operation. Going the other way, operating a lamp

Philips Lighting

Fig. 4 Service life of fluorescent lamps Lamps that operate at higher current, or output, have shorter lives. The number of starting cycles has a major effect of service life. Unfortunately, manufacturers don't like to publish data for starting cycles shorter than three hours.

continuously may increase the service life by about 50%. Figure 4 charts the effect of starting cycles on the service life of several conventional types of fluorescent lamps.

Lumen Degradation

Figure 5 charts the lumen degradation of several types of conventional fluorescent lamps. The figure shows that lumen degradation ranges from 10% to 40%, depending on the type of lamp.

The main causes of lumen degradation in fluorescent lamps are decay of the phosphors and darkening of the lamp by material lost from the electrodes. Phosphor decay is much greater in lamps having higher current.

How Fluorescent Lamps are Named

The features of fluorescent lamps have been changing continually since fluorescent lighting was developed, and the rate of change is now much greater than it was in the past. These features include lamp shape, starting method, wattage, lamp color, color rendering, efficiency, base type, etc. The naming of fluorescent lamps has become a muddle as manufacturers attempt to describe each new type of fluorescent lamp by its lamp code.

At present, the only way to completely decode a fluorescent lamp designation is to use a detailed catalog. Here are some examples:

- “F48T12/CW/WM” is a straight fluorescent tube, 48 inches long, 1.5 inches diameter, “cool white” color, Watt Miser (a General Electric trade mark). The wattage and other characteristics are unspecified.

- “F96T8/SPX41/HO” is a straight fluorescent tube, 96 inches long, 1.0 inch diameter, RE841 phosphor, “high output.” The wattage and other features are unspecified.
- “F13DBX23T4/SPX35” is a compact fluorescent tube, 13 watts input, Double Biax (a General Electric trade name) configuration with Type 23 base, 0.5 inches diameter, RE835 phosphor.

You can see that there are some common features here. All fluorescent lamp designations start with the letter “F.” The other consistent designation is the lamp diameter. In United States practice, the diameters of all types of fluorescent tubes are designated with the letter “T” in the lamp type code, followed by the diameter in eighths of an inch. For example, a “T4” compact fluorescent lamp has a tube diameter of one half inch.

The designation of lamp length is confused, and it may or may not appear in the lamp code. For example, “F96” means that the lamp is 96 inches long, but “F32” means that the lamp power is 32 watts.

With newer fluorescent lamps, the lamp’s output color is usually designated by a phosphor type. However, older types of fluorescent lamps use names for colors, such as “daylight” and “cool white.”

Conventional types of fluorescent lamps (that is, not compact types) are classified by starting method, such as “instant start.” Starting methods are discussed below. The starting method also implies the type of lamp base, in the case of the older, thick lamps. Most compact fluorescent lamps presently use preheat starting, so the starting method is usually not specified.

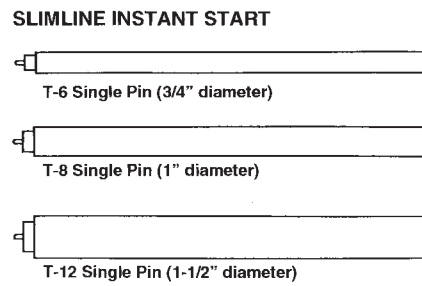

Compact fluorescent lamps are evolving with different naming patterns than the older, larger types.

Philips Lighting

Fig. 5 Lumen degradation The loss of light output occurs early in the life of the lamp. Lamps that operate with high current suffer much more loss than the best models. Therefore, “high-output” lamps are not a good bargain, especially in terms of efficiency.

FLUORESCENTS:

COMPACT FLUORESCENTS:

Fig. 6 Common types of fluorescent lamps

Osram Sylvania Inc.

Because compact lamps are spawning many base types, the base type code is likely to be included in the lamp designation. However, unless you always deal with the same type of base, you need a catalog to show you a picture of the base type.

Figure 6 shows most of the older types of fluorescent lamps, and a representative sample of compact fluorescent types.

Why Fluorescent Lamps Need Ballasts

All fluorescent lamps need a ballast to operate. The arc in an operating lamp has almost no electrical resistance. Without some means of regulating the current, the lamp current would be much too high for efficient light emission and the lamp would quickly destroy itself. The ballast regulates the lamp current independently of the lamp's changing resistance characteristics.

In addition, many fluorescent lamps need a voltage higher than the line voltage to get started. (The voltage requirement relates mostly to lamp length and the type of electrode.) The ballast provides the increased starting voltage.

The lamp's characteristics dictate the design of the ballast. The ballast and lamps must be closely matched to achieve best efficiency. Lamps may operate with the wrong ballasts, but not efficiently.

There are two main types of ballasts, magnetic and electronic. Magnetic ballasts have a more efficient variation called a hybrid ballast.

■ How Magnetic Ballasts Work

The original method of regulating lamp current is to use a coil in series with the lamps. The coil restrains alternating current by inductance. This type of ballast is still common. It is called a "magnetic" ballast because the coil produces a magnetic field, although this is irrelevant to the ballast's operation. It is also called an "electromagnetic" or "core and coil" ballast. A magnetic ballast is similar in construction to a transformer. The inductance of the secondary winding determines the lamp current, and the turns ratio between the primary and secondary windings determines the starting voltage.

A simple magnetic ballast is a large inductor, so it causes the lighting system to have a low power factor. This problem can be corrected easily by including a large capacitor in series with the coil.

