Because of the effect of air velocity, check for stratification across the full range of damper settings and fan speeds. The stratification pattern may change considerably if the ratio of outside air to return air changes. Variations are greatest where an economizer cycle is used, because the outside air flow may vary from a small percentage of system flow to 100% of system flow.

How to Minimize Stratification

Because air is viscous, it takes energy to mix two air streams. To keep from wasting energy when you correct stratification, remember your objective. You are trying to avoid freezing, control, and comfort problems, not to achieve perfect mixing for its own sake. You can reduce stratification in a variety of ways, which we will discuss here. In most air handling systems, you will use more than one of these methods. Try to create no more turbulence in the air stream than necessary, because turbulence wastes fan energy. Furthermore, the wasted energy appears as heat in the air stream, which increases the cooling load. Choose a method, or a combination of methods, that will limit stratification sufficiently under all conditions, from minimum to maximum outside air intake, and from minimum to maximum supply air flow.

■ Exploit the Mixing Action of Fans

If a fan has only a single inlet, it acts as an effective mixer, virtually eliminating stratification in the discharge path. However, the supply fan is usually located downstream of the coils, so it cannot remedy troublesome stratification that occurs ahead of the coils, where outside air enters alongside the return air.

The main exception is multizone units, where the fan is almost always located ahead of the coils.

If a fan has a double inlet, it may fail to eliminate stratification. This occurs if colder air enters through one side of the fan wheel, and warmer air enters through the other. The flow may still be separated in the fan discharge. The stratification may continue through the supply duct system, with warmer air going to one side and cooler air to the other.

■ Install Preheat Coils for Outside Air

Preheat coils do not eliminate stratification, but they reduce its effects by reducing the temperature difference between the air streams. Preheat coils do not increase the fan power requirement, and they may even reduce it. See [Measure 4.2.10](#) for more about them.

■ Design the Front End Duct Routing to Reduce Stratification

Experienced designers minimize stratification by using a number of tricks in laying out the front end of an air handling systems. Here they are:

- **make the passage leading to the outside air damper larger than the damper itself.** This causes the outside air to enter the damper at low velocity. Otherwise, the outside air flow could be concentrated through one part of the damper, creating a more concentrated stream of cold air in the air handling unit. (See [Measure 4.2.9](#) about other improvements to outside air intakes.)
- **make the outside air damper as small as possible.** Injecting a small stream of cold outside air into a larger stream of warm return air reduces the chance that a large amount of undiluted cold air will reach the coils. Keeping the outside air damper small also minimizes air leakage into the system when it is turned off. Size the outside air damper for no more than the maximum amount of outside air that may be required. If the system uses an economizer cycle (see [Measure 4.2.5](#) about this), the outside air damper must be large enough to provide the entire system air flow. Even in that case, the outside air damper should be no larger than the mixed air damper.

- **inject the outside air into the return air at right angles.** You don't want the two air streams to join smoothly at the front end of an air handling system. Instead, you want the outside air stream to crash into the return air stream, so that the inertia of the outside air carries it into the return air stream. Do not use parallel-blade dampers in the front end of the air handling system. They act as turning vanes, maintaining stratification around a bend. Opposed-blade dampers tend to aim the air flow into the crossing air stream, producing the desired result. In fact, they act as nozzles when they are in a partially closed position.
- **mix the outside air and return air, and then make them turn into the air handling unit together.** The basic idea is to avoid a situation in which one of the air streams can shoot directly into the air handling unit without mixing with the other air stream. Mixing occurs downstream of bends because the bends create turbulence. For most effective mixing, arrange for the outside air to merge with the return air in a direction perpendicular to the plane of turn that the mixed air makes into the air handling unit. For example, feed outside air downward into the return air, then have the mixed air turn horizontally into the air handling unit.
- **locate the last bend at some distance ahead of the filters.** Turbulence occurs downstream of a bend. Give the turbulence sufficient distance to work before the air enters the coil filters. This is because the filters damp out the turbulence and stop the mixing inside the air stream.

Fig. 2 Reducing stratification by clever damper arrangement This air handling system has an economizer cycle, which requires a wide range of outside air flow rates. When the economizer is not operating, it uses tight dampers to block most of the outside air intake area. The dampers needed to satisfy the lowest outside air flow rates are located closest to the return air stream, and they are oriented to create the greatest mixing. See Figure 2 in [Measure 4.2.2](#) for a photograph of this damper installation.

M&I Heat Transfer Products

All this being said, don't expect the front end duct configuration to completely eliminate stratification, no matter how cleverly you design it. A stratified air stream can turn many corners without mixing entirely. If the outside air can become very cold, you will need to combine good front end duct design with one or more of the other methods given here.

■ Select Outside Air Dampers that Create Turbulence

In contemporary practice, most control dampers used in the front ends of air handling systems are of the opposed-blade type. These dampers do not tend to mix the air stream. As they close, they shed sheets of turbulence that flow downstream from each blade. These thin sheets of turbulence do not mix air across the air stream. Opposed-blade dampers also tend to be leaky, wasting energy and allowing freeze problems when the system is shut down during cold weather. You can avoid both of these limitations by using the type of tightly closing outside air dampers described in [Measure 4.2.2](#). These dampers create larger, more penetrating vortices than opposed-blade dampers.

Tight-shutoff dampers are effective for the outside air and relief air paths, where it is important to have tight closing. Use opposed-blade dampers in the mixed-air path, because their good control characteristics and lower turbulence are important there.

Tight-closing dampers are designed primarily to block leakage when they are closed. They are not designed to function well as control dampers, modulating flow. To use this type of damper for controlling outside air over a wide range of flow, you need to install an array of individual dampers, as we discuss next.

Blender Products, Inc.

Fig. 3 Using mixing vanes to minimize stratification An air mixing device is installed so that both air streams must pass through it. Compare this to Figure 1.

■ Group the Dampers to Minimize Stratification

If the amount of outside air varies over a wide range, arrange all three sets of dampers in groups so that individual damper blades are either fully closed or fully open. This technique is especially valuable with air handling systems that have economizer cycles. When the economizer cycle is operating, a large fraction of the outside air intake area may be open, whereas the outside air dampers are mostly closed the rest of the time.

The mixed air dampers are grouped in the same way. Arrange the opening sequence of the dampers so that the open blades of the outside air damper and the open blades of the mixed air damper are on the same side of the inlet passage. See Figure 2. In this way, the outside air is guided into collision with the return air.

■ Install Mixing Vanes

A compact, effective method of reducing stratification is to install mixing vanes inside the air handling unit, as shown in Figure 3. The basic idea is to create a swirl in the mixed air passage, so that a portion of one air stream is rotated into the other.

At least one company makes patented prefabricated swirling devices that are inserted into air handling systems, across the entire area of flow. Figure 4 shows one of these units. The vanes in this device create one swirling air stream inside another, with the two streams rotating in opposite directions. This creates a strong mixing action. Furthermore, any remaining temperature differences in the mixed air stream are distributed across the face of the coil.

A less effective method is to attach vanes to the sides of the duct. As with other mechanical methods of mixing

Blender Products, Inc.

Fig. 4 Air mixing device This set of vanes creates one swirling air stream inside another, the two rotating in opposite directions. The mixing action is strong, and the swirling motion distributes any remaining temperature differences across the face of the coil.

air streams, mixing vanes must be matched to the geometry of the duct and coil configuration.

Mixing vanes increase flow resistance. However, if a mixing vane is designed efficiently, it will create less flow resistance in relation to the degree of mixing than any other method of mixing. In most cases, the resistance of mixing vanes is lower than the resistance of a coil or a dirty filter. Still, make sure that you have enough fan power to compensate for this. Manufacturers of prefabricated air blending devices can probably tell you how much increased resistance to expect.

The most reliable approach is to use a mixing device that covers the entire area of flow. Especially at lower air velocities, a fraction of the air will not be affected by vanes that cover only part of the passage.

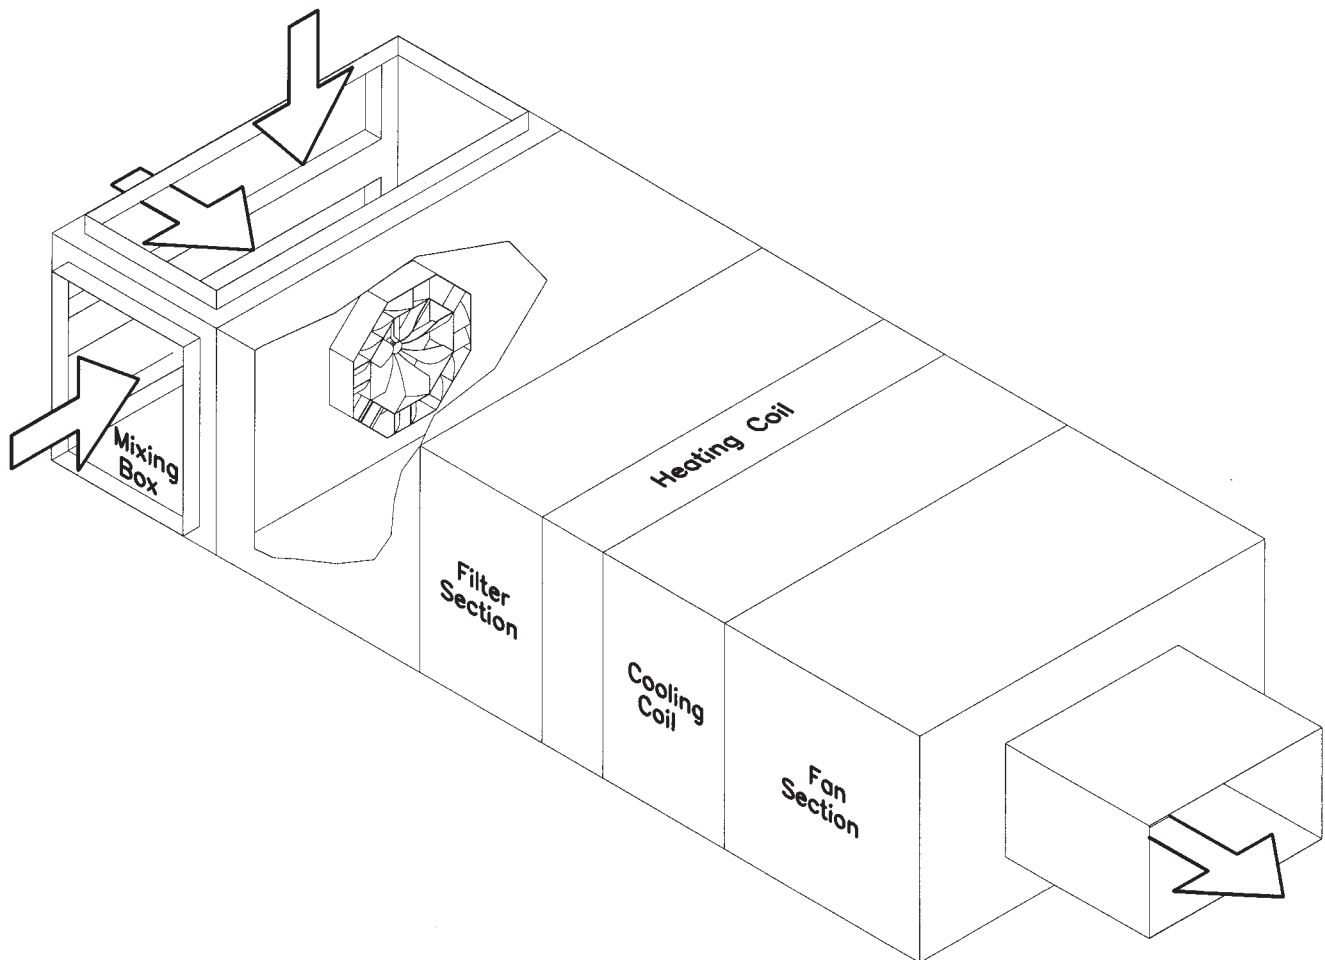

There is another tricky factor with air mixing devices. Try to use only one, as shown in Figure 5. If you use more than one, a large amount of stratification may remain. For example, consider an installation of two mixing devices of the type shown in Figure 4. If

they are installed so that cold outside air enters one of them, and warm return air enters the other, then you will still have two air streams of greatly different temperature.

Eliminate any rotary motion of the air stream before the air enters the fan inlet, to avoid loss of fan capacity and efficiency. In most air handling units, the coil is located ahead of the fan. (This is called a “draw-through” configuration.) In this configuration, the coil acts as an effective flow straightener, so you do not have to take any additional action.

■ Avoid Baffle Plates

Baffle plates are flat plates with holes. They are placed across an air stream. They are essentially turbulence generators, creating turbulence both in front of the plate and behind it. The turbulence in front of the plate is most effective in removing stratification because different portions of the air stream are mixed as flow backs up in front of the plate. The turbulence created downstream is not useful, because it is localized to the air streams coming out of individual holes in the plate.

Blender Products, Inc.

Fig. 5 Mixing device installation The mixing device should be as large as practical, to minimize the fan power penalty. Try to use only a single mixing device, so that all the air entering the air handling unit must pass through the mixing device together. Using an array of more than one mixing device allows stratification to remain.

Baffle plates are inefficient because they create too much flow resistance as the price of the mixing they provide. They are often a desperation measure employed in lieu of adequate thought.

(A coil acts as a baffle plate if the velocity of the air entering the coil is too high. Avoiding turbulence that results from high entry velocity is the main reason why coils are installed on the suction side of fans whenever possible.)

Do not confuse baffle plates with flow straighteners, which have the opposite effect. Flow straighteners are intended to make flow uniform. They typically are used in HVAC systems to provide greater accuracy of air flow measurements. They do not add much resistance, and they do not reduce stratification.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. Depends largely on how the system operators respond to problems caused by stratification.*

COST: *In new construction, extra sheetmetal and larger louvers for reducing stratification may add a few hundred dollars to a few thousand dollars per air handling unit. An array of tight-closing dampers costs about \$50 to*

\$100 per square foot (\$500 to \$1000 per square meter), for the equipment. Preheat coils cost thousands of dollars, depending on size and type. Prefabricated air mixing devices for air handling units cost about \$0.25 per CFM in the smallest sizes, down to about \$0.05 per CFM in large sizes.

PAYBACK PERIOD: *Several years or longer.*

TRAPS & TRICKS

RECOGNIZE PROBLEMS: *In designing new facilities, take a careful look at the front end configurations of all the air handling systems. In existing facilities, visually inspect the air mixing sections to find potential stratification problems. For clues to stratification problems, recall previous incidents of coil freezing and complaints about comfort that might be related to stratification. Use a thermometer with a remote probe to scan for stratification at times when the outside air is cold.*

CLEVERNESS: *The big challenge is to avoid stratification at all damper positions and fan speeds. Try to get good mixing without wasting too much fan power in creating turbulence.*

Single-Zone Systems

The Measures in this Subsection improve the efficiency of single-zone air handling systems. Figure 1, on the next page, shows the components of a typical single-zone air handling unit. Figures 1 and 2, in the [Section 4 Introduction](#), illustrate how single-zone systems compare to other types of air handling systems.

Single-zone systems are defined by the fact that they are controlled by a single space thermostat. They may heat or cool, or both. They may have separate heating and cooling coils, or a single coil may perform both functions. The coils may be electric, hydronic, or direct-expansion. Thermostatic control may be proportional or on-off. They may have any means of controlling outside air, humidification, and other functions.

Single-zone systems differ from room conditioning units primarily in size, in having more elaborate duct systems, and perhaps, in having more positive control of outside air intake. Their larger size often makes it economical to make design and component improvements that would not be practical with room conditioning units.

The basic single-zone system is an efficient type. The main opportunities for saving energy with single-zone systems are eliminating unnecessary conditioning and reducing fan energy consumption. The Measures in this Subsection exploit these opportunities.

INDEX OF MEASURES

4.3.1 Install placards at user controls to encourage efficient operation.

4.3.2 If conditioning cannot be turned off during unoccupied hours, install temperature setback.

4.3.3 Match fan output to the conditioning load.

4.3.3.1 Trim fan output.

4.3.3.2 Cycle the running of the fans and other air handling system equipment with the space thermostat.

4.3.3.3 Install multi-speed fan motors.

4.3.3.4 Convert the system to VAV operation.

4.3.4 Install thermostatic controls that allow space temperature to drift within comfortable limits.

4.3.4.1 Install thermostats that require manual switching between heating and cooling.

4.3.4.2 Install deadband thermostats.

4.3.4.3 Adjust or modify the coil controls to increase deadband.

Fig. 1 Typical single-zone air handling unit

MEASURE 4.3.1 Install placards at user controls to encourage efficient operation.

See Reference Note 12, Placards, for guidance in using placards to promote efficiency. This Measure relates specifically to installing placards at the controls of single-zone air handling units.

Install placards at all thermostats. Explain the thermostat settings and any other features, including fan control switches and heat/cool selector switches.

Also, install effective placards at all timeclocks and other devices that control the running of the systems. (See Measures 4.1.1 ff for these controls.)

Applications and Limitations

Thermostat placards have the greatest potential for saving energy with systems that only heat or only cool, or with systems that have separate thermostat settings for heating and cooling.

Thermostat placards are less effective with systems that maintain a fixed space temperature by using both heating and cooling. (Improving the thermostatic control efficiency of such systems is covered in Measures 4.3.4 ff.)

Energy Saving Potential

■ **Equipment Shutdown**

Placards save the most energy by motivating the operators of air handling units to turn them off when they are not needed. Turning off the air handling units reduces energy usage for these functions:

- **space conditioning.** The unit consumes energy to change space temperature and humidity. If the spaces are unoccupied, it is usually harmless to let the temperature and humidity drift within wide limits. The amount of conditioning energy that is wasted by unnecessary operation depends on the heat loss (or gain) of the space.
- **conditioning of outside air.** Most air handling units take in a considerable amount of outside air, which typically accounts for a major fraction of conditioning energy. (If the unit must run during unoccupied periods to maintain space temperature, consider turning off outside air ventilation during these periods, as recommended by Measure 4.2.1.1. If this function is controlled manually, install appropriate placards at the controls.)
- **auxiliary energy consumption.** Turning off air handling units saves the energy consumed by their fans, along with other auxiliary equipment that may be turned off, such as hydronic coil booster pumps.

SUMMARY

A basic way to save a substantial amount of energy at minimal cost. But, not as simple as it looks.

SELECTION SCORECARD

Savings Potential	\$	\$	\$

Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	

■ **Minimizing Heating and Cooling During Occupancy**

The amount of energy required for heating or cooling is roughly proportional to the temperature differential between inside and outside. Placards save energy while the system is operating by motivating occupants to reduce this temperature differential. This benefit is greatest in climates where heating or cooling is needed for a larger fraction of the year.

If occupants set the space temperature to require less conditioning, this also reduces the number of hours that the system operates. This benefit is greatest in mild climates, where the temperature hovers for long periods in a range that does not require either heating or cooling. In addition, buildings in mild climates are often poorly insulated, so they derive larger savings from a given change in the temperature differential.

(As a point of interest, the energy saving is related only to the temperature difference, not to the outside temperature itself, as long as there is a heating or cooling load. For example, lowering the heating temperature by 3°F saves the same amount of energy if the outside temperature is 0°F or 50°F.)

What the Placards Should Say

■ **Control Functions**

Ask occupants to perform all of these actions for which manual controls are available:

- turn off the unit when the space is not occupied
- set the heating temperature for the lowest comfortable setting
- set the cooling temperature for the highest comfortable setting

- turn the fan to the lowest comfortable speed
- set the fan control so that the running of the fan is controlled by the thermostat (see [Measure 4.3.3.2](#))
- turn off the outside air intake when it is not needed

■ Close Windows and Doors

If the space can lose conditioning through windows or doors, ask the occupants to keep these closed while the air handling unit is operating.

■ Identify the Space being Controlled

Each placard should say which spaces are covered by the controls, if this is not obvious. For example, the placard should say, “This thermostat controls the heating and cooling of the reception area.” Otherwise, occupants cannot associate the controls with the conditioning of their space, or they may not know if other spaces are also controlled.

■ Inform Occupants about Automatic Controls

Placards should inform occupants and staff about the operation of any automatic controls, if this might create confusion. For example, the placard should advise occupants if the air handling system will shut down automatically after a certain time. Refer to [Subsection 4.1](#) for automatic control Measures that should have placards.

■ Ask Occupants to Dress Appropriately

The way people dress has a major effect on the space temperatures they choose. Where appropriate, encourage occupants to dress warmly in cold weather, and to dress lightly in warm weather. In many environments, it is appropriate to say this on the thermostat placard.

Where to Install the Placards

Install placards adjacent to the controls that they explain. To encourage occupants to turn off conditioning at the end of the day, install another placard where occupants will see it upon leaving the space, requesting occupants to turn off the conditioning at the thermostat.

Let the Occupants Select the Space Temperatures

Don’t bother telling occupants to set specific space temperatures. This is usually not effective or desirable. Accept the fact that occupants will not make themselves uncomfortable for the sake of energy conservation.

In practice, it is impossible to maintain a stated space temperature. Room temperature varies from one part of the space to another. Even at the thermostat itself, the calibration of thermostat dials is usually crude, so the numbers on the dial are not a reliable guide.

Installing a thermometer in the space, at the thermostat or elsewhere, can serve as a check on the space temperature. However, installing thermometers usually has little influence on the thermostat setting. They may be useful for keeping the peace in spaces where the occupants disagree about the thermostat setting.

Avoid Locked Thermostats

For the same reasons, don’t use locked thermostats. Making thermostats inaccessible to the occupants of the spaces is a bad practice, except where it is necessary to protect controls from vandalism. If temperature limits are set too aggressively with a locked thermostat, occupants will be uncomfortable. On the other hand, if the locked thermostat is set to minimize complaints, energy efficiency is sacrificed.

It is bad policy to limit people’s ability to remain comfortable. This reduces work efficiency, invites health problems, and creates antagonism toward energy conservation in general.

Locked thermostats that are visible within the space irritate people because they overtly prevent people from being able to control their environment. As a result, they are a magnet for tampering. If you have to keep thermostats out of reach of the occupants, then conceal them entirely in the air return from the space.

ECONOMICS

SAVINGS POTENTIAL: 1 to 40 percent of conditioning cost, depending on which control functions are manual, the operating schedule, etc.

COST: \$5 to \$200 per placard, depending on quantity, materials, and complexity. This includes design cost.

PAYBACK PERIOD: Less than one year, in most cases.

TRAPS & TRICKS

EFFORT: See [Reference Note 12, Placards](#). The main hazard is failing to put enough effort into the design and installation of placards. Select materials that are durable and legible. Reject the temptation to use adhesives to attach placards where permanent methods are possible.

MEASURE 4.3.2 If conditioning cannot be turned off during unoccupied hours, install temperature setback.

The most effective way to save conditioning energy after hours is to turn off the air handling system, as recommended by Measure 4.1.1. However, this is not possible in all cases. The air handling system may be kept in operation to maintain a minimum temperature, or to continue providing ventilation, or for other reasons. Even if the air handling system fans are turned off, the coils may be kept active to warm air that is drawn into the building by the action of exhaust fans.

In these situations, you can often use temperature setback as a way to save energy. Setback is a thermostatic control technique in which heating and cooling are turned off during unoccupied periods until the temperature in the space drifts to a lower (or higher) fixed temperature. This relaxed temperature setting is called the “setback temperature.”

Energy Saving Potential

The conditioning load depends on the difference in temperature between the inside of the building and the outside. Temperature setback reduces this differential. For example, if the average space temperature can be reduced 10°F during the unoccupied period, and if the outside air temperature during this period averages 30°F below the occupied temperature, then heating energy consumption during this period can be reduced by about one third. (This example does not include the effect of heat gains, heat storage in the building structure, and other complications.)

This Measure also saves fan energy if the operation of the fans is controlled by the space thermostat. See Measure 4.3.3.2 for details.

You may be able to shut off outside air during the setback period, as recommended by Measure 4.2.1.1. This action typically saves a large part of the conditioning load.

How to Accomplish Temperature Setback

You can accomplish temperature setback in a variety of ways. The following are the main methods.

■ **Individually Programmable Setback Thermostats**

You can install individually programmable setback thermostats to control each air handling system. The time schedules and setback temperatures are set at each thermostat individually. In facilities that have only a small number of thermostats, this is the easiest and cheapest method. In facilities where thermostats are subject to vandalism, it takes disciplined maintenance to keep all the thermostats programmed and working properly.

SUMMARY

A basic energy conservation measure that saves energy during unoccupied periods. A standard feature in most electronic control systems. With other types of controls, it requires special thermostats.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	
Ease of Retrofit	😊	😊	

A setback thermostat has two thermostatic elements in one enclosure, one of which is set for normal occupancy, and the other for unoccupied conditions. (Electronic units may have only a single sensor, but the effect is the same.) The unit has its own timeclock to switch between temperature settings.

Individually programmable setback thermostats are common items for on-off electrical control of heating and cooling and for pneumatic thermostatic control. They may be available for analog electrical control and for some electronic control systems.

Different models of setback thermostats offer different degrees of flexibility in scheduling. A variety of options are available, such as override control and a backup power supply. Ease of use is an important criterion. Some models are much easier to use than others. See Reference Note 10, Clock Controls and Programmable Thermostats, for equipment features and installation practices that are important for achieving satisfactory performance.

■ **Electronic Control Systems**

Temperature setback is a standard capability with almost all centralized electronic control systems. Most electronic control systems allow you to select the schedule and setback temperature of each thermostat individually.

Special thermostat models are needed to provide occupant override within the spaces.

■ **Centralized Pneumatic Setback**

In pneumatic control systems, you can accomplish setback by changing the control air pressure at the air source. This requires special thermostats. Also, you need a control station at the air source to change the

Fig. 1 Pneumatic setback thermostat with override To restore normal space temperature during the setback period, depress the button on top of the thermostat. The button returns to its normal position during the next temperature cycle.

pressure at the appropriate times. A typical system sets the thermostats to daytime operation with 17 PSI supply pressure and nighttime operation with 22 PSI supply pressure.

The main disadvantage of this method is that all spaces served by the pneumatic system must operate on the same schedule.

Pneumatic setback thermostats with individual overrides are available. Figure 1 shows a typical unit.

Avoid Forcing the Setback Temperature

Be sure that conditioning energy is not used to drive the space to the setback temperature. This is a potential trap where a thermostat controls both heating and cooling equipment. This problem does not occur with true setback thermostats, but it can occur with simple changeover thermostats that are controlled automatically. It can also occur by programming a centralized electronic control system incorrectly.

Provide Efficient Overrides

A weakness of setback thermostats is that they operate on a fixed schedule, either individually or as part of an entire system. To overcome this problem, setback thermostats can be equipped with overrides. A person who wishes to work during the unoccupied period activates the override in his space, which causes the thermostat to call for normal temperature.

The override remains in effect until the next setback period, unless the occupant cancels the override. This is an efficiency weakness. It does not waste much energy

if the setback override is used only occasionally. However, if the override is used often by a user who forgets to cancel the override, much of the benefit of setback is lost.

One way to overcome this problem is to use a personnel sensor to activate the override. This is not yet a standard feature of setback controls, so you have to wire it on a custom basis.

Control Outside Air Appropriately

Many facilities do not need outside air ventilation during the unoccupied period. Use a control signal from a centralized setback system, or from an individually programmable setback thermostat, or from a timeclock to close the outside air dampers, if appropriate. See [Measure 4.2.1.1](#) for details.

Placards are Essential

Setback thermostats are operated by occupants, so they need instruction placards. See [Measure 4.3.1](#) for details. The most important part of the message is asking occupants to reset the temperature override after using it.

ECONOMICS

SAVINGS POTENTIAL: 5 to 15 percent of heating cost, if setback is applied only to heating. 20 to 60 percent of cooling cost. The saving are even greater if you can use setback to shut off outside air and to turn off the air handling system fans. See [Measure 4.2.1.1](#) for these savings.

COST: An individually programmable setback thermostat for a low voltage thermostatic system typically costs about \$100 to install. Setback typically adds about several thousand dollars to the cost of a centralized control system, plus about \$100 for each thermostat.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Select setback thermostats that are rugged and easy to use. Get sufficient scheduling flexibility. Always include an override and a backup power source.

EXPLAIN IT: Don't forget the instruction placards. These are essential to efficient operation and to minimize vandalism.

MAINTENANCE: Periodically, check the scheduling, setback operation, and override operation of each thermostat.

MEASURE 4.3.3 Match fan output to the conditioning load.

In constant-volume air handling systems, the fan output is selected to deliver heat or cooling during the most extreme load conditions. Most systems have an additional margin of capacity over this amount. Extreme heating or cooling conditions typically occur for only a small fraction of a system's running time. This makes it worthwhile to reduce fan output to meet the current load. You can do this in a variety of ways, which differ in efficiency, cost, and trouble. The four subsidiary Measures recommend these methods, respectively:

- **fan trimming** (Measure 4.3.3.1) is a one-time adjustment that gets rid of any excess margin above the capacity needed to meet peak loads
- **cycling the fans with the space thermostat** (Measure 4.3.3.2) stops the fans entirely when they are not needed to deliver heating or cooling
- **installing multi-speed fan motors** (Measure 4.3.3.3) reduces fan energy consumption for a large fraction of the time without sacrificing fan capacity
- **variable-air-volume (VAV) fan control** (Measure 4.3.3.4) keeps the output of the fan tuned precisely to the current load.

All these Measures can be used with hydronic cooling and heating coils. Only fan cycling (Measure 4.3.3.2) is advisable for direct-expansion (DX) cooling coils and staged electric heating coils. DX coils need a fixed amount of air flow to avoid freezing, and electric coils need a minimum air flow to keep from burning out.

You can combine any of the first three Measures, where they are appropriate. The last Measure eliminates the need for the others.

Energy Saving Potential

■ Fan Energy

A large saving in fan energy is often possible. The reason is that the power consumed by a fan discharging into an open duct system, such as a single-zone system, is approximately proportional to the third power of the air volume delivered. For example, reducing the air flow by half reduces the fan power requirement to approximately one eighth. Even a relatively small reduction in fan flow produces a significant reduction in fan power. For example, reducing air flow by 20% reduces the fan power requirement to approximately one half.

The key aspect of exploiting this is to reduce the output of the fan in an efficient manner. The subsidiary Measures reduce fan speed or turn off the fans, the most efficient methods of reducing air flow. In contrast, using dampers to reduce air flow would save little energy.

■ No Heating or Cooling Saving in Most Systems

Most single-zone systems do not offer a saving in heating or cooling energy when the fan output is reduced. The space conditioning load determines the heating and cooling requirement, except for conditioning of outside air. In systems with good control of outside air ventilation, outside air intake is fairly independent of the fan flow rate. If ventilation is affected by changes in fan output, this is usually an undesirable side effect.

■ Heating and Cooling Energy in 100%-Outside-Air Systems

Air handling systems that use 100% outside air are a special case where reducing fan output may save conditioning energy as well as fan energy. The reason is that the amount of outside air intake with such systems may greatly exceed the amount of outside air needed for ventilation. Heating, cooling, and dehumidifying outside air usually (but not always) requires more energy than conditioning air that is recirculated from inside the building.

■ Reheating Operation

In some single-zone systems, the cooling and heating coils are operated simultaneously (reheat) for the purpose of dehumidification. During periods of low conditioning load, reheat may consume much more energy than is actually delivered to the spaces. The sensible component of reheat energy loss is proportional to the air flow rate.

Reducing the air flow rate reduces reheat in these cases. However, this is not the best way of saving energy. In many cases, it would allow space humidity to rise, and it would not eliminate unnecessary reheat entirely. Instead, the efficient approach is to control reheat based on the need for dehumidification. You can do this by installing a humidistat in the space to control the heating coil, while the thermostat continues to control the operation of both coils to maintain the space temperature.

■ Auxiliary Equipment Energy

Some air handling systems have auxiliary equipment, such as hydronic coil booster pumps, that can be turned off if the fans are turned off. This opportunity for saving occurs only with fan cycling (Measure 4.3.3.2).

Factors to Consider Before Reducing Air Flow

Changing the fan output may have a surprisingly large number of effects. Consider the following factors when you decide whether, and how, to reduce fan output.

■ The Nature of the Application

The Measure does not apply in every facility that has an apparently extravagant air flow rate. Be sure that you understand all the reasons for the air flow settings. For example, surgical suites in hospitals typically require a high flow rate to provide “laminar” flow of air through the space. Laboratories typically require high air flow rates to prevent escape of contaminants from hoods. You may be able to save energy in such cases, but it will require more complex changes than these.

■ Heating and Cooling Capacity

Fan capacity trimming ([Measure 4.3.3.1](#)) reduces the system’s heating and cooling capacity. All the other Measures vary fan output in response to load, so they do not reduce conditioning capacity.

■ Humidity

All the subsidiary Measures lower the space humidity to some extent. With hydronic cooling coils, this happens because the coils operate at lower average temperature. This effect is greatest with multi-speed fans and VAV operation.

Fan cycling may reduce humidity for a different reason in air handling systems that use a cycling cooling unit, such as a reciprocating compressor. The fins of cooling coils retain a large amount of moisture. When the cooling compressor is running, the coil is cold and removes moisture from the air. When the compressor turns off, the space air continues to circulate air through the wet coil. Until the coil dries out, the coil acts as a humidifier.

In extreme cases, the cooling coil never dries out, and the space is continually re-humidified whenever the compressor turns off. In that extreme situation, fan cycling may solve the problem.

Multi-speed fan operation also reduces the adverse effect of moisture trapping in cooling coils, but much less effectively than fan cycling. It does this by increasing the fraction of the time that the coils are cooling.

(In humid climates, humidity tends to become a problem during mild weather because the dehumidifying effect of the cooling system is reduced along with the cooling load. Humidity is generally not a problem during cold weather because cold outside air cannot carry much moisture, and air exchange keeps internal humidity tied to the external humidity. Humidity is not a problem when there is a high cooling load because the coils operate long enough to keep the air dry.)

■ Outside Air Ventilation

In recirculating air handling systems, the method of controlling outside air quantity depends on the “front end” configuration of the air handling system. See [Measures 4.2.1](#) and [4.2.2](#) for details. A well designed air handling system maintains accurate control of outside

air intake even as the fan output changes. However, this is an ideal rarely achieved. The amount of outside air generally varies with fan output, in a manner that differs from one system to another. Be sure to account for this when using multi-speed and VAV fan control.

When the conditioning load is low, fan cycling and VAV operation may reduce outside air ventilation below acceptable limits. Solutions for both problems are given in the respective Measures. Fan trimming usually does not reduce air intake enough to infringe on ventilation.

■ Air Cleaning

If the air handling system is used for air cleaning, by filtering or other processes, the rate of cleaning is proportional to the flow rate. All the methods reduce air flow, or interrupt it, so all reduce air cleaning. Air cleaning is covered in [Measure 4.2.4](#).

■ Effect of Space Air Velocity on Comfort

The air velocity within a space may cause discomfort by being too high or too low. Air flow that is too high triggers complaints of “draft.” These complaints usually occur during colder weather, when the fans need to be near full output. Thus, these Measures have little effect on perceived draft.

Low air velocity leads to complaints of “stagnation” or “stiffness,” which tend to occur during mild or warm weather. All these Measures either reduce or interrupt air flow in the spaces, so all may aggravate these complaints.

Research suggests that complaints of “draft” are due primarily to low space temperature, and complaints of “stagnation” are due primarily to high space temperature. Lowering the space temperature usually resolves these problems. However, this increases cooling energy, which offsets the advantage of reducing fan output. (Consider installing space circulation fans to supplement mechanical cooling, in applications where this is appropriate.)

■ Diffuser Performance

If fan output is reduced when the system is cooling, the cold air tends to dump out of the diffusers, rather than diffusing throughout the space. This causes discomfort to persons situated under the diffusers.

A diffusion problem also occurs with heating when air flow is reduced. In this case, the problem is that the warm air tends to stay at ceiling level, rather than flowing downward and circulating throughout the space.

VAV operation is notorious for causing these problems because of the great reduction in fan output. Air distribution problems may also occur with multi-speed fans. The other Measures do not affect diffuser velocity enough to cause air distribution problems.

■ Building Pressure

Operation of the air handling system fans may have a major effect on building pressure. This includes the

outside-to-inside building pressure differential and the space-to-space pressure differentials.

All the Measures, except fan trimming, create large changes in fan output. Whether this will create pressure problems depends on the design of the air handling systems. [Measure 4.2.1](#) explains how the system design affects space pressure.

■ Fan Noise

Reducing fan output by reducing fan speed substantially reduces fan noise. However, the sudden changes in fan noise that occur with fan cycling and multi-speed fans may be objectionable. The potential for annoyance depends on how much noise the fans project into the space, the amount of background noise in the space, how often the fans cycle, and other subjective factors, such as the formality of the space.

■ Fan-Induced Resonances

At certain specific speeds, a fan may trigger resonances in the air handling sheetmetal or in the building structure. This is most likely to occur with VAV fan operation, because the fan operates across a continuous range of speeds. A resonance may be triggered at a fixed fan speed after fan capacity trimming or installing multi-speed fan motors.

Air handling system vibration is rarely serious, if the system equipment is installed properly, because the vibrational frequency of centrifugal fans is higher than the resonant frequencies of typical structures and ductwork. If a serious resonance does occur, it is likely to be caused by an unbalanced fan wheel, which you can correct by balancing the wheel. If this does not solve the problem, stiffen the vibrating components, which increases their resonant frequency and reduces the intensity of vibration.

■ Chiller Efficiency in Chilled Water Systems

If the volume of air is reduced during cooling, the temperature of the supply air must be lower to

compensate. At high cooling loads, achieving the lower air temperature may require lower chilled water temperature. Lowering the chilled water temperature reduces the efficiency of the chiller, as explained in [Measure 2.2.1](#).

Forcing the chiller to operate at lower chiller water temperature for long periods is usually a bad bargain. To achieve the best overall efficiency, make sure that the system controls keep the chilled water temperature as high as possible, with fan output adjusted accordingly.

■ Freeze Protection and Control of DX Refrigerant Coils

If cooling is provided by a direct expansion (DX) coil, reducing the air flow through the coil may cause coil freezing. In addition, varying the air flow by a large amount may incur control difficulties. VAV operation is almost certain to cause trouble, and problems are likely if multi-speed fan motors are retrofitted. If you are not an expert in DX systems, don't reduce the air flow through a DX coil without the advice of an expert on this topic.

■ Air Flow Requirements for Electric Heating Coils

Reducing air flow through electric heating coils, if done to excess, shortens coil life and may create a fire hazard. Fan trimming typically does not reduce air flow enough to create a problem, but check the coil specifications. Operation with multi-speed fan motors may require modifications of the heating coils. VAV operation is unlikely to be feasible with electric heating coils unless the system has unusual controls for this purpose.

Don't Overlook Any Fans

Consider reducing the flow of all the fans in the air handling system, as appropriate. Do not overlook return fans, remote relief fans, toilet and kitchen hood exhaust fans, etc.

MEASURE 4.3.3.1 Trim fan output.

RATINGS

New Facilities	Retrofit	O&M
□	□	B

Fan trimming is a one-time adjustment that gets rid of fan capacity in excess of the amount needed to satisfy peak loads. Refer to [Measure 10.3.1](#) for details.

This is the simplest method in this group of four Measures that save fan energy in single-zone air handling

systems. It is cheap and quick. However, it does not tailor fan output to a changing load. It may be the only way to save fan energy that is practical in smaller single-zone systems.