Two-tube magnetic ballasts also use capacitors for another purpose, to aid starting. A capacitor is connected in parallel with one of the lamps so that full ballast voltage first appears across the other lamp. After that lamp starts, its resistance disappears, the capacitor charges, and starting voltage appears across the first lamp.

Figure 7 shows the inside of a magnetic ballast that has all these features.

Substantial improvements in the efficiency of magnetic ballasts have been made in recent years. These include reducing the resistance of the windings, improving the cores to reduce eddy currents, shaping the wire so that there is less insulation dead space between the wires, and reducing losses in the capacitors.

Advance Transformer Co.

Fig. 7 Inside a magnetic ballast Most of this is a transformer, made of two large coils wound on an iron core. The large capacitor to the left of the coils improves power factor. The smaller capacitor next to it aids the starting of two lamps in series. On top is a small thermal switch for fire safety, which makes the ballast "P" rated.

Advance Transformer Co.

Fig. 8 Inside a hybrid ballast This is the same as the magnetic ballast in Figure 7, except that it includes a small electronic switch to turn off the lamp filament after the lamp starts.

“Hybrid” ballasts are magnetic ballasts that include an automatic switch to turn off the filaments of rapid-start lamps after the lamp starts. Figure 8 shows the inside of a hybrid ballast.

■ How Electronic Ballasts Work

Electronic ballasts are rapidly entering the field, although they are still substantially more expensive than magnetic ballasts. They eliminate the large coils and associated heat loss of conventional ballasts because they operate on an entirely different set of principles. Figure 9 shows the inside of a typical unit.

Electronic ballasts regulate lamp current by delivering it in high-frequency pulses. The ballast circuits can tailor the characteristics of the lamp current to optimize a variety of factors that affect efficiency.

Electronic ballasts not only operate more efficiently themselves, they also improve the efficacy of the lamps by about 10 percent, because of the high-frequency operation discussed previously.

The ability of electronic ballasts to tailor the lamp current makes it possible to provide efficient dimming of fluorescent lamps. Special models are needed to provide dimming.

Methods of Starting Fluorescent Lamps

The un-ionized mercury vapor in a cold fluorescent lamp has virtually infinite resistance. To get the lamp started, it is necessary to create ions and free electrons to form an arc and carry the current. The arc is started by ejecting electrons from the electrodes. The impact

Advance Transformer Co.

Fig. 9 Inside an electronic ballast The big coils are gone, replaced by a few small electronic components that drive the lamps at ultrasonic electrical frequency. The ballast itself has smaller losses, and it makes the lamps operate more efficiently. However, electronic devices are potentially less reliable than coils of wire, so expect to replace these ballasts more often.

of these electrons on gas atoms creates ions and more free electrons, as we discussed previously. The arc spreads down the length of the tube as the ions and electrons are accelerated by the electric field of the electrodes. Several methods are used in fluorescent lighting to get the arc started:

- **instant-start** systems use the brute force of high voltage to tear electrons out of the electrode surface. The starting voltage is about three times the operating voltage. Once lamp current starts to flow, bombardment of the electrodes by ions heats the electrodes, which reduces the amount of voltage needed to operate the lamp and improves efficiency. Instant-start tubes with single-pin terminals are often called slimline tubes.

- **rapid-start** systems heat the electrodes to eject electrons by thermal agitation. Rapid-start ballasts have separate windings to supply filament heating voltage.

Energy can be saved by turning off the filaments after the lamp is started. This can be done by a switch in the ballast or by a switch sealed into the tube itself.

- **preheat** systems also use electrodes in the form of heated filaments. In these lamps, the filaments are heated before voltage is applied across the lamp. Closing a switch in the secondary circuit of the ballast heats the filaments. Releasing the switch simultaneously turns off the filaments and applies an inductive jolt that starts the lamp.

In fixtures that are very old or very cheap, the switch is manual. Other fixtures use a simple automatic switch called a “starter.” With older tube types, the starter is usually contained separately from the ballast in a small replaceable canister. Preheat starting is used mostly with small lamps. This starting method was fading into history, but it has returned as the main method of starting compact fluorescent lamps.

- **trigger-start** ballasts operate preheat lamps without starters by operating the lamps as if they were rapid-start lamps.

Any of these starting systems needs to have a grounded surface near the entire length of the tube. This provides capacitive coupling between the lamp gases and ground that helps to ionize the cold gas. Without this, the starting voltage would have to overcome the resistance of the entire gas column between the electrodes.

The metal case of the fixture usually performs this function. The case needs a good ground connection to start the lamp properly. An alternative method is to install a conducting strip alongside the tube, or to give the tube a conductive transparent coating. Among lighting equipment designers, the grounded surface is called a “starting aid.”

Environmental Problems

Mercury is so well attuned to both fluorescent and HID lighting that it almost seems ordained to provide efficient lighting. Unfortunately, mercury is a serious environmental pollutant, and discarded lamps account for a large fraction of the mercury that is released into the environment. Although mercury is a necessary component of virtually all efficient lighting today, its

environmental penalty is a strong impetus for design compromises that reduce the quantity of mercury in lamps, and for development of efficient light sources that do not require mercury.

Expect that the mercury content of fluorescent lamps will make disposal increasingly difficult, and that the cost of disposal will grow to become a significant part of the cost of fluorescent lighting.

Characteristics of High-Pressure Sodium Lamps
Characteristics of Low-Pressure Sodium Lighting
Status of HID Lamp Efficiency
Status of HID Ballast Efficiency

This Reference Note explains the basics of high-intensity discharge (HID) lighting. This is a category of lighting that presently includes three distinct types of lamps:

- mercury vapor (which we will abbreviate “MV”)
- metal halide (“MH”)
- high-pressure sodium (“HPS”).

There are large differences in efficiency, color rendering, and other important characteristics within this category of lighting. Understanding the factors that cause these differences is essential for selecting HID lamps and the accessories that they need to operate.

An HID lamp of any type must be operated with a ballast, as with fluorescent lighting. All three types are installed in similar fixtures. Figure 1 shows a typical example.

Another type of lighting, low-pressure sodium (“LPS”), is similar in physical characteristics to HID lighting. It is made by manufacturers of HID lighting, and is usually cataloged with HID equipment. For these reasons, we will cover it here also.

How HID Lighting Works

The basic physical processes in HID lighting are similar to the first stage of fluorescent lighting, which is the emission of light from a mercury vapor. See [Reference Note 55](#), Fluorescent Lighting, for details of that process.

Like fluorescent lamps, HID lamps use an excited metal vapor as the main source of light. Beyond that similarity, the two types are different in the way that they produce light. The difference starts with the pressure of the vapor. The pressure of the metal vapors in HID lamps is thousands of times higher than the pressure of the mercury vapor in fluorescent lamps. Mercury vapor and metal halide lamps operate at a pressure of several atmospheres. High-pressure sodium lamps operate around one tenth of atmospheric pressure.

The higher pressure of the metal vapors is achieved by operating the lamp at high temperature. The metal vapors and inert gases are heated by using a relatively high current inside an arc tube that is kept small to

concentrate the heat. By the same token, the high density of atoms in HID lamps allows the higher current.

The light output of HID lamps is very intense in relation to the size of the lamp. In fact, the name “high-intensity discharge” originally was intended to distinguish these lamps from fluorescent lamps, which are discharge lamps that produce light at low intensity in relation to their surface area. The light-emitting region of an HID lamp is so small that the lamp can be used in focussing fixtures, like incandescent lamps.

The intense excitation of the gases results in a spectrum of light output that is mostly at visible wavelengths. This is a major difference from fluorescent lamps. In fluorescent lamps, most light emitted by the mercury vapor is in the ultraviolet region, so a phosphor is needed to convert the ultraviolet light to visible light.

Even so, some HID lamps use phosphors. These are used primarily to broaden the color spectrum, and to shift some of the light emission from the vapor toward the red end of the visible spectrum. They may also convert unwanted ultraviolet radiation to visible light.

HID lamps contain inert gases in addition to the metal vapors. The inert gases aid starting, in the same way as in fluorescent lamps. The inert gases are also used to control the electrical characteristics of the arc, which affect wattage and efficiency.

HID lamps do not need inert gases to serve as “buffer” gases, which are used in fluorescent lamps to shorten the average path of electrons between collisions. The high density of the metal vapors makes this function unnecessary.

HID Lamp Construction

HID lamps have a small inner arc tube that contains one or more metal vapors, plus inert gases. The arc tube is generally cylindrical, and it has electrodes at each end. The arc tube is made of materials, such as fused quartz or alumina, that withstand the high operating temperature and the chemical activity of the metal vapors.

Figures 2, 3, and 4 show the parts of each type of lamp. Figure 5 shows the parts of a low-pressure sodium lamp.

Ruud Lighting, Inc.

Fig. 1 Typical HID light fixture The ballast is in the upper left compartment. The capacitor and ignitor (if any) are in the other compartment. The two compartments are separated by an air space to isolate the heat of the ballast. The slot and set screw allow the height of the lamp socket to be changed, as a means of adjusting the light distribution pattern. The reflector should be made of glass if any light is intended to pass through it. Plastic diffusers are darkened by the ultraviolet light and heat of HID lamps.

Fig. 4 High-pressure sodium lamp

Osram Sylvania Inc.

Fig. 5 Low-pressure sodium lamp

HID lamps do not use filaments to heat the electrodes. Electrode heating is accomplished entirely by the impact of ions and electrons on the electrodes.

Most HID lamps for general lighting have an outer glass shell, which has several important functions:

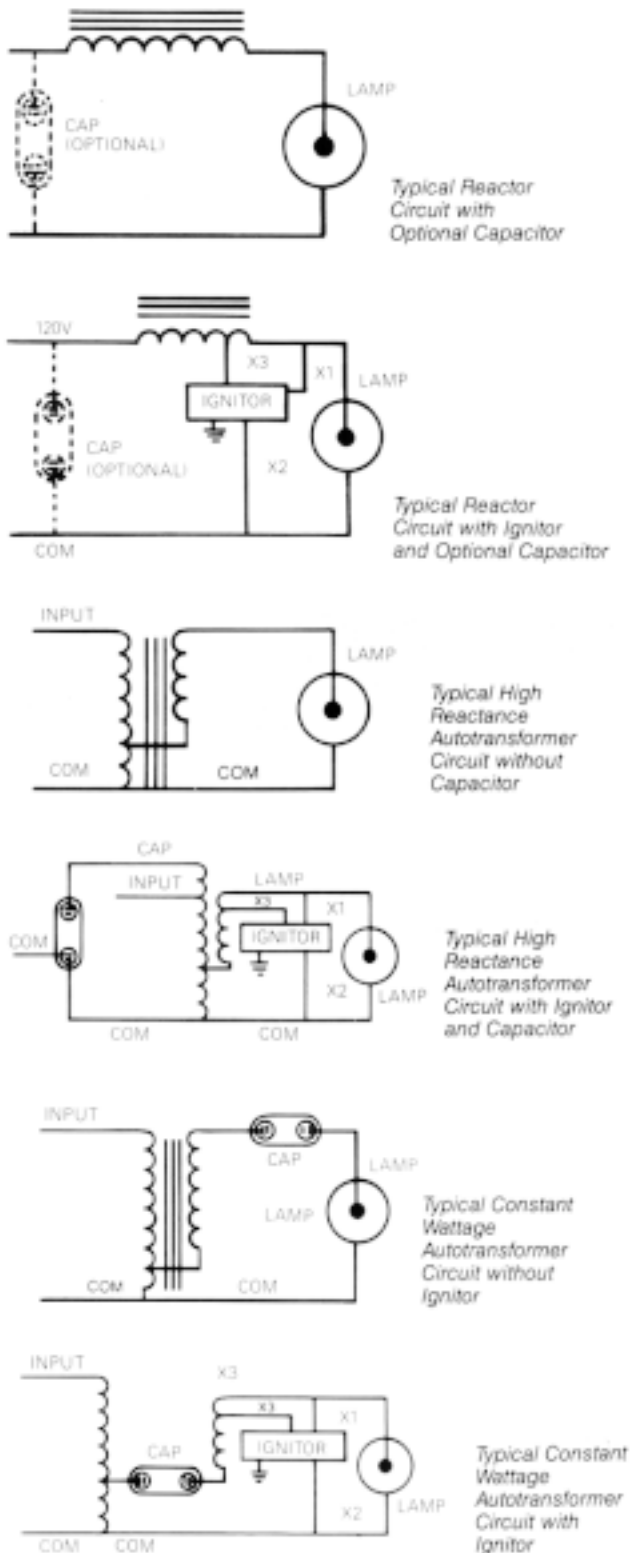

Fig. 6 HID ballasts

Philips Lighting

- ***maintaining high temperature.*** The outer shell reduces heat loss by convection and radiation, and allows the lamp to operate properly over a wide range of ambient temperatures. The entire arc tube surface must be kept warm, because the density of the metal vapor is determined by the coolest point on the surface.
- ***physical protection.*** The glass bulb protects the fragile components outside the arc tube, including the supports for the arc tube, the electrode connections, and perhaps a starting resistor. The outer bulb also keeps the arc tube clean. Dirt on the arc tube might absorb enough heat to shatter the tube. The bulb generally is filled with an inert gas to prevent corrosion of the hot components.
- ***holding phosphors.*** In lamps that have phosphors, the phosphors are coated on the inside of the outer shell. Phosphors could not tolerate the high temperature of the inner capsule.
- ***blocking ultraviolet.*** The light from mercury vapor and metal halide lamps contains a large amount of ultraviolet, which is dangerous to skin and eyes. Ultraviolet also bleaches fabrics and other organic materials, and it may cause other damage. The heat resistant material of the arc tube is transparent to ultraviolet, so the outer bulb is needed to block it.

HID lamps can operate even if the outer shell breaks away, which eliminates the protection against ultraviolet radiation. As a safety feature, some lamps have a fuse link that burns out when envelope breakage brings the link into contact with air. Some specialty lamps lack an outer bulb, so they must be installed in fixtures that include an ultraviolet filter.

HID Ballasts

As in fluorescent lamps, the arc inside an HID is an electrical short circuit. Therefore, the lamp needs a ballast to limit current. In addition, most HID lamps need a ballast that acts as a transformer to provide increased voltage for starting. Figure 6 shows the types of ballasts that are presently used in HID lighting.

If an HID lamp needs a ballast only for regulating current, the ballast may consist of nothing more than an inductor (coil) in series with the lamp. This type of ballast is called a “reactor” ballast. It is the usual type for small HID lamps.

If the lamp needs a voltage that is higher than the line voltage, the ballast is wired as a transformer. This type of ballast has the advantage that fluctuations in line voltage affect the power delivered to the lamp much less than with reactor ballasts. For this reason, ballasts of the transformer type are called “constant wattage” (CW), if they have a transformer with a completely isolated secondary winding, or “constant wattage autotransformer” (CWA), if they use an autotransformer.

CWA ballasts are presently the most common type for medium and large lamps.

Magnetic ballasts have low power factor because they are inductive devices. The power factor can be improved simply by adding a capacitor to the ballast circuit. The power factor can be improved as much as desired, up to 100%.

If a power factor correction capacitor is installed in a reactor ballast, it draws high current if the secondary is disconnected, as when the lamp fails. As a result, this type of ballast allows fewer lamps of a given wattage to be installed on a circuit. A model recently introduced solves this problem by disconnecting the capacitor when the lamp fails.

HID Lamps that Do Not Need Ballasts

An unusual type of HID lamp does not require an external ballast. Lamps of this type use an internal tungsten filament as a resistor to limit current. These lamps can be used as direct replacements for incandescent lamps, but they are no more efficient than incandescent lamps of comparable wattage. Their only advantage is longer life compared to incandescent lamps. Much more efficient alternatives to incandescent lighting are available, so we will say nothing more about them.

Ignitors

With most high-pressure sodium lamps and some low-wattage metal halide lamps, the starting voltage is so much higher than the operating voltage that it does not make sense to design the ballast to start the lamp. With these lamps, a small electronic device called an “ignitor” or “starter” generates high voltage pulses for starting. The ignitor may be a separately replaceable component, or it may be part of the ballast package.