MEASURE 4.3.3.2 Cycle the running of the fans and other air handling system equipment with the space thermostat.

RATINGS

New Facilities	Retrofit	O&M
B	C	□

Another way to improve the fan efficiency in single-zone air handling systems is to stop the fan(s) when conditioning is not needed. This method is common where cooling and heating are provided by equipment that cycles on and off. In such cases, simply use the space thermostat to cycle the fan as well as the conditioning equipment. You can also cycle the fans in hydronic heating and cooling systems, but the controls are more complex.

Where to Use Fan Cycling

This Measure is useful primarily for minimizing fan energy consumption during periods of normal operation. Other methods are appropriate for minimizing fan energy outside hours of normal operation, including turning off the equipment ([Measures 4.1.1 ff](#)) and temperature setback ([Measure 4.3.2](#)).

This Measure is used widely in smaller air handling systems and fan-coil units. However, this method has a number of limitations, especially in larger systems. The limitations are described below.

This Measure has a unique ability to solve humidity problems that occur during mild weather in some environments. See “Humidity,” in [Measure 4.3.3](#), for this special case.

Energy Saving Potential

■ **Fan Energy**

This Measure may reduce the operating time of fans to substantially less than half, especially in smaller systems. The relative saving may be substantially less in larger systems, because of steps needed to reduce adverse effects of fan cycling. The greatest savings in

SUMMARY

A common technique with small air handling units. Works best and costs little with heating and cooling equipment that has on-off thermostatic control. With other types of controls, the energy saving may not be worth the trouble. May prevent adequate ventilation and dehumidification during mild weather. Fluctuating noise and air flow may annoy occupants. Not advisable with large fans.

Ease of Retrofit	😊	😊	😊

fan energy occur during periods of low conditioning load. Therefore, this Measure is most effective in mild climates.

■ **Heating and Cooling Energy in 100%-Outside-Air Systems**

Air handling systems that use 100% outside air are a special case where fan cycling may save conditioning energy as well as fan energy. The reason is that the amount of outside air intake with such systems may greatly exceed the amount of outside air needed for ventilation. Heating, cooling, and dehumidifying outside air usually (but not always) requires more energy than

conditioning air that is recirculated from inside the building.

Typical savings are 20 to 50 percent of conditioning energy. The saving in the excess energy needed to condition outside air is proportional to the outside air temperature differential and humidity, and to the time that the fans are turned off. These two factors oppose each other, because the fans run the longest during periods of high conditioning load.

For example, consider a 100%-outside-air system that is converted to on-off operation. During a period when the heating load is one third of the peak load, the fan operates only one third of the time, and only one third as much outside air is heated. In a typical case, the net saving is about one third of the heating energy requirement.

(In the previous example, the air is heated to a higher temperature during the periods when the fan is operating. This does not affect the energy saving. The saving results from reducing the volume of air that must be heated from outside air temperature to space temperature. The total amount of energy required to heat the outside air from space temperature to supply air temperature remains the same, regardless of whether the fan is cycled or not.)

■ Reheating Operation

If the system allows reheating, the amount of reheating energy is proportional to the air flow rate while reheat is being employed. (In a single-zone system, reheat means that the heating coil can operate while the cooling coil is operating. Some systems use this technique to control humidity.) If the system controls are designed for efficiency, they should limit reheat based on the need for dehumidification. Thus, cycling the fan capacity should have little net effect. Verify these aspects of system control.

■ Auxiliary Equipment Energy

Some air handling systems have auxiliary equipment, such as hydronic coil booster pumps, that can be turned off when the fans are turned off.

Limitations

■ Type of Thermostatic Control

This Measure is easiest to accomplish if the thermostat produces a discrete on/off signal. Such thermostats are associated with heating and cooling equipment that operates in an on-off manner, such as electric heating coils and direct-expansion cooling with reciprocating compressors. With on-off thermostats, the fan can be controlled simply with a relay that is activated by the “on” signal from the thermostat.

With systems that use proportional thermostats, such as hydronic heating and cooling, this Measure is more difficult to accomplish in a satisfactory fashion. With a proportional thermostatic system, you need to install

control logic that senses the zero-load condition and turns off the fan within a given range of this signal. For example, the zero-load output of a pneumatic thermostat may be 10 PSI, in which case the control logic would turn off the fan when the thermostat output is between 9 PSI and 11 PSI.

The control logic also needs to have a sensitivity range that keeps the fan from short cycling. In the previous example, the controls would be set so that the fan does not turn back on until the control pressure drops to 7 PSI or climbs to 13 PSI.

In analog control systems, drift and inaccuracy in the controls may make it impractical to accomplish this change in a satisfactory manner. Accuracy is not a problem in digital control systems. With digital systems, the question is whether the system provides an offset signal that you can use to control the fans.

■ Limitations on Fan Size

The amount of wear that occurs to equipment when fans are restarted increases rapidly as the fans get larger. This is because both the starting force and the inertial resistance increase with size. Slamming the torque of a large motor against the inertia of a large fan causes rapid wear of drive belts, bearings, and other components. Above a certain fan size, the saving in energy does not justify the increased maintenance.

■ Maintaining Adequate Outside Air Ventilation

Stopping the fan may excessively reduce outside air ventilation, especially under low-load conditions. Whether this will occur depends on the design of the air handling system. [Measure 4.2.1](#) explains how the intake of outside air is affected by stopping the fans in different types of systems.

If necessary, you can solve this problem by adding a control feature that cycles the fans often enough to maintain adequate ventilation. If you do not have an electronic control system that you can program to perform this function, use two timer relays. One starts the fans if they have not run for a defined period of time, and the other keeps the fans running for the necessary duration.

■ Effect on Space Air Flow

This Measure stops air flow through the spaces when heating or cooling is not being provided. In some environments, this may lead to occupant complaints of stagnation or “stiffness.”

■ Noise Level Changes

An abrupt reduction in fan noise will be heard within the spaces as the fans cycle on and off. In some environments, this may be considered objectionable. On the other hand, occupants may welcome the intervals of silence.

The potential for annoyance depends on how much noise the fans project into the space, the amount of background noise in the space, how often the fans cycle,

and other subjective factors, such as the elegance of the space.

■ Building Pressure Fluctuations

Cycling the fans causes fluctuations in building pressure. With smaller single-zone systems, the pressure changes may be too small to notice. Their magnitude also depends on the design of the air handling system, the duct layout, and the building layout. Refer to [Measure 4.2.1](#) to understand how fan operation affects building pressure in different types of systems.

How to Reduce Short Cycling

Avoid frequent cycling of the fans, which causes most of the problems discussed previously.

One step in reducing the cycling rate is to widen the control range of the space thermostat. For example, a thermostat that keeps temperature within a range of 0.5°F cycles the fan approximately twice as often as a fan that controls temperature within 1.0°F. Many thermostats have an adjustable control range. If the installed thermostat is not adjustable, you may be able to substitute one with a larger control range.

Don't overdo this. If the control range is too great, there will be large swings in temperature, and occupants will increase conditioning to avoid discomfort.

The energy saving provided by this Measure occurs mostly at the low end of the load range, whereas cycling is a problem mostly at the higher end of the load range. You can exploit this fact by installing an override that keeps the fans running continuously when the conditioning load is high enough to cause the fans to cycle frequently. For example, you can use the outside air temperature to control the override.

Soft Starting

With larger fan motors, you can reduce the wear and noise that results from frequent starting by installing a motor starter that provides a "soft" start. Such units start the motor with reduced torque by limiting the starting current in one or more steps. Motors differ in their winding designs to respond to different starting torque requirements. Match the starter to the design of the motor windings and to the inertia of the fan.

Control of Outside Air Dampers

Air handling system controls often close the outside air dampers when the supply fan stops. This is to block infiltration during unoccupied periods. However, if the

fans are cycled during occupied periods, control the dampers to stay open so that exhaust fans in the building are not starved for air. If you make this change, ensure that the outside air dampers still close normally during off hours. Coordinate this action with the Measures in [Subsection 4.2](#) related to air handling system dampers.

Existing Thermostats with Integral "Fan" Switches

Existing systems that have on-off sources of heating and cooling, such as electric coils and reciprocating compressors, often have thermostats that allow occupants to control the running of the fans. In retrofitting such systems, the hard work is already done.

The remaining problem is that occupants are likely to set the fan switch haphazardly, defeating the purpose. The safest approach is to replace the thermostats or to re-wire them to keep the fan under the control of the thermostat.

Alternatively, if you want to give occupants control of fan operation, install a placard at the thermostat asking them to keep the fan under the control of the thermostat as much as possible. See [Measure 4.3.1](#) about effective thermostat placards.

Increased Potential with Deadband

In applications where deadband is effective (see [Measures 4.3.4 ff](#)), it also increases the time that the fan can be stopped. This effect occurs during periods of low load. Deadband does not help to reduce short cycling, because short cycling occurs at higher loads.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of the energy used by the air handling system fans and other cycled equipment. In 100%-outside-air systems, 20 to 50 percent of heating and cooling energy.

COST: Minimal to several hundred dollars, if only thermostatic modifications are required. Up to several thousand dollars, if motor starters and other equipment are installed.

PAYBACK PERIOD: Several months, to many years.

TRAPS & TRICKS

CHOICE OF METHOD: First, figure out whether this is a worthwhile way to save energy in your air handling system. Consider whether it may cause equipment or occupant problems. With analog control systems, is it worth the bother?

MEASURE 4.3.3.3 Install multi-speed fan motors.

RATINGS

New Facilities	Retrofit	O&M
B	B	

Installing multi-speed fan motors is a simple and efficient method of saving fan energy in a single-zone system. This method changes air flow in a stepwise manner that is appropriate for shifting between peak conditions and average conditions. It is well adapted to many single-zone systems, and it has few disadvantages. Unlike the previous two subsidiary Measures in this group, it requires more expensive equipment, but the additional cost is modest.

Energy Saving Potential

■ **Fan Energy**

In single-zone systems, fan power is proportional to approximately the third power of the air volume delivered. For example, if fan motors with a 2:1 speed ratio are installed, fan power is reduced to approximately one eighth at the lower fan speed. In typical applications, the fan motors operate at the lower speed for a large majority of the time. Thus, total fan energy consumption typically is reduced by well over half. Other speed ratios, and larger numbers of speeds, yield different results.

■ **Heating and Cooling Energy in 100%-Outside-Air Systems**

The excess energy consumption needed to condition outside air is proportional to the air flow rate, and to the temperature differential between inside and outside. For example, operating the fan at half speed reduces the conditioning of outside air by half. However, the fan must operate at high speed when the temperature differential is greatest, so the overall saving in heating and cooling energy is less than half.

(To be precise, the saving is half the amount of energy required to bring outside air to room temperature. Changing the fan speed has no effect on the amount of energy required to raise the air from room temperature to supply temperature, because this is determined by the space's heat losses.)

■ **Reheating Operation**

If the system allows reheating, the amount of reheating energy is proportional to the air flow rate while reheat is being employed. (In a single-zone system, reheat means that the heating coil can operate while the cooling coil is operating. Some systems use this technique to control humidity.)

If the system controls are designed for efficiency, they should limit reheat based on the need for dehumidification. Thus, fan speed should have little net effect. Verify these aspects of system control.

SUMMARY

May be the best compromise between efficiency and cost for single-zone systems. Usually free of annoyances. Automatic fan speed switching requires custom control work.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

Fan Speeds and Motor Selection

See [Reference Note 36](#), Variable-Speed Motors and Drives, for details of multi-speed motors. Select multi-speed motors for high efficiency, as with any motor. In retrofit applications, you can probably get a multi-speed motor that fits the mounting fixtures of the original motor, making installation simple. However, the motor will probably have a larger casing.

In most cases, a motor with two speeds is the reasonable choice. Motors with three or four speeds are available on a custom basis, but they are larger, more expensive, and suffer higher efficiency losses.

A 2:1 speed ratio is appropriate for most applications, although motors with other speed ratios are available. Operating at half speed reduces the system capacity to about 60 to 70 percent of maximum, which is enough for the load conditions that exist most of the time. (The loss of heating and cooling capacity is less than half because coil heat transfer improves at the lower air flow rate.)

How to Switch Fan Speeds

Manual switching of motor speeds is not reliable. After the fan is switched to high speed to satisfy a period of high load, switching the fan back to low speed is likely to be neglected. Therefore, automatic control is mandatory for success in most applications.

Automatic switching of motor speeds requires some custom control work of a simple nature. The speed control must sense when there is a high heating or cooling load in the space. For example, with a pneumatic control system, switching can be initiated with a pressure signal from the thermostat. If the zero-load output of the thermostat is 10 PSI, the motor might be switched

to high speed by an output signal lower than 6 PSI (for heating) or higher than 14 PSI (for cooling). Electrical and electronic control systems may also provide a signal that is proportional to the magnitude of the space load. To keep the fan from short cycling between high and low speeds, there needs to be difference between the signal at which the fan switches up to high speed and back down to low speed.

If the thermostat operates on an on-off basis, you cannot use it to control the fan speed, so you need some other indication of load. This can be tricky. For example, if the motor speed is based on the outside air temperature alone, this would keep the motor at low speed under most weather conditions, preventing a fast warm-up or cool-down at the beginning of an occupancy period. In this situation, consider adding a time control that keeps the fan at high speed during the warm-up or cool-down period.

Units with Electric Heating Coils

Reducing the air flow through electric heating coils shortens their life, and it may create a fire hazard. Check the coil specifications to see if reducing the air flow may cause a problem.

You may be able to accommodate reduced air flow by switching the heating elements between parallel and series connections when the fan speed changes. The wiring modifications should be simple. However, there may be a mismatch between coil output and fan speed that reduces the potential for low-speed operation. For example, in a two-element electric coil, switching from parallel to series reduces the heat output of the coil by approximately a factor of four. (The actual reduction is somewhat less than a factor of four because the resistance of heating elements increases with temperature.) Since heating output is reduced so much at the lower fan speed, the fan has to spend more time at high speed.

How to Avoid Resonances

Check for noisy mechanical resonances at each fan speed. Resonances occur because of interaction between

the fan and adjacent structure and ductwork. If a resonance occurs, correct any imbalance in the fan. Then, if necessary, try changing the fan speed. If this increases or reduces air flow too much, stiffen or preload the vibrating components to change their resonant frequencies.

Install Placards

Placards are important for both manual and automatic switching. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: 50 to 85 percent of fan energy, in typical HVAC applications. In 100%-outside-air systems, 25 to 45 percent of heating and cooling energy.

COST: Single-winding 2:1-ratio motors cost about \$400 per horsepower in small sizes and about \$100 per horsepower in large sizes. Motors with other speed ratios are more expensive. If a two-speed motor replaces an existing motor that is worn out, the cost differential is fairly small.

Installation labor for the motor itself is usually minor. Installation of manual switching typically costs several hundred dollars and up. Design and installation of automatic switching may cost several thousand dollars.

PAYBACK PERIOD: One year to many years, depending on the size of the motors, the duration of fan operation, and the complexity of controls.

TRAPS & TRICKS

DESIGN: Switch the motor speed automatically, if it is practical to do so. This is much more reliable than manual switching.

SELECTING THE MOTORS: Select the motors for high efficiency. This requires calls to motor manufacturers, because multi-speed motors are not yet rated for efficiency. See [Measure 10.1.1](#) for other motor criteria.

EXPLAIN IT: Unusual switching controls confuse the maintenance staff. Describe the controls clearly in the plant operating manual.

MEASURE 4.3.3.4 Convert the system to VAV operation.

Variable-air-volume (VAV) is a mode of air handling system operation in which the temperature of the space is controlled by varying the rate of air delivery. It tailors the output of the fan precisely as the load changes. Therefore, VAV is the most efficient in this group of Measures. Unfortunately, a number of limitations keep this method of fan control from being practical in most single-zone air handling systems.

Feasibility and Alternatives

VAV is rare in single-zone systems. In most cases, the saving in fan energy does not justify the cost. Using a multi-speed fan (Measure 4.3.3.3) saves almost as much fan energy, and does it at much lower cost.

VAV saves conditioning energy in single-zone systems that use 100% outside air. VAV typically reduces conditioning energy in these systems by about a third. Multi-speed fans produce somewhat less energy saving than VAV in these cases.

VAV is more likely to be economical in large fan systems, because the cost per unit of fan power drops rapidly with larger fan sizes.

If cooling is provided by a direct expansion (DX) coil, reducing the air flow through the coil may cause coil freezing. If the DX coil is fed from a compressor that cycles, retrofitting VAV would require special design features that are not economical.

Similarly, if heating is provided by electric resistance coils, the switching of coils in stages generally causes control problems that make it impractical to retrofit VAV.

Energy Saving Potential

■ Fan Energy

A fan operating in VAV mode always delivers the minimum amount of air needed at any given moment. In a single-zone system, the fan power is proportional to the third power of the fan speed, so VAV operation usually saves well over half of the energy that would be used by a constant-volume fan.

All variable-speed fan drives have inefficiencies that partially offset the saving in fan power. The best of these devices have relatively low losses.

■ Heating and Cooling Energy in Once-Through Systems

Air handling systems that use 100% outside air are a special case where VAV may save a substantial amount of conditioning energy in a single-zone system. By reducing air intake at each instant to the amount that is needed for conditioning the spaces, VAV reduces the heating and cooling of outside air.

SUMMARY

The ultimate refinement in saving energy, but usually too expensive for single-zone systems. Usually not practical to retrofit with direction-expansion cooling coils or electric heating coils. May not provide adequate ventilation, dehumidification, and space air distribution at low loads.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	
Rate of Return, Retrofit	%	%	
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	

The energy consumption needed to condition outside air is proportional to the air flow rate, and to the temperature differential between inside and outside. Unfortunately, the flow rate required to deliver heating and cooling to the spaces is highest when the temperature differential is greatest. As a result of this interaction, the typical saving produced by VAV is limited to roughly a third of conditioning energy, in typical applications. Even so, this is a large amount of energy in big air handling systems.

(To go into greater detail, the energy saving results from reducing the volume of air that must be heated from outside air temperature to space temperature. The amount of heat required to heat the air from space temperature to supply air temperature depends on the space load. VAV does not save conditioning energy that is related to the space load.)

The potential saving is reduced if the application requires a high ventilation rate.

■ Reheating Operation

If the system allows reheating, the amount of reheating energy is proportional to the air flow rate while reheat is being employed. (In a single-zone system, reheat means that the heating coil can operate while the cooling coil is operating. Some systems use this technique to control humidity.)

If the system controls are designed for efficiency, they should limit reheat based on the need for dehumidification. Thus, fan speed should have little net effect. Verify these aspects of system control.

How to Use VAV in a Single-Zone System

Using VAV in a single-zone system is much easier than using it in a multiple-zone system. One reason is that no VAV terminal units are required. Another is that simultaneous heating and cooling does not occur, so you do not have to go through the contortions that are needed in typical VAV systems to minimize reheat energy waste. Nonetheless, VAV is always tricky. Consider the following aspects carefully.

■ Selecting the Fan Drive

Review [Reference Note 36](#), Variable-Speed Motors and Drives. In the present state of technology, the best choice is usually a variable-speed electronic motor drive. In retrofit applications, consider replacing the motor as well.

■ Control Functions

Select a variable-speed drive package that includes an appropriate control package. The basic mode of operation is for the space thermostat to control the fan output. With hydronic coils, the coil discharge temperatures are held constant.

In most cases, you will want to establish a minimum fan speed. One reason is to maintain adequate ventilation. Another is to maintain proper operation of the diffusers, as explained below. Control packages for variable-speed drives typically include a minimum-speed setting.

When the fan speed falls to the minimum setting, the controls should switch to a mode of operation in which the space thermostat controls the coil discharge temperatures. You will probably need additional controls to perform this function.

If the system provides both heating and cooling, install a control changeover that selects heating or cooling as needed.

■ Outside Air Ventilation

In recirculating air handling systems, the method of controlling outside air quantity depends on the “front end” configuration of the air handling system. This aspect is covered by [Measures 4.2.1](#) and [4.2.2](#). To maintain adequate ventilation under low loads, set the fan controls for an appropriate minimum air flow rate.

■ Air Distribution Velocity

Refer to “Effect of Space Air Velocity on Comfort” and “Diffuser Performance,” in [Measure 4.3.3](#).

Use diffusers that distribute air effectively at low air volumes. Some types of diffusers are designed to exploit Coanda effect to cause the air flow to adhere to the ceiling. This is effective for cooling, but creates a problem with heating. There is no perfect solution to this problem. Using the same diffusers for heating and cooling is a challenge in all VAV systems.

With any type of diffuser, you usually have to set a minimum fan output to prevent dumping of cold air during cooling and to force warm air downward during heating. You can improve diffuser performance at low air volumes by setting the temperature reset to commence before the fan reaches its minimum speed. In this way, the cold air is not as cold by the time the fan falls to minimum speed, and the warm air is not as warm at the minimum speed.

■ Flow and Control Requirements of Refrigerant (DX) Coils

Direct-expansion (DX) refrigerant coils, which are used with heat pumps and direct expansion cooling, usually have minimum flow requirements to avoid coil freezing.

If DX coils are fed by refrigerant units that vary output in stages (for example, by unloading individual cylinders in a reciprocating compressor), insurmountable control problems may occur. The controls that modulate air flow would be confused by the abrupt changes in coil temperature, causing unstable operation.

If the DX coils are fed refrigerant by a continuously modulating compressor, or if the coils draw refrigerant from an accumulator (refrigerant holding tank), the system may be able to operate satisfactorily in VAV mode.

■ Flow Requirements of Electric Coils

Electric coils require a specified air flow in order to avoid burning up. In VAV operation, air flow under low load conditions may not be sufficient for electric coils.

Switching coil elements to vary heat output is generally not satisfactory, because the abrupt changes in heat output would confuse the air flow controls, causing unstable operation. At the present time, there is no satisfactory solution to this problem.

■ Fan Noise and Resonances

VAV keeps the fans as quiet as possible. The fans always operate at the minimum possible speed, and there are no abrupt speed changes. On the other hand, you may have to take steps to correct vibration resonances in the fan system that may occur at certain speeds. See [Measure 4.3.3](#) for more about these topics.

■ Building Pressure

VAV changes fan output over a large range, so it may have a significant effect on building pressure. Whether pressure problems will occur depends on the design of the air handling systems. Refer to [Measure 4.2.1](#) for more about this. The changes in building pressure caused by VAV are gradual, unlike the changes with fan cycling ([Measure 4.3.3.2](#)) and multi-speed operation ([Measure 4.3.3.3](#)).

ECONOMICS

SAVINGS POTENTIAL: 50 to 80 percent of fan energy. In 100%-outside-air systems, 20 to 50 percent of heating and cooling energy.

COST: The cost of variable-flow fan drives is covered in [Reference Note 36](#), *Variable-Speed Motors and Drives*. In retrofit applications, the control modifications, diffuser replacement, and design work cost at least a few thousand dollars.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

CHOICE OF METHOD: Although this Measure provides the best fan efficiency, it is unusual and specialized. Choose another method unless you are sure that the resulting low air flow rates will not cause problems.

DESIGN: This is the simplest application for VAV. Still, design of VAV systems is tricky. Study successful VAV installations of this type, if you can find any.

SELECTING THE EQUIPMENT: Selecting the best fan drive involves many factors. To get it right, study [Reference Note 36](#), *Variable-Speed Motors and Drives*.

MEASURE 4.3.4 Install thermostatic controls that allow space temperature to drift within comfortable limits.

In most HVAC applications, comfort does not require a fixed space temperature. People remain comfortable within a range of temperatures. You can save energy by using thermostatic controls that turn off heating and cooling within this temperature range. The term “deadband,” or “temperature deadband,” means the range of space temperature in which the thermostatic controls do not call for heating or cooling.

The three subsidiary Measures offer different ways of achieving temperature deadband:

- **Measure 4.3.4.1** recommends installing manual switches with the space thermostats that require occupants to select either heating or cooling. This method is commonly used with heating and cooling equipment that cycles on and off. It can be adapted to hydronic coils.
- **Measure 4.3.4.2** recommends installing deadband thermostats, which turn off heating and cooling within the comfortable temperature range. This method is commonly used with hydronic coils, and it can be adapted to cycling equipment.
- **Measure 4.3.4.3** recommends adjustments or modifications of hydronic coil control valves to create a temperature gap between heating and cooling. This method may be limited to a smaller deadband, but it requires no changes to the thermostats.

Energy Saving Potential

Adding a deadband temperature range in the thermostatic controls keeps the system from wasting energy in these ways:

- **unnecessary heating and cooling while the space temperature is within the comfort range.** The rate of energy waste is low because the conditioning load is small. However, in mild climates, the conditioning system may operate for many hours per year within the comfort range.
- **excessive heating or cooling whenever the system is operating.** Energy consumption for heating and cooling is proportional to the difference between inside and outside temperatures. If the temperature is set arbitrarily within the range of comfort, the system will maintain a larger temperature differential than necessary. For example, if the space temperature is fixed at 76°F during heating operation, instead of being allowed to drift down to 72°F, there is always an additional 4°F of temperature differential to force heat out of the building.

- **heating adds to cooling energy, and vice versa.** In mild climates, the space temperature may drift up and down within the comfort range. For example, it is usually cool in the morning, it gets warmer at midday, and it gets cooler again in the evening. If the space temperature is fixed, cooling is wasted in removing the heat that was added just a short while before, and vice versa.
- **unintentional reheat.** If the heating and cooling temperatures are set close together, small defects or incorrect adjustments in the control system can cause simultaneous heating and cooling. If this occurs, both heating and cooling operate continuously to cancel each other. This overlapping operation may result from incorrect thermostat adjustments, from sticky control components, or from aging of control components. This flaw can waste a lot of energy.
- **unnecessary operation of fans.** In some situations, the fans can be turned off when heating or cooling is not needed. (See [Measure 4.3.3.2](#).) In those situations, failing to use deadband control increases the duration of fan operation.

How Wide Can You Make the Deadband?

People are comfortable indoors within a range of temperatures. For most people, the range extends from a low of 70°F to 72°F, to a high of 76°F to 80°F. This implies a possible deadband range of 4°F to 10°F. Experience confirms this. The highest and lowest acceptable temperatures are variables that are modified by humidity, air flow velocity inside the space, the temperature of walls, clothing, body weight, and other factors.

In many environments, you can increase the deadband range by encouraging occupants to dress appropriately for the weather.

On the other hand, the deadband range is limited by hot spots and cold spots within the space. For example, a person seated near a cold wall may require that the thermostat be set near the top of the comfort range, eliminating most opportunity to exploit deadband. This makes it important to eliminate hot spots and cold spots in the occupied portions of spaces.

Obviously, deadband is not acceptable in environments where close control of temperature is needed for reasons other than comfort.

Dealing with Reheat for Dehumidification

In some cases, a single-zone system may be designed so that the cooling and heating coils operate

simultaneously (“reheat”) to reduce space humidity. The cooling coil chills the air to remove moisture while the heating coil reheats the air to maintain the space temperature. Reheat is used for dehumidification primarily in humid climates during mild weather.

Reheat consumes large amounts of energy because the heating and cooling coils are continuously expending energy to cancel each other. The system controls should limit reheat operation to weather conditions that require dehumidification. At other times, deadband can operate in the usual way.

You can accomplish this fairly easily by using a humidistat in the space to energize the heating coil when

the space humidity becomes too high. If the weather is warm and humid, the space humidistat will start the heating coil at the top of the deadband range. This increases the operation of the cooling coil, which acts to dehumidify the space.

If the weather is cool and humid, the space humidistat will turn on the heating coil, which raises the space temperature. The higher space temperature reduces the relative humidity. If the space temperature reaches the top of the deadband range, cooling will commence, holding the space temperature at the top of the deadband range.

MEASURE 4.3.4.1 Install thermostats that require manual switching between heating and cooling.

RATINGS

New Facilities	Retrofit	O&M
A	B	

You can keep the conditioning system from shuttling between heating and cooling by installing a switch in the space that requires the occupants to select either heating or cooling exclusively. Thermostats that include such a switch are common items. They are intended primarily for use with cycling equipment that is controlled with electrical on-off signals, such as electric heating coils, forced-air furnaces, and direct-expansion cooling units. However, you can use the same principle to control any kind of heating and cooling equipment.

Standard Thermostat Features

Many control companies make thermostats that include a switch for selecting between heating and cooling. Figure 1 shows a typical unit. Look for these features:

- **a switch that selects “heating,” “cooling,” and “off.”** In the “heating” position, the thermostatic can turn on only the heating equipment. In the “cooling” position, the switch can turn on only the cooling equipment. In the “off” position, the switch disables both the heating and cooling equipment. The action of this switch is simply to open or close an electric circuit activating the heating equipment, and another electric circuit activating the cooling equipment.
- **separate thermostats and thermostat settings for heating and cooling.** The thermostats can be any type (electric on-of, pneumatic, electronic, etc.) Not all changeover thermostats have dual settings, so

SUMMARY

Alternately shuts off the heating or cooling equipment. Requires action by the occupant to get conditioning. May save fan energy. Standard thermostats are available for cycling heating and cooling equipment. Can be adapted to hydronic coils.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

look for this feature. It allows the optimum heating and cooling temperatures to remain set. Without it, occupants must reset the temperature every time they change from heating to cooling, or vice versa.

- **a switch that controls the operation of the fan(s).** This switch typically has two positions, labeled “on” and “auto.” In the “auto” position, the fan turns off when the heating or cooling equipment turns off. In the “on” position, the fan runs continuously. The usual reason to keep the fan running without heat or cooling is to provide outside air ventilation. This applies to systems where the

main fans must run to bring in outside air. This feature is available with thermostats that control the heating and cooling equipment with an on-off electrical signal. You probably cannot find this feature with modulating (e.g., pneumatic) thermostats.

How to Switch with Modulating Controls

This Measure is most commonly used with heating and cooling equipment that is controlled with an on-off electrical signal. Connecting the thermostat to this kind of equipment is simple. If the heating or cooling equipment has modulating control (pneumatic, electric analog, etc.), it is easier to use a deadband thermostat, as recommended by Measure 4.3.4.2.

However, you can also install manual selection of heating and cooling with modulating temperature controls. Doing so has some advantages over Measure 4.3.4.2, even though it may be a bit awkward to install. It allows heating or cooling to be turned off individually. It provides for turning off the fan when conditioning is not needed. You can use the “off” position of the selector switch to turn off any other auxiliary equipment, such as hydronic booster pumps.

■ **An Example**

Figures 2 and 3 illustrate how to add heat-cool-off switching to a modulating thermostatic control. Figure 2 shows a typical air handling unit with hydronic heating and cooling coils and pneumatic coil valves. The heating valve is a “normally open” (NO) type, which means that it is held open by spring pressure. The cooling valve is a “normally closed” (NC) type, which means that it is held closed by spring pressure. The thermostat provides air pressure to the valves. Lower space temperatures lower the air pressure, and higher space temperatures

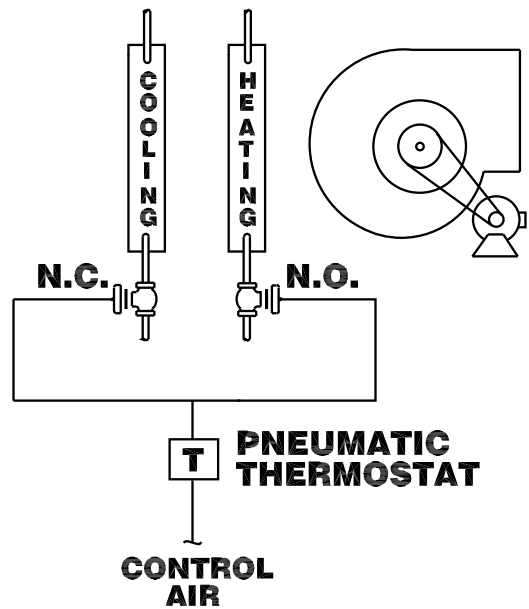

Fig. 2 Typical pneumatic temperature control This simple arrangement provides modulating temperature control, but not the ability to limit operation to either heating or cooling.

Fig. 1 Thermostat with manual switching between heating and cooling The user can also select whether to operate the fan continuously or only during heating and cooling.

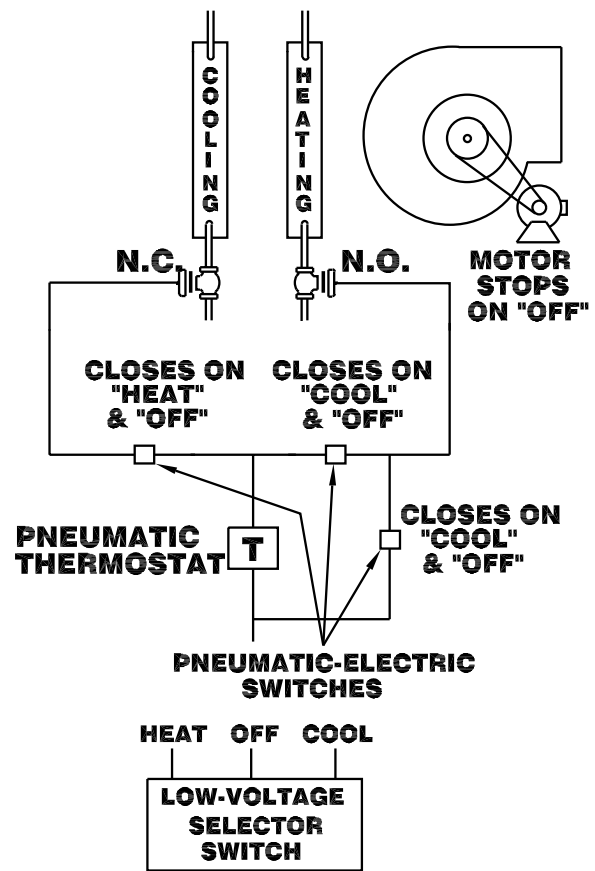

Fig. 3 How to add manual heat-cool-fan selection to modulating control This is the air handling system shown in Figure 2. The additional capability requires three P/E switches and a three-way manual selector switch.

raise the air pressure. This type of control is the cheapest and simplest that is possible with pneumatic valves.

To provide separate control of heating and cooling, install pneumatic-electric switches in the control air lines to the coil valves, as shown in Figure 3. To turn off cooling, the switch in the air line to the cooling coil valve shuts off air pressure. To turn off heating, the switch in the air line to the heating coil valve applies full pressure to the valve. A check valve is installed in this air line to prevent the air pressure from flowing back toward the thermostat. The “heat/cool/off” switch sends the appropriate electric signals to the pneumatic-electric switches.

In retrofit applications, you can keep the original pneumatic thermostat. Add a three-position electric switch to control the pneumatic-electric valves in the control air lines. However, this retrofit does not provide separate heating and cooling temperature settings.

You can use similar methods with electric and electronic controls.

Install Effective Placards

This method of control depends on occupants to select the modes of operation and to set the space

thermostat efficiently. Therefore, an effective placard is an integral part of the installation. See [Measure 4.3.1](#) for details.

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of conditioning cost. The higher percentages occur in milder climates, where the overall energy consumption is lower.

COST: One hundred dollars to several hundred dollars per thermostat.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Select controls that are easy to understand and easy to manipulate. In environments where vandalism is a risk, make them exceptionally rugged. If you can, use a standard thermostat with a built-in changeover switch and separate settings for heating and cooling. Let the thermostat control the fan, if the application allows it.

EXPLAIN IT: You are depending on the people in the space to select heating or cooling. Make it easy for them to understand. If necessary, install a big, conspicuous placard at the thermostat.

MEASURE 4.3.4.2 Install deadband thermostats.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Often the easiest way to achieve temperature deadband is to install a deadband thermostat. The purpose of a deadband thermostat is to insert a range of temperature between heating and cooling in which no conditioning occurs. In retrofit applications, a deadband thermostat is used to replace a single thermostat that controls both heating and cooling sequentially. Deadband thermostats are available for pneumatic, electric, and electronic control systems.

Deadband thermostats correct most of the causes of energy waste listed in Measure 4.3.4. Most deadband thermostats do not save fan energy, but some models are available with a fan switch and connections that allow the thermostat to turn off the fan when there is no heating or cooling.

Types of Deadband Thermostats

A deadband thermostat is essentially two independent thermostats in one housing. One thermostat controls heating and the other controls cooling. There

SUMMARY

Inexpensive. Usually easy to install. Different types provide different control characteristics.

SELECTION SCORECARD

Savings Potential	\$ \$ \$

Rate of Return, Retrofit	% % %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

are several different versions of dual-element thermostats. The differences between them are important, as follows.

■ **Fixed-Deadband, Dual Output Signal**

The most common type of deadband has a single temperature setting. The occupant cannot control the deadband interval.

The thermostat produces two separate control signals, one for the heating equipment and one for the cooling equipment. Some deadband thermostats allow you to adjust the sensitivity of each element individually. This is important if the heating and cooling equipment have different control characteristics. Also, some models allow one element to be connected direct-acting, while the other element is connected reverse-acting. (“Direct-acting” means that the output signal rises as the temperature rises. “Reverse-acting” means the opposite.)

Most deadband thermostats allow the staff to adjust the deadband interval by removing the thermostat cover. Get this important feature.

Figures 1 and 2 show how a deadband thermostat works. Figure 1 is the same type of system used as an example in Measure 4.3.4.1, without deadband. The graph in Figure 1 shows how the pressure output signal of the thermostat changes with space temperature, when the thermostat is set for a space temperature of 75°F.

Figure 2 shows how the control behavior changes when installing a deadband thermostat. One element in the deadband thermostat controls the heating valve, and the other controls the cooling valve. The graph in Figure 2 shows the pneumatic pressure output from the two elements when the thermostat is set to maintain a space temperature of 75°F. The graph shows that both valves are closed between 73°F and 77°F.

Electric and electronic (digital) deadband thermostats operate in a similar manner, except that they

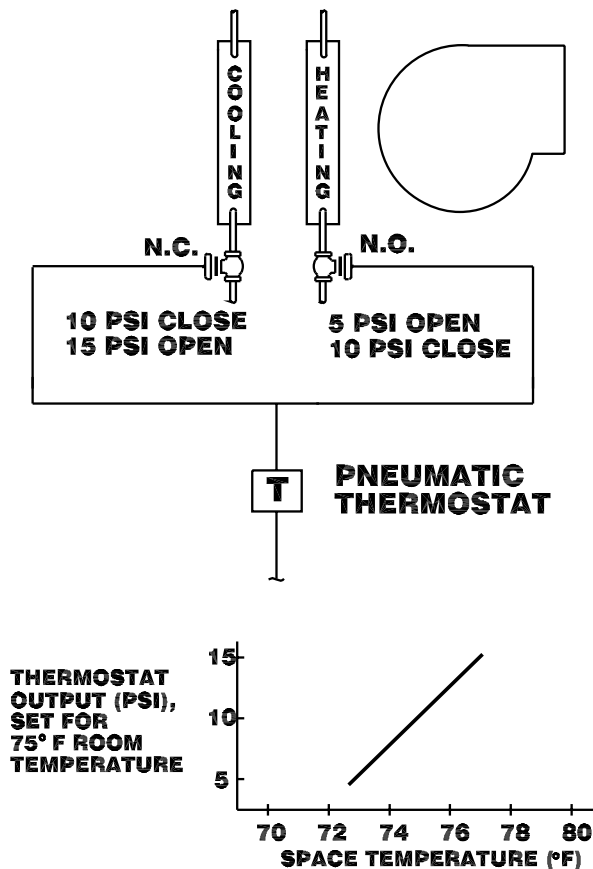

Fig. 1 Typical pneumatic temperature control The graph shows the strength of the output signal as the space temperature changes.

respond to electrical input signals rather than to air pressure.

■ Fixed-Deadband, Single Output Signal (Hesitation Thermostat)

A “hesitation” thermostat is a variation of a deadband thermostat that has a single output signal. The name derives from the fact that there is a plateau, or hesitation, in the output signal within the deadband temperature range. Figure 3 shows how a hesitation thermostat works in our example system.

In many applications, you can use either a conventional deadband thermostat or a hesitation thermostat. Hesitation thermostats do not have the control signal flexibility of the dual-output type. For example, use them where heating and cooling are both provided by hydronic coils having similar control valve characteristics.

■ Separately Adjustable Heating and Cooling Temperatures

Some thermostats have separate temperature settings for heating and cooling. The heating and cooling settings

are interlocked so that the heating temperature is always lower than the cooling temperature. These are not true deadband thermostats, because there is no way to maintain a fixed deadband when either temperature setting is changed.

The amount of deadband is under the control of the occupants. The advantage of this type is that it gives occupants more explicit control of heating and cooling temperatures. The disadvantage is that occupants may not exploit the energy saving potential of the thermostat. Consider using this type in environments where occupants are permanently assigned to spaces, especially where a single responsible individual controls the thermostat.

How to Set the Deadband

Set the deadband as high as the thermostat allows. Reduce the deadband incrementally if there are legitimate comfort complaints. Expect the maximum acceptable deadband to differ between spaces, especially between interior and perimeter spaces.

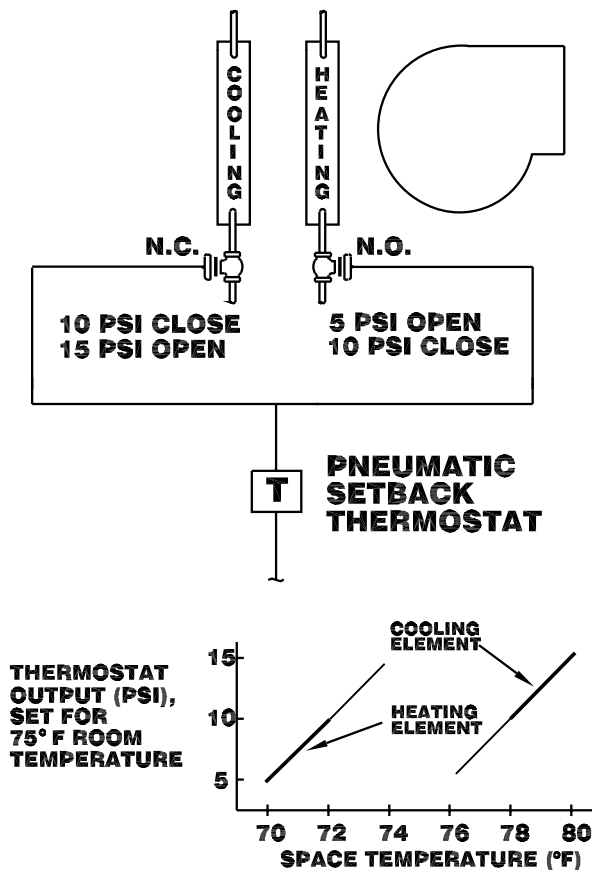

Fig. 2 Dual-output deadband thermostat This is the most common type of deadband thermostat. It has two separate sensing elements, each with its own output characteristics and adjustments. The cooling element controls only the cooling coil, and the heating element controls only the heating coil.

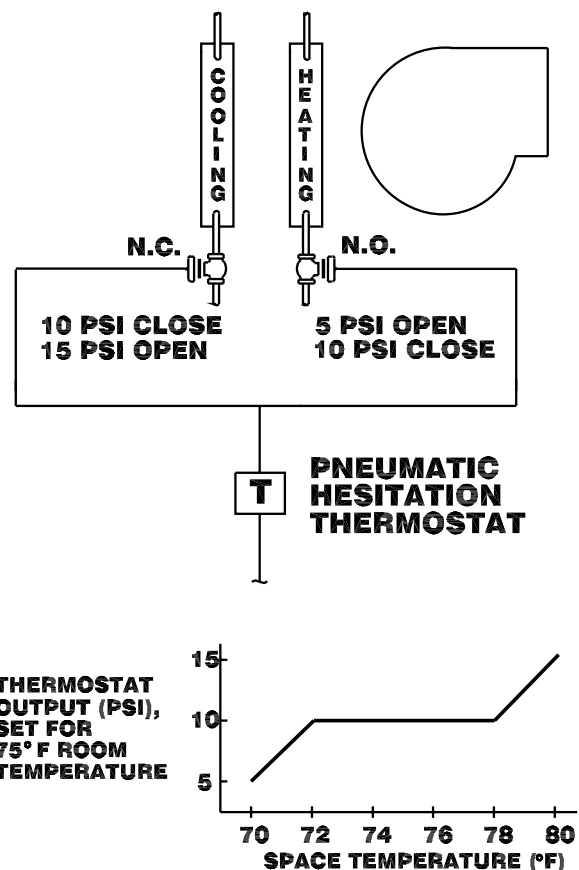

Fig. 3 Single-output (hesitation) deadband thermostat This variation has a single output that goes to both coils. It is less versatile than the dual-output type.

Install Thermostat Placards

This Measure depends on occupants to set the space thermostats efficiently. Therefore, an effective instruction placard is an integral part of each thermostat installation. See [Measure 4.3.1](#) for details.

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of conditioning cost. The higher percentages occur in milder climates, where the overall energy consumption is lower.

COST: Deadband thermostats cost less than \$100. In retrofit applications, they can replace the original thermostat in an hour or two.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING THE THERMOSTATS: For most applications, select true deadband thermostats, the kind that have a fixed deadband setting that can be changed only by the maintenance staff. Select units that make it easy for occupants to set the space temperature.

EXPLAIN THEM: To forestall vandalism and comfort complaints, install instruction placards that tell occupants how the thermostats control the space temperature. See [Measure 4.3.1](#).

STAFF TRAINING: The energy saving is determined by the person with the small screwdriver who sets the deadband in each thermostat. Make sure that the staff are trained to set the maximum acceptable deadband. Put clear instructions in the plant operating manual.

MEASURE 4.3.4.3 Adjust or modify the coil controls to increase deadband.

RATINGS

New Facilities	Retrofit	O&M
□	C	B

Look for opportunities to create deadband in existing comfort control systems by adjusting or modifying the coil valves or valve actuators. In some installations, you can simply exploit adjustments that are available on the existing coils or actuators. Deadband adjustments may be available with any of the major types of controls (pneumatic, electric, and electronic). We will use pneumatic controls to illustrate the basic methods.

If the coil valves in a pneumatic system are not adjustable, you can achieve the same effect by adding a simple device that offsets the control signal to one of the coils.

These modifications affect the way the thermostat behaves, so expect to adjust the thermostat afterward.

Modifying Valve Actuator Response

Pneumatic controls work by using air pressure from the control system to force valves open or closed against spring pressure. The previous [Measures, 4.3.4.1 and 4.3.4.2](#), increase deadband by modifying the control air pressure. The approach we use here is to change the response of the springs to the air pressure.

For example, in the typical pneumatic controls system shown in [Measure 4.3.4.1](#), the heating coil closes fully at a pressure of 10 PSI and the cooling coil starts to open at the same pressure, so there is no deadband. However, if you increase the tension on the cooling coil spring so that it does not start to open until the air pressure is 15 PSI, this creates a deadband between heating and cooling operation.

Some pneumatic valve actuators have built-in spring tension adjustments. The adjustments may even be calibrated in terms of air pressure. Adjusting these units is simply a matter of turning a knob. Figure 3 in [Measure 2.5.2](#) shows a valve like this. Other types of actuators provide for increasing the spring pressure by placing shims under springs.

Another possibility is replacing the existing actuators with units have different spring ranges. This approach is usually more expensive and less desirable than installing deadband thermostats.

With electric and electronic controls, you may be able to achieve similar results by adjusting the linkages between the electric motors and the valves. An electronic control system may provide a way for you to program it to provide deadband without making mechanical adjustments.

Signal Offset Relays

In pneumatic control systems, an offset relay is a device that changes the pressure in a line by a fixed

SUMMARY

Inexpensive ways to increase deadband in existing coil controls. With some types of controls, especially pneumatic, the available deadband range may be limited. Does not provide fan control.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓
Ease of Retrofit	😊 😊

amount. You can use offset relays in cases where the actuators themselves are not adjustable. In our previous example, the cooling coil valve starts to open at a pressure of 10 PSI. By inserting a offset relay in the line between the thermostat and the cooling valve to lower the air pressure, the opening of the cooling valve is delayed. For example, if you install a 5 PSI offset relay, the cooling coil valve will not open until the thermostat sends 15 PSI to the valve. This creates the same deadband range as in the previous example.

Offset relays that lower air pressure are inexpensive and easy to install. They are simply inserted into the pneumatic line, and require no other connections. Relays that increase air pressure are also available, but these require a connection to the system air supply, and they are more expensive.

Deadband Range Limitations with Pneumatic Controls

Depending on the type of control system, you may not be able to achieve the maximum comfortable deadband using these methods. With pneumatic controls, the deadband range is limited by the control air supply pressure. For example, if the maximum pressure that the thermostat can produce is 22 PSI and if the cooling valve operates over a 5 PSI range, then the offset relay should not increase the opening pressure above 17 PSI. Otherwise, the cooling valve will not be able to open fully.

With typical thermostat characteristics, supply air pressure limits the maximum deadband to about 2°F to 4°F. This is considerably less than comfort allows.

You can increase deadband somewhat by increasing the control air pressure. This is usually a simple matter of changing the setting of the pressure regulator at the air source. Do not exceed the maximum safe pressure

of any component served by the pneumatic system. You may not be able to change the system pressure if the pneumatic system has devices, such as setback thermostats, that are activated by changes in the supply pressure.

Another way to increase deadband in pneumatic systems is to reduce the sensitivity of the space thermostats. The sensitivity of the thermostat is the difference in control output that the thermostat produces for a given change in temperature. For example, a typical pneumatic thermostat has an adjustable range of sensitivity from 1 to 4 PSI per degree Fahrenheit.

Here is an example that illustrates the effect of changing the thermostat sensitivity. Assume that the cooling valve in our example opens at a pressure 6 PSI greater than the heating valve closes. If the thermostat is set for highest sensitivity (4 PSI/°F), the deadband is only 1.5°F. On the other hand, if the thermostat is set for lowest sensitivity (1 PSI/°F), the deadband is 6°F.

If you push this method to far, it affects comfort. Reducing the thermostat sensitivity too much allows the space temperature to drift too far from the thermostat setting.

Thermostat Calibration

The temperature figures on the thermostat become meaningless when you create deadband. To minimize confusion, calibrate the thermostat dial so that the numbers correspond approximately to the center of the deadband range.

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of conditioning cost. The higher percentages occur in milder climates, where the overall energy consumption is lower.

COST: Equipment costs, if any, are typically minor. For example, an offset relay costs about \$20. An experienced controls technician should be able to accomplish the work in an hour or two.

PAYBACK PERIOD: Less than one year, if you can create deadband with simple adjustments. Several years, if you need to make controls modifications.

TRAPS & TRICKS

EXPLAIN IT: Don't expect anyone to figure out what you did unless you explain it. Spell out the deadband setting procedure in the plant operating manual. Be sure to explain interactions between your method of setting deadband and other thermostat adjustments, such as sensitivity.

Single-Duct Reheat Systems

The Measures in this Subsection improve the efficiency of single-duct reheat systems. In these systems, the supply air is cooled at the air handling unit. The temperature of individual spaces is controlled by reheating the supply air in terminal units. The terminal units are controlled by the space thermostats. Figures 1 and 2, in the [Section 4 Introduction](#), sketch a typical single-duct reheat system.

There are two common variations of single-duct reheat systems:

- **terminal reheat systems**, in which each space has one or more reheat terminal units controlled by the space thermostat
- **zone reheat systems**, in which one reheat terminal unit serves several spaces that make up a zone of thermostatic control

In physical features, there is no difference between these two types except for the number of terminal units. A larger number of terminal units provides more accurate control of temperature in localized areas. This is important when there are significant differences in heat gain or heat loss between areas.

Induction systems are a related type, but they have major differences in equipment. In these systems, the air handling unit delivers chilled air at exceptionally high pressure. This “primary” air is passed through a venturi terminal unit in each space that induces the flow of “secondary” space air through a heating or cooling coil. Because of their special hardware and operational requirements, induction systems are covered separately in [Subsection 4.9](#).

By far the largest energy saving opportunity in single-duct reheat systems is minimizing reheat. Reheat is very wasteful. First, excess energy is expended to cool the supply air. Then, still more energy is expended to partially re-warm the same air before it enters the space. During low-load conditions, much more energy may be cancelled out

INDEX OF MEASURES

4.4.1 Set the cooling coil discharge at the highest temperature that maintains satisfactory cooling.

4.4.1.1 Install automatic chilled air temperature reset control.

4.4.2 Turn off the air handling unit cooling coils when cooling is not needed.

4.4.3 Turn off reheat coils when practical.

4.4.4 In terminal units that blend supply air with reheated air, block the reheat passages during the cooling season.

4.4.5 Trim the fan output.

4.4.6 Install multi-speed fan motors.

4.4.7 Convert the system to variable-air-volume (VAV) operation.

4.4.8 Replace all reheat coils in a system with heating/cooling coils and minimize operation of the air handling unit cooling coil.

4.4.9 Install self-contained heating/cooling units, and use the air handling system only for ventilation.

RELATED MEASURES

- [Subsection 4.7](#), for Measures that improve the efficiency of existing VAV single-duct systems
- [Subsection 4.9](#), for Measures that improve the efficiency of induction systems

in this manner than actually enters the space to provide cooling or heating.

The main justification for the popularity of reheat systems is comfort. They provide a high level of comfort because air flow is constant, control of temperature can be maintained precisely as the load changes from heating to cooling, and humidity can be controlled at any desired level. In making changes for the sake of efficiency, try to preserve these comfort advantages as much as possible.

Perhaps another factor in the popularity of constant-volume reheat systems is that any fool can lay one out without spending much effort on calculations or control design. All that is required is to install an oversized cooling coil, oversized reheat coils, and let the sizing mistakes cancel when the air is mixed. The owner pays for this negligence with high energy bills throughout the life of the building.

The Measures in this Subsection are oriented primarily toward reducing the energy waste that occurs from reheat. Some of the Measures also

save a substantial amount of fan energy. In new construction, none of these Measures adds a relatively large cost increase, unless the systems are small.

In retrofit applications, first decide whether or not to make major changes to the existing constant-volume system. This decision usually depends on two factors: how much money you can spend, and whether you can forego the tight control of humidity and ventilation that constant-volume reheat systems provide. If you cannot afford expensive changes, accomplish all of [Measures 4.4.1](#) through [4.4.5](#) that are relevant to your systems and applications.

If you can afford major system modifications, consider [Measures 4.4.7](#) through [4.4.9](#). These three Measures are alternatives to each other. Any of the three will provide the combined benefits of the less expensive Measures. [Measure 4.4.6](#) is an intermediate approach that saves less energy than the latter three Measures, and also costs considerably less. You can combine it with the first five Measures.

MEASURE 4.4.1 Set the cooling coil discharge at the highest temperature that maintains satisfactory cooling.

RATINGS

New Facilities	Retrofit	O&M
		A

The amount of energy that is wasted by reheat depends on the cooling coil discharge temperature in the air handling unit. A lower chilled air temperature forces each terminal unit to expend more energy to re-warm the air to the appropriate supply temperature for the space. Therefore, the simple act of raising the chilled air temperature is a powerful energy conservation action. And, it is easy to accomplish. See Figure 1.

The optimum chilled air temperature changes continuously, unless the cooling load is constant. Don't expect the staff to keep resetting the chilled air manually as conditions change throughout the day. The best they can do manually is to reset the chilled air at intervals, perhaps on a seasonal basis. Subsidiary Measure 4.4.1.1 improves on this Measure with continuous automatic resetting of the chilled air temperature. Use manual adjustment as a stopgap method until you install automatic reset controls.

SUMMARY

Save a lot of energy just by turning a screw.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	%
Reliability	✓	✓		
Ease of Initiation	😊	😊	😊	

Energy Saving

Let's calculate the energy saving at an individual terminal unit under typical conditions. Here are the conditions:

- the terminal unit delivers 1,000 CFM
- the space is cooled to 75°F
- the cooling coil maintains a supply air temperature of 55°F
- the air is dry enough so that all the cooling load is sensible
- the cooling load in the space is half its maximum, so that a supply air temperature of 65°F would suffice at this particular moment.

This table shows the effect of raising the chilled air temperature:

Energy Input, BTU/hr	Supply Air Temperature		
	55°F	60°F	65°F
cooling energy to space	10,800	10,800	10,800
cooling energy from coil	21,600	16,200	10,800
reheat energy	10,800	5,400	0
total input energy	32,400	21,600	10,800

This example shows how horribly wasteful reheat systems can be. At the original chilled air temperature of 55°F, the system consumes three times as much energy as is needed to cool the space. Experience with actual buildings confirms that reheat systems really are this wasteful.

Reheat systems are most wasteful at low loads. In fact, a reheat system consumes the most energy in absolute terms when the space load is zero, because the output of the cooling coil must be completely cancelled with reheat energy. In most climates, the cooling requirement is only a fraction of the design maximum

WESINC

Fig. 1 Chilled air temperature control Just by setting this knob the right way, you can save a large amount of energy in a reheat system.

load for much of the time. This fact keeps the reheat system in a very wasteful mode of operation.

How to Maximize the Chilled Air Temperature

Most reheat air handling systems have a chilled air thermostat that controls the cooling coil discharge temperature. You can reset this thermostat easily with a pocket screwdriver. If you have a centralized energy management system, you can achieve the same result by tapping on a keyboard.

Designers sometimes shave installation cost in hydronic reheat systems by omitting the control valve from the cooling coil. In such cases, the chilled air temperature is tied to the chilled water temperature. To raise the chilled air temperature independently, install a cooling coil valve that is controlled by a supply air thermostat. If you go to that expense, spend the additional money to install a reset controller, as recommended by subsidiary [Measure 4.4.1.1](#).

Limitations Caused by Load Diversity

Your ability to raise the chilled air temperature may be seriously limited by diversity in the cooling loads of the different terminal units. The chilled air temperature can be set no higher than the temperature needed by the terminal unit having the largest cooling load.

A single space that has inadequate cooling can thwart your attempt to raise the chilled air temperature. The space may have an exceptionally high load, or the terminal unit serving the space may be undersized, or a control defect may limit the output of the terminal unit. As you raise the chilled air temperature, be aware of which spaces run out of cooling capacity first. Examine the cooling of these spaces to see if any of these situations exists. For example, if a space with high solar gain requires exceptionally low chilled air temperature, try shading the space. Or, replace the terminal unit with one having higher air flow capacity. (Of course, the former solution is more efficient.)

Load diversity depends on the way the building is zoned. For example, if a reheat system serves a zone with extensive glazing on both the east and west sides of the building, then the load remains high for most of the day. This illustrates a major reason to pay attention to zoning when laying out an air handling system. Seize this opportunity in new constructions and renovations, because changing zoning on a retrofit basis is expensive.

Effect on Humidity

Raising the supply air temperature setting causes the coil surface to be warmer, so the coil does not condense as much moisture out of the air. As a result, raising the chilled air temperature allows the humidity inside the building to rise, assuming that the air entering the coil is humid. The dew point of the supply air is always somewhat lower than the supply air temperature.

For example, if the supply air temperature is 65°F, the dew point may be 60°F. The difference depends on the surface temperature of the cooling coil surface, the bypass ratio of the coil, and the percentage of outside air.

Problems with excess humidity may arise when the weather is mild and humid. They may also occur if a large amount of moisture is released within the space, for example, if there is a lot of decorative foliage. Basements are a special humidity problem, because contact with the earth keeps basement walls cool enough to condense moisture out of the air. Lower humidity may be needed to satisfy comfort standards in posh environments. Some manufacturing and storage applications require exceptionally dry air. In such situations, be cautious about reducing the chilled air temperature.

Humidity is not a problem during cold weather because cold outside air cannot carry much moisture, and air exchange keeps internal humidity tied to the external humidity. Humidity is not a problem during warmer weather if mechanical cooling is used, because operation of the cooling equipment dries the air.

Two factors keep humidity from becoming a problem in most locations, even during mild weather. One is that the outside air temperature swings widely during the day in most locations, so that conditions that create high internal humidity persist only for a few hours, usually not long enough for humidity to become objectionable. The normal operation of cooling equipment during part of the day dries out the spaces.

The other helpful factor is heat gain. In a building with typical levels of heat gain, the heat gain alone usually keeps humidity from becoming excessive. As an extreme example, consider a rainy day in New Orleans with the outside temperature at 65°F. If heat gain (from solar gain, lighting, etc.) provides a temperature rise of 8°F, the relative humidity inside the building can be no higher than 77%, even if the air handling system is turned off. If the cooling system operates at all, even without reheat, the relative humidity in the space will fall even lower.

Explain It and Keep Reminding!

This activity is easily forgotten. Therefore, document the procedure in a manner that keeps it in the eye of the plant operators. Install an effective placard at the discharge air thermostat that explains how to set it. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: 10 to 40 percent of cooling and reheat energy.

COST: Minimal.

PAYBACK PERIOD: *Immediate.*

TRAPS & TRICKS

TRAINING AND DILIGENCE: *This Measure depends on the diligence and skill of the plant operators to keep the chilled water temperature as high as possible. The cooling load changes widely over the course of a day, so almost continuous attention is needed to achieve the maximum saving. Make sure that plant operators are trained and understand the importance of the*

adjustment. Put clear instructions in the plant operating manual. Install a placard at the thermostat that identifies it and explains its purpose. Schedule periodic checks of the procedure.

CHOICE OF METHOD: *If you cannot be sure of maintaining effective staff performance, install an automatic chilled water reset controller, as described next. In fact, there are few instances where manual control is more than a stopgap approach.*

MEASURE 4.4.1.1 Install automatic chilled air temperature reset control.

This is a refinement of [Measure 4.4.1](#) that automatically keeps the chilled air temperature as high as possible under all load conditions.

How to Install Chilled Air Temperature Reset

Chilled air temperature reset is a standard control function. Usually, the reset controller determines the appropriate chilled air temperature by sensing the signal from a space thermostat. In pneumatic control systems, a receiver-controller is used to perform the function. In buildings that have an energy management computer system, you can usually accomplish this function through the computer system.

For maximum efficiency, connect the reset controller to all the space thermostats that may dictate the chilled air temperature at one time or another. You may need to sense the thermostat signals from a number of spaces, because the heat loads of different spaces do not vary in unison. The thermostat that is calling for the greatest cooling at any given moment is selected by installing a signal discriminator. For further detail, see [Reference Note 14](#), Control Signal Polling.

For example, solar load is greatest in east-facing perimeter spaces in the morning, but in west-facing spaces in the afternoon. In addition, the reset controller should sense thermostats in any spaces that may experience exceptionally high heat gains, such as auditoriums, conference rooms, dining areas, and computer rooms.

■ Increase the Potential for Reset

The benefit of this Measure is limited by load diversity, or by any conditions that cause a space to require abnormally low chilled air temperature. Once the reset control has been installed, it becomes easier for you to find out which spaces are limiting your ability to raise the chilled water temperature.

If one space, or a small number of spaces, require substantially lower chilled water temperature, reduce the load on these spaces, or provide greater cooling air flow, as suggested by [Measure 4.4.1](#). Repeat this process until further improvements no longer provide enough increase in chilled water temperature to be economical.

■ Humidity Override

In applications where space humidity may become excessive, install a space humidistat to override the chilled air temperature reset when necessary. See [Measure 4.4.1](#) about conditions that may require a humidity override.

SUMMARY

Most reheat systems with hydronic cooling coils should have this control feature. It is the only way to keep chilled air near its optimum temperature.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓		
Ease of Retrofit	😊	😊	😊	

■ Systems with Economizer Cycles

Economizer cycles are methods of exploiting low outside air temperatures to cool the interior of a building. In a reheat air handling system that is equipped with an economizer cycle, the controls should keep the chilled air temperature as high as possible while the economizer cycle is operating. This is the same as with the operation of the cooling coil. See [Measure 4.2.5](#) about airside economizer cycles, and [Measure 2.9.4](#) about waterside economizer cycles.

ECONOMICS

SAVINGS POTENTIAL: 20 to 60 percent of cooling and reheat energy, typically.

COST: The control components for a typical installation typically cost from several hundred dollars to several thousand dollars. Connection to thermostats at widely dispersed locations can incur high labor cost. If an energy management computer is installed, programming the computer to accomplish chilled air temperature reset typically costs several thousand dollars.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

PLANNING AND DESIGN: This is more than a control modification. To get the most benefit from this Measure, correct any conditions that cause some spaces to require lower chilled water temperature than the rest. In climates that are humid when temperatures are mild, you will need controls that respond to humidity as well as to temperature.

EXPLAIN IT: Describe the reset control in the plant operating manual. If you use a separate control panel for this function, install a placard on the panel to identify it.

MONITOR PERFORMANCE: The reset control can fail, or it can be adjusted improperly, without anyone noticing.

Therefore, check performance periodically. Include a column in the plant operating log to record the chilled air temperature, or use your energy management computer to log this information. Review the record periodically to verify that the chilled air temperature rises as the cooling load falls.

MEASURE 4.4.2 Turn off the air handling unit cooling coils when cooling is not needed.

RATINGS

New Facilities	Retrofit	O&M

If you turn off the cooling coil in an air handling system, you eliminate all reheat. If your system lacks control features to eliminate reheat, turn off your cooling coils during periods when you expect that cooling will not be needed.

Almost all air handling systems with hydronic cooling have cooling coil isolation valves that you can shut. In systems with direct expansion cooling, you can turn off the power to the compressors.

If your systems do not have supply air temperature reset controls, this Measure is a stopgap until you install reset controls, as recommended by [Measure 4.4.1.1](#). If the reset controls are adjusted properly, they will turn off the cooling coils when there is no cooling load.

Even if your systems have reset controls, it is still a good idea to turn off the coils on a seasonal basis to protect against inadvertent reheat resulting from coil leakage or a control failure. Put this on your schedule.

Energy Saving Potential and Limitations

The Measure eliminates reheat losses when they are greatest. This is because reheat systems consume the largest amount of energy when there is no cooling load. In a constant-volume reheat system, the cooling coil is always at maximum output (if the cooling coil discharge temperature is held constant). Therefore, operation of the system when there is no cooling load requires an amount of reheat energy equal to the cooling energy. All the cooling energy is wasted, along with the heating energy needed to cancel it.

Conversely, this Measure can provide an energy saving only during periods of time when the system has no cooling load. In practice, the staff cannot be standing by each air handling unit to turn off the cooling coils whenever the cooling load disappears. For this reason, this Measure is likely to be a seasonal activity.

The cooling coils may be turned off in different air handling units at different times. For example, air handling systems serving perimeter spaces with substantial solar gain must keep their cooling coils turned on longer than air handling units serving only shaded perimeter spaces. In many buildings, the core area of the building requires cooling all year. If a particular air handling system serves any spaces located in the core

SUMMARY

An easy method of eliminating reheat during periods when cooling is not needed. A stopgap measure to use until you install a chilled air temperature reset controller ([Measure 4.4.1.1](#)). Also a safety feature to use with a reset controller.

area, you may have to keep the cooling coil operating continuously for the benefit of these spaces.

Explain It and Keep Reminding!

Neglecting this procedure produces no discomfort or other apparent effects, so the action is likely to be neglected. Document the action in a manner that keeps the operating staff aware of it.

ECONOMICS

SAVINGS POTENTIAL: 10 to 60 percent of cooling and reheat energy, depending primarily on the weather and the system zoning.

COST: None, usually.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

EXPLAIN IT: Success depends on training and supervision. Provide clear instructions that explain when to turn off the cooling coils, e.g., when the outside air temperature is below a certain temperature. Optimize the schedule for each air handling unit or group of units. Install placards at the cooling coil valves or at the controls of the compressors in self-contained air handling units.

MONITOR PERFORMANCE: This Measure is easy to forget. Schedule periodic checks of the procedure in your maintenance calendar.

MEASURE 4.4.3 Turn off reheat coils when practical.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

You can eliminate reheat by turning off the reheat coils. This method eliminates the ability of the air handling systems to control the different spaces individually. In effect, it turns a reheat system into a single-zone cooling system.

For most applications, this is a crude stopgap measure. It has been used widely during energy shortages because it eliminates energy waste due to reheat. The discomfort that results from eliminating individual space temperature control can be serious. When applied indiscriminately, this kind of desperate action gives energy conservation a bad name.

Applications, Limitations, and Alternatives

This method is used during warm weather, at times when all the spaces served by the air handling system require cooling. It can also be used during cooler weather with systems that exclusively serve the interior areas of a building.

This action is likely to create some discomfort except in the most favorable cases, such as a system that serves only similar core areas. If the system serves the perimeter area of the building, they must all have the same exposure to the sun, which is unlikely because of differences in window area, shading by adjacent buildings, etc.

Don't use this method unless you are desperate. If you need to reduce energy consumption immediately and you don't have much money for efficiency improvements, try [Measures 4.4.1 ff](#) and [Measure 4.4.5](#) first.

Control Changes

With the reheat coils turned off, you need to change the way the cooling coil discharge temperature is controlled. Originally, the coil is controlled to maintain a constant discharge temperature. When you turn off the reheat coils, the discharge temperature needs to

SUMMARY

Saves a lot of energy cheaply, but is usually limited to situations where you need to save energy on an emergency basis. Likely to cause discomfort because it eliminates individual space temperature control.

follow the space load. To do this with a hydronic cooling coil, use a space thermostat to control the coil, instead of the original coil discharge thermostat. With a refrigerant (DX) coil that is controlled by staging the compressor, use a space thermostat to control the compressor.

With the reheat coils in operation to provide heating, use the original thermostatic controls. Make it easy to switch between the original controls and the modified controls.

ECONOMICS

SAVINGS POTENTIAL: 10 to 50 percent of cooling energy. 30 to 80 percent of reheat energy.

COST: Minimal.

PAYBACK PERIOD: Short.

TRAPS & TRICKS

CHOICE OF METHOD: This is a desperation measure for systems that do not have the proper controls. If you need to do this, get your system fixed.

MEASURE 4.4.4 In terminal units that blend supply air with reheated air, block the reheat passages during the cooling season.

RATINGS

New Facilities	Retrofit	O&M
		C

The Measure applies to a type of reheat terminal in which supply air is discharged through two parallel passages. One is straight through, and the other is through a heating coil. See Figure 1. Flow through the two passages is controlled by linked dampers that respond to the space thermostat. The volume of air flow is intended to remain approximately constant.

With this type of terminal, you can eliminate reheat during part of the year by blocking the reheat coil passage. This makes the terminal unit behave like a shutoff VAV terminal.

Applications and Limitations

If you have this unusual type of terminal unit, you can use this trick as long as no heating is required in the space served by the terminal. In a given air handling system, you may be able to use this method with some terminal units, but not with others. Or, you may have to use it on different schedules with different terminal units.

Fig. 1 Terminal unit with separate reheat path You can make this type of terminal unit act as a VAV terminal by blocking the reheat passage.

SUMMARY

An inexpensive but clumsy way to eliminate reheat seasonally in systems that use an uncommon type of terminal units. May cause noise and inadequate air flow.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	✓
Ease of Initiation	😊		

The activity is awkward and takes time, so you can do it only on a seasonal basis. You may be able to permanently modify terminal units that serve core areas, provided that the core areas need only cooling. This does not work if the core area needs a morning warm-up during cold weather.

In perimeter areas, the eligible period of the year depends on the climate and internal heat gains.

This Measure has all the limitations of a shutoff VAV system, which are explained in Measure 4.4.7. These include the possibilities of poor diffuser performance, inadequate air circulation, inadequate outside air ventilation, and diffuser noise at low loads.

This Measure is compatible with other inexpensive methods of reducing reheat losses, especially with chilled air temperature reset (Measures 4.4.1 ff) and fan trimming (Measure 4.4.5).

Energy Saving

This Measure eliminates all or most reheat and excess cooling in spaces where it is used, during the period of time when it can be used. This Measure functions only during the warmer part of the cooling season. Reheat losses are lowest under these conditions, but they are still serious.

The annual saving varies widely, depending mostly on the climate. In warm climates, the Measure may eliminate a majority of reheat energy, along with the cooling energy that it cancels. In colder climates, the Measure may be limited to only a couple of months per year.

The saving potential is greater in core spaces than in perimeter spaces, because the Measure can be used there for longer durations.

The Measure provides a small reduction in fan energy because the reduction in total system air flow causes the fan to draw less motor power.

How to Modify the Terminal Units

Take a look and see whether you have this type of terminal unit. It is uncommon because it is bulky and offers no significant advantages compared to simpler reheat terminals. (These units do not require reheat coil valves, but this cost saving is offset by additional dampers and sheetmetal.)

If you have this type of terminal, you need to devise a method of blocking the reheat passage of the terminal unit. You may have a choice of locations for doing this, as shown in Figure 1. With some models, you can do this easily by inserting a rectangular piece of sheetmetal through a joint in the casing. Unless you intend to block the reheat passage permanently, make the barrier easy to install and remove.

Expect it to be awkward to install and remove the inserts. You will have to bring a ladder into the space, find each terminal unit, and work through the ceiling.

ECONOMICS

SAVINGS POTENTIAL: *In predominantly warm climates, 50 to 80 percent of reheat energy and 30 to 60 percent of cooling energy. In predominantly cool climates, less than 30 percent of reheat and cooling energy. Also, 2 to 15 percent of fan energy.*

COST: *\$30 to \$100 per terminal unit for the initial modification, plus a fraction of an hour of labor per terminal unit each season to install and remove the blocking insert.*

PAYBACK PERIOD: *Several months, typically.*

TRAPS & TRICKS

SCHEDULING AND DILIGENCE: *This is a kind of job that the staff would rather avoid. Make sure that it gets done. Designate a reliable place to store the terminal unit inserts during the periods when they are not needed.*

MEASURE 4.4.5 Trim the fan output.

Fan trimming is a one-time adjustment that gets rid of fan capacity in excess of the amount needed to satisfy peak loads. Refer to [Measure 10.3.1](#) for details.

This is a cheap and simple way to reduce reheat significantly while saving a modest amount of fan energy. In a reheat system, both excess cooling energy

and reheat energy are proportional to the air flow rate. This Measure reduces both “off the top.” However, it does not tailor fan output to a changing load.

Consider this a stopgap action to save energy until you can accomplish one of [Measures 4.4.6](#) through [4.4.9](#).

RATINGS		
New Facilities	Retrofit	O&M
□	□	B

MEASURE 4.4.6 Install multi-speed fan motors.

RATINGS

New Facilities	Retrofit	O&M
C	C	

In a reheat system, both excess cooling energy and reheat energy are proportional to the air flow rate. In a constant-volume reheat system, the fan output is determined by the need to deliver heat or cooling during extreme load conditions. However, extreme heating or cooling conditions typically occur for only a small fraction of a system’s operating hours. This makes it worthwhile to adjust fan output to follow the cooling and heating loads.

One method of doing this is to install a multi-speed fan motor. This method changes air flow in a stepwise manner that is appropriate for shifting between peak conditions and average conditions. It is a compromise between efficiency and installation cost.

Comparison to VAV

The principle of this Measure can be extended to its extreme by converting the system to variable-air-volume (VAV) operation. This is recommended by [Measure 4.4.7](#), next. Multi-speed fans do not provide all the savings that are possible with VAV. On the other hand, multi-speed fans maintain a substantial minimum air flow rate. This avoids much of the trouble that arises in VAV systems when they are operating at very low flow rates.

In retrofit, this Measure is much less expensive than VAV because it avoids the cost of replacing all the existing terminal units, and it avoids the higher cost of a VAV fan drive and fan controls.

Energy Saving Potential

■ **Reheat and Excess Cooling Energy**

In a reheat system, both reheat energy and the excess cooling energy required to cancel it are proportional to the air flow rate. (This is not precise, because coil heat transfer improves somewhat as the flow rate is reduced.) For example, if you install a motor with a 2:1 speed ratio, air flow will be reduced by half for much more than half the time. Therefore, reheat energy and the corresponding excess cooling energy typically are reduced by more than half.

■ **Fan Energy**

In constant-volume reheat systems, fan power is proportional to approximately the third power of the air volume delivered. For example, if fan motors with a 2:1 speed ratio are installed, fan power is reduced to approximately one eighth at the lower fan speed. In typical applications, the fan motors will operate at the

SUMMARY

Saves a large amount of reheat, cooling, and fan energy. Not as efficient as VAV, but much less expensive as a modification and less susceptible to problems.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺		

lower speed for a large majority of the time. Thus, total fan energy consumption typically is reduced by well over half.

■ **Heating and Cooling Energy in 100%-Outside-Air Systems**

In 100%-outside-air systems, the air handling systems must cool and/or dehumidify the air starting from outside conditions. In warm weather, this is more energy intensive than conditioning return air. This Measure reduces the excess energy consumption in proportion to the air volume reduction.

(To be precise, reducing the fan output reduces proportionately the amount of energy required to bring outside air to room temperature. It has no effect on the amount of energy required to raise the air from room temperature to supply temperature.)

In cool weather, reducing the amount of outside air may not save energy. It may require less energy to take in outside air than to cool recirculated air. This is the principle of the outside air economizer cycle, which is explained in [Measure 4.2.5](#).

How to Select the Multi-Speed Motor

See [Reference Note 36](#), Variable-Speed Motors and Drives, for details of multi-speed motors. Also, see [Measure 10.1.1](#) about selecting efficient motors in general.

In retrofit applications, you can usually find a multi-speed motor that fits the mounting fixtures of the original motor, making installation simple. However, a multi-speed motor is larger in overall dimensions.

How to Switch Fan Speeds

For most applications, use automatic fan speed switching. Manual switching of motor speeds is not reliable. After the fan is switched to high speed to satisfy a period of high load, switching the fan back to low speed is likely to be neglected.

Automatic switching of motor speeds requires some custom control work that can sense when there is a high heating or cooling load in the space. For example, with a pneumatic control system, you can switch the motor speeds with a pressure signal from the thermostat. If the zero-load output of the thermostat is 10 PSI, the motor might be switched to high speed by an output signal lower than 6 PSI (for heating) or higher than 14 PSI (for cooling). Electrical and electronic controls systems may also provide an offset signal that indicates the magnitude of the space load. To keep the fan from short cycling between high and low speeds, there needs to be a difference between the signal at which the fan switches up to high speed and back down to low speed.

Control the fan speed with the space thermostat that has the greatest conditioning requirement. The fan switches to the lower speed only when the reduced air flow can satisfy the conditioning requirement of this thermostat. The maximum conditioning load may shift from one space to another, so you may have to install controls that identify the space with the greatest load. See [Reference Note 14](#), Control Signal Polling, for the methods of doing this.

How to Avoid Resonances

Check for noisy mechanical resonances at each fan speed. Resonances occur because of interaction between the fan and adjacent structure and ductwork. If a resonance occurs, correct any imbalance in the fan. Then, if necessary, try an adjustment in fan speed to eliminate the noise. If this throws off the fan speed too much, stiffen or preload the vibrating components to change their resonant frequencies.