Characteristics of Mercury Vapor Lamps

In a warmed-up mercury vapor lamp, almost all the light is emitted by excited mercury atoms. Unlike fluorescent lamps, most of this radiation is in the visible spectrum. This is because the mercury atoms are hit by electrons so frequently that they are likely to be excited to progressively higher states before they can relax to their lowest state. Mercury tends to relax from its higher energy levels in stages, so the energy of the emitted light is lower and the wavelengths are longer.

Mercury vapor lamps are the least efficient type of HID lamp. They are substantially less efficient than conventional fluorescent lamps.

The color rendering of uncoated mercury vapor lamps is poor, most of the light being concentrated in a few narrow wavelength bands. Clear mercury vapor lamps emit a blue-green light, and they make colors in illuminated objects look muddy. Figure 7 shows the typical spectrum of a mercury vapor lamp.

Mercury vapor lamps may use phosphors to improve color. Usually, the phosphors are selected to create one or more bands of wavelengths in the normally unoccupied red end of the mercury spectrum.

Argon is the usual starting gas for mercury vapor lamps, as in fluorescent lamps. Most mercury vapor lamps have a single starting electrode that is close to one of the main electrodes. The starting electrode is connected to the opposite main electrode through a resistor. Once the lamp starts to operate normally, the low resistance of the arc short-circuits the starting resistor, so little current continues to flow through the starting electrode.

Mercury vapor lamps suffer serious lumen degradation, as shown in Figure 10. Some lamps eventually lose half their light output. Lumen loss occurs most rapidly in the early part of the life cycle.

If a mercury vapor lamp is turned off, it cannot be restarted for several minutes. The reason is that the un-ionized hot mercury vapor is so dense that it prevents the available voltage from ionizing the vapor.

The mounting position of the lamp affects its operation to some extent. Best efficiency is achieved if the arc tube is oriented vertically, which keeps the arc in the center of the arc tube. Some mercury vapor lamps are designated for specific mounting positions.

Characteristics of Metal Halide Lamps

Metal halide lamps evolved from mercury vapor lamps. Their major improvement is using a variety of metal vapors, rather than mercury vapor alone. Some of the selected metals produce light more efficiently than mercury, which improves the overall efficiency of the lamp. Each of the metal vapors produces a different variety of colors, so that the sparse color spectrum of a mercury vapor lamp expands to a thicket of many color bands. Figure 8 shows the light spectrum of a typical clear metal halide lamp.

Metal halide lamps may use phosphors to provide a more uniform color spectrum. Phosphors incur a small efficiency penalty.

The term “metal halide” is used because the additional metals are introduced as compounds with some of the halogen elements (fluorine, chlorine, bromine, or iodine). Iodine is the usual halogen that is used. A combination of sodium, scandium, and lithium halides is common, along with the necessary mercury. Another common combination is holmium, thulium, and dysprosium halides, along with the mercury.

Compounding the metals with a halogen is necessary to vaporize them at the lamp operating temperatures. Also, some of the metals would attack the arc tube materials in their elemental form. In the hot arc, the halide compound breaks down and the excited metal atoms emit light. If the pure metal wanders out of the

arc, it recombines with the halogen before it can cause trouble.

Unfortunately, metal halide lamps are not interchangeable with mercury vapor lamps, except in some small sizes. Argon is used for starting, as with mercury vapor lamps, but the starting voltage is higher in relation to the current. This requires a different ballast. Smaller metal halide lamps have arc tubes that are too small to accommodate starting electrodes, so they require ignitors for starting.

Exceptionally high temperature is needed to break down the metal halide compounds in the arc. This creates a number of disadvantages for metal halide lamps:

- the emissive material evaporates more quickly from the electrodes, so lamp life is only about half as long as for mercury vapor and high-pressure sodium lamps
- restarting a hot lamp requires an exceptionally long time
- the high operating temperature (about 1750°F, or 950°C) and pressure of the arc tube pose an explosion hazard. This makes it prudent to install metal halide lamps in special fixtures that can contain the hot fragments of an exploding arc tube. Metal halide lamps typically suffer somewhat less lumen degradation than mercury vapor lamps. However, they may still lose over a third of their output before failing, as shown in Figure 11. As

with mercury vapor lamps, the lumen loss increases most rapidly in the early part of the life cycle.

Metal halide lamps are especially sensitive to mounting position. Efficiency suffers and color changes if the arc comes in contact with the wall of the arc tube by convection. Some lamps have bimetal switches for their starting electrodes that require the right mounting position to operate reliably. The allowable mounting positions for metal halide lamps are usually coded into the lamp designation. Figure 13 charts the loss of light output from a typical metal halide lamp at various mounting angles.

Characteristics of High-Pressure Sodium Lamps

As the name implies, high-pressure sodium lamps use sodium as the main light emitting element. Unlike mercury, the first excited state of sodium lies almost in the middle of the visible spectrum. The high density and temperature of the lamp do not strongly excite the sodium atoms to higher energy levels, but randomly alter the first excited level. This causes the light to be emitted over a broad, continuous spectrum of visible wavelengths. This spectrum is skewed toward the red. The lamp itself looks very orange, but the illumination may not seem unbalanced to the naked eye. Figure 9 shows the spectrum of a typical lamp.

High-pressure operation reduces lamp efficiency because the atoms do not dissipate all their collision energy in the form of light, and because a certain amount of light is shifted out of the visible spectrum. Ironically,

Fig. 7 Spectrum of a clear mercury vapor lamp Virtually all the light output is restricted to these five narrow bands of wavelengths. Any colors in a scene that are not contained in these bands will disappear.

Osram Sylvania Inc.

Osram Sylvania Inc.