How to Avoid Problems at Reduced Air Flow

A number of problems may appear at the reduced air flow rate. You can probably find satisfactory solutions to these problems. See [Measure 4.3.3](#) for details. For example, if changing the fan speed affects outside air intake, add control capability to readjust the outside air quantity when the fan speed changes.

ECONOMICS

SAVINGS POTENTIAL: 30 to 60 percent of cooling and reheat energy, typically. 50 to 80 percent of fan energy, typically.

COST: Single-winding 2:1-ratio motors cost about \$400 per horsepower in small sizes and about \$100 per horsepower in large sizes. Two-winding motors, which are needed to achieve other speed ratios and larger numbers of speeds, are considerably more expensive.

The cost of installing the motor itself is usually minor. Installing manual switching typically costs several hundred dollars and up. Designing and installing automatic switching may cost several thousand dollars.

PAYBACK PERIOD: One year to many years, depending on the size of the motors, the duration of fan operation, and the complexity of controls.

TRAPS & TRICKS

CHOICE OF METHOD: Consider this as a cheaper and less efficient alternative to VAV. In retrofit, it may be the only practical alternative, but consider [Measures 4.4.8](#) and [4.4.9](#) also. When installing new systems, VAV or another efficient type of system is usually the best choice.

SELECTING THE EQUIPMENT: Select the motors for high efficiency. This requires calls to motor manufacturers, because multi-speed motors are not yet rated for efficiency. See [Measure 10.1.1](#) for other motor criteria.

EXPLAIN IT: The operation of unusual switching controls is not obvious. Describe the controls clearly in the plant operating manual.

MEASURE 4.4.7 Convert the system to variable-air-volume (VAV) operation.

RATINGS

New Facilities	Retrofit	O&M
B	C	

In principle, you can eliminate virtually all the energy waste of the constant-volume reheat design by converting the system to variable-air-volume (VAV) operation. The principle of VAV is simple. The cooling input to individual spaces is controlled by varying the flow rate of the supply air, rather than by reheating the supply air. This offers two major efficiency advantages: (1) the system provides only the amount of cooling that is needed by the space, which eliminates the need for reheat to control temperature, and (2) fan power is minimized at all times.

Although the VAV concept is simple, making it work well in practice has proven to be challenging. Many VAV systems infringe on comfort or they sacrifice much of the efficiency potential of the concept. The changing air flow rates that are an inherent part of the concept create a variety of problems. To achieve a satisfactory installation, you need to deal with each of these problems individually. As you do this, the simple concept may lead to complex control requirements.

Energy Saving

■ **Reheat Energy and Excess Cooling Energy**

The example at the beginning of [Measure 4.4.1](#) illustrates the extreme level of energy waste that occurs in reheat systems. This example is confirmed by actual experience, which shows that reheat systems may consume several times more energy than the amount actually delivered to the spaces for cooling and heating.

To calculate the saving in reheat that you can expect from using VAV operation instead of constant-volume operation, you need to calculate the total energy consumption of each terminal unit for both types of systems. Do this as illustrated by the example in [Measure 4.4.1](#).

In new construction, you can design a VAV system that eliminates all or most of this energy waste. A well designed VAV system typically has reheat losses less than 10% of those in a constant-volume reheat system. In retrofit applications, you may not be able to reduce reheat as well as you can in designing a new conditioning system.

For reasons explained below, you may be forced to use VAV terminals that have heating coils. This practice incurs considerable reheat. However, the reheat occurs only at the low end of the air flow range. As a result, the energy loss is much lower than that which occurs in constant-volume reheat systems, where reheat must overcome excess cooling at full air flow.

SUMMARY

The most efficient configuration for reheat systems. You have to work out a lot of details to achieve both comfort and high efficiency.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊		

With VAV terminals that have heating coils, reheat energy waste occurs at each terminal unit individually. The amount of reheat that occurs at each terminal unit depends on these factors:

- **whether the space requires cooling or heating.** The cooling coil in the air handling unit produces chilled air. If the space needs cooling, and if the terminal unit can throttle the air flow sufficiently to match the amount of supply air to the cooling load in the space, then no reheating occurs.
On the other hand, when the space requires heating, a heating unit must operate. The heating unit may be a coil inside the terminal unit, or it may be an entirely separate heating unit. The heating unit must satisfy the heating load in the space, and it must also cancel any cooling that enters the space through the air handling system.
- **the minimum-flow requirement.** For reasons explained below, it may be necessary to maintain a minimum flow through the terminal unit under all conditions. If the amount of chilled air that passes through the terminal provides more cooling than needed, the excess cooling must be cancelled by reheat. Using heat/cool changeover control of the terminal units, as discussed below, may eliminate or greatly reduce the minimum-flow requirement. If you use terminal units that can close to shutoff, leakage in the terminal units becomes an important factor. Any leakage behaves as a minimum-flow setting, and it wastes energy in the same way.
- **the chilled air temperature.** If the chilled air temperature is raised, the amount of cooling provided by a given amount of air flow through the terminal is reduced. Under conditions when reheat is required, raising the chilled air temperature

reduces the amount of reheat that is necessary to cancel unwanted cooling. Chilled air temperature reset is a powerful energy conserving technique. However, it is limited by diversity of space cooling loads. This is because the chilled air temperature must be set low enough to satisfy the cooling load on the terminal unit with the greatest cooling requirement.

It is important to understand that the amount of reheat energy waste in a VAV system is not fixed and predictable at the time the system is designed. On the contrary, energy waste depends largely on system adjustments that are made at the time of installation and later throughout the life of the system. These adjustments are needed to deal with issues that we will discuss below. To a large extent, the adjustments are arbitrary, or they are a matter of preference. A terminal unit in one space may be adjusted to eliminate most reheat energy waste, whereas an identical terminal unit in the adjacent space may be adjusted in a way that causes a large amount of reheat energy waste. To minimize reheat energy waste in a VAV system, adjust each terminal unit properly. In addition, exploit chilled air temperature reset as much as possible.

■ Conditioning Outside Air in Once-Through Systems

In systems that require 100% outside air, such as those used in hospitals, VAV additionally provides a major reduction in the amount of energy required to condition outside air. This is because the constant-volume system must take in enough outside air to convey heating and cooling under peak load conditions. However, the average conditioning load is much less than the peak load. A VAV system takes in only enough outside air to convey the heat or cooling that is required at the moment.

This component of savings is greatest in warm, humid climates. In such locales, the constant-volume system must waste a large amount of energy in cooling and dehumidifying a large quantity of air. Conversely, in cool climates, bringing in outside air saves cooling energy by reducing the cooling load on the cooling coil. (This is the principle of the economizer cycle, which is covered by [Measure 4.2.5](#).) When space heating becomes the dominant load, VAV substantially reduces the amount of energy needed to heat outside air.

■ Fan Energy

A fan operating in VAV mode delivers only enough air flow to carry the required amount of heating or cooling energy into the spaces.

The relationship between fan power and air flow varies considerably, depending on the type of terminal units, the zoning of the system, the duct layout, the method of fan control, and other factors. The power required by the fan to overcome the air flow resistance of the coils and ductwork is approximately proportional

to the third power of the air flow rate. The power required to overcome the resistance of the dampers in the terminal units is roughly proportional to the first power of the flow rate. (The latter is because the dampers act to keep the pressure opposing the fan constant, instead of letting the pressure drop at lower flow rates.) The actual power required by the fan varies between these two extremes.

(There is a widespread misconception that fan power in a VAV system is proportional to the third power of the air volume delivered. This error leads to excessively optimistic estimates of fan energy savings. This misconception results from failure to recognize the variable resistance of the terminal units.)

All the methods of varying fan output in VAV systems (variable-speed drives, inlet vortex dampers, discharge dampers, etc.) have inefficiencies that partially offset the saving in fan power. The best of the methods preserve most of the fan energy savings. The worst dissipate a large fraction of the potential savings.

VAV Design Challenges

Behind the simple concept of VAV lies a multitude of potential problems. These problems arise mainly because of two difficulties that are characteristic of VAV systems:

- **providing heating.** A single-duct VAV system is basically a cooling system, whereas a reheat system can provide either cooling or heating with equal ease. If some of the spaces served by a VAV system require heating, you need to add heating capability to the VAV system. Selecting the heating method involves serious compromises, especially in retrofits.
- **low air flow at low load.** VAV operation produces large variations in air delivery to the spaces. This variation may cause a number of problems. Dealing with these problems involves further compromises.

These characteristics tend to force VAV system design into a compromise between discomfort, energy waste, and control complexity. As you design a VAV installation, consider the following factors. Many of them are related, which makes VAV design a feat of mental juggling. If you deal with all these factors systematically, you will be able to predict the performance of your system with reasonable certainty and you will avoid unpleasant surprises. Further below, we discuss specific heating methods and specific methods of dealing with the problems of low space air flow.

■ Outside Air Ventilation

If you need to maintain uninterrupted outside air ventilation, this is likely to require some reheat. In a single-duct VAV system, the chilled air supply from the air handling unit is the only source of outside air. When cooling is needed, this presents no problem. However,

when heating is needed, the outside air coming through the chilled air supply needs to be heated.

The amount of energy waste depends on the ventilation requirement, on the fraction of outside air in the supply air, and on the supply air temperature. For example, a typical U.S. ventilation requirement for commercial buildings is 15 CFM per person. If outside air comprises one third of the supply air, then 45 CFM of chilled air is delivered to the space for each person. The extra 30 CFM of supply air has to be cooled and then reheated to room temperature.

With a shutoff VAV system, no outside air ventilation can enter the space while the terminal unit damper is closed. In a shutoff system with deadband thermostats, this condition may persist for long periods during mild weather. This problem occurs only during mild weather, so the solution may be simply to open a window. However, this option is not available in many buildings.

A system may waste more energy by sloppy control of outside air quantity than by heating the air that is actually needed to satisfy ventilation standards. In recirculating air handling systems, the method of controlling outside air quantity depends on the “front end” configuration of the air handling system. A well designed air handling system maintains accurate control of outside air intake even as the fan output changes. Unfortunately, this ideal is rarely achieved. The amount of outside air intake tends to vary strongly as the fans change output. Overcoming this tendency may require improvements to the system’s “front end,” as recommended by [Measure 4.2.2](#).

Even if the amount of outside air drawn into the total system is controlled well, the outside air is still distributed unevenly to individual spaces. For example, if a system serves both core and perimeter spaces, most of the air may be delivered to the core spaces on a cool day, and to the perimeter spaces on a hot day. You have to decide whether it is satisfactory to distribute ventilation air by letting it diffuse from one space to another. This may be acceptable if the occupant density is low and the air quality is benign.

The only way to eliminate energy waste in ventilation and to distribute it accurately is to install a separate outside air ventilation system, with its own ducts, fans, heating, and cooling elements. This approach is worth considering, although it is rare at present.

■ Dehumidification

Reducing the air flow rate into a space reduces the dehumidifying effect of the air handling system. This is most likely to be a problem in humid climates when mild temperatures keep the dampers in the terminal units closed. [Measure 4.4.1](#) covers situations that may encounter humidity problems.

If there are times when normal cooling does not provide adequate control of humidity, some reheat may

be needed. The cooling coil is operated to wring moisture out of the air, and the heating coil (or other heating equipment) restores the temperature. If the system uses reheat for dehumidification, design the controls to limit reheat to the amount needed.

The most efficient approach is to use a space humidistat to control reheating at low loads when necessary. A danger is that humidistats, especially cheaper types, are poorly calibrated and tend to drift. Thus, they could waste energy for years without the fact being noticed. To minimize this problem, use humidistats of the highest quality.

■ Diffuser Performance

When the system is providing cooling at low fan outputs, cold air tends to dump out of the diffusers, rather than diffusing throughout the space. This can cause discomfort to occupants located near the diffusers. VAV systems have become notorious for this problem.

Reduced air flow can also cause a problem when heating. In this case, the warm air tends to stay at ceiling level, rather than mixing with the rest of the air in the space.

There are large differences in the effectiveness of diffusers at low air velocity. In converting constant-volume systems, be prepared for the possibility that the present diffusers will not be satisfactory for VAV. This is especially likely if you install VAV boxes that can shut off completely. This issue is discussed further, below.

Chilled air temperature reset (explained in [Measure 4.4.1](#)) substantially reduces the tendency for chilled air to dump at low loads. Reset increases the volume of air at low cooling loads. This improves diffusion. It also decreases the temperature differential between the chilled air and the space air, which reduces the convective force that causes dumping.

Another solution is to use fan-powered VAV terminals, which maintain a minimum air flow through the diffusers by recirculating air within the space. This type of terminal unit is covered below.

■ Circulation of Air Within the Space

VAV operation greatly reduces the air delivery rate during periods of low cooling or heating load. It is not clear whether this factor contributes to discomfort, in itself. In early comfort theory, lack of air movement was considered to be uncomfortable. However, experience shows that many people are comfortable in spaces that have minimal air circulation.

Later research suggests that complaints of “stagnation” are due primarily to high space temperature or humidity. Lowering one or both usually satisfies a complaint of “stagnation,” but at the cost of increased cooling energy.

Complaints of “draft” in a VAV system are usually not due to air flow that is too high, but to dumping of cold air from the diffusers, as discussed previously.

In many environments, you can provide air circulation with little energy cost by installing high-volume, low-velocity circulation fans, such as ceiling paddle fans. A bonus is that the cooling effect of circulation fans can significantly reduce the cost of mechanical cooling. However, each fan can serve only a limited amount of space. Ceiling fans also create an annoying stroboscopic effect if they are installed underneath ceiling light fixtures.

Fan-powered VAV terminals can maintain a minimum air velocity in the space, but they are not as effective as in-space circulation fans for this purpose. Both in-space fans and fan-powered VAV terminals have a noise penalty.

■ Space Pressure Differentials

The large variations of air delivery in a VAV system may cause troublesome changes in building pressure. Whether problems occur depends on the nature of the facility, the layout of the air handling systems, the layout of the spaces, and the “front end” design of the air handling systems. [Measure 4.2.1](#) covers the design of systems to minimize pressure problems.

The amount of air delivered to each space is independent of the amount delivered to the others, so pressure differences can occur between spaces. In applications where isolation is important, such as hospitals and laboratory buildings, this characteristic may disqualify a VAV system. The pressure differences are usually not a problem in non-critical applications, such as office buildings.

■ Noise

Modulating the speed of the supply and return fans, which is the best method of modulating air flow, substantially reduces their average noise level. The changes in noise level that occur as the fan output changes are so gradual that they are not noticeable.

VAV terminal units may produce noise that is loud enough to be annoying, especially when they are operating near the fully closed position. Minimize this problem by selecting the terminal units for low noise, as discussed below. In addition, you can reduce terminal unit noise by lowering the duct pressure at low loads, as discussed below.

■ Fan-Induced Resonances

At certain specific speeds, a fan may trigger resonances in the air handling sheetmetal or in the building structure. This is a significant possibility in VAV systems because the fan operates across a continuous range of speeds.

Air handling system resonances are rarely serious, if the system equipment is installed properly. The vibrational frequency of centrifugal fans is higher than the resonant frequencies of typical structures and ductwork. If a serious low-frequency resonance does occur, it is likely to be caused by an unbalanced fan

wheel, which you can correct by balancing it. If this does not solve the problem, stiffen the vibrating components, which increases their resonant frequency and reduces the intensity of vibration.

■ Air Cleaning

Air cleaning is covered by [Measure 4.2.4](#). If the air handling system is used for air cleaning, by filtering or other processes, the rate of cleaning is proportional to the flow rate. VAV reduces air flow, so it also reduces air cleaning.

Design Outline for VAV

Follow these steps to convert a constant-volume air handling system to VAV, either in designing a new system or in converting an existing system:

- Decide how to provide heating in spaces that require heating. This decision affects most of the other aspects of the modification.
- Replace the reheat terminals with VAV terminals.
- If necessary, replace the air diffusers in the spaces to provide good performance at all air delivery rates.
- Install an efficient means of varying the output of the air handling system fans.
- Install a control system for the fan output.
- Install reset control for the supply air temperature, and perhaps, for the duct pressure.
- Provide controls for various auxiliary functions, such as morning warm-up, night setback, outside air economizer cycle operation, smoke relief, etc.

There may also be other modifications that are appropriate at the same time, such as changing the duct layout, even though these are not an inherent part of the VAV concept. The rest of this discussion covers these steps in greater detail.

How to Provide Heating

VAV systems are basically cooling systems. Converting a constant-volume system to VAV raises the question of how to provide heating. In principle, you could use any kind of heating equipment with a VAV system. Practical considerations usually limit the choice to heating coils in the terminal units, or to convectors in the spaces, or to heating coils in the air handling unit. The difficulties of providing heating with a VAV system at reasonable cost tempt the designer to make compromises with comfort and health. If compromises are necessary, keep them reasonable. Here are some important factors to consider in selecting the heating equipment for a VAV system.

■ Morning Warm-Up

The need for morning warm-up may require heating equipment to be installed even where it is not needed for normal occupancy. This situation commonly occurs in core areas of the building. Even though these spaces may always have positive heat gain during normal

occupancy, they can cool down during a period of temperature setback.

An alternative to installing heating equipment in all the spaces is installing a single warm-up coil in the air handling unit. This approach reduces initial cost if it avoids the need for a large number of heating units. However, in a system where some of the terminal units have heating coils, the fan must overcome the resistance of the coils in the terminal units in series with the resistance of the warm-up coil in the air handling unit.

■ Terminal Units with Heating Coils

The most common choice of heating method when converting a constant-volume system to VAV is to install terminal units that have heating coils. This decision usually is driven by cost constraints and by the need to minimize interference with the operation of the facility during conversion.

Unfortunately, this choice commits the system to a certain amount of reheat, because some chilled air is needed to carry heat from the coils into the space. The amount of energy that is wasted in this manner depends on the diversity of space loads. Especially during mild weather, some spaces may require heating while other spaces served by the same air handling system require cooling.

For example, if a system serves heavily glazed spaces on both the east and west sides of the building, the west side may require a large amount of cooling in the late afternoon of a cold day, while the east side needs heating. This example shows that zoning has a major effect on your ability to minimize reheat in a VAV system that uses reheating terminal units.

Reheat energy loss occurs even with shutoff VAV terminals, if they have heating coils. However, shutoff terminals have much less reheat loss than terminals with minimum-flow settings.

Fan-powered terminal units are an important special case, which is discussed below. Fan-powered terminals can avoid reheat entirely because they do not depend on the chilled air supply to carry heat into the space.

It may seem ironic to remove one set of terminal units with heating coils, only to replace them with other terminal units that also have heating coils. The key point of this swap is that the heating coils in VAV terminals waste energy only during periods of low cooling load, whereas the heating coils in a constant-volume reheat system waste energy during all cooling operation, and most severely during periods of high cooling load.

Selection of VAV terminal units is covered more extensively below.

■ Heating Equipment that is Separate from the VAV System

In principle, you can eliminate reheat entirely by installing a heating unit in each space that does not depend on air flow from the VAV system to distribute

heat. For example, you can combine a cooling-only VAV system with a baseboard heating system, or with fan-coil units, or with unit ventilators, etc.

(In practice, separate heating equipment may not entirely eliminate reheat. If the system is not controlled properly, or if perimeter spaces are not isolated from core spaces, heat from the perimeter system may move into the core and cancel cooling. If you are careful in laying out the system, this effect is minor.)

Baseboard convectors are by far the most common type of separate heating equipment that is used with VAV systems. Many people consider convectors to be the most comfortable type of heating. They are quiet and free of drafts, and they warm the interior surfaces of outside walls. They take up little space. They are less expensive than other types (but they are usually much more expensive to retrofit than terminal units with heating coils). Also, most other types of separate heating equipment, such as fan-coil units, could perform both heat and cooling, making VAV unnecessary.

If you install baseboard convectors, you have to work around their inability to provide outside air ventilation. You could install a small, separate ventilation system. Or, you could ventilate through the VAV system. The latter approach may not be possible without substantial reheat or control complexity.

A combination of in-space heating units and shutoff VAV terminals cannot provide dehumidification during mild, humid weather. Providing dehumidification requires reheat or a separate dehumidifier.

How to Select the Terminal Units

A VAV terminal unit, or “VAV box,” is basically a damper that is controlled by the space temperature. The damper throttles the air supply as the cooling load drops. VAV terminals have many variations. Figures 1, 2, and 3 show typical examples. For a good introduction to VAV design, make a study of all the types available and the

M&I Heat Transfer Products

Fig. 1 VAV terminal unit This externally powered unit has an aerodynamically shaped plug that provides accurate flow control, low noise, and tight shutoff. It wastes a minimum of fan power in creating turbulence.

reasons for them. The following are the major issues to consider.

■ Shutoff or Minimum-Flow?

VAV systems are designed in one of two basic ways. “Shutoff” systems have terminal units that can stop air flow completely. “Minimum-flow” systems have terminal units that do not close below a particular minimum flow rate. This flow rate is typically fairly high, around 40% of maximum flow.

The distinction between shutoff and minimum-flow is a matter of design intentions and terminal unit adjustments, not primarily a matter of hardware. Virtually all VAV boxes have mechanical stops that can be used to set minimum-flow limits. VAV boxes intended for shutoff applications need better construction to prevent air leakage at shutoff, and to minimize noise at low flow rates.

In minimum-flow systems, each terminal unit has reheat losses when the space load is low. This is because heating equipment must cancel the excess minimum-flow cooling from the terminal unit.

The amount of reheat loss that occurs in a minimum-flow system depends on the system zoning. If a system serves spaces with loads that vary in different patterns, this diversity limits the opportunity to raise the chilled air temperature. As a result, the reheat loss is higher.

Minimum-flow terminals are especially wasteful in systems where reheat depends on heating equipment installed in the space. (This configuration is rare.) To avoid discomfort from the cold supply air in such cases, the space temperature must be kept fairly high by the heating equipment, increasing the reheat loss.

■ Reheat Coils

Minimum-flow VAV terminals almost always have reheat coils. Hydronic reheat coils can be modulated to

provide any percentage of heat output. This allows them to be controlled to minimize reheat losses. Hydronic heat may have much lower operating cost than electric heat, if a cheaper boiler fuel is used. The main disadvantage of hydronic reheat coils is the high cost of piping.

Reheat cannot be reduced as well with electric heating coils, because these are installed in fixed blocks of capacity. Furthermore, control of electric coils is more complex because of the need to avoid burn-out. The simple controls used for electric coils in many VAV systems are wasteful. See [Measure 4.7.7](#) for details.

■ Power Source for Terminal Unit Dampers

VAV terminal units may be “externally powered” or “system powered.” Externally powered units use pneumatic actuators or electric motors to move the dampers. System-powered terminal units use the pressure of the air in the duct system to drive the damper.

System-powered boxes require higher fan pressure than externally powered boxes because a minimum duct pressure is required to activate the damper mechanism. The minimum pressure at the box is typically about one inch of water column. The extra fan pressure required to operate system-powered VAV boxes costs a significant penalty in fan energy.

A third type of terminal unit is self-powered. It has a damper that is powered by the expansion of a fluid in a specialized space thermostat. The damper and the thermostat may be installed on the diffuser assembly, making a compact package that is inexpensive to install. The primary advantage of this type is low cost. The lack of external control can be a major disadvantage because spaces that are served by this type of terminal unit cannot be shut down individually.

Trane Company

Fig. 2 VAV terminal valve with flow sensor Air flows from the left. The disc in the center moves along the shaft to throttle the flow. The narrow coiled tube at the entrance to the air valve has holes that face into the supply duct. This provides an indication of air flow and duct pressure that is used to optimize control of the unit.

Trane Company

Fig. 3 Simple VAV terminal This inexpensive model uses a single-blade damper that is driven by an electric motor. This type of damper has relatively poor control at the lowest and highest flow rates, and it is susceptible to leakage.

■ Sensitivity to Duct Pressure

For a given damper position, the amount of air flow through a terminal unit is strongly affected by the duct pressure. This is significant because large fluctuations can occur in the pressure at a given terminal. The fluctuations are greatest when a terminal unit is located at the end of a duct run that has other terminal units. The operation of the upstream terminal units bleeds air pressure out of the duct, reducing flow through the downstream terminals.

In principle, the space thermostat should compensate for differences in duct pressure. However, any thermostat requires a certain temperature offset to function, and the offset is greatest when the conditioning load is greatest. This resulting temperature drift can be large enough to cause discomfort.

To deal with system pressure fluctuations, “pressure-independent” VAV boxes were developed. These typically contain two dampers. One regulates flow in response to the thermostat. Another damper is added upstream to regulate the pressure that is felt by the flow regulating damper.

“Pressure-independent” boxes require more fan power than “pressure-dependent” units because of the additional resistance of the pressure regulating damper. For this reason, try to design the system so that pressure-independent boxes are not needed. Good duct layout helps to achieve this goal, by reducing pressure fluctuations in the duct system.

Another way to deal with duct pressure changes is to use thermostatic controls that are capable of maintaining close temperature control in the presence of large pressure fluctuations. See [Reference Note 37](#), Control Characteristics, for methods.

■ Terminal Unit Noise

Terminal units can generate a substantial amount of flow noise when the damper approaches its minimum position. In the worst cases, the terminal unit emits a distinct whistle. Good terminal unit design can reduce this noise to levels that are acceptable for most applications.

Some types of terminal units have used internal silencers to reduce noise. Silencers increase flow resistance, so avoid units that use them.

■ Air Leakage at Shutoff

Shutoff terminal units should close tightly. Otherwise, cold air will leak into the space, causing discomfort and wasting energy. Tight shutoff is mainly a matter of sturdy construction. The units should be designed so that any seals needed for tight shutoff last a long time and can be replaced easily.

■ Retrofit Difficulty

Replacing the terminal units in an existing system can be a knuckle-bleeding chore. It helps to keep the replacement terminal units as small as possible. If the replacement units are larger than the original ones, there will probably be places where installing them is difficult.

Fan-Powered VAV Terminals

Fan-powered terminals are a newer development in the history of VAV. They avoid or minimize some of the problems of VAV, but they introduce some new problems of their own. They are important as an option to consider. We will discuss them separately because they are different from conventional VAV terminals in construction, operation, and control.

Fan-powered terminals are more than a substitute for conventional VAV terminals and diffusers. They

Fig. 4 Fan-powered VAV terminal, series flow The fan operates continuously as long as conditioning is required. The difference between the fan's flow rate and the chilled air flow rate is made up by recirculation from the space or the ceiling plenum. The heating coil operates only when the space requires heating. During heating, the chilled air damper may close completely, or it may remain partially open to provide outside air ventilation. Recirculating air from the ceiling plenum recovers the heat of light fixtures, either for space heating or for reheat to reduce humidity. Most units have fans that operate at fixed output, but modulation is a possible option.

change the overall design of the system. A VAV system that uses fan-powered terminals is a hybrid between a central air handling system and a system that uses fan-coil units installed inside the spaces.

In terms of hardware, fan-powered VAV terminal units are fundamentally different from the terminal units discussed previously, which are simply dampers that restrict air flow. Fan-powered terminals contain a built-in fan, in addition to a chilled air damper, which helps to overcome problems related to low air flow rates into the spaces. They may also contain a heating coil, which can be controlled in a way that eliminates reheat losses.

Fan-powered terminals can make a VAV system much more reliable in terms of avoiding reheat energy waste over the life of the facility. This is because the control of the heating coil, if installed, is less subject to abuse than control of a reheat coil in a conventional terminal.

During cooling operation, the heating coil in a fan-powered unit turns off, and the flow of chilled air into the space is modulated by a simple damper. During heating operation, the chilled air damper closes, the heating coil turns on, and air from the return air plenum (usually, the ceiling) is circulated through the coil by the fan. Reheating is avoided because delivery of heated air does not depend on the flow of air from the air handling unit.

There are two distinctly different types of fan-powered terminals. One type, called “series flow,” is sketched in Figure 4. The other type, “parallel flow,” is shown in Figure 5.

In a series-flow unit, the fan operates continuously as long as the space requires conditioning, typically at a constant flow rate. If the chilled air damper closes completely, the air delivered to the space is entirely recirculated. At other times, the air delivered to the space

is a mixture of chilled air and recirculated air, the ratio being determined only by the position of the chilled air damper.

In a parallel-flow unit, the fan operates only when space heating is required, either by the self-contained heating coil or by recirculating plenum air to the space. During cooling operation, air to the space comes only from the air handling system. During heating operation, the air delivered to the space may be entirely recirculated, or it may be a mixture of chilled air and recirculated air.

Fan-powered VAV terminals cannot solve the problem of inadequate outside air ventilation at low conditioning loads. If the units operate without any mixing of heated and cooled air, ventilation is limited by the position of the cooling damper. The terminal unit may have a minimum-flow setting, but this incurs the same reheat loss that would occur with any other type of minimum-flow terminal unit.

■ Advantages of Fan-Powered VAV Terminals

Both types of fan-powered VAV terminals offer these advantages, compared to other types of VAV terminal units:

- **reduced or eliminated reheat loss.** In principle, reheat energy waste can be eliminated entirely by not allowing heating coils to operate as long as the chilled air damper is open. Chilled air can be “tempered” by mixing it with plenum air, which requires no additional energy consumption for reheat. However, fan-powered units that have heating coils can waste energy through reheat. The amount of energy waste depends on the type of terminal unit and on the setting of the control that starts the heating coil.
- **light fixture heat recovery.** When the fan is recirculating air from the ceiling plenum, the heat

Fig. 5 Fan-powered VAV terminal, parallel flow During cooling operation, the fan is turned off, and the unit behaves like a simple shutoff VAV terminal. The fan operates only when the space requires heating, drawing air from the space or the ceiling plenum. In other respects, the control issues and options are similar to those for series-flow units.

of the light fixtures is captured to assist in space heating. This provides a double bonus because the heat of the lighting fixtures would otherwise be returned to the cooling coil, increasing the cooling load.

- **positive air circulation.** Fan-powered VAV terminals provide positive air circulation whenever the fan is running. The strong air flow also provides good diffuser performance.

■ Disadvantages of Fan-Powered VAV Terminals

Both types of fan-powered VAV terminals have these disadvantages, compared to other types of VAV terminals:

- **no outside air ventilation at low conditioning loads,** unless the terminal sacrifices its efficiency advantage by adding a reheat coil
- **noise.** The terminal unit fans are located close to the point of air discharge, so they transmit a significant amount of fan noise to the space.
- **large size.** The bulkiness of fan-powered terminals may be a major impediment to installation, especially if the ceiling space is already tightly packed. In some existing buildings, retrofit may be impractical.
- **higher cost.** The terminal units themselves are more expensive. However, using fan-powered terminals may reduce costs in other parts of the system, for example, by simplifying the system controls.

■ Comparison of Series and Parallel Units

There are significant differences between series and parallel fan-powered units. Neither is clearly better than the other for all applications. You have to decide which to use. Here are the major ways in which they differ:

- **space air circulation.** With series units, space air circulation is continuous and constant. With parallel units, circulation is constant only when heating. When cooling, space air circulation depends entirely on the position of the chilled air damper, unless the fan is started to provide supplementary circulation.
- **reheat loss.** As we said earlier, it is possible to control either a series or a parallel terminal unit to avoid reheat completely. However, the temptation to use a heating coil for reheat is greater in a parallel unit. This is because the fan does not run continuously, resulting in low air flow to the space as the chilled air damper closes.

On the other hand, in series terminals, light fixture heat that is recirculated from the ceiling plenum cancels some of the cooling energy. Some of this cooling load would return to the cooling coil in the air handling unit anyhow, but some of it would be discharged in the relief air. This is a factor only when cooling during cooler weather.

- **noise.** In series units, the fan operates continuously, creating noise continuously. On the other hand, the cycling operation of the fan in parallel units may also be objectionable.

- **bulk.** Parallel units are usually somewhat larger than series units. However, the fans in series units are larger than in parallel units.

- **overall fan power.** This is a tricky comparison. The fans in series units operate continuously, as long as the space requires conditioning, whereas the fans in parallel units may operate for only a small fraction of the time. Furthermore, the fans in series units must be sized for the larger of the maximum cooling load or the maximum heating load. In parallel units, the fan is sized only for the maximum heating load.

However, if all the terminal units are series units, they allow the air handling unit fan to operate at lower pressure differential. In the series unit, the chilled air is discharging into a box that is kept at pressure slightly lower than the space pressure. In a parallel unit, the chilled air must discharge at pressure comparable to the discharge pressure of the terminal unit fan.

(In any event, fan power is much less significant as a factor in overall system energy consumption than the ability of fan-powered terminals to minimize energy waste from reheat.)

- **control.** Control of series units is simple because the air flow rate is constant. The space thermostat controls the chilled air damper, along with the output of the heating coil (if installed). Control of parallel units is more complex. During cooling, the space thermostat controls the position of the chilled air damper. During heating, the space thermostat controls the running of the terminal unit fan, or the speed of the terminal unit, or the heating coil output, or some combination of these.

- **cost.** Parallel units are somewhat more expensive than series units. This is because they are bulkier. Also, they should have a backflow damper, and the fan motor should be designed to avoid damage from backward rotation of the fan at start-up. On the other hand, series units have larger fans, usually.

How to Select the Diffusers

Diffusers for VAV systems are designed to distribute air at the low velocities that can occur in VAV operation. Some types of diffusers are designed to exploit the Coanda effect, which causes the air flow to adhere to the ceiling. This is desirable for cooling, but it creates a problem with heating. There is no perfect solution to this problem. Reconciling heating air distribution with cooling air distribution is a challenge in all VAV systems. This problem was one of the major reasons for the introduction of the fan-powered VAV terminal, but only

the series type of fan-powered VAV terminal can eliminate the dumping problem under all conditions.

With any type of diffuser, dumping of cold air will occur at some minimum velocity. The minimum velocity is higher if you use chilled air temperature reset, because this increases supply air velocity at low cooling loads. The higher supply air temperature also makes dumping more tolerable.

If you convert an existing constant-volume reheat system to VAV operation, you may have to replace the diffusers in the spaces. A diffuser selected for constant-volume operation is unlikely to work well in a VAV mode of operation.

Your Fan Modulation Options

As the VAV terminals throughout the system close, the system fans need to deliver less total air volume. The method of modulating the fans to accommodate changing air flow has major effects on efficiency, comfort, and cost.

See [Measure 4.7.8](#) for an overview of your choices. In brief, these are the characteristics of the flow modulation methods that are used most commonly in contemporary VAV systems:

- **variable-frequency electronic drives** are the most efficient, the easiest to install, the most flexible, and the most expensive. Their major technical disadvantage is creating a high level of electrical noise in the electrical power system. See [Reference Note 36](#), Variable-Speed Motors and Drives, for details.
- **variable-pulley drives** are efficient, reliable, and free of adverse side effects. They are limited in turndown range, and they cannot handle larger motors. See [Reference Note 36](#) for details. They may be difficult to retrofit on existing fans.
- **inlet vortex dampers** are substantially less efficient than the previous two, especially at lower loads. They are simple, reliable, and inexpensive. Usually, they cannot be retrofitted, although this might be possible if the fan manufacturer offers a vortex damper for the particular fan model.
- **“riding the fan curve”** is a fancy way of saying that no fan modulation is used. Instead, the supply air is choked off by the terminal units. This is poor practice in all but the smallest systems. The only advantage is cheapness. The fan’s power consumption declines relatively little as air flow is reduced. Riding the fan curve results in higher duct pressure as the VAV boxes close, which results in poor control and increased noise. To compensate, the designer may specify “pressure-independent” boxes. The higher cost of these boxes offsets the cost saved by omitting the fan modulation control.
- **multi-speed fan motors** are a compromise approach that may be appropriate in smaller systems. Multi-

speed motors allow air flow to ride the fan curve at different fixed fan speeds. Fan power is greatly reduced at the lower speeds, along with the pressure at the terminal units. Multi-speed motors are covered by [Reference Note 36](#).

How to Control the System

The efficiency and comfort of a VAV system depends on its terminal unit settings and its control settings. A VAV system may operate wastefully for its entire life because a control function was omitted from the design. Or, the system may waste energy for years because the controls are adjusted haphazardly. Optimize the following control functions as well as you can, and keep them optimized.

■ Setting the Minimum Flow of Terminal Units

Virtually all VAV boxes have mechanical stops that can be adjusted to prevent the damper from closing beyond a desired amount. The setting of minimum air flow at the VAV terminals has an enormous influence on the behavior of the system, to a greater extent than any other aspect of the system controls. The minimum-flow setting determines:

- the heating capacity of the terminal unit
- the amount of energy waste from reheat
- the amount of outside air ventilation
- the ability to dehumidify during periods of low cooling load
- diffuser performance and space air circulation
- if the heating coils are electric, the actions needed to prevent coil burn-out.

Minimum-flow is the Achilles heel of VAV system efficiency because it opens the door to reheat. Give priority to keeping the minimum-flow settings as low as possible, consistent with maintaining comfort and ventilation.

■ Heating/Cooling Changeover

If heating is provided by heating coils in the terminal units, there are two methods of changing from cooling to heating. The most efficient method is to let the damper close to zero, or to a much lower flow rate that is dictated by ventilation requirements. The heating coil turns on at the minimum-flow position of the damper. At the same point, the output signal of the thermostat reverses so that the damper opens as the space temperature drops. The thermostat may also control the output of the heating coil.

The other method is much less efficient, but it is more common because it is simpler. You should avoid it. In this method, the minimum flow of the terminal unit is set so that it is high enough to handle the peak heating load. Typically, this is about 40% of the maximum rated flow. (The air flow needed for heating is usually much less than the flow needed for cooling because the heating temperature differential is higher.)

As the cooling load drops, the damper closes until it reaches its minimum-flow limit, at which point the heating coil turns on. The heating coil's output is controlled by the space thermostat. As the cooling load drops further and becomes a heating load, the heat output of the coil continues to increase.

Energy waste from reheat begins as soon as the damper reaches the minimum-flow limit. Energy waste is high because the heating coil must heat the relatively large air flow dictated by the peak heating requirement. Energy waste continues as long as the cooling coil in the air handling unit produces chilled air.

The first method wastes less energy because reheat does not begin until the conditioning load is much lower, and the amount of reheat energy is greatly reduced within the range in which reheat occurs.

■ Control of Fan Modulation

The most common way of controlling the output of the supply fan is to sense the pressure in the duct system. The pressure in the duct system is set high enough to provide rated air flow through the terminals under maximum load conditions. This method is simple and fairly efficient. It provides predictable terminal unit performance.

If many terminals are installed along a supply duct, a large pressure drop occurs between the fan and the end of the duct run. Therefore, the pressure in the portion of the system near the fan must be higher than necessary for that part of the system. The location of the duct pressure sensor affects the response of the fan to the flow requirements of the terminal units. If many terminals are strung out along the duct runs, there is no optimum location for the duct pressure sensor. It is a common rule to place the pressure sensor two-thirds of the way toward the end of the longest duct run. As with all general rules, be cautious in applying this one.

The duct pressure you need depends on the type of terminal unit. Externally powered terminals with good thermostatic controls require the least pressure. System-powered terminals and "pressure-independent" terminals require additional pressure to overcome their increased resistance.

If a VAV system has a return fan or a relief fan, the return or relief fan must remain coordinated with the supply fan as the system flow changes. This is necessary to maintain the correct amount of outside air ventilation and to minimize the waste of fan energy that occurs in overcoming the resistance of the air handling system dampers. The only accurate control method is to control the return fan or relief fan by using air flow monitors. One flow monitor is always located in the outside air intake. The location of other air flow monitors, if needed, will depend on the front end configuration of the system. See [Measure 4.2.2](#) for details about the different types of front end configurations that control outside air intake.

With a return fan, the return fan flow rate should always equal the supply fan flow rate minus the desired outside air intake rate. With a relief fan, the relief fan flow rate should always equal the outside air intake rate.

A less desirable method of controlling the supply fan output is to sense the return air volume. This method is based on an assumption that lower return air flow indicates that the zone dampers are more closed, which means that the duct pressure is higher. This method is not as accurate as measuring the fan discharge pressure directly. The only significant advantage of this method is that the air flow sensor can be packaged in the air handling unit, in contrast with the expense of installing a pressure sensor at some distant point in the duct system.

If the system uses multi-speed fans, sensing duct pressure is not the appropriate method of controlling fan speed, because this would cause the fan to oscillate between speeds. Usually, the best method of switching fan speed is to sense the conditioning load in the space that has the largest load. For details, see [Reference Note 14](#), Control Signal Polling.

■ Chilled Air Temperature Reset

Chilled air temperature reset is covered by [Measures 4.4.1 ff](#) and [4.7.6 ff](#). The basic idea is that the reset control keeps the air temperature at a minimum until the VAV terminals close down to their minimum-flow settings. Then, the chilled air temperature is raised in response to decreasing cooling load.

Chilled air temperature reset lessens the problems that occur in VAV systems at low cooling load, especially reheat energy waste and poor diffuser performance. Your VAV systems should have this control feature.

The chilled air temperature must be kept low enough to serve the terminal with the highest cooling load. In a system with large load diversity, this limitation substantially reduces the benefit of chilled air temperature reset.

■ Duct Pressure Reset

An unusual technique is to reduce the duct pressure setting as fan output is reduced. This causes the terminal unit dampers to open more at low loads. The benefits are:

- reduced fan power
- reduced leakage through shutoff terminals when they are closed
- reduced leakage from the duct system
- reduced terminal unit noise
- more accurate and stable temperature control as terminals approach the fully closed position.

The cooling or heating output of the terminals is not affected, because the flow rate through the terminals remains unchanged. The only potential problem is failure to cool a space that has a higher load than the other spaces on the system. Prevent this problem with

the same methods used to prevent excessive chilled air temperature reset.

■ Temperature Setback

During night setback operation, the system is used only for heating. At the beginning of the setback period, the cooling coil is turned off and the temperature is allowed to drift. (If the cooling coil were kept in operation, it would force the building to the setback temperature, wasting cooling energy.) The fan is usually turned off as well.

Setback operation can be controlled by a single thermostat at a critical location, saving control cost. In more sophisticated systems, setback operation may be controlled from all the space thermostats. If any space requires heating, the fan is started.

■ Morning Warm-Up

If the system has night setback, it should also have a special control sequence for morning warm-up. During warm-up operation, the cooling coil is turned off to avoid any reheat.

■ Space Thermostat Deadband

Converting a single-duct system to VAV opens the door to using deadband in the thermostatic control of the terminal units. Deadband is possible only if the terminal units can shut off completely. Deadband saves energy in several ways. Refer to [Measure 4.7.2](#) for details of deadband in single-duct VAV systems.

■ Control of Humidity

As discussed previously, reheat may be necessary for dehumidification in climates that are mild and humid, and in spaces where a considerable amount of moisture is released. Reheat consumes a lot of energy, so limit it to the bare minimum needed to provide the desired level of dryness.

The simplest and most efficient way to control reheat for dehumidification is by using a reliable humidistat in the space to control the operation of the heating coil in the terminal unit. Connect the humidistat so that its signal overrides the signal from the thermostat to the heating coil.

Chilled air temperature reset is an important energy conserving feature, but it reduces dehumidification. The humidistat should override this control function when humidity is high.

■ Control of Outside Air Intake

Refer to the previous discussion of the problems of controlling outside air in a VAV system. Refer to [Measures 4.2.1 ff](#) for controls that tailor outside air intake to variable ventilation requirements.

■ Control of Building Pressure

Refer to the previous discussion of pressure fluctuation problems that may arise in VAV systems. Only specialized facilities, such as medical laboratories, have controls that are designed explicitly for controlling

space pressure. The appropriate design for the controls depends on the configuration and purposes of the spaces and the system, and on the pressure relationships that have to be maintained.

■ Economizer Cycle Operation

Economizer cycle control is not changed when converting from constant-volume to VAV operation. Refer to [Measure 4.2.5](#) about economizer cycles.

■ Purge Cycle Operation

Refer to [Measure 4.2.7](#) about purge cycles. If a VAV system has shutoff terminals, the purge cycle must include a control function that opens all the terminals during the purge period.

■ Isolation of Space Conditioning

If the terminal unit dampers can close to shutoff, you can shut off conditioning to the spaces they serve. This saves conditioning energy, reheat energy (if any), and fan energy in spaces that operate on different schedules from the rest. When you do this, treat each terminal unit as a separate conditioning unit. Use the methods recommended in [Subsection 5.1](#) to turn off individual terminal units.

Improve Duct Zoning, If Practical

Diversity among the space loads increases the need for reheat, as explained previously. Resetting the chilled air temperature can reduce reheat. However, load diversity also limits the potential of chilled air temperature reset. ([Measure 4.4.1](#) explains why.) To get around this basic limitation, lay out the different air handling systems so that each system serves spaces with similar loads.

In retrofit applications, you may be able to change the connections between ducts and air handling units to achieve this purpose. In order for this to be practical, the air handling units need to be close together, and you need clearance for relocating some of the ductwork.

Other Efficient Systems

[Measures 4.4.8](#) and [4.4.9](#), which come next, are alternatives to VAV that avoid most of the energy waste of reheat systems and are less tricky to accomplish. However, they typically are more expensive.

ECONOMICS

SAVINGS POTENTIAL: All or most of the reheat energy used by the system; 20 to 60 percent of the cooling energy; 30 to 70 percent of the fan energy.

COST: In new construction, the additional cost elements are the VAV fan drive(s), controls for fan operation, the cost differential between reheating and VAV terminal units, the cost of heating equipment other than reheat coils, and the differential cost of space thermostatic controls. See [Reference Note 36](#) for the cost of variable-

speed fan drives. VAV terminal units typically cost several hundred dollars apiece, although you can use units costing as little as \$100 apiece in limited applications.

Retrofitting existing facilities is usually much more expensive than installing VAV in new facilities. Retrofitting heating capability that is separate from the VAV terminals greatly increases cost.

PAYBACK PERIOD: In new facilities, typically about one year. In existing facilities, typically several years.

TRAPS & TRICKS

DESIGN: VAV systems that are comfortable, highly efficient, and reliable are still rare. The large number of design issues makes it easy to overlook some of them. Do your homework. Find successful systems to study.

SELECTING THE EQUIPMENT: Your choice of terminal units is critical. Good equipment is available, but there is a lot of cheap junk on the market. Study [Reference Note 36](#) about selecting variable-speed fan drives.

INSTALLATION: Details matter. Work with the installers of the terminal units and the fan drives. Ensure that minimum-flow limits and other settings are adjusted properly.

EXPLAIN IT: The way the facility staff adjust and maintain the system has a major effect on efficiency and comfort. These systems can have many important features that are not obvious. Describe the system clearly in the plant operating manual. Include a table of the settings for all terminal units. Install placards on all unfamiliar equipment. Buy an extra terminal unit to use as a training aid.

MEASURE 4.4.8 Replace all reheat coils in a system with heating/cooling coils and minimize operation of the air handling unit cooling coil.

This Measure consists of replacing the reheat coils in the terminal units with coils that can provide both heating and cooling. In effect, each terminal unit becomes a fan-coil unit, with the air handling unit supply fan acting as a common fan for all the terminal units. No cooling coil is needed in the air handling unit.

Like VAV (Measure 4.4.7, previous), this design avoids most of the energy waste of reheat systems. The advantages of this Measure arise mostly from the fact that the heating and cooling of each space is independent of the central system. There is no common supply of chilled air that requires reheating to adapt to conditions in different spaces, so there are none of the associated problems involved in minimizing reheat.

This change to the system layout makes it behave like the “damperless multizone” system shown in Figure 2 of the Section 4 Introduction.

Comparison to VAV

Think of this Measure as a constant-volume alternative to VAV. In comparison to VAV, it has these advantages:

- **greater saving in reheat energy.** There is no need for reheat to compensate for differences in space conditioning loads, or to maintain a minimum air flow.
- **avoids comfort problems associated with low space air flow,** including space air stagnation and poor diffuser performance.
- **provides outside air ventilation** under all conditions
- **no fluctuations in space pressurization,** unless you modulate the fan output
- **simpler and less critical controls.** There is no possibility of reheat (in most installations), so no critical control adjustments are needed to minimize reheat.
- **simpler hardware**
- **low noise.** There are no dampers or fans in the terminal units to create noise.

These are the relative disadvantages:

- **difficult installation,** in both new construction and retrofit, because of the need to add cooling and condensate drainage at each terminal unit.
- **likely to be more expensive** than VAV, mostly for the same reason.
- **less fan energy saving.** In fact, fan energy may be increased by the resistance of the additional cooling coils in the terminal units.

SUMMARY

An unusual, major modification that eliminates reheat losses. Avoids most of the problems of VAV, but saves less fan energy and requires additional pump energy.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	
Rate of Return, Retrofit	%	%

Ease of Retrofit	☺			

- **requires pump energy** to move chilled water through the added cooling coils in the terminal units.

A VAV conversion with fan-powered terminals is similar to this Measure in some of its advantages. However, fan-powered terminals cannot provide steady ventilation without reheat, and they add noise to the space.

Comparison to Individual Fan-Coil Units

The terminal units are similar to fan-coil units. The main advantages of this method, compared to conditioning the spaces with individual fan-coil units, are:

- **no loss of floor space**
- **lower noise,** since there are no fans within the space
- **outside air ventilation,** without the need for wall penetrations

The main disadvantages of this method, compared to conventional fan-coil units, are:

- **higher cost,** because of the need for air handling units and ducts
- **additional building space** for air handling units and ducts
- **greater complication** to isolate spaces that operate on different schedules
- **draining condensate** from the cooling coils may be more difficult.

Where to Consider This Approach

This approach has no serious comfort or efficiency shortcomings. It is likely to be preferable to VAV in applications where the disadvantages of VAV pose serious limitations.

In particular, this approach is a strong contender for specialized applications that need a constant flow of air. For example, it might be used in a biological research facility, where the air handling system provides the air flow necessary to prevent escape of contaminants for fume hoods.

This approach is not a good choice in mild, humid climates where reheat is needed for dehumidification for long periods of time. By using tandem cooling and heating coils (an option discussed below), you can provide dehumidification in individual spaces. However, this is a significant complication. Furthermore, the waste of energy from reheat is proportional to the air flow through the terminal units. This Measure either does not reduce air flow, or it reduces air flow less effectively than VAV.

The difficulty of draining or pumping cooling coil condensate from each of the terminal units may make this Measure impractical in some facilities.

How to Install the Coils

■ Coil Arrangements

There are two practical ways to arrange the terminal unit coils for heating and cooling. If heating is hydronic, the most compact method is to install a single hydronic coil that is changed from heating to cooling by switching from heating water to chilled water. The weakness of this arrangement is the requirement for changeover valves. These may develop internal leakage, which wastes energy by mixing water from the heating and cooling supplies.

The other arrangement is to install separate heating and cooling coils in tandem, as is typical in small fan-coil units. The disadvantages of this arrangement are greater bulk, higher cost, and greater resistance to air flow. Also, a defect in the controls or leakage in the coil valves may allow some simultaneous operation of both coils.

■ Whether to Use Existing Reheat Coils

Existing reheat coils usually cannot be converted to serve as heating/cooling coils. Reheat coils have too little heat transfer surface for cooling, because they are designed to operate with higher temperature differentials. Also, they lack provision for condensate drainage.

■ Whether to Abandon the Air Handling Unit Cooling Coil

This modification eliminates the need for the cooling coil in the air handling unit. If practical, remove it to minimize air flow resistance and fan power.

It may be tempting to keep the cooling coil for pre-cooling, to reduce the size of the cooling coils in the terminal units, or as a means of dehumidification during

mild weather. However, this will inevitably lead to waste of energy by reheat. In effect, this restores the original constant-volume reheat mode of operation.

Zoning

Unlike VAV systems, zoning is not critical with this type of system. This is because the air flow does not shift from one space to another, as it does in a VAV system that serves spaces with different load profiles. Even so, it pays to be clever about zoning. You can save money on terminal units, ductwork, and fans, and you can save fan energy in two ways.

You can save fan cost and fan energy by assigning the terminal units to air handling systems in such a way that the total system loads vary as little as possible. In particular, use one system for the core area alone, because the core load tends to remain constant. Similarly, use one system for the north perimeter alone, because the cooling load remains low on the north side.

If you modulate the fans to follow the system load, as recommended below, you can save fan energy by assigning terminal units with similar load profiles to the same air handling systems. For example, use one air handling system for the east perimeter, and another for the west perimeter.

Isolation of Unoccupied Spaces

If the system serves spaces that operate on different schedules, you can save more energy by turning off the conditioning to individual unoccupied spaces. To do this, you need a damper in the duct that leads to the space. To keep the cooling coil from sweating when the air supply is turned off, the cooling coil should also have a shutoff valve. If the heating coil is electric, it needs to be turned off to prevent burnout.

Use the methods recommended in [Subsection 5.1](#) to turn conditioning on and off. This capability provides the greatest benefit if the unoccupied spaces have high heat gains or losses, and if they are physically isolated with walls and doors.

Chilled Water and Condensate Piping

Piping is a major consideration. Each terminal unit needs chilled water piping and a condensate drain. Installing new piping is especially troublesome in retrofit applications. Select the locations of the terminal units to minimize piping cost and difficulty.

Try to rely on gravity for condensate drainage. The alternative of many small, hidden condensate pumps would become a maintenance headache. However, gravity drainage requires a path that has a continuous downward pitch all the way to the sewer. In many cases, structural interferences make it impossible to install gravity drains.

Dehumidification at Low Loads

Refer to [Measure 4.4.7](#) about humidity control during periods when the normal operation of the cooling coils does not provide adequate dehumidification. In summary, anticipate a problem if the climate is mild and humid, if there are major sources of moisture within the spaces, and in basement spaces.

In such cases, this Measure may not be the best choice. You could dehumidify during mild weather by overlapping the operation of the cooling and heating coils, if separate coils are installed. This reheating mode of control is covered in [Measure 4.4.7](#).

Variable Fan Output

You can save fan energy in this type of system by modulating the fan output to follow the conditioning load. Fan modulation saves only fan energy, because this system usually has no reheat energy to be saved.

Once-through systems (systems that use 100% outside air) are an important exception. In such systems, reducing air flow may save a large fraction of conditioning energy.

In principle, you can use any type of fan modulation with this type of system. With small and medium sized fans, consider a two-speed fan motor. Variable-frequency electronic drives and variable-pulley drives provide even better turndown. However, low fan speeds incur ventilation and air flow problems, described in [Measure 4.4.7](#). In large fan systems, electronic drives may be the only efficient method of fan modulation that is available, and the price per kilowatt drops sharply with increasing size. See [Reference Note 36](#), Variable-Speed Motors and Drives, for details of fan drives.

Controls

This system is simple to control. The space thermostats control the coils in the terminal units, as with fan-coil units. For the best energy efficiency, install space thermostats that have heating/off/cooling selector switches. Add other control efficiency features, such as deadband and temperature setback, as appropriate. Refer to [Subsections 4.1](#) and [4.3](#) for these features.

Install effective placards at all manual controls. See [Measure 4.3.1](#) for tips in making the placards effective.

If the system has fan output modulation, the most efficient method of fan control is to follow the conditioning load in the space that has the largest load. See [Reference Note 14](#), Control Signal Polling, for methods of doing this.

ECONOMICS

SAVINGS POTENTIAL: *All or most of the reheat energy used by the system; 20 to 60 percent of the cooling energy. The savings are reduced by the need for greater chilled water pumping energy. Fan energy consumption may be more or less than in the original reheat system, depending on the nature of the coil installation.*

COST: *This Measure requires more expensive terminal units, widespread chilled water piping, cooling coil condensate drains, and more expensive thermostatic controls. These items are much more expensive in retrofit than in new construction. In new construction, this design avoids the cost of a cooling coil in the air handling unit.*

PAYBACK PERIOD: *Several years, or much longer.*

TRAPS & TRICKS

DESIGN: *Designing the system should be relatively simple, but it is unusual enough to make you a pioneer.*

MEASURE 4.4.9 Install self-contained heating/cooling units, and use the air handling system only for ventilation.

This Measure consists of replacing reheat terminal units with self-contained room conditioning units that provide both heating and cooling. The room conditioning units can be any type, depending on the needs of the space. The most likely replacements are fan-coil units. The air handling system is retained only to provide outside air ventilation. The cooling coil and the preheat coil (if any) are used only to condition outside air. The reheat coils in the terminal units are omitted or abandoned.

As with converting to a VAV configuration (Measure 4.4.7), this system layout avoids most of the energy waste of reheat systems. As with the layout of Measure 4.4.8, this layout has a major advantage over VAV, which is that the heating and cooling of each space is independent of the central system. There is no common supply of chilled air that requires reheating to adapt to conditions in different spaces, and none of the associated problems involved in minimizing reheat.

In new construction, this system layout approaches the ideal of efficiency that is suggested in the Section 4 Introduction, which is to completely separate the heating, cooling, and ventilation functions.

In retrofit applications, this approach uses even less of the original reheat system than Measure 4.4.8. It reduces the original system to the status of a ventilation system, delivering air at much lower flow rates than originally.

Comparison to VAV

This Measure may be considered as a more drastic alternative to VAV conversion. In comparison with VAV, the advantages of this Measure are:

- **no reheat**, except where reheat is used deliberately for dehumidification.
- **ability to localize conditioning** to occupied spaces
- **avoids problems of poor diffuser performance**
- **provides outside air ventilation** under all conditions
- **no fluctuations in space pressurization**
- **simpler hardware and controls**

This Measure has the following disadvantages, compared to VAV:

- **much higher cost to retrofit**, because most of the functions of the existing reheat system's equipment are abandoned. High conversion cost keeps this approach from being feasible as a retrofit except in specialized circumstances, such as a major renovation.

SUMMARY

Can be very efficient. Simpler than VAV, and free of its annoyances. As a retrofit, this is a drastic modification that involves abandoning most of the functions of the original system. Configurations vary with the types of heating and cooling equipment used.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	
Ease of Retrofit	😊			

- **increased maintenance workload.** Having a large number of individual space conditioning units increases the maintenance workload, especially for routine cleaning and changing filters.
- **higher noise level.** Fan-coil units and self-contained air conditioning units put more noise into the space than a well designed central system. However, this approach is no more noisy than fan-powered VAV terminals.

Aside from the saving in reheat energy, energy savings cannot be stated in general. The total fan power is greater than with VAV, but possibly less than with a reheat system. If hydronic heating and cooling equipment is used, additional pump energy is required.

Optimize Your Choice of Conditioning Equipment

This change in the system layout gives you the opportunity to exploit the advantages of any type of room conditioning equipment. By the same token, be prepared to minimize the disadvantages of the type you select. Each type of space conditioning equipment has its own art. Refer to Section 5 for the efficiency characteristics of the different types of room conditioning equipment.

Localize Conditioning As Much As Possible

A major advantage of this Measure is its ability to turn off conditioning in individual unoccupied spaces. If the air handling system serves spaces that operate on different schedules, take full advantage of this energy saving opportunity. Install dampers in the ducts that provide ventilation to the individual spaces, and control each damper to close when its space is vacated. See Subsection 5.1 for the appropriate control methods.

ECONOMICS

SAVINGS POTENTIAL: All or most of the reheat energy used by the system; 20 to 60 percent of the cooling energy. The savings are reduced by additional chilled water pumping energy if you use hydronic space conditioning equipment. Fan energy consumption may be more or less than in the original system.

COST: In retrofit, typically several thousand dollars per heating/cooling unit, plus the cost of piping, pumps, modification of the original air handling system, and system controls. In new construction, the additional cost depends heavily on the design of the buildings. In the most favorable cases, this design approach may cost little more than a reheat system.

PAYBACK PERIOD: In retrofit, typically many years. This approach is too expensive to be retrofitted for the sake of energy conservation alone. Consider it as a design option in new construction and in major mechanical renovations, where appropriate.

TRAPS & TRICKS

CHOICE OF METHOD: This is close to starting with a blank slate. In retrofit, you have the additional challenge of exploiting pieces of an existing system. Lots of work and lots of fun for a clever designer. Study [Section 5](#) to learn more about specific types of independent space conditioning equipment.

Dual-Duct Reheat Systems

The Measures in this Subsection improve the efficiency of dual-duct air handling systems. This type of system is sketched in Figures 1 and 2, in the [Section 4 Introduction](#).

In these systems, the air handling unit has a continuously operating cooling coil that feeds air into a cold air duct, and a continuously operating heating coil that feeds air into a hot air duct. The two ducts run in parallel throughout the facility. At each space, air from the two ducts is mixed in a terminal unit (“mixing box”) that is controlled by the space thermostat. The terminal units mix the air in proportions that keep the volume of air flow into the space essentially constant.

In the early days of dual-duct systems, virtually all were designed to provide an essentially constant flow of air to the space. This requires mixing large quantities of heated and chilled air, which makes these “reheat” systems. The high energy cost of this mode of operation led to the later development of dual-duct VAV systems, which are covered in [Subsection 4.8](#).

The primary justification for dual-duct reheat systems is close control of space conditions. They allow any number of spaces to be controlled independently. They provide a high level of comfort because air flow is constant, temperature control can be maintained precisely as the load changes from heating to cooling, humidity can be controlled at any desired level, and outside air ventilation is maintained under all load conditions. When you make changes for the sake of efficiency, preserve these qualities to the extent that the application requires them. Each of the Measures discusses the relevant comfort and health issues.

INDEX OF MEASURES

4.5.1 Keep the temperature of the cold duct as high as possible and the temperature of the hot duct as low as possible.

4.5.1.1 Install temperature reset controllers for both the cold duct and the hot duct.

4.5.2 Turn off the heating coil and/or the cooling coil whenever practical.

4.5.3 Trim the output of the air handling system fans.

4.5.4 Install multi-speed fan motors.

4.5.5 Convert the system to variable-air-volume (VAV) operation.

RELATED MEASURES

- [Subsection 4.8](#), for Measures that improve the efficiency of existing VAV dual-duct systems

The Measures in this Subsection are oriented primarily toward reducing the energy waste that occurs from reheat. Reheat systems are very wasteful because a large amount of heating and cooling energy is cancelled out in the mixing process. During low-load conditions, a dual-duct system may consume much more energy in reheat than it does in conditioning the space. Some of the Measures also save fan energy.

In new construction, none of the Measures adds much cost, unless the systems are small. Variable-output fan drives were once a major cost addition, but the relative cost of this equipment has fallen sharply, especially for larger systems. Furthermore, exploiting the VAV principle may allow some savings in initial cost, such as smaller ducts.

In retrofit applications, first decide whether or not to make major changes to the existing constant-volume system. This decision depends mainly on two factors: whether you can afford to make a major change, and whether you can sacrifice the tight control of humidity and the continuous ventilation that reheat systems provide. If you can afford only inexpensive changes, accomplish [Measures 4.5.1 ff](#) through [4.5.3](#). If you can afford a major system change, select [Measure 4.5.5](#). [Measure 4.5.4](#) is an intermediate approach that saves less energy than [Measure 4.5.5](#), but it is less expensive.

Energy Behavior of Dual-Duct Systems

The energy consumption behavior of dual-duct systems is not obvious, so we will use a small dose of mathematics to help clarify it. Formula 1 tells us the amount of energy that is absorbed by an individual terminal unit in a dual-duct system. It is

expressed in terms of the actual cooling load in the space, the air flow rate through the terminal unit, and the duct temperatures. The formula shows how important the temperature settings are to the efficiency of the system.

First of all, the formula reveals the wasteful behavior of dual-duct reheat systems under typical operating conditions. In the second term of the formula, input energy is directly proportional to the product of the cooling temperature differential times the heating temperature differential. If the temperature differentials are large, the second term of the formula becomes large in relation to the first. Therefore, at low loads, mixing losses consume much more energy than actually conditioning the spaces.

To see how dominant mixing losses can be, consider what happens when the heating and cooling temperature differentials happen to be equal. In that case, the first term in the formula becomes zero, and the amount of energy consumed by the terminal is completely independent of the space load! (What happens in this case is that mixing losses increase exactly as the space load declines, and vice versa.)

The way the two temperature differentials multiply in the second term of the formula makes it important to keep both the hot duct and cold duct temperature differentials as low as possible. (This is the basis of [Measures 4.5.1 ff](#).) In dual-duct systems, the two temperature differentials are independent. This is different from single-duct reheat systems, where the reheat temperature differential is determined by the cooling temperature differential.

FORMULA 1

$$\text{Input Power} = \left(\frac{\Delta T(H) - \Delta T(C)}{\Delta T(H) + \Delta T(C)} \times \text{Space Conditioning Load} \right) + 2.16 \times \left(\frac{\Delta T(H) \times \Delta T(C)}{\Delta T(H) + \Delta T(C)} \times \text{Terminal Unit CFM} \right)$$

where:

- the units of power are BTU's per hour
- the units of temperature are degrees Fahrenheit
- the units of air flow are cubic feet per minute (CFM)
- $\Delta T(H)$ is the temperature difference between the hot duct and the space, always positive
- $\Delta T(C)$ is the temperature difference between the cold duct and the space, always positive
- "Space Conditioning Load" (in BTU/hr) is positive for heating, negative for cooling
- the elevation is sea level.

(The formula assumes that the air flow rate of the terminal unit is constant. The formula is valid only if the temperature differentials and flow rates are large enough to satisfy the space load.)

Going further, if conditions let you turn off either the cooling coil or the heating coil, the second term of the formula becomes zero. In this case, reheat loss disappears, and the input energy equals the conditioning load, as you would expect. (This is the basis of [Measure 4.5.2](#).)

The second term of the formula also shows that energy waste from reheat is proportional to the supply air volume. You can reduce the supply air volume by trimming the fan output ([Measure 4.5.3](#)), by installing multi-speed fans ([Measure 4.5.4](#)), or by converting the system to variable-air-volume operation ([Measure 4.5.5](#)).

Note that this formula relates to the energy consumption of an individual terminal unit, not to the system as a whole. The flow rate in the formula relates to the terminal unit, but the hot and cold air temperature differentials are common to the entire

system. Your ability to reduce the temperature differentials depends on the load diversity among the spaces.

Triple-Duct Systems

“Triple-duct” systems look similar to dual-duct systems. However, their energy behavior is entirely different. Triple-duct systems have a third duct that carries unconditioned air (a mixture of return air and outside air) for mixing with either the heated air or the chilled air. If properly installed, these systems have no mixing losses. Triple-duct systems are efficient, comfortable, and fairly simple. They are rare because they look expensive to designers and because they require a lot of duct space.

If you are dealing with triple-duct systems, refer to [Subsection 4.8](#) for Measures that optimize their efficiency.

MEASURE 4.5.1 Keep the temperature of the cold duct as high as possible and the temperature of the hot duct as low as possible.

RATINGS

New Facilities	Retrofit	O&M
		A

The introduction to this Subsection makes the point that lowering the hot duct temperature and raising the cold duct temperature by even modest amounts can greatly reduce mixing losses. During the extended periods when conditioning loads are low, most of the system’s energy consumption may consist of mixing losses.

Raising the chilled air temperature and lowering the hot air temperature is a powerful energy conservation technique. It is easy, and it costs nothing.

The optimum duct temperatures change continuously, along with the cooling load. Don’t expect the staff to keep resetting the temperatures manually as conditions change throughout the day. The best they can do manually is to reset the temperatures at intervals, perhaps on a seasonal basis. Subsidiary [Measure 4.5.1.1](#) improves on this Measure with continuous automatic resetting of the two duct temperatures. Use manual adjustment as a stopgap method until you install automatic reset controls.

Energy Saving Potential

■ **Reduced Mixing Losses**

The saving potential varies widely among facilities, typically ranging from 20 to 50 percent of total cooling and heating energy. Achieving this potential requires diligence in adjusting the duct temperatures to match changing load conditions.

■ **Improved Chiller Efficiency**

In hydronic systems, increasing the cold duct temperature may allow you to raise the chilled water temperature. This may improve chiller efficiency by several percent, as explained in [Measure 2.2.1](#).

Try to Minimize Load Diversity

Your ability to reset duct temperatures is reduced if the air handling system serves spaces that have different loads. Some amount of reheat will occur if one space requires cooling at the same time that another space requires heating. The chilled air temperature must remain low enough to serve the terminal with the greatest cooling load, and the hot air temperature must remain high enough to serve the terminal with the greatest heating load.

Load diversity is determined by the way that spaces in the building are connected to the air handling systems. For example, if a dual-duct system serves a zone with extensive glazing on both the east and west sides of the building, there may be many hours per year when there

SUMMARY
Save a lot of energy just by turning two screws.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	%
Reliability	✓	✓		
Ease of Initiation	😊	😊	😊	

is a large cooling load on one side of the system while there is a large heating load on the other side.

The load diversity is even worse if a system serves both core and perimeter spaces. This is because core areas may have a large cooling load throughout the year. If the same system serves perimeter spaces, reheat will occur any time a perimeter space has a heating load.

This makes it important to pay attention to zoning when designing air handling systems. Major renovations may also provide opportunities for improving zoning.

Duct temperature reset can be thwarted by a single space that has an inadequate air supply, because this space creates a demand for more extreme duct temperatures. Therefore, when planning the reset controls, make a survey of the cooling and heating capacities in all spaces, and correct any deficiencies in heating or cooling capacity. You can do this by increasing the capacity of the terminal unit, or by decreasing the load. For example, if a space has an exceptionally high solar load, consider shading the windows.

The diversity problem fades away when the weather becomes warm enough to allow heating in the hot duct to be turned off entirely. This eliminates all mixing losses. For this reason, be aggressive about minimizing the hot air temperature when the weather is mild.

Effect on Humidity

Raising the chilled air temperature may allow the humidity inside the building to rise excessively when the outside air is mild and humid. Refer to “Effect on Humidity,” in [Measure 4.4.1](#), to see if this may become a problem.

How to Adjust the Duct Temperatures

The discharge air temperatures of the hot and cold coils are controlled by thermostats in the air handling unit. You can easily reset these thermostats with your

pocket screwdriver. If you have an electronic control system, you can change the discharge temperatures from the keyboard.

Adding Cooling Coil Control Valves

There is one unusual case in which you have to spend some money to optimize the cold duct temperature. Designers sometimes cut installation cost in chilled water coils by omitting a control valve. In such cases, the chilled water temperature directly controls the chilled air temperature. To get around this limitation, install a cooling coil valve in each air handling unit and control it with a chilled air discharge thermostat.

Don't Forget the Placards!

This activity is easy to forget. Therefore, install placards at the discharge air thermostats to explain how to set them. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: 20 to 50 percent of total cooling and heating energy, typically. The potential for savings is limited by space load diversity.

COST: Minimal, in most cases. If the cooling coil presently has no thermostatic control, installing a cooling coil valve and discharge thermostat typically costs about one thousand dollars.

PAYBACK PERIOD: Immediate, in most cases. One year to many years, if you have to install a cooling coil valve and discharge thermostat.

TRAPS & TRICKS

CHOICE OF METHOD: Consider manual control as a stopgap until you install automatic duct temperature reset controllers, as recommended next.

DILIGENCE: This Measure is completely dependent on the diligence and skill of the plant operators in adjusting the duct temperatures. Conditioning loads vary widely over the course of a day, so it would take almost continuous attention to achieve the maximum potential of this technique.

EXPLAIN IT: Make sure that plant operators are trained and understand the importance of the adjustments. Put clear instructions in the plant operating manual. Install placards at the thermostats that identify them and explain how to set them.

MEASURE 4.5.1.1 Install temperature reset controllers for both the cold duct and the hot duct.

RATINGS

New Facilities	Retrofit	O&M
A	B	

The technical weakness of [Measure 4.5.1](#) is that it cannot adapt to the continuous variations in conditioning load. This Measure consists of installing two automatic temperature reset controls, one to keep the cold duct temperature as high as possible and the other to keep the hot duct temperature as low as possible. The control components are identical for the two functions.

In many applications, this Measure can save large amounts of energy at relatively modest cost. Load diversity limits the potential savings, as explained in [Measure 4.5.1](#). Take a good look at the system to see whether you can reduce the load diversity within each air handling system.

How to Control the Duct Temperatures

The air temperature in the cold duct is controlled by throttling the output of the cooling coil. The cooling coil is controlled by the space thermostat that has the greatest requirement for cooling. The reset control needs to sample the thermostat signals from a number of spaces because the cooling loads in spaces do not vary in unison. For example, solar load is greatest in east-facing perimeter spaces in the morning, but in west-facing spaces in the afternoon.

Therefore, connect the reset controller for the cold duct to all the space thermostats that may, at some time or other, dictate the minimum chilled air temperature. The cooling reset controller typically should sense at least one thermostat on the east, west, and south sides of the building and the core area. It should also sense thermostats in all spaces that may have exceptionally high heat gains, such as auditoriums, conference rooms, dining areas, and computer rooms.

Similarly, connect the reset controller for the hot duct to all the space thermostats that may dictate the maximum hot air temperature. The heating reset controller typically should sense at least one space on the north perimeter, and any other space that may get colder than the others.

[Reference Note 14](#), Control Signal Polling, explains how to select a signal from a group of thermostats. If you have an energy management computer system, you can usually perform these functions through the computer system. In pneumatic control systems, an ordinary receiver-controller is used to accomplish the temperature reset function.

SUMMARY
 This is the way to minimize reheat at all times. A basic control feature.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of cooling and heating energy.

COST: The control components for a typical installation typically costs from several hundred to several thousand dollars. Connection to thermostats at widely dispersed locations can incur extensive additional labor cost.

If an energy management computer is installed, reprogramming the computer to accomplish chilled air temperature reset typically costs several thousand dollars.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

PLANNING AND DESIGN: This is more than a control modification. To get most of the benefit from this Measure, you must fix any conditions that cause some spaces to require lower chilled air temperature or higher hot air temperature than the rest. In climates that commonly have high humidity during mild weather, you may have to add some control complications to maintain adequate dehumidification.

EXPLAIN IT: Describe the reset controls in the plant operating manual. Install placards on the controls to identify them.

MONITOR PERFORMANCE: These important controls can fail, or they can be adjusted improperly, without anyone noticing. Include a column in the plant operating log to record the duct temperatures, or use your energy management computer to log this information. Review the record periodically to verify that the cold duct temperature rises as the cooling load falls, and that the hot duct temperature falls as the heating load falls.

MEASURE 4.5.2 Turn off the heating coil and/or the cooling coil whenever practical.

RATINGS

New Facilities	Retrofit	O&M

The formula in the introduction to this Subsection shows that mixing losses disappear in a dual-duct system if you turn off either the heating coil or the cooling coil. Once the weather has warmed up to the point that heating is no longer required, there is no reason why you cannot turn off the heating coil. If the coil is hydronic, close the isolation valve. If the coil is electric, disconnect the power to the coil.

Similarly, you can turn off the cooling coil whenever the system has no cooling load.

When to Turn Off the Heating and Cooling Coils

In principle, you can eliminate all mixing losses by turning off the cooling coil whenever the heating coil is turned on, and vice versa. In practice, this may not be acceptable. Even if the zoning of the building allows this, fluctuations in weather make it advisable to keep both coils in operation during the transition seasons. Turn off the cooling coil after cold weather has arrived to stay, and turn off the heating coil after cold weather has definitely gone for the year.

You can always turn off the heating coil as soon as the outside temperature becomes as warm as the inside temperature (except for warm-up periods). In contrast, you may not be able to turn off the cooling coil during cold weather. If the air handling system serves any spaces with high heat gains, you must keep the cooling coil operating for the benefit of those spaces.

If possible, try to arrange the air handling systems so that each serves spaces that have loads as similar as possible. This increases the fraction of time that you can turn off one coil or the other.

Relationship to Duct Temperature Reset

Duct temperature reset controls, which are recommended by [Measure 4.5.1.1](#), perform the same function as this Measure. But, even with duct temperature reset, it is still a good idea to turn off the coils seasonally to protect against unnecessary reheat if a reset controller fails.

Conversely, you can use this Measure as a cheap substitute for installing a reset controller. However, it is effective only under certain conditions, whereas a reset controller works continuously.

Don't Forget

Neglecting this procedure produces no discomfort or other apparent effects, so it is easy to forget. Keep the procedure in mind by appropriate methods, especially a good reminder schedule and effective

SUMMARY
A seasonal method of eliminating reheat that costs nothing.

placards. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

Alternative: Control Chiller and Boiler Operation

In cases where several air handling units are served by a central chiller, turning off the chiller has the same effect as turning off all the cooling coils. Minimizing the duration of chiller operation is covered by [Measures 2.1.2 ff.](#) However, control at the chiller usually cannot save as much energy, because some air handling units are likely to operate longer than others.

You can take the same approach with control at the heating plant, provided that the heating plant does not serve purposes, such as water heating, that keep it operating during warm weather. See [Measures 1.1.1 ff.](#) Again, this is usually less efficient than controlling the heating operation of the individual air handling systems.

ECONOMICS

SAVINGS POTENTIAL: 30 to 80 percent of mixing losses, depending on climate and system zoning. This typically corresponds to about 20 to 50 percent of total conditioning energy.

COST: Minimal.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

EXPLAIN IT: Provide clear instructions that explain when to turn off the cooling coil and heating coil, e.g., when the morning outside air temperature is above or below a certain value. Optimize the schedule for each air handling unit or group of units. Install placards at the appropriate valves or at the controls of self-contained compressors.

MONITOR PERFORMANCE: This activity is easy to forget. Schedule periodic checks of the procedure in your maintenance calendar.

MEASURE 4.5.3 Trim the output of the air handling system fans.

The formula at the beginning of this Subsection shows that the energy consumption of the terminal unit is partly proportional to their air flow rates. Fan trimming is a one-time adjustment that gets rid of fan capacity in excess of the amount needed to satisfy peak loads. Refer to [Measure 10.3.1](#) for the details.

By reducing the constant air flow rate in the system, this action reduces reheat “off the top.” However, it does not tailor fan output to a changing load. This is a cheap and simple way to reduce reheat significantly while saving a modest amount of fan energy. Consider this a stopgap action to save energy until you can accomplish either [Measure 4.5.4](#) or [Measure 4.5.5](#).

RATINGS

New Facilities	Retrofit	O&M
□	□	B

MEASURE 4.5.4 Install multi-speed fan motors.

The formula at the beginning of this Subsection shows that the energy requirement of the terminal units is partly proportional to their air flow rates. Installing multi-speed motors in the air handling units reduces the

air flow rate in steps that follow the system load. This Measure is virtually identical to [Measure 4.4.6](#) in theory, installation, and economics. Refer to there for details.

RATINGS

New Facilities	Retrofit	O&M
C	C	□

MEASURE 4.5.5 Convert the system to variable-air-volume (VAV) operation.