Fig. 8 Spectrum of a clear metal halide lamp This large number of broad bands come from a combination of metal vapors. Together, they provide much more coverage of the visible spectrum than mercury vapor. At least some light is provided at all visible wavelengths. The red end of the spectrum has somewhat less illumination than the rest.

Osram Sylvania Inc.

Fig. 9 Spectrum of a high-pressure sodium lamp Most of this spectrum is expanded from a narrow band of wavelengths that occurs in low-pressure sodium at 589 nanometers. Making the sodium vapor hot and dense causes collisions among the sodium atoms, which randomly distort the emission wavelengths. This wastes some energy as heat and as light outside the visible spectrum. The lamp can be designed for different pressures, changing the spectrum and the compromise between color rendering and energy efficiency.

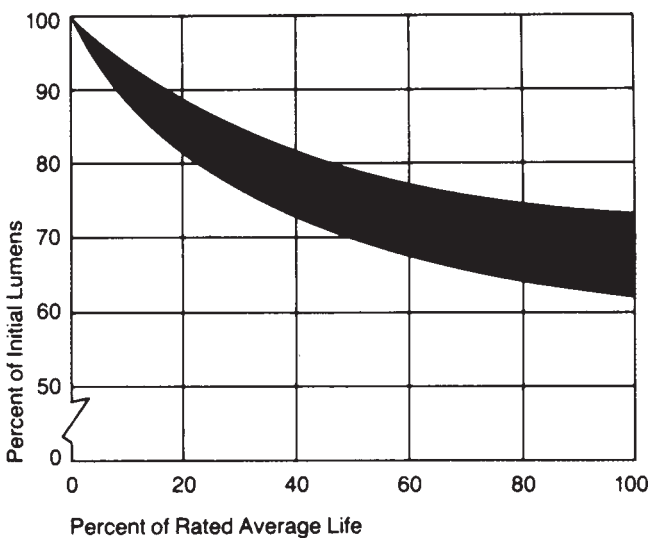

Philips Lighting

Fig. 10 Lumen degradation of mercury vapor lamps

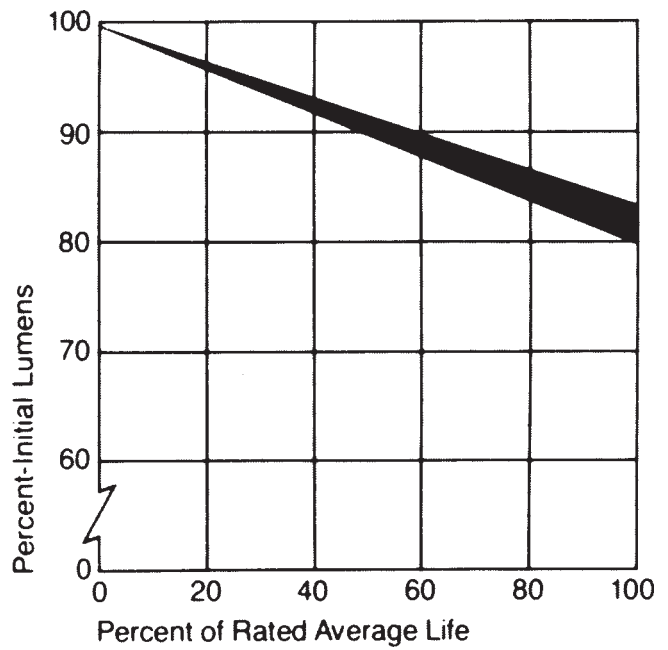

light output near the original sodium wavelength is blocked because the dense un-ionized gas surrounding the arc absorbs light strongly at this wavelength. By changing the vapor pressure, the manufacturer can adjust the compromise between efficiency and color rendering over a wide range.

Lumen degradation is less severe with HPS lamps than with the other two types. Typically, light output falls by 20% or less by the end of service life. Unlike the other two types, the rate of light loss remains steady

Philips Lighting

Fig. 11 Lumen degradation of metal halide lamps

Philips Lighting

Fig. 12 Lumen degradation of high-pressure sodium lamps

throughout life, which results in a higher average light output. See Figure 12.

Most HPS lamps require an ignitor in addition to the ballast. Such lamps usually use xenon as a starting gas. Some HPS lamps avoid the ignitor and achieve a lower starting voltage by using argon and neon together as starting gases. These lamps can be used to replace mercury vapor lamps without changing ballasts, but they are not as efficient as lamps designed to use ignitors.

HPS lamps use much less mercury than the other two types of HID lamps. As a result, they have virtually no ultraviolet emission.

Most HPS lamps are not sensitive to mounting position.

Philips Lighting

Fig. 13 Loss of light output caused by mounting position This is for a typical metal halide lamp.

Characteristics of Low-Pressure Sodium Lighting

As the name implies, the main physical difference between low-pressure sodium lighting and high-pressure sodium lighting is the pressure of the sodium vapor in the lamp. LPS is optimized for lumens-per-watt efficacy, but sacrifices output and color rendering to achieve it.

At very low pressure and density, excited sodium vapor emits a large fraction of its energy at one wavelength in the middle of the visible spectrum near 589 nanometers. (Actually, there are two very closely spaced wavelengths.) LPS lamps have very high lumen-per-watt efficiency for three reasons: (1) the high efficiency of light emission, (2) the absence of wasteful conversion processes, and (3) the fact that the wavelength of sodium emission falls in the most sensitive range of human vision.

LPS lamps have achieved an efficacy of 300 lumens/watt in the laboratory, and some commercial lamps claim 180 lumens/watt. (The theoretical maximum efficacy for a white light source is about 220 lumens/watt, which demonstrates that the high efficacy of LPS lamps is achieved partly at the cost of color rendering.)