The principle of a VAV dual-duct system is simple. Instead of controlling space temperature by mixing hot and cold air, the terminal unit selects either hot air or cold air, but not both. The terminal unit regulates the space temperature by throttling the amount of hot air, or cold air, that is delivered to the space.

Because of the throttling action of the terminal units, the total air flow rate delivered by the system fans varies over a wide range. Therefore, the fans should have an efficient method of modulating their output. This keeps fan power to a minimum under all load conditions, and maintains a constant pressure in the duct systems.

Although the VAV concept is simple, putting it into practice has proven to be tricky. You may need to make compromises that infringe on comfort or that give up some of the efficiency potential of the concept.

SUMMARY

This is the most efficient configuration for dual-duct systems. Achieving both comfort and high efficiency is challenging.

Ease of Retrofit	😊	😊		

To avoid repetition, some of the following topics refer you to the corresponding topics in [Measure 4.4.7](#),

which converts single-duct reheat systems to VAV. Converting a dual-duct reheat system is usually easier and cheaper than converting a single-duct system, but getting it right is still a challenge.

Less Expensive Alternatives

Measures 4.5.1 through 4.5.4 attack the same sources of energy waste as VAV conversion, namely, reducing reheat and fan power. In some applications, a combination of those Measures may provide a large part of the savings provided by VAV conversion, at much lower cost.

Energy Saving

■ Energy Waste from Mixing Heated Air and Chilled Air

The introduction to this Subsection points out that reheat systems may consume more energy in mixing losses than in actually conditioning the spaces. In principle, you could design a VAV dual-duct system that eliminates virtually all reheat. In actual practice, you may need to mix air at low flow rates to provide adequate ventilation or dehumidification.

Using VAV in dual-duct systems eliminates most reheat loss because it restricts reheat to the low end of the air flow range. Formula 1, in the introduction to this Subsection, shows that reheat loss is roughly proportional to air flow. Therefore, if you restrict reheat to low-flow conditions, the system wastes much less energy loss than a conventional reheat system, where the hot and cold air are mixed at maximum flow rate. Going further, you can add duct temperature reset to reduce reheat at the low end of the load range. By using all available techniques, you can typically eliminate over 90% of the reheat loss that would occur in a constant-volume dual-duct system.

To calculate the saving the saving in reheat that you can expect from using VAV operation instead of constant-volume operation, you need to calculate the total energy consumption of each terminal unit for both types of systems. Do this by using Formula 1, in the introduction to this Subsection.

Reheat energy waste occurs at each terminal unit individually. The amount of reheat that occurs at each terminal unit depends on these factors:

- **the minimum-flow requirement.** For reasons explained below, it may be necessary to maintain a minimum flow through the terminal unit. If the amount of chilled air that enters the terminal at the minimum-flow setting provides more cooling than needed, the excess cooling must be cancelled by mixing with heated air. Similarly, if the amount of heated air that enters the terminal provides more heating than needed, the excess heat must be cancelled by mixing with chilled air.

If you use terminal units that can close to shutoff, then leakage in the terminal units becomes an important factor. Any leakage behaves as a minimum-flow setting, and it wastes energy in the same way.

- **the duct temperatures.** If the chilled air temperature is raised, the amount of cooling provided by a given amount of air flow through the terminal is reduced. Under conditions when reheat is required, raising the chilled air temperature reduces the amount of reheat that is necessary to cancel unwanted cooling. The same applies to lowering the heated air temperature. Duct temperature reset is a powerful energy conserving technique.

Duct temperature reset is limited by diversity of conditioning loads. This is because the chilled air temperature must be set low enough to satisfy the cooling load on the terminal unit with the greatest cooling requirement, and the heated air temperature must be high enough to satisfy the terminal that has the highest heating load. This limitation occurs only during conditions when the system must provide both heating and cooling. Therefore, zoning of the system is an important factor in exploiting duct temperature reset.

It is important to understand that the amount of energy waste from air mixing in a dual-duct VAV system is not fixed and predictable. On the contrary, it depends largely on system adjustments that are made at the time of installation and later throughout the life of the system. These adjustments are needed to deal with issues that we will discuss below. To a large extent, the adjustments are arbitrary, or they are a matter of preference. A terminal unit in one space may be adjusted to eliminate most mixing losses, whereas an identical terminal unit in the adjacent space may be adjusted in a way that causes a large amount of energy waste. To minimize mixing losses, adjust each terminal unit to minimize overlap of the heated air and chilled air dampers. In addition, exploit duct temperature reset as much as possible.

■ Fan Energy

A fan operating in VAV mode delivers only enough air to carry the required amount of heating or cooling energy into the spaces.

The relationship between fan power and air flow in a dual-duct VAV system cannot be stated precisely. The power required by the fan to overcome the air flow resistance of the coils and ductwork is approximately proportional to the third power of the air flow rate. The power required to overcome the resistance of the dampers in the terminal units is roughly proportional to the first power of the flow rate. (The latter is because the dampers act to keep the pressure opposing the fan constant, instead of letting the pressure drop at lower

flow rates.) The actual power required by the fan varies between these two extremes.

All the methods of varying fan output (variable-speed drives, inlet vortex dampers, discharge dampers, etc.) have inefficiencies that partially offset the saving in fan power. The best fan modulation methods have low losses, while the worst would dissipate a large fraction of the potential savings. A well designed VAV system should use substantially less than half the fan energy of a constant-volume system.

■ Energy to Condition Outside Air in Once-Through Systems

In systems that require 100% outside air, such as those used in hospitals, VAV can substantially reduce the amount of energy that is consumed to condition outside air.

A constant-volume reheat system is sized to provide enough air to convey heating and cooling under peak load conditions. This is wasteful because the average conditioning load is much lower than the peak load. A VAV system reduces this waste by taking in only enough outside air to convey the heat or cooling that is required at the moment.

The amount of energy saved by converting a 100%-outside-air dual-duct system to VAV depends primarily on the climate and the conditioning loads. In mid-latitude climates and typical applications, VAV conversion may reduce outside air heating and cooling by half.

How to Convert a Dual-Duct Reheat System to VAV

The steps in converting a dual-duct reheat system to VAV operation are:

- replace the constant-volume mixing terminals with VAV terminals, or modify the existing terminals to operate in a VAV mode
- replace the space thermostats, if necessary. If the terminals are able to close to shutoff, consider deadband thermostats.
- if necessary, replace the air diffusers in the spaces to provide good performance at all air delivery rates
- install an efficient means of varying the output of the air handling system fans
- install a control system for the fan output
- install temperature reset controls for both the hot and cold ducts
- provide controls for various auxiliary functions, such as morning warm-up, night setback, purge cycle operation, smoke relief, etc.

You may encounter a variety of problems, including unsatisfactory air distribution, inadequate outside air ventilation, and complaints of stagnation. The main source of these problems is the large reduction of space air flow that occurs during periods of low load. A tempting solution is to add reheat back into the design, but this wastes energy. The design challenge is to maintain comfort and health while minimizing reheat. Make sure you cover all the following points. Many of

WESINC

Fig. 1 Dual-duct terminal unit, partly disassembled The inlet end is on the right. The duct with foil faced insulation admits chilled air. The duct with unfaced insulation admits warm air. The entering air immediately encounters a baffle plate, which creates a large amount of resistance. The inside of the box contains a sound attenuator.

these points are related, which makes good VAV design a feat of mental juggling.

■ How to Select Terminal Units or Conversion Kits

Dual-duct reheat terminal units are often called “mixing boxes,” which accurately describes their function. They mix air from the hot and cold ducts in a manner that provides approximately constant air flow to the space under all load conditions. The cheapest type of dual-duct mixing box has a single damper vane that swings between the chilled and hot air supplies inside the box, allowing more chilled air to flow as the hot air is blocked, and vice versa. Figures 1 and 2 show a mixing box of this type.

There are also mixing boxes with separate dampers for hot and cold air. The space thermostat controls the movement of the damper or dampers inside the terminal.

The VAV version of a dual-duct mixing box is similar to the constant-volume version. The difference is the way the dampers behave. In a VAV system, if the space has a cooling load, only the cooling damper opens, modulated by the space thermostat to satisfy the load. Similarly, if the space has a heating load, only the heating damper opens. There is no mixing of hot and cold air, except perhaps at low loads.

In retrofit applications, you may have a choice of two paths in converting to VAV. One is to install entirely new VAV terminal units in place of the original ones. The other is to convert the existing terminals to operate as VAV terminals.

Several manufacturers offer conversion kits for specific models of dual-duct terminals. Some constant-volume mixing boxes can be converted easily. This option provides a large saving in equipment cost. It may also save a large amount of labor cost because it is usually possible to convert the unit in place.

Before deciding to convert existing boxes, make sure that the converted boxes will operate efficiently. In particular, the converted box should not have an appreciable amount of leakage that allows air mixing. Compare the features that are available in new VAV terminals and in conversion kits.

■ Reduce Flow Resistance in Converted Terminal Units

In addition to the flow-regulating dampers, dual-duct terminal units may also contain volume dampers to limit the total flow through the box, baffles to mix the hot and cold air, and sound attenuators. These add a significant amount of resistance to air flow, increasing fan energy requirements. If you convert existing mixing boxes, take the opportunity to eliminate the flow resistance of these obstructions whenever possible. Figures 1 and 2 show some of the flow restricting hardware that you may encounter.

Remove any volume regulating dampers, because they serve no purpose in VAV operation.

If you intend to convert the terminal units to shutoff operation, remove any mixing baffles. They serve no

WESINC

Fig. 2 Mixing vane in dual-duct terminal unit This is the unit shown in Figure 1, looking into the ends of the chilled air and heated air ducts. The air is proportioned by a simple vane that swings between the two duct openings, so that the total flow remains approximately constant. The amount of energy wasted by air mixing is enormous, often much larger than the conditioning load of the space.

purpose if the converted terminal units do not allow air mixing.

If you intend to retain air mixing at low loads, you may need to retain the mixing baffles because low velocity air streams tend to remain stratified. In case of doubt, experiment to find out whether stratification continues into the space. Remove the mixing baffles from several units. Take a quick-response thermometer and see if the air comes out of the diffuser in all directions at a reasonably uniform temperature. The duct and the diffusers downstream of the mixing box may eliminate the stratification before the air enters the space.

Sound attenuators are installed in some mixing boxes to trap noise that originates in the air handling system. The attenuators may be intended to reduce noise that is generated upstream of the terminal unit, especially by the fan, or they may be intended to reduce noise generated inside the terminal unit itself. Fan noise may not be significant if the terminal is distant from the fan, but a noise attenuator may be necessary for terminals located near the fan.

The terminal unit itself may generate substantial noise. This noise is especially troublesome because of the short path to the space. Much of the noise generated inside the terminal unit is caused by mixing baffles and flow limiting dampers. If you remove those, the sound attenuator may become unnecessary.

The noise generated by any given air handling system rises sharply with increasing air flow. The VAV mode of operation reduces air flow significantly under most conditions, so converting the system to VAV should reduce the average system noise level considerably. The exception is noise generated by the terminal unit dampers as they approach the closed position. To minimize this whistling noise, control the fans to reduce their output to match system flow requirements.

■ Minimize Minimum-Flow Settings

VAV terminal units generally have some kind of adjustable mechanical stop that prevents each damper from closing fully. This feature allows you to establish a minimum flow from the cold and hot ducts. You may need to maintain a minimum air flow for several reasons, including:

- proper diffuser operation
- maintaining an adequate level of outside air ventilation
- maintaining in-space air velocity to prevent a feeling of “stiffness” and to facilitate cooling by perspiration
- providing dehumidification during periods of low cooling load.

These requirements are covered below. Consider the requirements of each space to decide the appropriate minimum-flow settings for the terminals. Minimum-flow is the Achilles heel of VAV system efficiency

because it opens the door to reheat. This is so important that you should take all possible steps to minimize the minimum-flow setting of each terminal unit, consistent with maintaining comfort and ventilation.

A subtle difference in the manner of setting minimum flow can make a big difference in reheat energy waste. The least efficient method is to have a separate minimum-flow stop for the chilled air and hot air. With this method, there is some reheating under all load conditions. Some cheap retrofit kits may resort to this method.

In contrast, the proper way to deal with reheat (if it cannot be avoided) is to have mixing only if both the chilled air and hot air flows have fallen to a minimum value. For example, the chilled air damper remains fully closed during heating operation until the hot air flow falls to its minimum value, at which point the chilled air damper starts to open.

■ Diffuser Performance

See [Measure 4.4.7](#).

■ Space Air Velocity

See [Measure 4.4.7](#).

■ Night Temperature Setback and Morning Warm-Up

Night temperature setback is easy to accomplish in a dual-duct VAV system. The setback controls should perform these functions during the setback period:

- **control the heating coil with a setback thermostat.** The simplest way to do this is with a single thermostat located in the coldest or most critical space. If you have an energy management control system, you can probably program it to perform heating setback.
- **turn off the cooling coil.** Be sure that controls turn off the cooling coil at the beginning of the setback period, allowing the space temperature to drift. If the cooling coil is not turned off, it will force the space to the setback temperature, wasting cooling energy.
- usually, **turn off the air handling unit fans** as long as the spaces are within the deadband temperature range.
- for maximum efficiency, use **optimum-start** to extend the setback period as long as possible. (See [Measure 4.1.1.2](#) for details.)

■ Space Temperature Deadband

In spaces where you use shutoff terminal units, you may be able to save additional energy by using deadband temperature control. [Measure 4.7.2](#) explains deadband control in dual-duct systems.

You cannot use deadband control if you need to maintain a minimum flow through the terminals. Maintaining minimum air flow requires overlapping the operation of the heating and cooling dampers, whereas

deadband involves inserting a temperature gap between the closing of one damper and the opening of the other. The way to minimize the energy waste resulting from minimum-flow is to use duct temperature reset (Measures 4.5.1 ff).

■ How to Select the Fan Modulation Method

See Measure 4.4.7 for your choices.

■ How to Control Fan Modulation

See Measure 4.4.7.

The hot and cold duct systems operate independently of each other. Sometimes one duct will have lower pressure, sometimes the other. To deal with this, install a pressure sensor in each. Control the fan to respond to the lower pressure.

Larger dual-duct systems may have two separate air handling units, one for the hot duct and the other for the cold duct. In this case, control the pressure in each duct independently.

■ Exploit Duct Temperature Reset

Duct temperature reset is explained in Measure 4.5.1.1. It is a primary method of improving efficiency and comfort at low space air flow rates. Virtually all VAV systems should have this control feature.

■ Dehumidification

See Measure 4.4.7.

■ Outside Air Ventilation

A dual-duct VAV system provides outside air ventilation through the air handling unit whenever a space is either heated or cooled. Outside air ventilation may be inadequate at low conditioning loads, when both the heating and cooling dampers are closed. If deadband thermostats are installed, both dampers may remain closed for long periods.

If a VAV system needs to provide full ventilation during low-load conditions, the only way to do it is to use reheat so that air flow can be increased enough to carry the ventilation air.

If you have recirculating air handling systems, your ability to control outside air intake depends on the “front end” configuration of the air handling system. Examine the design of your air handling systems to see if they allow accurate control. A well designed air handling system is able to maintain accurate control of outside air intake even as the fan output changes. See Measure 4.2.2 for the details.

Even if a VAV system is designed to maintain accurate control of total outside air intake, it cannot distribute ventilation air in proportional amounts to individual spaces. This is because the volume of air delivered to individual spaces varies with their conditioning loads. For example, if a system serves both core and perimeter spaces, most of the outside air may be delivered to the core spaces on a cool day, and to the perimeter spaces on a hot day. It may be satisfactory to

let ventilation air diffuse from the perimeter zone into the core zone, or vice versa. This is most likely to be acceptable if the occupant density is low and there are no major sources of pollution inside the spaces.

You can provide perfectly controlled outside air ventilation without energy waste by installing a separate outside air ventilation system that has its own ducts, fans, and heating elements. (The “triple-duct” system is one version of this arrangement.) A separate ventilation system also solves the problem of distributing outside air properly to individual spaces.

A simpler option is to open windows during mild weather, when the VAV boxes close down. This option is not available in buildings with fixed windows. Even in buildings with openable windows, it may not be acceptable. Controlling the use of windows to avoid wasting energy during hot and cold weather is difficult and unreliable.

Supply air temperature reset is important for reducing the reheat loss that occurs for the sake of ventilation. For example, if the outside air is warmer than the inside air, the hot duct reset control should completely turn off the heating coil, which eliminates reheat.

■ Zoning

Zoning affects energy consumption in dual-duct VAV systems, but its effects are less serious than they are with single-duct VAV systems. The main benefit of good zoning is that it maximizes the potential for using duct temperature reset. See Measure 4.5.1 for details. Exploit this in new construction. In retrofit applications, it is rarely economical to change the zoning of a dual-duct system.

■ Duct Layout

Converting an existing dual-duct system to VAV may provide a valuable opportunity for improving the basic duct layout. While you are making the conversion, the duct system is exposed and accessible. Use this opportunity to reduce pressure losses in the duct system. This allows you to reduce the fan pressure, saving fan energy. It may also improve temperature control in the spaces.

The upstream terminal units bleed air pressure out of the duct system, reducing flow through the downstream terminals. This may create flow problems in the downstream terminal units that motivate using “pressure-independent” terminals. This type of terminal requires higher fan pressure than the “pressure-dependent” type, and it is more expensive. Classic methods of “equal pressure” duct design cannot solve this problem, because the load relationship among VAV terminals varies continuously.

It is usually not necessary or economical to upgrade an entire duct system. You may be able to make some localized improvements that significantly improve air

flow. For example, if two long pairs of ducts serve different zones, connecting them at the ends to form loops may considerably reduce the pressure differences in the system.

At the same time, ferret out localized duct defects that rob fan power and create excessive pressure differences. The common culprits are non-smooth bends, multiple bends within a short distance, and sharp-cornered takeoffs. Before making changes, spend some time studying how ducts can obstruct air flow. Air moves in strange ways in ducts, and you need to understand this behavior to get the most benefit from changes.

■ Shutting Off Conditioning of Unoccupied Spaces

If the terminal unit dampers can close to shutoff, you can stop conditioning individual spaces when they are not occupied. This saves conditioning energy and fan energy in spaces that operate on different schedules from the rest. Use [Measures 4.1.1 ff](#) to control conditioning based on occupancy.

■ Building Pressure Differentials

See [Measure 4.4.7](#).

■ Economizer Cycle Operation

Installing an outside air economizer cycle ([Measure 4.2.5](#)) in a dual-duct system is not effective if the air handling unit has only a single supply fan. The single fan makes it impossible to route the cold outside air exclusively to the chilled air duct.

If the system has a separate fan for each duct, an outside air economizer can operate with full efficiency. See [Measure 4.8.8](#) for details.

In existing systems, it is usually impractical to retrofit a two-fan configuration. As an alternative, consider installing a “waterside” economizer coil in the cooling side of the system. See [Measure 2.9.4](#) about waterside economizers.

■ Purge Cycle Operation

See [Measure 4.2.7](#) about purge cycles. A purge cycle requires an additional control function that opens all the terminal unit dampers during the purge period.

■ Fan-Induced Resonances

See [Measure 4.4.7](#).

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of heating and cooling energy; 40 to 80 percent of fan energy. The savings depend on the climate, zoning, and other factors, including other energy conservation activities.

COST: In new construction, the cost elements are the VAV fan drive(s), perhaps a more complex air handling unit, controls for fan operation, the cost differential between reheat and VAV terminal units, and the differential cost of space thermostatic controls. See [Reference Note 36](#) for the cost of variable-speed fan drives. The last two differential costs are small.

Retrofitting existing facilities is much more expensive, primarily because of the need to replace or modify the terminal units. VAV terminal units typically cost several hundred dollars apiece.

PAYBACK PERIOD: A few years or less, in new construction. Several years or longer, in retrofit.

TRAPS & TRICKS

DESIGN: VAV systems that are comfortable, highly efficient, and reliable are still rare. There are many design issues, so it is easy to overlook some of them. Do your homework. Try to find successful systems to study.

SELECTING THE EQUIPMENT: Make an effort to select the best terminal units or conversion kits. Good equipment is available, but there is a lot of flimsy junk on the market. Inspect sample units. Study [Reference Note 36](#) about selecting variable-speed fan drives. Variable-speed fan drives are easier to design and have fewer practical problems than other methods of fan modulation.

INSTALLATION: Work with the installers of the terminal units to ensure that minimum-flow limits and other settings are adjusted properly.

EXPLAIN IT: Describe the system in the plant operating manual. Include a table of the settings for all terminal units. Buy an extra terminal unit to use as a training model.

Multizone Systems

In multizone air handling systems, zone dampers mix heated air from a heating coil and chilled air from a cooling coil to regulate the temperature of the air supplied to a space, or zone. Each zone has a separate duct that extends all the way from the air handling unit. Each pair of zone dampers is controlled by a space thermostat. Figure 1, on the next page, shows the distinguishing features of a multizone unit. Figures 1 and 2, in the [Section 4 Introduction](#), compare this type of system to other air handling systems. The energy behavior of multizone units is the same as that of dual-duct systems. See the introduction to [Subsection 4.5](#) for details.

In conventional multizone units, the dampers mix hot and cold air in proportions that keep the flow of mixed air to each zone approximately constant. This can result in an enormous amount of mixing loss if both coils are operating. By far the largest opportunity for energy conservation in multizone reheat systems is minimizing this source of energy waste. During low-load conditions, the system may consume much more energy in mixing losses than in conditioning the spaces. All the Measures in this Subsection reduce mixing losses. Some of the Measures also save fan energy.

The primary justification for using multizone systems is comfort. They provide a high level of comfort because air flow is constant, temperature control can be maintained precisely as the load changes from heating to cooling, and humidity can be kept at any desired level. In making changes for the sake of efficiency, preserve these qualities to the extent that they are needed by the application.

WESINC

Fig. 1 Large multizone air handling unit Each of the ducts serves a zone with individual thermostatic control. The zone thermostat controls the damper actuator that is visible at the entrance to each zone duct. In this unit, the hot deck and cold deck dampers for each zone are installed rigidly on a common shaft, which is moved by the actuator. Large mixing losses are unavoidable with this arrangement.

A minor matter of terminology is the use of the terms “hot deck” and “cold deck” with multizone units, whereas the corresponding terms for dual-duct systems are “hot duct” and “cold duct.” In multizone units, heated air is discharged from the hot coil into a chamber or “hot deck” in the air handling unit, from which it passes through mixing dampers into the individual zone ducts. Similarly, cooled air from the cooling coil is discharged into a “cold deck” before passing through mixing dampers into the zone ducts.

Three to eight zones is typically the maximum number that can be served by each air handling unit. The limitation is the amount of physical space needed to attach the zone ducts to the air handling unit. As a rule, larger air handling units can accommodate a larger number of zones.

In new construction, none of these modifications incurs a relatively large cost increase, unless the systems are small. Variable-output fan drives were once a major cost addition, but the relative cost of this equipment has fallen sharply, especially for larger systems.

In retrofit applications, first decide whether or not you will make major changes to the existing constant-volume system. This decision depends mainly on two issues: whether you can afford a major equipment change, and whether you can forego the tight control of humidity and the continuous ventilation that constant-flow operation provides. If you can afford only inexpensive changes, accomplish [Measures 4.6.1 ff](#) through [4.6.3](#). If you can afford a major modification and it is justified by the energy savings, accomplish [Measure 4.6.5](#). [Measure 4.6.4](#) is an intermediate approach that saves less energy than the latter, but it is much less expensive.

Three-Deck Multizone Systems

Three-deck multizone systems are similar in appearance to conventional multizone systems. However, their energy behavior is entirely different. Three-deck systems have a third deck that is not served by a coil. It recirculates unconditioned air (a mixture of return air and outside air) for mixing with either the heated air or the chilled air. If

properly installed, these systems have greatly reduced losses. Three-deck systems are unusual. They are similar in energy behavior to the triple-duct systems described in the introduction to [Subsection 4.5](#).

Damperless Multizone Systems

Another type of multizone system uses an air handling unit that has no dampers. Instead, each zone has its own heating and cooling coils. Each coil is controlled independently by a thermostat in its respective zone. This unit has no hot and cold decks. It is like a number of single-zone units in a single housing, all served by a common fan.

Figure 2, in the [Section 4](#) Introduction, sketches this type of system.

Damperless multizone units do not mix heated and cooled air, so they avoid the most severe energy waste in conventional multizone units. This type does waste some fan energy because it uses a single blow-through fan to serve all the coils together, even though the flow requirements for different zones vary individually. Like all multizone units, this arrangement is not well adapted to an economizer cycle, because the zones differ in their supply temperature requirements.

If you are dealing with damperless multizone systems, refer to [Subsection 4.3](#) for Measures that can optimize their efficiency.

MEASURE 4.6.1 Keep the temperature of the cold deck as high as possible and the temperature of the hot deck as low as possible.

This Measure is virtually identical to [Measure 4.5.1](#) in theory, procedures, and economics. Refer to there for details.

RATINGS		
New Facilities	Retrofit	O&M
	B	A

MEASURE 4.6.1.1 Install temperature reset controllers for both the cold deck and the hot deck.

This Measure is similar to [Measure 4.5.1.1](#) in theory, installation, and economics. Refer to there for details.

As a retrofit, the cost of this Measure is less than for [Measure 4.5.1.1](#) because the signals from all the zone

thermostats already go to the air handling unit, where they are available for the signal discriminators. This avoids the need to add extensive wiring or pneumatic lines.

RATINGS		
New Facilities	Retrofit	O&M
A	B	

MEASURE 4.6.2 Turn off the cooling coil or the heating coil whenever practical.

This Measure is virtually identical to [Measure 4.5.2](#) in theory, procedures, and economics. Refer to there for details.

RATINGS		
New Facilities	Retrofit	O&M
		A

MEASURE 4.6.3 Trim the fan output.

RATINGS		
New Facilities	Retrofit	O&M
		B

The formula at the beginning of [Subsection 4.5](#) shows that the energy consumption of each zone is partly proportional to its air flow rate. Fan trimming is a one-time adjustment that gets rid of fan capacity in excess of the amount needed to satisfy peak system loads. Refer to [Measure 10.3.1](#) for the details.

By reducing the constant air flow rate in the system, this action reduces reheat “off the top.” However, it does not tailor fan output to a changing load. This is a cheap and simple way to reduce reheat significantly while saving a modest amount of fan energy. Consider this a stopgap action to save energy until you can accomplish either [Measure 4.6.4](#) or [Measure 4.6.5](#).

**MEASURE 4.6.4 Install multi-speed fan motors.**

RATINGS		
New Facilities	Retrofit	O&M
C	C	

The formula at the beginning of [Subsection 4.5](#) shows that the energy requirement of each zone is partly proportional to its air flow rate. Installing a multi-speed fan motor in the air handling unit reduces the air flow

rate in steps that follow the system load. This Measure is virtually identical to [Measure 4.4.6](#) in theory, installation, and economics. Refer to there for details.

MEASURE 4.6.5 Convert the system to variable-air-volume (VAV) operation.

RATINGS

New Facilities	Retrofit	O&M
D	C	

The principle of a VAV multizone system is simple. The difference between VAV multizone operation and conventional multizone operation is primarily in the air handling unit dampers. Instead of controlling the temperature of each zone by mixing hot and cold air, the zone dampers operate independently to provide either hot air or cold air to each zone, but not both. If there is no overlap in the opening of hot and cold dampers, all mixing losses are eliminated.

Since the total amount of air delivered by a VAV system varies over a wide range, the system fan(s) should have variable output. This saves a certain amount of fan energy, but not as much as in other types of VAV systems.

Although the VAV concept is simple, putting it into practice has proven to be tricky. You may have to make some compromises that sacrifice efficiency to satisfy comfort and health requirements.

This Measure is primarily for improving the efficiency of existing multizone systems. In new construction, if you desire a multizone type of system, the damperless multizone system is a better choice. See Figure 2 in the Section 4 Introduction for a sketch of this type of system. Damperless multizone systems avoid the leakage and maintenance problems of dampers, and they avoid the problems of low air flow in the spaces. In addition, new construction affords you the opportunity of considering other types of efficient systems.

Is it Practical to Retrofit an Existing Multizone Unit?

The physical changes that you need to convert a conventional multizone system to VAV are concentrated at the damper section of the air handling unit. The way the mixing dampers were originally installed is the main factor that determines whether it is practical to convert the unit. Refer to “Zone Damper Modifications,” below, for details.

The energy savings are proportional to the capacity of the air handling unit. In contrast, the cost of the modifications does not relate strongly to the size of the air handling unit. In fact, it may be easier to retrofit a larger unit. Therefore, this modification should pay for itself quickly in large systems, but it may not be economical in small systems.

When analyzing the potential savings, consider the benefit that this Measure can provide in excess of Measures 4.6.1 ff through 4.6.3, which you can accomplish at low cost.

SUMMARY

The most efficient configuration for multizone systems with dampers. Combining comfort and high efficiency is challenging. Lack of space at the damper end of the air handling unit can be a serious obstacle to retrofit.

Energy Saving Potential

Refer to this heading in Measure 4.5.5. VAV conversion of multizone systems saves energy in the same ways as VAV conversion of dual-duct systems, and in similar amounts.

How to Convert a Multizone Unit to VAV

To convert a conventional mixing (reheat) multizone system to VAV operation:

- modify the zone dampers and their actuators so that the hot deck and cold deck dampers of each zone operate in a VAV mode
- replace the zone thermostats, if necessary. If the zone dampers can close to shutoff, consider deadband thermostats.
- if necessary, replace the air diffusers in the spaces to provide good performance at all air delivery rates
- install an efficient means of varying the output of the air handling system fans
- install a control system for the fan output
- install temperature reset controls for both the hot and cold decks
- provide controls for various auxiliary functions, such as morning warm-up, night setback, purge cycle operation, smoke relief, etc.

Be prepared to deal with a variety of problems in making this conversion, including unsatisfactory air distribution, inadequate outside air ventilation, and complaints of stagnation. The main source of these problems is the large reduction of space air flow that occurs for long periods of time. It is tempting to add reheat back into the design to increase the low-load air

flow, but this wastes energy. The design challenge is to maintain comfort and health while minimizing reheat.

Consider the following points. You will see that many of them are related. To avoid repetition, some of the following topics refer you to the corresponding topics in [Measure 4.4.7](#), which converts single-duct systems to VAV, and to [Measure 4.5.5](#), which converts dual-duct systems to VAV.

■ How to Modify the Zone Dampers

The first step is to modify the hot and cold deck mixing dampers so that they (1) operate independently of each other, and (2) close tightly enough to restrict air flow to the minimum required by the application.

Many multizone units have crude damper arrangements in which the hot and cold damper for each zone are mounted on a common shaft. Figure 1 shows a typical arrangement of this type. In such cases, remove the existing dampers entirely and replace them with independent dampers and actuators. This change is not difficult in itself. However, the zone ducts and dampers are jammed together on one side of the air handling unit casing. If the air handling unit is crammed into a tight space, there may not be enough room to make the change.

In many multizone units, especially larger ones, the hot and cold dampers are mounted on the air handling unit casing as separate assemblies with separate actuators. In such cases, you may be able to retain the original dampers and actuators, and simply change the control signals to the actuators.

Don't let the apparent ease of this situation seduce you into keeping leaky dampers. The original dampers probably were not designed to close tightly. In most cases, you will want to replace the present dampers with dampers that are designed to close tightly. Damper leakage allows mixing of hot and cold air, which wastes energy.

Replace leaky dampers even if you design the system for minimum-flow operation. If the dampers cannot close tightly, they will cause mixing losses under all load conditions, not just minimum-flow conditions.

For example, consider a VAV multizone system in which the heating capacity equals the cooling capacity, and the dampers leak 5% of their full load capacity when closed. Assume that a zone has a cooling load that is 50% of maximum. The heating leakage, plus the additional cooling required to cancel it, represents another 10% of full load. Thus, apparently minor damper leakage adds 20% to energy consumption.

In reality, multizone unit dampers may leak much more than 5% when closed, because tight shutoff was not a requirement foreseen in the design of multizone units. Some retrofit damper improvements, such as blade seals, may substantially reduce leakage, but they are unlikely to provide tight closure. Furthermore, blade

seals have a limited life. Therefore, expect to replace the dampers entirely.

■ Zone Damper Controls

The dampers in an ordinary, air mixing multizone system move together to maintain an approximately constant airflow into each zone duct. Both dampers are partially open at all times. In converting to VAV, the objective is to keep one damper closed, except perhaps for minimum-flow at low loads. You can achieve this mode of operation easily by using conventional damper actuators and space thermostats.

For example, if the system has pneumatic controls, select a zone thermostat that produces air pressure in the range of 5 to 15 PSI. Select the cooling damper actuator so that the cooling damper is wide open at 5 PSI, and closes at 10 PSI. Select the heating damper actuator so that the heating damper starts to open at 10 PSI, and is fully open at 15 PSI.

■ How to Select the Fan Modulation Method

See [Measure 4.4.7](#) for your choices.

■ How to Control Fan Modulation

The device that modulates fan output must receive some signal that tells it how much air to deliver. The best method is to measure the pressure in the hot and cold decks. The pressures in the hot and cold decks are independent of each other, so install a pressure sensor in each deck, and design the controls so that the fan responds to the lower pressure.

There is another reason why it is a good idea to install the pressure sensors in the hot and cold decks.

Trane Company

Fig. 1 Candidate for VAV retrofit This old multizone unit has pairs of hot and cold deck dampers installed on common shafts. There is no economical way to salvage the existing dampers. Instead, unbolt the old damper section and throw it away. Install separate hot and cold dampers of good quality for each zone.

The air that is discharged from the supply fan crashes into the front of the two coils, creating a region of great turbulence. For this reason, it would be difficult to get an accurate, stable pressure reading on the fan side of the coils. In contrast, the air flow on the discharge side of the coils is the most uniform anywhere inside the air handling unit. This is because the coils act as baffles, and straighten the air flow.

Even in the hot and cold decks, getting a good, stable signal from the pressure sensors may be tricky. Try to locate the pressure sensor where it is not excessively influenced by fan turbulence or by the drop in pressure at the zone dampers. You might install each sensor inside a pressure averaging tube that traverses the deck. The tube is perforated with tiny holes, so the pressure inside the tube is the average of all points on the outside of the tube.

The controls should keep the system pressure high enough to satisfy the air flow requirement of the zone with the greatest requirement. To avoid wasting fan energy, the pressure should be no higher than this.

(In this type of system, don't try to control fan output based on return air volume. Return air indicates only the average of the hot deck and cold deck flow volumes. The pressures in the hot deck and cold deck may differ radically for a given average flow volume.)

■ Satisfy Requirements for Minimum Air Flow

You may be forced to establish minimum-flow damper settings for a variety of reasons, including:

- proper diffuser operation
- maintaining an adequate level of outside air ventilation
- maintaining in-space air velocity to prevent a feeling of “stiffness” and to aid cooling by perspiration
- providing dehumidification during periods of low cooling load.

These requirements are covered below. Assess each one to determine the minimum flow that each zone requires. Minimum-flow is the Achilles heel of VAV system efficiency because it causes reheat. Focus on keeping the minimum-flow requirement as low as possible, consistent with maintaining comfort and ventilation.

Minimum air flow is maintained by having both dampers open slightly at low load. For example, in the previous example of pneumatic control, the cold air damper might operate between 6 and 11 PSI, and the hot air damper might operate between 10 and 15 PSI.

■ Zone Temperature Deadband

Temperature deadband is a thermostatic control technique that creates a comfortable range of temperature in which there is no heating or cooling. If there are zones where you can shut off the air flow

completely, consider saving additional energy by using deadband temperature control. See [Measure 4.7.2](#) for details.

You can't use deadband in zones where you set up the dampers to maintain minimum flow. Minimum-flow overlaps the opening of the heating and cooling dampers, whereas deadband involves inserting a temperature gap between the closing of one damper and the opening of the other. If you must use minimum-flow, conserve energy at low loads by using deck temperature reset ([Measures 4.6.1 ff](#)).

■ Space Air Velocity

See [Measure 4.4.7](#).

■ Diffuser Performance

See [Measure 4.4.7](#).

Multizone systems encounter an additional problem in diffuser performance because their duct systems are designed to withstand only minimal pressure. Diffusers designed to operate well at low flow rates may have a significant amount of resistance, thereby raising pressure in the zone ducts. The pressure is not great, but if the ducts are large, the additional pressure may deform the ducts or cause “oil can” noise.

■ Night Temperature Setback and Morning Warm-Up

See [Measure 4.5.5](#).

■ Deck Temperature Reset

Automatic deck temperature reset is covered by [Measure 4.6.1.1](#). It increases efficiency and reduces comfort problems at low space air flow rates. Expect to include this control feature.

■ Dehumidification

See [Measure 4.4.7](#).

■ Outside Air Ventilation

See [Measure 4.5.5](#).

■ Zoning

See [Measure 4.5.5](#).

■ Isolation of Space Conditioning

See [Measure 4.5.5](#).

■ Building Pressure Differentials

See [Measure 4.4.7](#).

■ Economizer Cycle Operation

See [Measure 4.5.5](#).

■ Purge Cycle Operation

See [Measure 4.2.7](#) about purge cycles. If you want to have a purge cycle, include a function that opens the zone dampers fully during the purge period.

■ Fan-Induced Resonances

See [Measure 4.4.7](#).

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of heating and cooling energy; 40 to 80 percent of fan energy. The savings depend on the climate, zoning, control features, and other factors.

COST: In new construction, the cost elements are the VAV fan drive(s), a more complex air handling unit, controls for fan operation, and the differential cost of space thermostatic controls, which is minor. See [Reference Note 36](#) for the cost of variable-speed fan drives.

In retrofit applications, the main costs are a VAV fan drive and controls, and damper and sheetmetal modifications. The latter cost varies widely. You may have to relocate nearby equipment or partitions to gain access for the modifications.

PAYBACK PERIOD: One year or less, in new construction. One year or longer, in retrofit.

TRAPS & TRICKS

DESIGN: VAV multizone systems are uncommon. Furthermore, it is still difficult to find VAV systems of any type that are comfortable, efficient, and reliable. Therefore, you are pioneering. Make sure to deal with all the design issues covered above.

SELECTING THE EQUIPMENT: Select dampers for tight closing, long-term durability, and ease of maintenance. Install damper linkages that cannot slip. See [Reference Note 36](#) about selecting variable-speed motors and drives.

EXPLAIN IT: Provide a clear explanation of how the system works in your plant operating manual. Include a table that specifies the correct settings of all dampers and controls, including minimum flows or deadband temperatures, the deck temperature reset schedule, and other control functions.

Variable-Air-Volume Single-Duct Systems

The Measures in this Subsection improve the efficiency of variable-air-volume (VAV) single-duct systems. Figures 1 and 2, in the Section 4 Introduction, sketch this type of system.

In these systems, chilled air is distributed to spaces from an air handling unit, and the temperature of individual spaces is controlled by throttling the quantity of air into each space. The throttling is accomplished by terminal units that are controlled by the space thermostats.

VAV systems were originally introduced as a more efficient alternative to constant-volume reheat systems (which are covered in Subsection 4.4). The VAV concept offers two major efficiency improvements: (1) it reduces or eliminates reheat and (2) it minimizes fan power. Unfortunately, the full efficiency potential of many VAV systems has not been achieved in practice. In many systems, the terminal units contain heating coils. These are used to provide space heating, or to reheat the chilled air to allow a minimum air flow to be maintained in the spaces, or for both purposes.

As VAV systems became widespread during the 1980's, it became apparent that they incur a number of conflicts with comfort and air quality. Indeed, VAV has become notorious for its comfort problems. Attempts to resolve the comfort problems and to reduce the installation cost of the systems often resulted in systems that squandered much of the efficiency potential of the VAV concept.

All the Measures in this Subsection, except the last, make system temperature control more efficient. The last Measure improves the efficiency of fan modulation.

INDEX OF MEASURES

- 4.7.1 In spaces with shutoff VAV terminals, install thermostat placards.**
- 4.7.2 In spaces with shutoff VAV terminals, install deadband thermostats.**
- 4.7.3 If the air handling systems cannot be turned off during unoccupied hours, install temperature setback.**
- 4.7.4 Turn off the air handling unit cooling coil when cooling is not needed.**
- 4.7.5 Minimize the minimum-flow settings of terminal units.**
- 4.7.6 Set the cooling coil discharge at the highest temperature that maintains satisfactory cooling.**
 - 4.7.6.1 Install automatic chilled air temperature reset control.**
- 4.7.7 With minimum-flow terminals, install heating/cooling changeover.**
- 4.7.8 Improve the efficiency of fan modulation.**

MEASURE 4.7.1 In spaces with shutoff VAV terminals, install thermostat placards.

Placards are one of the most powerful tools of energy efficiency. See [Reference Note 12](#), Placards, for general guidance in designing and installing placards. This Measure provides additional guidance for installing thermostat placards in VAV systems that have shutoff terminals.

Where to Use Thermostat Placards with VAV Systems

This Measure applies to individual spaces, not to the system as a whole. Thermostat placards are useful only in spaces where cooling and heating of the space can be shut off and controlled separately. To shut off cooling, the VAV system must have shutoff terminals. In addition, the system must have an explicit way to select either cooling or heating, such as a heating/cooling changeover control ([Measure 4.7.7](#)) or fan-powered VAV terminals.

Thermostat placards may be useless or counterproductive in spaces where the VAV system uses reheat. For example, consider what happens in a space where reheat terminals are installed. If the space has a small cooling load, the terminals in the space are held at their minimum-flow positions, and space temperature is controlled by using the reheat coils in the terminals. The normal instinct is to raise the thermostat setting to conserve cooling energy. However, if someone does this, the cooling output remains the same, and reheat energy increases.

Energy Saving

The amount of energy required for heating or cooling a space is roughly proportional to the temperature differential between the inside and the outside. Placards save energy by motivating occupants, in effect, to reduce this temperature differential. The benefit is greatest in climates where heating or cooling is needed for a larger fraction of the year.

During low-load conditions, resetting the space temperature may substantially reduce the number of hours that the space needs conditioning. This effect is more dramatic in mild climates, where the temperature hovers for long periods in a range that does not require either heating or cooling. In addition, buildings in mild climates are often poorly insulated, so they derive larger savings from a given temperature adjustment.

Thermostat placards can save the most energy in systems that have temperature deadband, or that have separate thermostat settings for heating and cooling. (Converting to deadband is covered by [Measure 4.7.2](#).) Thermostat placards are less effective with systems that maintain a fixed space temperature by using both heating

SUMMARY

A cheap way to save energy, but it takes effort to make placards effective.

SELECTION SCORECARD

Savings Potential	\$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% % % %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺

and cooling. The advantage of deadband is greatest in mild climates.

(As a point of interest, the energy saving does not relate to the outside temperature itself, but only to the temperature difference between the inside and outside, as long as there is a heating or cooling load. For example, lowering the heating temperature by 3°F saves the same amount of energy whether the outside temperature is 0°F or 50°F.)

What the Placards Should Say

- The placards should request occupants to:
- set the heating temperature as low as possible
 - set the cooling temperature as high as possible
 - close windows and exterior doors, if any, while the unit is operating.

If there may be doubt, the placard should state which spaces the thermostat controls. For example: “These controls operate the heating and cooling system for the reception area.” Otherwise, occupants may not associate the controls with the conditioning of their space, or they may not know if other spaces are also controlled by them.

The placards should make occupants aware of the operation of any automatic controls, if this might create confusion. For example, if a timer control is installed to shut down the air handling system after a certain time interval, the placard should state this. Refer to [Subsection 4.1](#) for automatic control Measures that require placards.

Don’t Be Too Specific about Temperature

As a rule, don’t try to tell people what temperatures to set in their spaces. The perception of comfort is what guides most occupants in deciding how far they will limit conditioning for the sake of energy conservation.

Furthermore, the calibration of thermostat dials may be inaccurate. Sometimes, thermometers are installed on or near thermostats as a guide to setting the thermostats. These little thermometers may not be accurate either, so the thermometers and the thermostats may disagree by several degrees.

Dress for the Environment

The temperatures that human beings prefer inside buildings depend largely on how they dress. Where appropriate, encourage occupants to dress warmly in cold weather, and to dress lightly in warm weather. Say this on the thermostat placard, if doing so is appropriate for the environment.

Make Thermostats Accessible, Usually

A basic principle of good energy conservation is to avoid infringing comfort. It is bad practice to try to conserve energy by making controls inaccessible. Locked thermostats irritate people because they overtly prevent people from being able to control their environment. Locked thermostats also create an adverse attitude toward energy conservation, resulting in loss of efficiency elsewhere.

If you put a locked enclosure around the thermostat and let the temperatures go to extremes, occupants will be uncomfortable. On the other hand, if you set the

locked thermostat to minimize complaints, you waste energy. Only the occupants can optimize the temperature in each space. If the occupants disagree among themselves about the thermostat settings, at least it won't be your problem.

If you need to protect controls from vandalism, keep them entirely out of sight. Locked thermostats that are visible are a magnet for tampering.

ECONOMICS

SAVINGS POTENTIAL: 1 to 5 percent of conditioning cost, depending on which control functions are manual, the operating schedule, etc.

COST: \$5 to \$200 per placard, depending on quantity, materials, and complexity. Design accounts for a majority of placard cost, if you are doing it right.

PAYBACK PERIOD: Less than one year, in most cases.

TRAPS & TRICKS

CHOICE OF METHOD: Do not install placards if the system uses any reheat, unless you are sure that you can save energy this way.

PLACARD DESIGN, MATERIALS, AND INSTALLATION: The main pitfall is thinking that placards are simple. Study [Reference Note 12, Placards](#).

MEASURE 4.7.2 In spaces with shutoff VAV terminals, install deadband thermostats.

RATINGS

New Facilities	Retrofit	O&M
A	C	

If the space thermostat maintains a fixed temperature, the system must consume energy continuously to maintain that temperature. Some of this energy consumption is unnecessary because human beings can be comfortable within a range of temperatures.

You can avoid unnecessary conditioning within the comfortable temperature range by using thermostatic “deadband.” This is an optional feature of thermostatic controls in which both cooling and heating are turned off as long as the space temperature is within the comfort range. The way to achieve deadband in a single-duct VAV system is to install deadband thermostats to control the terminal units, instead of conventional thermostats.

How Wide Can You Make the Deadband?

The usual range of comfortable indoor temperature extends from a low of 70°F to 72°F, to a high of 76°F to 80°F. This implies a possible deadband range of 4°F to 10°F. Experience confirms that this is acceptable. These figures are for sedentary work. The deadband range is somewhat wider when people are physically active. You can increase the acceptable deadband range by encouraging occupants to dress appropriately for the weather.

On the other hand, the deadband range will be limited by any hot spots and cold spots within the space. For example, a person seated near a cold wall may require that the thermostat be set near the top of the comfort range, eliminating most opportunity to exploit deadband. This makes it important to eliminate hot spots and cold spots in the occupied portions of spaces.

Where to Use Deadband Thermostats

Deadband is possible only if the system can completely shut off delivery of heating and cooling to the space. To shut off cooling, the VAV system must have shutoff terminals.

Note that your ability to install deadband thermostats relates to the space, not to the system. A given VAV system may have some spaces that use shutoff terminals and other spaces that do not.

Obviously, deadband control is not appropriate in applications where close control of temperature is desired.

Ventilation and Dehumidification Limitations

In VAV systems with shutoff terminals, using deadband may greatly extend the periods of time during which the system does not provide any outside air

SUMMARY

A thermostatic control change that saves a few percent of system energy consumption at modest cost. Usually simple to accomplish. Not applicable where close control of temperature is needed.

SELECTION SCORECARD

Savings Potential	\$ \$
Rate of Return, New Facilities	% % %
Rate of Return, Retrofit	% %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

ventilation to the space. Therefore, use deadband only in spaces with limited ventilation requirements, or where ventilation air can be provided in other ways, such as by opening windows or by letting air circulate from other spaces. Outside air ventilation requirements are covered in [Measure 4.2.1](#).

The system provides no control of humidity within the deadband temperature range. The climate determines whether this is likely to create a problem.

Energy Saving Potential

Deadband thermostatic control eliminates energy waste from these causes:

- **unnecessary operation while the space temperature is within the comfort range.** There is no need to provide conditioning when the space temperature is within the range of comfort.
- **excessive heating or cooling whenever the system is operating.** Conditioning load is largely proportional to the difference in temperature between the inside of the building and the outside. If the temperature is set arbitrarily within the range of comfort, the system maintains a larger temperature differential than necessary, with correspondingly greater energy consumption. For example, if the space thermostat is set at 75°F, this is several degrees higher than needed for heating, and several degrees lower than needed for cooling.
- **unnecessary shuttling between heating and cooling.** Especially in mild climates, the space temperature may tend to drift up and down within the comfort range. For example, it is cool in the morning, warmer at midday, and cooler again in

the evening. If the space temperature is fixed, cooling energy will be expended to cancel the energy that was added by heating just a short while before, and vice versa.

- **unintentional reheat.** If the heating and cooling temperatures are set close together, it is easy for the temperature ranges to overlap inadvertently. This may result from a defect in the controls, from an incorrect adjustment, or from aging of control components. If the temperature ranges overlap, both heating and cooling will operate continuously to cancel each other.
- **unnecessary operation of equipment.** In some systems, fans or other equipment can be turned off within the deadband range. For example, this is possible with fan-powered VAV terminals.

Types of Deadband Thermostats

■ Manual Heat/Off/Cool Thermostats

This type of thermostat requires occupants to select either heat or cooling. Although this technique is not usually considered to be “deadband,” it achieves the purposes of deadband. See [Measure 4.3.4.1](#) for details about this type of thermostat.

This type of thermostat is well adapted to human temperature response, in that people usually do not want cooling until the temperature has started to rise considerably, and they do not want heating until the temperature starts a definite downward trend. In contrast with true deadband thermostats, a manual changeover thermostat keeps the system from alternating automatically between heating and cooling during mild weather.

The thermostat should have two elements that can be set independently for heating and cooling, respectively. If the thermostat has only one element, occupants are likely to leave the same temperature set when switching between heating and cooling.

■ Deadband Thermostats

A deadband thermostat is essentially two independent thermostats in one housing. One thermostat controls heating and the other controls cooling. Typically, a deadband thermostat is used to replace a single thermostat that controls both heating and cooling sequentially. The deadband thermostat inserts a range of temperatures between heating and cooling in which no conditioning is accomplished.

Some deadband thermostats allow the upper and lower temperature limits to be set by the occupants, and others do not. The former type has two dials, one for the low limit and one for the high limit. The latter type has a single dial, with the deadband set internally. The latter type is typically used in plusher environments, such as luxury hotels, which desire to maintain the illusion that the occupant has precise temperature control. The

deadband in these types is kept narrow to avoid occupant complaints, and hence they are less efficient.

A “hesitation” thermostat is a variation of a deadband thermostat that has a single output signal. The name derives from the fact that there is a plateau, or hesitation, in the output signal within the deadband temperature range.

In many cases, it does not matter whether you use a conventional deadband thermostat or a hesitation thermostat. The dual-output type is more flexible because it allows the sensitivity of each element to be adjusted individually. Furthermore, some models allow one element to be connected direct-acting, while the other element is connected reverse-acting. (“Direct-acting” means that the output signal rises as the temperature rises. “Reverse-acting” means the opposite.)

Don’t Forget the Placards!

Getting the most benefit from deadband depends on the way that the occupants use the thermostats. Install effective thermostat placards. See [Measure 4.7.1](#) for details.

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of conditioning cost. The larger percentages applying to mild climates, but the absolute saving is greater in buildings that have higher conditioning loads.

COST: Deadband thermostats cost less than \$100. The cost of installation varies with the type of system, and the difficulty of wiring.

PAYBACK PERIOD: Several years, to many years. Depends on the conditioning load of the space.

TRAPS & TRICKS

CHOICE OF METHOD: Do not use deadband with terminal units that use reheat. Deadband is suitable for most comfort applications, but not for environments where close temperature control is needed.

SELECTING THE THERMOSTATS: Select thermostats that make it easy for occupants to set the space temperature. In environments where vandalism is a risk, select thermostats for ruggedness. If you select true deadband thermostats, buy the kind that have a fixed deadband setting that can be changed only by the maintenance staff. If you select “heat/cool/off” thermostats, buy the kind that has separate temperature setting levers for heating and cooling. Add setback features (see [Measure 4.7.3](#)), if appropriate.

INSTALLATION: When installing any thermostat, select a location where it senses the actual temperature of the space. Do not mount the thermostat on an exterior wall or other surface that is heated or cooled from behind. If

necessary, use a long standoff mounting bracket. Do not install the thermostat where sunlight can shine on it or on adjacent surfaces.

EXPLAIN THEM: All thermostats should have appropriate placards. With true deadband thermostats, the energy saving is determined by the person with the

small screwdriver who sets the deadband in each thermostat, or in the case of electronic systems, by the person who sits at the keyboard. Make sure that the staff are trained to set the maximum acceptable deadband. Put clear instructions in the facility operating manual.

MEASURE 4.7.3 If the air handling systems cannot be turned off during unoccupied hours, install temperature setback.

The most effective way to save conditioning energy after hours is to turn off the air handling system, as recommended by Measures 4.1.1 ff. However, this is not possible in all cases. The air handling system may be kept in operation to maintain a minimum temperature, or to continue ventilation, or for other reasons. Even if the air handling system fans are turned off, the coils may be kept active to warm air that is drawn into the building by the action of exhaust fans.

In many of these situations, you can still save energy after hours by using temperature setback. This is a thermostatic control technique in which heating and cooling are turned off during unoccupied periods until the temperature in the space drifts to a lower (or higher) setback temperature.

Energy Saving Potential

Temperature setback reduces the temperature differential between the inside of the building and the outside during the setback period. The conditioning load is largely proportional to this temperature differential.

For example, if the average space temperature can be reduced 10°F during the setback period, and if the outside air temperature during the setback period averages 30°F below the occupied temperature, then approximately one third of heating energy consumption can be saved during the setback period. (This example does not include the effect of heat gains, heat storage in the building structure, and other complications, most of which would reduce the percentage of savings.)

Additional fan energy can be saved if fans or other equipment are controlled by the space thermostat.

In most cases, you can shut off outside air during the setback period, as recommended by Measure 4.2.1.1. This action typically saves a large part of the conditioning load.

Methods and Limitations

■ Setback That Shuts Down the Entire Air Handling System

If the entire air handling system is being controlled as a single unit, use a single setback thermostat to control the fans, the cooling coil, and all heating coils. Install the setback thermostat at the location that is most sensitive to temperature. If the space temperature falls to the setback level, the heating equipment alone is turned on.

This method is simple. However, if someone activates an override to provide conditioning for a single space outside of normal operating hours, the override

SUMMARY

A basic energy conservation measure that saves energy during unoccupied periods. A standard feature in most electronic control systems. With other types of controls, requires special thermostats.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	
Ease of Retrofit	☺	☺	☺

will cause the system to provide conditioning to all the unoccupied spaces served by the system.

■ Setback that Shuts Down Individual Spaces

If the system serves some spaces that may be used during the setback period, install separate setback thermostats in each space. Each thermostat needs an override that can be used by after-hours occupants to obtain normal space temperature.

The air handling unit fan may continue to operate during the setback period, or it may be started if any one space calls for an override.

If all the spaces served by the system have shutoff terminals, each space can have both heating and cooling overrides during the setback period. During setback operation, the VAV boxes are closed by the setback thermostat, and the heating equipment is controlled to maintain the setback temperature. An override in any space restores normal conditioning to that space. This mode of operation requires the cooling coil in the air handling unit to operate.

If some of the spaces served by the system have minimum-flow VAV boxes, the central cooling coil must be turned off to save any energy. In this case, an override in an individual space can restore heating to the space, but it should not restore cooling.

Types of Setback Thermostats

■ Individually Programmable Setback Thermostats

A setback thermostat has two thermostatic elements in one enclosure, one of which is set for normal occupancy, and the other for unoccupied conditions. (Newer electronic units may have only a single sensor, but the effect is the same.) You can buy electronic

thermostats that include setback along with a number of other functions, such as multiple setback schedules, an override, backup power supply, and perhaps other features. See [Reference Note 10](#), Clock Controls and Programmable Thermostats, for the features, installation practices, and operating procedures that are important with time controls.

You can use a thermostat of this type to control an entire air handling system, or you can install them in individual spaces. In the latter case, the setback thermostat replaces the original thermostat.

■ Centralized Setback

In a facility with many thermostats, it may be preferable to use a centralized setback system. Such systems can send a signal from a central station to reset all thermostats to the setback temperature.

Temperature setback is a standard capability of centralized electronic control systems. These systems may allow different space thermostats to be set on individual schedules. If you have the capability, use it.

In pneumatic control systems, setback thermostats can be triggered by changing the control air pressure at the air source. This retrofit requires changing all the individual thermostats, plus adding a control station at the air source to change the pressure at the appropriate times. A typical system sets the thermostats to daytime operation with 17 PSI supply pressure and nighttime operation with 22 PSI supply pressure.

Control Issues

■ Avoid Forcing the Setback Temperature

Be sure that conditioning energy is not used to drive the space to the setback temperature. This is a potential trap where a thermostat controls both heating and cooling equipment. This problem does not occur with true setback thermostats. If you set space temperatures with a centralized control system, this problem may occur as a result of an incorrect input.

■ Setback Overrides

A weakness of centralized temperature setback systems is that all thermostats are controlled on the same schedule. To overcome this problem, thermostats used with centralized setback systems should include individual overrides. A person who wants to work during the unoccupied period activates the override in his space, which causes the thermostat to call for normal temperature. The override remains in effect until the next setback period, unless the occupant cancels the override.

Individually programmable setback thermostats usually have quick overrides of the setback temperature that work in a similar way.

Overrides have an efficiency weakness if they are used often. If a person who works late forgets to cancel the override when he leaves, the system will continue to operate at the daytime temperature. This does not waste much energy if it happens only occasionally. However, if the override is used often by someone who forgets to cancel the override, much of the benefit of the setback feature is lost.

■ Control of Outside Air

Many facilities do not need to continue outside air ventilation during the unoccupied period. In such cases, use a control signal from a centralized setback system, or from an individually programmable setback thermostat, or from a timeclock to close the outside air dampers. See [Measure 4.2.1.1](#) for details.

Don't Forget the Placards!

Setback thermostats require occupant action to avoid wasting energy, so they need instruction placards. Make sure that the placards request occupants to reset the temperature override after using it. See [Measure 4.7.1](#).

ECONOMICS

SAVINGS POTENTIAL: 5 to 15 percent of heating cost.

COST: In new construction, adding setback typically costs less than \$100 per thermostat. It is a standard feature with some electronic control systems. In retrofit, adding setback typically costs several hundred dollars per thermostat.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

CHOICE OF METHOD: You may have a variety of ways to accomplish setback. Study your system to select the most effective.

SELECTING THE EQUIPMENT: Select thermostats for ease of use and for ruggedness. Add deadband features (see [Measure 4.7.2](#)), if appropriate.

INSTALLATION: When installing any thermostat, select a location where it senses the actual temperature of the space. Do not mount the thermostat on an exterior wall or other surface that is heated or cooled from behind. If necessary, use a long standoff mounting bracket. Do not install a thermostat where sunlight can shine on it or on adjacent surfaces.

EXPLAIN IT: Don't forget the instruction placards. Make sure that the staff are trained to set the proper setback temperature for each location. List these temperatures in the plant operating manual.

MONITOR PERFORMANCE: Verify proper operation of the setback feature at the start of the heating season. Put this in your tickler file.

MEASURE 4.7.4 Turn off the air handling unit cooling coil when cooling is not needed.

RATINGS

New Facilities	Retrofit	O&M
		A

This is a method of eliminating reheat during the heating season. It applies to systems that have not been designed with a great deal of attention to efficiency. See [Measure 4.4.2](#) for the procedures.

Energy Saving

The potential savings depend on how the VAV system is designed and operating, on the way systems are zoned, and on the diversity of heat gains within each system.

Limitations and Alternatives

This Measure cannot be used with systems that serve spaces with continuous cooling loads, such as spaces in core areas.

Chilled air temperature reset control (see [Measures 4.7.6 ff](#)) is more effective than this Measure. However, even if you have reset control, consider turning off the cooling coils seasonally as a safety feature.

ECONOMICS

SAVINGS POTENTIAL: 3 to 20 percent of cooling energy; 10 to 30 percent of reheat energy.

COST: Minimal.

SUMMARY

An easy method of eliminating mixing losses when cooling is not needed.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

EXPLAIN IT: Success depends on training and supervision. Provide clear instructions that explain when to turn off the cooling coils, e.g., when the outside air temperature is below a certain temperature. Optimize the schedule for each air handling unit or group of units. Install placards at the cooling coil valves or at the controls of the compressors in self-contained air handling units.

MONITOR PERFORMANCE: This Measure is easy to forget. Schedule periodic checks of the procedure in your maintenance calendar.

MEASURE 4.7.5 Minimize the minimum-flow settings of terminal units.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

The main efficiency advantage of VAV systems over constant-volume reheat systems is eliminating the mixing of heated air with chilled air. However, many VAV systems are designed to retain a substantial amount of air mixing. This is done as a cheap way of providing heating, and as a way of avoiding comfort and ventilations problems that occur at low air flow rates.

The air mixing is accomplished by preventing the dampers in the terminal units from closing fully. This is usually done with mechanical stops inside the units. Such terminals are called “minimum-flow” units, in contrast with “shutoff” terminals. Minimum-flow settings can also be made through the control system, especially with terminal units that include their own air flow monitors.

The minimum-flow settings may be a large fraction of full flow, especially when the purpose is to provide space heating. It is not unusual for the minimum-flow settings to be as much as 40% of maximum flow. This wastes a large fraction of the savings potential of the VAV concept.

In many cases, you can reduce the minimum-flow setting by a large amount. This saves a substantial amount of energy at lower cooling loads, which typically occur for a large fraction of the time.

Minimum-Flow Always Causes Mixing Losses

Any VAV system that uses minimum-flow terminal units suffers mixing losses when the space load is less than the minimum-flow capacity of the terminal unit. Most minimum-flow terminals have reheat coils, but not all. Even if minimum-flow terminals do not have reheat coils, mixing losses must occur somewhere. Otherwise, the spaces would overcool if there were no means of compensating for the unnecessary cooling provided by the minimum supply air flow. In such cases, reheat is usually provided (whether or not the designer intended) by a separate heating system, such as a perimeter baseboard system.

Minimum-flow terminals without heating coils may be more wasteful than units that have integral heating coils. This is because they deliver colder supply air, so the space must be kept at a higher temperature to prevent discomfort. For a given chilled air temperature, a higher space temperature requires more reheat.

Energy Saving

Mixing losses occur whenever the terminal is operating at its minimum-flow setting. The loss increases as the cooling load declines, reaching a

SUMMARY

A simple adjustment in minimum-flow terminal units that reduces mixing losses. Much easier to accomplish if you have a central energy management control system. May cause discomfort if you overdo it.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓
Ease of Initiation	☺ ☺

maximum at zero space load. The loss remains at this maximum whenever the space has a heating load.

To appreciate how large mixing losses can be, consider a typical VAV reheat terminal in which the minimum flow has been set at 40% of maximum flow. The cooling energy delivered by the terminal is proportional to the flow rate, so the cooling energy consumption is always at least 40% of maximum. If the space load is zero, an equal amount of heating energy is required to cancel the cooling energy. Thus, at zero space load, the mixing losses (in absolute energy units) are equal to 80% of the maximum cooling load! Furthermore, this same amount of mixing loss continues whenever the space has a net heating load.

Generalizing this example shows that the maximum mixing losses, expressed as a percentage of the maximum cooling load, are always equal to twice the minimum flow percentage. In many cases, you can reduce the minimum-flow settings by 10% to 50%, reducing the energy waste correspondingly.

How Much Can You Reduce Minimum-Flow Settings?

To decide how much you can reduce the minimum-flow settings, examine the system to find out which factors dictate the minimum-flow requirement of each terminal unit. Minimum-flow may be needed to:

- provide proper diffuser operation
- maintain an adequate level of outside air ventilation
- create in-space air velocity to prevent a feeling of “stiffness” and to facilitate cooling by perspiration
- provide dehumidification during periods of low cooling load
- provide space heating

- if electric reheat coils are used, to ensure sufficient flow to prevent coil burn-out.

Review [Measure 4.4.7](#) to see how each of these requirements may affect the minimum flow requirement.

The most wasteful minimum-flow requirements occur when the terminal unit is used for heating the space. This requirement exists only during heating weather, so consider adjusting the minimum-flow settings seasonally. For example, you might adjust the minimum-flow setting to a low level during warm weather, then increase it in steps as the weather becomes colder.

Where heating is the deciding factor in the minimum-flow requirements, adjust the minimum-flow settings on a space-by-space basis. The minimum-flow settings needed to provide adequate heating may vary radically from one terminal unit to another within a given VAV system. For example, the terminals in the core area of the building may be able to function with low minimum-flow settings, while terminals in the perimeter areas may need high minimum-flow settings.

The other factors that determine the minimum-flow setting vary considerably among different facilities, different air handling systems, and different terminal units. The minimum-flow requirement may be vague. In case of doubt, the best approach may be to reduce the minimum-CFM settings progressively until a problem becomes apparent, and then increase the flow slightly.

How to Adjust the Terminal Units

If you have a centralized electronic control system, you may be able to adjust the minimum-flow settings of the terminals from your keyboard. In this case, the effort is almost trivial, and you can easily experiment to find the optimum settings.

If you do not have a central control system, you can adjust each VAV box manually. Unfortunately, VAV terminals are often jammed tightly into the ceiling plenum, and reaching them can be time consuming. Terminal unit manufacturers have no shame about leaving sharp edges all over their equipment, so bring a box of bandages. Working with the boxes may disrupt the activities in the spaces, so expect the occupants to be annoyed. Because of these difficulties with manual

adjustments, you have to decide whether it is practical to keep adjusting the boxes on a periodic basis.

■ Record the Damper Settings

If you can reset the terminal units remotely, keep a list of the appropriate setting for each terminal, by season or load condition. If you adjust the boxes manually, mark the damper stop positions in a clear and permanent manner. If you change the damper stops at different seasons, label the appropriate positions for each season.

A Better Alternative

[Measure 4.7.7](#) is a more efficient alternative to this Measure, and it is completely automatic. It keeps the dampers of each terminal unit at the minimum position needed to satisfy the current space conditioning requirements.

ECONOMICS

SAVINGS POTENTIAL: 20 to 60 percent of the energy expended for reheat; 5 to 30 percent of cooling energy. The saving is greatest in systems that have extended periods of heating load and low cooling load.

COST: The cost is entirely for labor, so it depends on the availability of manpower, and on the number and accessibility of terminals.

PAYBACK PERIOD: Less than one year, typically.

TRAPS & TRICKS

PLANNING: Before you start changing settings, figure out all the factors that determine the minimum-flow settings for each terminal or group of terminals. Then, decide whether to change the settings periodically, and when. If the system has electronic controls that allow you to adjust the settings remotely, plan to do so as often as needed.

EXPLAIN IT: Put a clear description of the procedures in the plant operating manual. Include a table of settings for each terminal unit, including different time periods. Do the adjustments yourself before delegating this job to others. It will be educational, and it will give you a feel for the drudgery involved.

SCHEDULING: This procedure can be forgotten with no visible effects. It is not the sort of work that the staff will remind you about. Schedule it in your maintenance calendar.

MEASURE 4.7.6 Set the cooling coil discharge at the highest temperature that maintains satisfactory cooling.

This is an easy way to save a lot of energy that is wasted by reheat. This Measure is similar to [Measure 4.4.1](#) in theory, procedures, and limitations. Refer to there for details.

The energy saving is smaller than with [Measure 4.4.1](#) (which deals with constant-flow reheat systems), but it is worth pursuing. This Measure has an additional benefit when used with VAV systems, namely, it lessens problems that are caused by low air flow, especially in spaces served by shutoff terminals.

Energy Saving

In any reheating VAV terminal, mixing losses occur whenever the reheat coil is operating. When the terminal is providing cooling, the reheat coil typically operates whenever the damper has closed to the minimum-flow limit. When the terminal is providing heating, the reheat coil is always turned on, and mixing losses are always at a maximum.

In the previous [Measure 4.7.5](#), you saw the interesting fact that the maximum mixing losses, expressed as a percentage of the maximum cooling load, are equal to twice the minimum flow percentage. This assumed that the chilled air temperature is held constant. By raising the chilled air temperature, you can reduce mixing losses substantially below this amount.

■ An Example

To illustrate the benefit of raising the supply air temperature, let's examine the effect on an individual terminal unit, under these conditions:

- terminal unit maximum flow: 1,000 CFM
- terminal unit minimum-flow setting: 400 CFM
- space temperature: 75°F
- cooling load: none
- all cooling is sensible.

This table shows the energy savings that result from raising the chilled air temperature:

Energy Input, BTU/hr	Supply Air Temperature		
	55°F	65°F	75°F
cooling energy to space	0	0	0
cooling energy from coil	8,640	4,320	0
reheat energy	8,640	4,320	0
total input energy	17,280	8,640	0

To emphasize the magnitude of the energy waste, consider that the maximum cooling capacity of the VAV

SUMMARY
 Reduce reheat losses just by turning a screw. May improve comfort and ventilation.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

terminal is 21,600 BTU/HR (at a supply air temperature of 55°F). This shows that mixing losses can be severe even in a VAV system. For an even bigger thrill, compare this example with the similar one in [Measure 4.4.1](#) for constant-volume reheat systems.

Comfort and Ventilation Advantages

VAV systems are notorious for problems that result from low air flow. These occur when the space has a low conditioning load. This Measure increases air flow at low loads. It may significantly improve performance in these areas:

- **diffuser operation.** The tendency of diffusers to “dump” cold supply air is reduced because the air is warmer and is delivered at higher velocity.
- **outside air ventilation.** If the terminals are able to close fully, they shut off outside air that is delivered through the air handling system. Increasing the chilled air flow to the spaces increases outside air ventilation proportionally.
- **in-space air velocity.** The increased air flow acts to prevent a feeling of “stuffiness” and it aids cooling by perspiration.

For more about these factors, see [Measure 4.4.7](#).

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of cooling energy; 30 to 70 percent of reheat energy. Increases fan energy somewhat at low conditioning loads.

COST: Minimal.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

See [Measure 4.4.1](#).

MEASURE 4.7.6.1 Install automatic chilled air temperature reset control.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Most VAV systems should have this control feature to avoid energy waste from reheating. This Measure is similar to [Measure 4.4.1.1](#) in theory, procedures, and limitations. Refer to there for details.

People tend to think of variable-air-volume systems as supplying chilled air at a constant temperature, in contrast with constant-volume systems, which provide air at variable temperature. However, you can achieve additional efficiency and comfort benefits by modulating the temperature of the chilled air supply as well as its volume. In a VAV system, temperature modulation is called “reset.”

Where to Install Chilled Air Reset Controls

Chilled air reset controls are most valuable if the chilled air temperature is dictated by large, variable cooling loads, such as perimeter cooling loads in a glass curtain wall building. In such cases, a reset controller usually pays for itself quickly.

On the other hand, reset controls may not be economical in systems where the chilled air temperature is dictated by core zone cooling loads. Core areas always have a net cooling load (except perhaps for morning warm-up), and this load tends to remain constant. In this case, there is little need for an automatic reset control. Optimizing the chilled air temperature manually is almost as efficient.

How the Reset Control Should Work

To conserve fan energy, the reset control should keep the chilled air temperature low when the cooling load is high. Chilled air temperature reset should start to take effect just before any of the terminals shut down to their minimum-flow limit. Then, as the cooling load drops

SUMMARY

Most VAV systems with reheating terminal units should have this control feature. The only way to keep chilled air near its optimum temperature.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

further, the reset control should raise the supply air temperature as much as possible.

ECONOMICS

SAVINGS POTENTIAL: 30 to 80 percent of reheat energy, and 10 to 40 percent of cooling energy. The savings potential of this Measure is limited by system load diversity, and by spaces with large, constant cooling loads.

COST: The control components for a typical installation typically cost from several hundred to several thousand dollars. In addition, connections to thermostats at widely dispersed locations can add a large labor cost.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

See [Measure 4.4.1.1](#).

MEASURE 4.7.7 With minimum-flow terminals, install heating/cooling changeover.

Many VAV systems have a crude method of providing heating that wastes a lot of energy. In these systems, heating is provided by heating coils in the terminal units. The heating coils need a minimum amount of air flow to deliver peak heating capacity. To accommodate this, each terminal unit has a stop or limit that prevents the damper from closing below this amount of air flow. In typical systems, this may be about 40% of maximum flow.

The Problem

Energy waste occurs any time the cooling load falls below the level at which the minimum cooling air flow is required. This is because the heating coil must provide heat to cancel excess cooling that occurs because of the minimum-flow limit. As the cooling load of the space falls, even more heat is required to cancel the cooling.

The Solution

The key to reducing this energy waste is to allow the dampers in the terminal units to close fully. You can do this by using space thermostats that switch their terminal units between cooling and heating modes of operation. In cooling operation, space temperature is controlled in the normal manner, by the position of the chilled air damper in the terminal unit. The heating coils remain off during cooling operation. If the space temperature falls below the thermostat setting, the heating coil turns on and the thermostat reverses so that the damper opens as the space temperature falls. In some cases, the thermostat may also control the output of the heating coil.

The two new features are eliminating (or reducing) the minimum-flow limit, and adding a reversing feature to the space thermostats. There may be additional complications required by conditioning requirements, which are explained below.

At the same time, install chilled air temperature reset (see [Measures 4.7.6 ff](#)), if you don't already have it. This control feature raises the chilled air temperature as the cooling load falls, eventually turning off cooling completely. This reduces the reheat losses that occur during heating operation, while increasing the air flow to the space at low loads.

Energy Saving

We will use a typical example to illustrate the energy saving that can be achieved by using changeover between heating and cooling control. Assume that using changeover control allows the minimum-flow setting to be reduced from 40% of maximum flow to 10% of

SUMMARY

Greatly reduces the waste of energy from air mixing in systems where terminal units have minimum-flow limits. Requires new thermostatic controls, and in some cases, changes to terminal units, diffusers, and fan modulation. Can be tricky if the terminal units have electric heating elements.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

maximum flow. The chilled air temperature reset schedule is the same for both configurations.

First, energy is saved because reheat does not commence until the cooling load falls to 10% of full load, rather than 40% of full load. Thus, reheating occurs for a much smaller fraction of the cooling season.

Second, energy is saved because reheating wastes much less energy when it does occur. When the conditioning load in the space is zero, the waste of cooling energy is reduced from 40% to 10%. In addition, there is an equal saving in the amount of heating energy needed to cancel the excess cooling.

If the space has a heating load that requires more than 10% of the maximum flow rate, the damper must open further to satisfy the heating load. This increases the amount of chilled air that enters the terminal, which further increases the amount of heat that is needed to cancel the unwanted cooling. As a result, chilled air temperature reset is very important for gaining the greatest benefit from changeover control.

Conditions That May Require Minimum-Flow Terminal Settings

The system is most efficient if the terminal unit dampers can close completely. Unfortunately, there may be factors that require minimum-flow setting in some or all of the terminal units. These are:

- **outside air ventilation.** Complete shutoff of terminal air flow blocks ventilation. In benign environments with a low occupant density, it may be acceptable to tolerate periods of shutoff. This is

a judgement call that is usually driven more by code requirements than by occupant perception.

- **dehumidification**, especially in humid climates. Dehumidification requires some reheat. The terminal unit must provide a relatively low rate of dry air flow into the space to keep the humidity level down.
- **dumping of chilled air from diffusers** at low flow rates. This problem can be reduced or eliminated with chilled air temperature reset. Diffuser design also affects dumping, but any diffuser will dump at very low flow rates. You can also solve this problem by substituting fan-powered VAV terminals, but they are expensive and noisy.
- **“stagnation”** of air in the space. This problem is occasional and subjective. Research suggests that complaints of “stagnation” appear to be related more to temperature and humidity than to the air velocity in the space, although the latter is a factor. Other physical and psychological factors also affect the sensation of “stagnation.” Many people are comfortable in spaces that have virtually no air velocity. You may be able to solve actual stagnation problems by using inexpensive circulation fans in the spaces. Substituting fan-powered VAV terminals is an expensive solution that may not solve the real problem.
- **terminal unit noise**, which increases as the damper approaches a closed position. This problem is reduced or eliminated by proper fan modulation, so that the air velocity through the partially closed damper is not excessive. A well designed terminal unit will not have this problem. You may be able to modify existing terminal units to reduce noise. For example, attach fuzzy material to the edges of damper blades.

Refer to “VAV Design Challenges,” in [Measure 4.4.7](#), for more about these problems.

Even if shutoff is not practical, try to minimize the minimum-flow setting. Start by identifying all the reasons why the system may need minimum-flow settings. Calculate the amount of air flow needed to satisfy each requirement. Then, figure out whether there is an economical way to reduce the air flow needed to satisfy the biggest requirement. Combat the energy waste further by using chilled air temperature reset aggressively.

Changeover control is simplest if the heating coil is fully modulating, i.e., if it is hydronic. After the damper reaches its minimum-flow position as the cooling load drops, the temperature in the space drops. This causes the thermostat to switch to heating mode, and heat is added by the coil to keep the space at proper temperature. On the other hand, if the heating coils are electric, get ready for more complications, which we now consider.

Dealing with Electric Heating Coils

The use of electric heating coils in terminal units, combined with inept design, is probably responsible for most of the energy waste in VAV systems. Electric heating coils need a minimum air flow rate to keep the coil itself from overheating and burning out. Designers who are careless about efficiency deal with this requirement by setting a minimum flow rate that is high enough to protect the coils. Not thinking beyond this, they simply specify a minimum-flow setting that is high enough to provide the peak heating load. While it avoids the need to think much about control design, this stupid approach is enormously wasteful.

To improve efficiency when using electric heating coils in terminal units, you need control methods that are presently unconventional, and therefore risky. If air flow to the space can be cut off completely, control cooling by letting the damper move all the way to shutoff, with the heating elements turned off. This completely eliminates reheat during cooling operation. When the thermostat calls for heating, the controls open the damper enough to protect the heating coil, while turning on the heating coil. When the space temperature is restored, the heating coil turns off and the damper closes.

This modification makes heating an on-off proposition, similar to the operation of a forced-air furnace. This mode of operation may surprise occupants who are accustomed to the continuous air flow usually provided by a VAV system. However, the cycling during heating operation is quiet, so it should not be objectionable.

When the damper first opens, the air entering the space is cool until the heating coil warms up slightly. This puff of cool air should last no longer than a few seconds, but it may be objectionable in some environments.