The operating temperature of the lamp is critical to efficiency because it determines the pressure of the sodium vapor. The optimum temperature is about 500°F (260°C). To maintain this temperature, the lamp has an outer bulb and internal heat reflecting films to concentrate the lamp's waste heat. These features are needed because the current density in LPS lamps is low, so they need fairly large surface areas to produce much light. The large surface area invites heat loss, and it makes the lamp vulnerable to changes in ambient temperature. As a result, LPS lamps operate much of the time at efficacies that are lower than advertised.

Smaller LPS lamps are started by high voltage from a transformer ballast. Some larger lamps have preheat electrodes. In most LPS lamps, a mixture of 99% neon and 1% argon is used as a buffer and starting gas. This combination is used to exploit the same type of energy exchange between the excited states of argon and mercury vapor that is exploited in HID lamps. Helium, xenon, and other gases may also be included to optimize efficiency.

In LPS lamps of lower wattage, the inner arc tube is usually bent in the shape of a hairpin, which allows both electrode connections to be made at one end of the tube. Larger lamps have electrodes at opposite ends.

Because of their specific ballast requirements and unusual lamp sockets, low-pressure sodium lamps are not interchangeable with other lamp types.

Low-pressure sodium lamps require an exceptionally long time to reach full output, up to 15 minutes. This is because the cold sodium metal is being vaporized by a heat source of relatively low intensity. A hot lamp usually restarts immediately, but don't depend on it.

Table 1. TYPICAL H.I.D. LAMP EFFICACIES

	70+	P		125	

NOTES:

- The figures do not include ballast losses.
- "C" indicates clear lamps.
- "P" indicates phosphor coated lamps.

The crippling disadvantage of LPS lighting is its poor color rendering. In fact, if a Color Rendering Index is listed at all for an LPS lamp, it may be zero! People dislike LPS road and parking lot lighting because it makes the world look black-and-white. It is difficult to visualize applications for which LPS is the best choice. In the past, it was used too much for general lighting, and it is now being used less.

Status of HID Lamp Efficiency

There is a wide range of efficiencies among HID lamps. As with other types of lamps, efficiency is called "efficacy" when expressed in terms of lumens per watt. HID and LPS lamps have the following ranges of efficacy, which are compared with the range for fluorescent lamps:

mercury vapor	35 - 65
metal halide	70 - 130
high-pressure sodium	50 - 150
low-pressure sodium	100 - 190
fluorescent	30 - 95

Note that these figures do not include ballast losses. Ballast losses are large in contemporary HID lighting, and they vary considerably with lamp size and type, as discussed next.

This simple listing may be misleading because the higher HID efficacies are available only in very large lamps with poor color rendering. Table 1 displays the relationship between efficacy, color rendering (expressed by the "color rendering index", CRI), and wattage for some typical HID lamps used in general lighting.

Status of HID Ballast Efficiency

As of the mid-1990's, virtually all HID ballasts produced by major manufacturers are the old magnetic type. Some versions of magnetic ballasts with improved efficiency are entering the market. In general, ballast efficiency rises dramatically with increased lamp wattage. Stated differently, the efficiency of ballasts for smaller lamps is relatively poor, so they dissipate a substantial fraction of lighting power. Table 2 displays typical ballast losses as a percentage of lamp wattage, calculated from the listings of a major ballast manufacturer.

Table 2 shows that there is considerable room for improvement, even with the old magnetic technology. There is no doubt that adoption of electronic ballast

Table 2.

* The figures with asterisks are for high-power-factor reactor ballasts. The other ballasts are CWA units.

technology similar to that now used in fluorescent lighting could offer even greater improvements.

This beckoning market for better HID ballasts will undoubtedly attract manufacturers, so shop around. But, beware. Remember the years of trouble that beset the first electronic fluorescent ballasts. High-efficiency magnetic ballasts are a safer bet for the time being.

The U.S. National Energy Policy Act of 1992 calls for vaguely defined improvements in HID efficiency, but any improvements will not become mandatory until 1999, if at all. This indicates that the industry has not yet decided how to go about making major improvements in HID efficiency.

Most energy losses occur in the winding and the steel core, not in the capacitor or ignitor, so efficiency is not a factor in selecting the latter components (when they are separate from the ballast).

Light Distribution Patterns of Fixtures

Distribution Patterns of Common Fixture Types
Effect of Lamps on Distribution Pattern
General Geometrical Principles

In order to position fixtures rationally, you need to know how the fixtures distribute their light. Light fixtures differ greatly in their light distribution patterns. This Note points out the factors to consider.

Distribution Patterns of Common Fixture Types

The light distribution patterns of many types of fixtures are illustrated in a table in the *IESNA Lighting Handbook*. The table displays most of the common types of fluorescent and HID fixtures.

The table in the *IESNA Handbook* covers only a sampling of incandescent fixture types. The range of incandescent fixture designs is too vast to be covered by any listing, and each design distributes light differently with different types of lamps.

For non-symmetrical fixtures, the *IESNA Handbook* shows the light distribution in two directions, parallel and perpendicular to the long axis of the fixture. The differences in these two patterns should caution you that the orientation of a fixture is important.

The light distribution pattern depends on the distance from the fixture. At distances less than several times the longest dimension of the fixture, the actual pattern may differ substantially from the patterns shown in the *IESNA Handbook*. Light distribution becomes more uniform closer to the fixture, especially if the fixture has a large surface area.

Effect of Lamps on Distribution Pattern

Fluorescent and HID fixtures integrate the lamp's light distribution pattern into the design of the fixture. Therefore, the published light distribution pattern for the fixture tells you all you need to know. Usually, all the lamps that fit a particular fixture will produce the same light distribution pattern.

The opposite is true with incandescent lamps. Their light distribution patterns may vary radically, depending on the filament design, the use of frosting on the bulb, and the use of reflective surfaces built into the lamp. Since different types and wattages of incandescent lamps are interchangeable in fixtures that use common types of sockets, it is your job to select the most efficient type of lamp for the fixture. This is a continuing problem, because incandescent lamps must be replaced continually. See [Measure 9.1.3](#) for details.

Effect of Diffusers
How to Measure Distribution Patterns

General Geometrical Principles

For light sources that are elongated, the laws of geometry require that light is emitted most intensely in a direction perpendicular to the longer axis. A bare fluorescent tube is an extreme example. At a distance several times the length of the tube, its light distribution pattern is shaped like a doughnut surrounding the tube, i.e., the light is emitted most intensely perpendicular to the axis of the tube, and little light is emitted along the axis of the tube. Size is not a factor here. The same pattern applies to a straight lamp filament.

Any significantly unsymmetrical light source, such as a 2-tube fluorescent fixture with a wraparound diffuser, has a significantly unsymmetrical light distribution pattern. Exploit this when moving fixtures around. For example, if fluorescent fixtures are used to illuminate corridors, traffic lanes, tunnels, and other narrow spaces, light is distributed much more uniformly if the fixtures are turned perpendicular to the length of the space. The improved light distribution may allow the number of tubes to be reduced by half or more.

At the same time, distributing the light along the length of the space may produce intense source glare if you are not careful. This is because a viewer looking down the narrow space sees all the fixtures at maximum intensity. You can minimize this problem by using fixtures that block light emission along the line of sight, or by installing baffles near the fixtures.

Similarly, if a single oblong fixture illuminates a desk, turning the fixture so that its long side faces the desk increases the illumination level. It also reduces annoying shadows on the desk.

The rules of geometry apply to light sources of any size. The filaments in incandescent light bulbs have strongly unsymmetrical light distribution patterns, which makes it important to select bulbs for the type and orientation of the fixture. See [Measure 9.1.3](#) for details of selecting incandescent lamps.

Effect of Diffusers

Diffusers radically alter the light distribution pattern of a fixture. In fact, the diffuser may have a greater effect on the light distribution pattern than any other aspect of the fixture. Expect unusual light distribution patterns from fixtures with fresnel lenses, shielding

vanes, embossed plastic diffusers, egg crate grilles, etc. When purchasing new fixtures, ask the manufacturer for the light distribution patterns before you do the lighting layout.

How to Measure Distribution Patterns

You can measure the light distribution patterns of installed fixtures by using an ordinary light meter to make a plot. Select a representative fixture that is far away from a wall, disconnect all nearby fixtures, and eliminate daylight. After the lamps are warmed up, measure illumination intensities at the working height,

keeping the light meter aimed straight up. (If the fixture is intended to illuminate surfaces that are not horizontal, orient the light meter perpendicular to the illuminated surface.) Make one traverse along the long axis of the fixture, and another perpendicular to the long axis. The results may not meet scientific standards of accuracy, but they will be good enough to guide you in making improvements.

The next step is to measure the effect of overlapping patterns of adjacent fixtures. To do this, simply repeat the measurements with all the fixtures turned on.

DISCLAIMER & WARNING

In these times of declining personal responsibility, it has become common for people who make mistakes or suffer injuries to seek someone else to blame. A legal system that feeds this impulse has made it advisable to warn against even the most absurd misuse of products, such as warning users of windows not to fall out of them. In this climate, it has even become advisable for publishers to warn readers that the information contained in books is not perfect and complete.

The *Energy Efficiency Manual* includes suggestions for your consideration. Energy efficiency is still evolving, and many of the concepts have not been tested extensively. The suggestions are based on the knowledge of the author, who does not claim to have complete or perfect knowledge of each topic. This book is not intended to be your sole source of information about any activity. Neither the author nor the publisher can guarantee the accuracy of any information provided.

Many energy conservation activities involve the risks of pioneering. For this reason, we start the book with "The Right Way to Do Energy Conservation." It is a major objective of the *Energy Efficiency Manual* to indicate the potential reliability of each activity, but risks of failure vary with the circumstances of the application and with the skills of the people who do the work. Furthermore, it is impossible to foresee all the conditions that may occur.

Energy efficiency often involves situations that have safety implications or the potential for consequential damage. It is not a purpose of the *Energy Efficiency Manual* to deal with such issues. Safety may be mentioned, but only as an issue that is peripheral to the primary issue of energy efficiency. The ways in which a party may suffer injury are legion, and unpredictable in general. The author and publisher of this book specifically disclaim any liability for damages or injuries that may occur. Again, it remains the responsibility of the reader to select the necessary personnel and equipment to accomplish any activities effectively and safely.

We caution the reader that the *Energy Efficiency Manual* is not an engineering, architectural, or contract document. Where expert or specialized services are required, it is essential for the work to be planned and performed by appropriately qualified practitioners.

The author and later readers will be grateful for any suggestions and for identification of any errors. Please address them to the publisher.

Notice Regarding Patented Devices, Systems, or Concepts

Many of the ideas presented in this book are unusual, or even novel. It is conceivable that some of the concepts may be covered by patents. It is the responsibility of the user to avoid infringing any patent rights that may exist.