In all but the smallest terminal units, electric heating is provided in stages, with several heating elements. This may cause further complications. The air flow rate needed for the first stage may be less than the air flow needed for later stages. In this case, the damper position may have to be controlled in stages that correspond to the flow requirements of the heating stages.

■ Electric Heating Coils with Minimum-Flow Settings

If the terminal units require minimum-flow settings, there are still more complications. To minimize energy waste, satisfy two conditions:

- select the first-stage heating element to operate safely at the minimum-flow rate. This means that the element must operate at low temperature. You may be able to achieve this by connecting two of the elements in series as the first stage. The unit may already be connected this way. If not, you

may be able to modify the switching of the elements.

- select the first-stage heat output to be no greater than necessary to cancel the cooling input at the minimum-flow rate. Bear in mind that this cooling output is determined by the chilled air temperature, which is a variable that is determined by the chilled air temperature reset control. You have to estimate the lowest chilled air temperature that will occur at minimum flow. You can achieve very low heat output by connecting three or four elements in series as the first stage. If the terminal unit does not have enough elements to allow this, install one coil of lower wattage to serve as the first stage, but make sure that you retain enough heating capacity for peak loads.

Load Diversity Reduces Changeover Efficiency

If the loads in all the spaces were to fall to zero at the same time, the chilled air temperature reset control could be adjusted so that cooling is turned off at zero load. This would eliminate reheat losses entirely. You can't achieve this ideal, because a VAV system serves spaces with differing loads. Instead, you have to keep the supply air temperature low enough to accommodate the space with the highest cooling load. This causes some reheat loss in the terminal units of the other spaces. To minimize these losses, optimize chilled air reset as much as possible. See [Measures 4.7.6 ff](#) for details.

How the Thermostats Should Work

When a space needs cooling, the thermostat closes the terminal unit dampers as the space temperature drops. When the space needs heating, the thermostat opens the dampers as the space temperature drops.

In retrofit applications where pneumatic or electric thermostats are installed, you can achieve this change in function by installing dual-element thermostats, such as a deadband thermostat. These are described in [Measure 4.7.2](#).

If you have an electronic control system, you may be able to program the appropriate response using the existing control hardware.

Provide Effective Fan Modulation

In systems where the terminals are allowed to shut completely, or nearly so, inadequate turndown of fan output may cause excessive duct pressure. This aggravates terminal unit noise and leakage from the duct system. These problems are most severe in systems that “ride the fan curve.” This is a fancy way of saying that

the fan lacks any type of modulation. On the other hand, a VAV system that has good fan modulation probably will not suffer from these problems. See [Measure 4.7.8](#), next, about improving fan modulation.

Consider Deadband with Shutoff Terminals

If the terminal units can close to shutoff, consider adding deadband to the space thermostats ([Measure 4.7.2](#)) at the same time. This saves additional energy during periods when the conditioning load is low. But, bear in mind that deadband may aggravate any of the problems discussed previously that are associated with low air flow rates.

ECONOMICS

SAVINGS POTENTIAL: 60 to 90 percent of the cooling and heating energy that is wasted by reheating.

COST: In new construction, the main cost element is additional control complexity, which is a small fraction of total system cost.

In retrofit applications, the thermostatic control changes alone typically cost several thousand dollars. Changes to electric heating coils, if needed, may cost roughly \$100 per terminal unit.

PAYBACK PERIOD: In new construction, typically about one year. In retrofit, several years.

TRAPS & TRICKS

PLANNING: Before you can optimize your systems, you need to study how they work. Determine the actual minimum air flows that are acceptable for each terminal unit. Study the performance of other systems that have the features you intend to install. In retrofit, understand the present control sequences. Expect to be innovative in modifying terminal units having electric heating coils.

INSTALLATION: Don't expect the installers to understand your design or to adjust everything optimally by themselves. Be there to oversee the adjustments and to work out problems.

EXPLAIN IT: Describe how the system operates in your plant operating manual.

MONITOR PERFORMANCE: Wasteful operation is invisible, so it persists until you check for it. If your energy management control system has the ability to do trend logging, use it to record the chilled air temperature, the supply air temperature from each terminal unit, and the space temperature at each unit. Review the trend logs periodically to verify that the controls are operating properly.

MEASURE 4.7.8 Improve the efficiency of fan modulation.

The promise of reduced fan energy consumption was one of the main reasons for the initial popularity of VAV. Unfortunately, the methods that were available for modulating fan output in the early days of VAV had serious efficiency losses themselves. This is no longer true. Efficient fan modulation is now available, and it has become relatively inexpensive.

Efficient fan modulation also improves the heating and cooling efficiency of the system, and it may improve comfort. Also, you need fan modulation with a good turndown ratio to exploit the energy savings of Measures that reduce the minimum flow of terminal units (especially, Measures 4.7.5 and 4.7.7). This is to avoid problems that occur at low flow, including terminal unit noise, terminal and duct leakage, and unstable temperature control.

In new construction, use the most efficient method of fan modulation that is appropriate for the size of the air handling system. Efficient fan modulation simplifies the design of the system, and eliminates some potential problems.

In existing facilities, examine all your existing VAV systems to see whether you can improve fan modulation. Many VAV systems lack efficient fan modulation, or they may have none at all.

Energy Saving

The saving that you can achieve by improving fan modulation depends primarily on these factors:

- **the power of the fan motors.** The savings are directly proportional to the average power at which the fans operate.
- **the duration of system operation.** The savings are directly proportional to the number of hours that the system operates.
- **the load profile of the system.** All fan modulation methods provide the greatest benefit at reduced loads. VAV systems used for comfort conditioning in typical mid-latitude locations operate most of the time at low fan loads.
- **in retrofit, the efficiency improvement between the new and old modulation methods.** There are major differences in the efficiencies of the common fan modulation methods. Most incur a small efficiency penalty at peak load, but not all do. The largest differences occur at partial loads, where typical systems spend the most time operating.

If you are upgrading existing systems, don't expect to be able to make a precise estimate of savings. This is because the load changes continuously and the efficiency of the new and old modulation methods vary with load.

SUMMARY

Saves fan energy. May avoid system performance problems that occur at low flow rates. Usually expensive.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

You get the most accurate estimate by using an energy analysis computer program. This takes a considerable amount of effort. (See Reference Note 17 about these programs.) If you use a computer program, you need to estimate the load profile with reasonable accuracy, and to get accurate efficiency profiles for both the new and existing fan modulation methods. However, you may not be able to get information about existing equipment that is accurate enough to justify the effort of a computer analysis.

In retrofit applications, if you cannot get accurate efficiency data on your existing fan modulation methods, you have to guess its efficiency based on the type of equipment. In principle, you could measure input energy and output flow. In practice, the accumulated error involved in measuring or estimating all the factors would make the result no better than a guess based on the type of modulation device.

You can make the most accurate estimate when the fans presently have no method of fan modulation, i.e., when they "ride the fan curve." The energy behavior of the system in this situation is shown in Figure 1. In this case, estimate the present fan efficiency by using a fan curve acquired from the fan manufacturer.

To make the savings estimates as accurate as possible, be resolute about getting reliable efficiency data. Even reputable manufacturers publish generalized performance figures that are sweetened for marketing purposes. Major manufacturers at least have the capability of measuring actual performance data, but they are likely to do so only if requested to certify the numbers.

Request performance figures that are based on the fan operating against the duct system pressure. Idealized performance curves issued by drive manufacturers may be based on fans discharging into an open duct (if they

Carrier Corporation

Fig. 1 Riding the fan curve This is the typical behavior of the supply fan in a VAV system if it lacks any method of throttling output. As the flow of air is choked off by the closing of the terminal units, the fan power is reduced. However, in a typical range of throttling, as between points A and B, the power reduction is not great. The inset at lower right shows where the system pressure drops occur under the two conditions. Power consumption is proportional to the pressure drop.

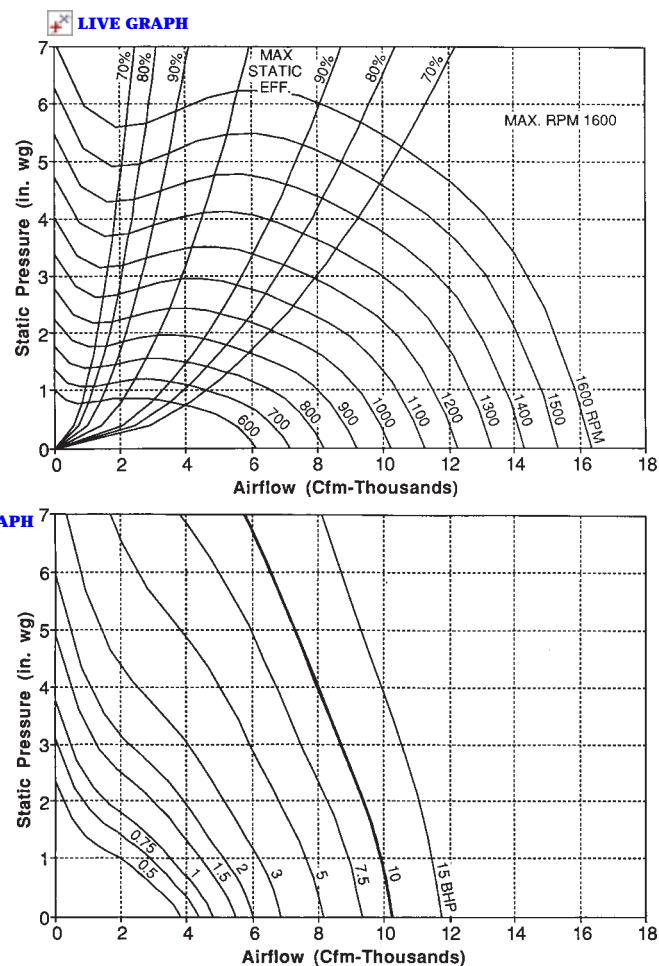

Trane Company

Fig. 2 Power saving of different fan throttling methods These curves are typical, and subject to wide variation. The top curve shows what happens to the power consumption of a fan with no throttling method as the terminal units close. Note that the curve for each modulation method is expressed as a fraction of the full-load power of that particular method. Compared to a fan with no modulation method, all these methods actually increase the power requirement near full load because they add drive losses and/or additional friction in the air stream. The curve for variable-speed drives does not include drive or motor losses, which vary widely among different types of equipment.

are based on anything). Such curves are not relevant to real VAV systems, and they are too optimistic. This is because VAV systems are not open duct systems. The terminal units must work against a certain amount of duct pressure in order to control air flow properly. Therefore, the action of the terminal units tends to maintain a constant duct pressure against which the fans must work.

Relative Performance of Fan Modulation Methods

Figure 2 shows the typical throttling performance of different methods of modulating fan output. In this figure, note that the curves show the power requirement as a fraction of the full-load power of each throttling method. Near full output, each throttling method actually increases power consumption, compared to a fan having no throttling. This is because of drive losses and/or additional friction in the air stream.

Carrier Corporation

Fig. 3 Effect of variable-speed drives on fan performance The upper curve shows the effect of changing speed on air flow and fan pressure. The lower curve shows how air flow and fan pressure affect fan power. These curves do not include losses in the fan drive or motor.

These are the most efficient fan modulation methods:

- *electronic variable-frequency drives (VFD's)*
- *variable-pulley drives*
- *direct current (DC) drives*
- *variable-pitch propeller fans.*

See Reference Note 36, Variable-Speed Motors and Drives, for a detailed explanation and comparison of the first three of these types. There are major differences within each of these types, mainly in characteristics other than efficiency. In existing facilities, it is not economical to upgrade drives of these types as long as they are working properly.

Figure 3 shows the effect on fan power of using any type of continuously modulating variable-speed drive. Note that this figure does not include drive losses.

These methods of modulating fan output are substantially less efficient than the previous methods:

- *multi-speed motors or multiple motors*
- *eddy current clutch drives*
- *inlet vortex dampers.*

Reference Note 36 covers the first two of these. Multi-speed motors may offer a good compromise between efficiency and cost in small fan systems. Eddy current clutches disappeared from the market under competition from VFD's, but they have recently returned. Inlet vortex dampers have a limited range of efficient turndown, and they are rarely a good choice, although they are relatively inexpensive. Figure 4 shows a fan with an inlet vortex damper.

In existing facilities, it is usually not economical to replace any of these types of modulation in smaller air

Trane Company

Fig. 4 Fan with inlet vortex damper This method of fan modulation is most efficient at high percentages of output. It is much less efficient than speed modulation at lower outputs. Its main attraction is low cost.

handling systems. Upgrading may be economical in systems that have larger fan motors and that operate for long durations at reduced output.

You can make the greatest improvement when a VAV system presently has no method of fan modulation, as shown in Figure 1. Installing efficient fan modulation in such systems may yield comfort improvements, such as reduced noise, in addition to major energy savings.

Some VAV systems that lack fan output modulation may have one-time output adjustments, including:

- *discharge dampers* (which may be installed at some distance from the fan)
- *scroll housing dampers*
- *inlet (not vortex) dampers*.

Get rid of these devices wherever you can. To make a one-time adjustment of fan output, trim the fan speed. This method is much more efficient, and it is usually cheap. See [Measure 10.3.1](#) for details.

The Leading Contenders

For fan systems of medium and large size, variable-frequency drives are the leading contender. They are among the best of methods in terms of efficiency (except near peak load). They are easy to install, even in retrofit applications. They are a major cost item, but they are similar in price to other efficient variable-speed drives, or less expensive. Their cost per kilowatt falls rapidly with larger sizes. Adverse side effects, especially electrical interference, are being brought under control.

For small fan systems, multi-speed motors, two-motor drives, and inlet vortex dampers may offer the best compromise between efficiency and cost. Of these types, only multi-speed motors are easy to retrofit.

Coordinate with Other Measures

Upgrading the fan modulation method is expensive. If you are going to spend this much money, consider additional improvements to the system. The lower air flow rates that result from improved fan modulation may create problems. To improve system efficiency and minimize the problems, install supply air temperature reset (see [Measure 4.7.6.1](#)). If the system does not have heating/cooling changeover, think seriously about installing it (see [Measure 4.7.7](#)).

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of fan energy, depending on the present method of fan modulation, the load profile, the type of VAV terminals, and other factors. Several percent of system cooling energy may also be saved as a result of reduced system leakage.

COST: The costs of variable-speed drives are covered in [Reference Note 36](#), *Variable-Speed Motors and Drives*.

PAYBACK PERIOD: Several years, to many years. The payback period is shorter in larger systems and in systems that operate for longer durations.

TRAPS & TRICKS

DESIGN: Consider all the opportunities and problems of this modification. See "VAV Design Challenges," in [Measure 4.4.7](#).

SELECTING THE EQUIPMENT: Variable-frequency drives are probably your best choice, but don't assume this. Their popularity is not based entirely on merit. See [Reference Note 36](#) for guidance.

Variable-Air-Volume Dual-Duct Systems

The Measures in this Subsection improve the efficiency of VAV dual-duct systems. This type of system is sketched in Figures 1 and 2, in the [Section 4 Introduction](#).

In these systems, the air handling unit has a continuously operating cooling coil that feeds air into a cold air duct, and a continuously operating heating coil that feeds air into a hot air duct. The two ducts run in parallel throughout the facility. At each space, air is tapped from the two ducts by a terminal unit. The terminal unit has a hot air damper and a cold air damper. When the space thermostat calls for heating, the hot air damper opens. When the thermostat calls for cooling, the cold air damper opens.

Dual-duct VAV systems are mechanically similar to dual-duct reheat systems, which are covered by [Subsection 4.5](#). The crucial difference is that the VAV version throttles the air flow in the terminal units to conform to the space conditioning load, whereas the reheat version mixes hot and cold air in the terminal units to maintain a constant flow of air into the space.

VAV dual-duct systems have the potential of being efficient and comfortable. Efficiency suffers if chilled air is mixed with heated air in the terminal units. The system may be designed to do this deliberately under low conditioning loads to maintain a minimum air flow into the spaces.

The first three [Measures](#), [4.8.1](#) through [4.8.3](#), reduce the conditioning load by improving the efficiency of thermostatic control. [Measures 4.8.4](#) through [4.8.6](#) are inexpensive activities that reduce the energy waste that occurs from mixing heated and chilled air. [Measure 4.8.7](#) is an expensive improvement in fan output modulation that saves fan energy, and may also improve system performance. [Measure 4.8.8](#) is a major change to the fan

INDEX OF MEASURES

- [4.8.1](#) In spaces with shutoff VAV terminals, install temperature setting placards on thermostats.
- [4.8.2](#) In spaces with shutoff VAV terminals, modify thermostatic controls to maximize deadband.
- [4.8.3](#) If air handling equipment cannot be turned off during unoccupied hours, install temperature setback.
- [4.8.4](#) Turn off the heating coil and/or the cooling coil whenever practical.
- [4.8.5](#) Adjust minimum-flow terminals to minimize overlap of hot and cold air flow.
- [4.8.6](#) Keep the cold duct temperature as high as possible and the hot duct temperature as low as possible.
 - [4.8.6.1](#) Install duct temperature reset controllers for both the cold duct and the hot duct.
- [4.8.7](#) Improve the efficiency of fan modulation.
- [4.8.8](#) Install an outside air economizer cycle with separate hot and cold duct fans.

arrangement that allows a dual-duct system to exploit the principle of the outside air economizer cycle, saving both cooling and heating energy.

All the Measures in this Subsection may be used together.

Triple-Duct Systems

“Triple-duct” systems are similar in appearance to dual-duct systems. See the diagram in Figure 2 of the [Section 4](#) Introduction. The main difference

is a third duct that carries unconditioned air (a mixture of return air and outside air) for mixing with either the heated air or the chilled air. If properly installed, these systems have no mixing losses, except for leakage that occurs inside the terminal units. They can maintain any desired space air flow rate without mixing losses by recirculating unconditioned air through the third duct.

All the Measures of this Subsection apply to triple-duct systems as well as to dual-duct systems.

MEASURE 4.8.1 In spaces with shutoff VAV terminals, install temperature setting placards on thermostats.

RATINGS

New Facilities	Retrofit	O&M
A	A	

Placards are one of the most powerful tools of energy efficiency. Where appropriate, use them at thermostats

that control dual-duct VAV terminal units. This activity is similar to [Measure 4.7.1](#). Refer to there for details.

MEASURE 4.8.2 In spaces with shutoff VAV terminals, modify thermostatic controls to maximize deadband.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Deadband is a method of thermostatic control that eliminates unnecessary conditioning as long as the space temperature remains within comfortable limits. This Measure is similar to [Measure 4.7.2](#). Refer to there for background.

The priority, methods, and economics of this Measure may differ from [Measure 4.7.2](#). In particular, you can sometimes create deadband in dual-duct systems simply by making adjustments or minor modifications to the terminal units. This may require no changes to the thermostats or other control elements.

How to Create Deadband in Dual-Duct VAV Systems

Most dual-duct VAV terminals use a mechanical linkage to coordinate the operation of the hot and cold duct dampers. You increase deadband by adjusting this linkage to increase the range of motion in which both the chilled air damper and the hot air damper are closed.

If the linkage is not adjustable, you have to modify or replace the VAV terminals to increase deadband. Some manufacturers may offer retrofit kits for this purpose.

If the terminal unit has separate actuators for the hot and cold dampers, you can use other methods to achieve deadband. One is to use a deadband thermostat (see [Measure 4.7.2](#)). Another is to use a signal offset relay (see [Measure 4.3.2.3](#)).

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of conditioning cost. The larger percentages applying to mild climates, but the absolute saving is greater in buildings that have higher conditioning loads.

COST: If only adjustments are required, the cost is limited to a small amount of labor. Deadband thermostats, if needed, cost less than \$100 apiece, plus

SUMMARY

May save a few percent of system energy consumption at modest cost. Usually simple to accomplish. Not suitable where close control of temperature is needed.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊		

installation labor. Modifying or replacing terminal units may cost several hundred dollars per unit.

PAYBACK PERIOD: *Less than one year, if only adjustments are required. Several years, to many years, if deadband thermostats are installed.*

TRAPS & TRICKS

CHOICE OF METHOD: *This Measure applies to individual terminal units rather than to the entire system. It does not apply to terminal units that use reheat. Deadband is suitable for most comfort applications, but not for environments where close temperature control is needed. If your application can benefit from deadband, study your terminal units and their thermostats to select the most effective method of creating it. You may be able to design a simple modification that serves the purpose.*

SELECTING THERMOSTATS: *If you plan to achieve deadband by changing the thermostats, get all the*

efficiency features that apply. See [Measures 4.7.2 and 4.8.3](#).

EXPLAIN IT: All thermostats should have placards, at least to state which spaces they control and that they allow a temperature deadband. With “heat/cool/off” thermostats, you are depending on the people in the spaces to select heating or cooling. With true deadband thermostats, the energy saving is determined by the person with the small screwdriver who sets the deadband

in each thermostat. Make sure that the staff are trained to set the maximum acceptable deadband. Put clear instructions in the plant operating manual.

INSTALLATION: When installing any thermostat, select a location where it senses the actual temperature of the space. Do not mount the thermostat on an exterior wall or other surface that is heated or cooled from behind. If necessary, use a long standoff mounting bracket. Do not install the thermostat where sunlight can shine on it or on adjacent surfaces.

MEASURE 4.8.3 If air handling equipment cannot be turned off during unoccupied hours, install temperature setback.

RATINGS		
New Facilities	Retrofit	O&M
A	C	

Temperature setback is a powerful and inexpensive method of saving conditioning energy during

unoccupied periods. This Measure is similar to [Measure 4.7.3](#). Refer to there for details.

MEASURE 4.8.4 Turn off the heating coil and/or the cooling coil whenever practical.

RATINGS		
New Facilities	Retrofit	O&M
		A

This Measure can eliminate reheat losses for a large fraction of the system’s operating hours. It costs nothing. It is identical to [Measure 4.5.2](#) in methods and limitations. Refer to there for details.

The energy saving is substantially less than in [Measure 4.5.2](#) because VAV systems have much lower mixing losses than constant-volume (reheat) systems. But, mixing losses are a major inefficiency even in some VAV systems. Even if the system has shutoff terminal units, this Measure eliminates mixing losses due to damper leakage inside the terminals.

SUMMARY
A seasonal method of eliminating reheat that costs nothing.

MEASURE 4.8.5 Adjust minimum-flow terminals to minimize overlap of hot and cold air flow.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

The main efficiency advantage of VAV systems over constant-volume reheat systems is eliminating the mixing of heated air with chilled air. However, many VAV systems use terminals that allow a reduced amount of mixing to maintain a minimum air flow into the spaces. Such terminals are called “minimum-flow” terminals, in contrast with “shutoff” terminals. In dual-duct VAV systems, the minimum flow typically is maintained by a linkage connecting the dampers for chilled air and heated air. The linkage prevents both dampers from closing simultaneously.

The air mixing that occurs with minimum-flow dampers wastes energy. This energy waste occurs only at low conditioning loads, so the energy waste is much less than in constant-volume dual-duct systems. Still, it is large enough to deserve aggressive action to minimize it.

Minimum-flow is used to avoid a number of comfort and ventilation problems that occur at low air flow rates, which are explained in [Measure 4.5.5](#). Make sure that the minimum-flow settings are not higher than needed to satisfy these requirements. Check each terminal unit in the system and adjust it to satisfy the requirements of the space that it serves.

In some spaces, you may be able to eliminate damper overlap completely. In these cases, consider the possibility of saving more energy in these spaces by using “deadband” thermostats ([Measure 4.8.2](#)).

Energy Saving

The formula in the introduction to [Subsection 4.5](#) applies to a VAV dual-duct terminal unit when it is operating in the minimum-flow region. (In this case, the term in the formula, “Terminal Unit CFM,” is the value at the minimum-flow setting.) The formula shows that mixing losses are proportional to the minimum-flow rate.

Mixing losses peak at zero space load, because no useful conditioning is being done by the terminal air flow. As an example of how much energy waste occurs at zero load, consider a terminal in which the minimum flow has been set at 40% of the maximum cooling flow rate. If the heating temperature differential is three times the cooling temperature differential, some algebra will show that the amount of energy being consumed at zero load is equal to 60% of the maximum cooling load. That’s a lot of wasted energy.

In this example, mixing losses occur as long as the cooling load remains below 40% of maximum. When the space has a heating load, mixing losses occur for an

SUMMARY
An important adjustment that reduces mixing losses and limits the conditions under which they occur. Affects comfort if done to excess.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓
Ease of Initiation	☺ ☺

even larger fraction of the time. This is because the high temperature of the heating air results in low air flow, so that chilled air must be mixed with the heated air to satisfy the minimum-flow limit. In this example, a typical load profile may result in mixing losses that consume as much energy as the space conditioning load itself.

Now, for example, if you reduce the overlap of heating and cooling so that the minimum flow is reduced to half its previous value, the mixing losses at zero space load are reduced to half. Even better, the total losses are reduced to much less than half. The reason is that mixing losses now disappear when the cooling load reaches 20% of maximum, and similarly, mixing losses stop sooner during the heating season. As a result, the system spends much less time operating with mixing losses.

What Determines the Minimum Acceptable Flow

A minimum rate of air flow through the terminals may be needed to:

- provide proper diffuser operation
- maintain an adequate level of outside air ventilation
- create in-space air velocity to prevent a feeling of “stiffness” and to facilitate cooling by perspiration
- provide dehumidification during periods of low cooling load.

Review “VAV Design Challenges,” in [Measure 4.4.7](#), to figure out how each of these requirements affects the minimum-flow settings in your systems, and how you may be able to reduce these requirements.

In practice, you will probably determine the minimum air flow setting for each terminal unit by trial-and-error, keeping an eye on each of the previous requirements.

How to Adjust the Terminal Units

If you have a centralized electronic control system, you may be able to adjust the minimum-flow settings of the terminals from your keyboard. In this case, the effort is almost trivial, and you can easily experiment to find the optimum settings.

If you do not have a central control system, you can adjust each terminal unit manually. Unfortunately, they are often jammed tightly into the ceiling plenum, and reaching them can be time consuming. Terminal unit manufacturers have no shame about leaving sharp edges all over their equipment, so bring a box of bandages. Working with the boxes may disrupt the activities in the spaces, so expect the occupants to be annoyed. Because of these difficulties with manual adjustments, you have to decide whether it is practical to keep adjusting the boxes on a periodic basis.

■ Record the Settings

If you can reset the terminal units remotely, keep a list of the appropriate setting for each terminal, by season or load condition. If you adjust the boxes manually, mark the damper stop positions in a clear and permanent

manner. If you change the damper stops at different seasons, label the appropriate positions for each season.

ECONOMICS

SAVINGS POTENTIAL: 10 to 50 percent of cooling energy; 10 to 50 percent of heating energy; a small fraction of fan energy.

COST: Perhaps one hour of labor per terminal, on average.

PAYBACK PERIOD: Short.

TRAPS & TRICKS

OPTIMIZING THE SETTINGS: The work is tedious, but not difficult. Before you start changing settings, figure out all the factors that determine the minimum-flow settings for each terminal or group of terminals. Expect some trial-and-error in paring down the reheat.

EXPLAIN IT: For maintenance and future reference, put a clear description of the procedures in the plant operating manual, including tables of settings for all the terminal units.

MEASURE 4.8.6 Keep the cold duct temperature as high as possible and the hot duct temperature as low as possible.

RATINGS

New Facilities	Retrofit	O&M
		A

This Measure greatly reduces mixing loss. It is easy and it costs nothing. It is similar to [Measure 4.5.1](#) in theory, procedures, and limitations.

The energy saving is substantially less than with [Measure 4.5.1](#) because VAV systems have much lower mixing losses than constant-volume (reheat) systems. Still, minimum-flow terminals have substantial mixing losses. In shutoff terminals, this Measure reduces losses from unintended mixing that is caused by air leakage inside the terminals.

Energy Saving

The formula in the introduction to [Subsection 4.5](#) applies to a VAV dual-duct terminal unit when it is operating in the minimum-flow region. The formula shows that mixing losses are approximately proportional to the cooling temperature differential and to the heating temperature differential. Thus, for example, reducing either temperature differential by half reduces the losses by half.

The two differentials are multiplied by each other in the formula, so reducing both differentials drastically reduces mixing losses. As explained in [Measure 4.8.5](#), previous, the mixing losses in a dual-duct terminal peak at zero space load. Using the same example given there, if the heating and cooling temperature differentials are both reduced to half their previous values, the mixing losses at zero space load are reduced to one fourth of their previous level.

SUMMARY

Trim mixing losses just by turning two screws. Especially important in systems that have minimum-flow terminals.

MEASURE 4.8.7 Improve the efficiency of fan modulation.

RATINGS		
New Facilities	Retrofit	O&M
B	C	

This Measure is similar to [Measure 4.7.8](#). Refer to there for details. Note the following difference in the method of controlling duct pressure, which is needed with dual-duct systems.

Sense Both Duct Pressures

In dual-duct systems, the hot and cold ducts operate independently. Therefore, design your system's controls to sense the pressure in both ducts, modulating the fans to maintain the minimum needed pressure in each duct.

MEASURE 4.8.8 Install an outside air economizer cycle with separate hot and cold duct fans.

RATINGS

New Facilities	Retrofit	O&M
B	D	

Conventional dual-duct systems that employ a single supply fan are poorly adapted to economizer cycle operation. (Measure 4.2.5 explains economizer cycles.) This is because the cold outside air used during economizer cycle operation would enter the heating coil as well as the cooling coil. The saving in cooling energy would be offset by increased heating energy. As a result, economizer cycles are usually not employed in dual-duct systems.

You can work around this obstacle by installing separate fans for the hot and cold ducts. In this configuration, outside air is taken in through the cold side of the system. Warm return air can be restricted to the hot side of the system. This eliminates heating of cold air, and vice versa. The two-fan configuration also saves energy in lesser ways that are not related to economizer operation.

Where to Apply This Measure

The primary benefit of the two-fan design is its ability to exploit economizer cycle operation. Consider it for facilities located in cooler climates where the air handling systems serve large spaces with high heat gains. Economic feasibility increases with the size of the system and the number of hours that an economizer cycle can provide an energy saving.

In new construction, the two-fan configuration increases cost by a relatively small percentage. In existing facilities, this is a specialized and expensive modification. It requires additional space in the vicinity of the present air handling unit. Typically, you would replace the existing air handling unit with two smaller air handling units, one for each duct.

Energy Saving

■ **Cooling Energy**

Refer to Measure 4.2.5 for the cooling energy savings of economizer cycles. In brief, an economizer cycle may save a large amount of energy if two conditions exist: (1) the facility has high internal heat gains, and (2) the climate has a large number of hours during which the outside air temperature is below about 55°F.

■ **Heating Energy**

If return air is heated as it returns to the air handling unit, using a separate fan for the hot duct allows the heat to be fully recovered, which saves heating energy and reduces cooling load. This advantage is significant in facilities where air is returned through ceiling plenums that are heated by lighting fixtures.

SUMMARY
 The only way to make an economizer cycle work properly in a dual-duct system. Unusual.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % %
Rate of Return, Retrofit	% %

Ease of Retrofit	☺

■ **Fan Energy**

Using two fans requires less total fan energy. With a single fan, the fan must deliver all the air at a pressure that is dictated by the hot or cold duct that has the highest pressure requirement. With two fans, each fan can modulate to satisfy the minimum pressure requirement of its respective duct.

Achieving this saving requires an efficient method of fan modulation. Without efficient fan modulation, fan energy consumption may be increased because of the larger total fan capacity.

In a two-fan installation, both fans can operate in a draw-through mode. Draw-through operation is more efficient than the blow-through configuration used in conventional dual-duct installations.

(In conventional dual-duct systems, the fan must operate in a blow-through mode so that a single fan can serve two coils. The disadvantage of this arrangement is that a fan discharges air at high velocity. Some of the kinetic energy that the fan adds to the air is dissipated as turbulence when the air strikes the coils. In a draw-through fan configuration, the high velocity of the fan discharge is converted to static pressure by proper design of the fan discharge duct. The static pressure does useful work in moving the air through the system.)

Outside Air Ventilation

Outside air ventilation requirements are covered in Measure 4.2.1. The cold duct system has a large outside air intake capability to allow economizer cycle operation. This does not satisfy ventilation requirements when the spaces are getting their air primarily from the hot duct, i.e., during cold weather. For this reason, the hot duct system also needs enough outside air intake capacity to satisfy ventilation requirements.

To control outside air intake efficiently, both the cold duct system and the hot duct system need good “front end” design. This is covered by [Measure 4.2.1](#).

How to Design the System

The basic steps in adding an economizer cycle to a dual-duct VAV system are:

- Install two separate fans, one with the cooling coil and the other with the heating coil. Install the coils in a draw-through configuration. The cold duct fan is sized for the maximum cooling load, and the hot duct fan is sized for the maximum heating load. There is no need for the two air handling units to be located close together. For example, the cold-duct unit can be located near an outside wall to minimize economizer intake ductwork, and the hot-duct unit can be located close to the boiler to minimize the length of heating water pipe.
- Provide independent flow modulation controls for each fan. Use the most efficient method of fan modulation to minimize fan energy consumption. See [Measure 4.8.7](#) about efficient fan modulation.
- Install appropriate dampers, ducting, and controls in the cold air system to achieve economizer cycle operation, as explained by [Measure 4.2.5](#).
- If necessary, install a small set of dampers, ducting, and controls in the hot air system to provide outside air ventilation.
- Design the fan modulation controls of the system return air and exhaust fans to accommodate the fact that the hot air and cold air supply fans are modulating independently. You will probably need a fan modulation control system that monitors air flow and duct pressure.

In retrofit applications, the simplest approach is to replace the original air handling unit with two new ones, one for the cold air system and one for the hot air system. You won't be able to salvage much of the original equipment. In larger systems where the air handling units are field erected, you may be able to salvage the fan and coils.

Alternative: Waterside Economizer

An alternative way of adding an economizer cycle to a dual-duct system is to use a waterside economizer. This is an additional water coil for the cold duct that is cooled directly by a cooling tower, rather than by the chiller. Waterside economizers are described in [Measure 2.9.4](#).

A waterside economizer avoids the extensive equipment modifications that are required for an outside air economizer, provided that the economizer coil can be added to the existing unit. This may be more difficult

than it looks. Even if the additional coil can be fitted into the casing, the existing fan may not be able to overcome its additional resistance.

In comparison with outside air economizers, waterside economizers may be able to provide somewhat more free cooling in dry climates because of the evaporative cooling available from the cooling tower. However, in humid climates, a waterside economizer provides less cooling because of the additional resistance to heat flow in the coil. Waterside economizers require additional fan energy, as well as a small amount of energy for pumps. They do not require as much sheetmetal as an airside economizer, but they require additional piping to bring water from the cooling tower.

ECONOMICS

SAVINGS POTENTIAL: 30 to 80 percent of cooling energy. Up to 50 percent of heating energy (but limited to the amount of heat that is captured by the return air). A small fraction of fan energy, but only if the modulation method is efficient.

COST: In new construction, the increase in system cost may be small. Using separate air handling units for the hot and cold ducts provides design flexibility that may save some cost.

In retrofit, the cost of this Measure may be prohibitive. The main cost components are the new air handling unit(s), economizer ductwork, relocation of equipment to provide space, and new controls.

PAYBACK PERIOD: In new construction, typically a few years or less. In retrofit, typically several years, or much longer.

TRAPS & TRICKS

PIONEERING: This configuration is unusual, so be careful to resolve all the details. Start by studying [Measure 4.2.5](#).

INSTALLATION: Make sure that the controls contractor understands what you are trying to achieve. Check out each mode of operation.

EXPLAIN IT: Since this involves dampers and controls, it is vulnerable to operating personnel trying to make quick fixes in response to comfort complaints. Explain the system to the staff. Describe it clearly in your plant operating manual.

MONITOR PERFORMANCE: Schedule checks of system performance during periods of the year when the economizer cycle should be operating. If your energy management control system has the ability to do trend logging, use it to record the temperature (or enthalpy) of the outside air, return air, and mixed air. These will tell you whether the economizer control is working properly.

Induction Systems

The Measures in this Subsection improve the efficiency of induction air handling systems. Figure 2, in the [Section 4 Introduction](#), sketches an induction system.

The most visible distinguishing feature of an induction system is the terminal unit. Figure 1, on the next page, shows a typical induction terminal unit. Induction terminal units have no fans. Air movement through coils in the terminal unit is induced by high-pressure air, called “primary” air, that comes from a central air handling unit. The primary air is passed through an array of nozzles in the terminal unit that create a venturi effect, or vacuum. The vacuum draws air from the space through the terminal unit coil. The space air, called “secondary air,” mixes with the primary air. The mixed air is discharged into the space.

The primary air is cooled by a coil in the air handling unit. The temperature in individual spaces is regulated by the coil in the terminal unit, which is controlled by the space thermostat.

Induction terminal units commonly are packaged in enclosures that are similar in size and appearance to fan-coil units. They may also be installed in ceiling plenums. The coils are virtually always hydronic. The temperature of the coil may be controlled by throttling the water through the coil, or a damper may be installed in the terminal unit to bypass air around the coil.

Unlike other air handling systems, only a fraction of the air circulation in the space comes from the air handling unit. The volume of secondary air is approximately twice the volume of the primary air. As a result, an induction system can use smaller

INDEX OF MEASURES

4.9.1 Maximize the primary air temperature.

4.9.1.1 Install automatic temperature reset control for the primary air.

4.9.2 Turn off the air handling unit cooling coil when cooling is not needed.

4.9.3 Install temperature setback.

4.9.4 Clean, adjust, and repair induction terminal units at appropriate intervals.

4.9.5 Avoid discharging conditioned air on exterior surfaces.

supply ducts, smaller return ducts, and a smaller air handling system than other systems. This saves space, and it may save material cost.

On the negative side, the high pressure requirement increases fan power, even though the volume of air delivered by the fan is less than in other types of air handling systems. Also, induction systems are designed to operate with low primary air temperatures. This may require lower chilled water temperatures, which reduces the efficiency of the chiller. The terminal units have a constant hissing sound, which is caused by the flow of high-velocity air through the venturis.

Induction systems cannot exploit economizer cycles to full effect, because the air from the air handling unit is only about a third of the air circulated in the space. For the same reason, induction systems are not well adapted to spaces that require high outside air ventilation rates.

Efficiency and System Variations

As with other central air handling systems that provide separate temperature control of individual

M&I Heat Transfer Products

Fig. 1 Induction terminal unit In this typical unit, high-pressure “primary” air enters through the duct at lower left. It passes through an array of nozzles, some of which are visible through the cutaway in the coil. The nozzles create a vacuum which draws air through the coil from the space. The conditioned space air mixes with the cooled primary air, and both are discharged into the space through the top of the unit.

spaces, reheat is a potential cause of energy waste. In reheat, excess energy is expended to cool the supply air, and then still more energy is then expended to partially re-warm the same air before it enters the space. During low-load conditions, much more energy may be cancelled out by reheat than actually enters the space to provide cooling or heating.

The amount of reheating that occurs in an induction system depends on the way that the terminal unit coils operate. If the terminal unit coils can only provide heat, then reheat will be a major cause of energy waste. In this case, the system operates similarly to other single-duct terminal reheat systems, which are covered in [Subsection 4.4](#).

If the terminal unit coils are designed to change between heating and cooling, the system will have much less reheat energy waste than if the coils are designed only for heating. When the space requires cooling, both the coil in the air handling unit and the coils in the terminal units cool the air. Reheat does not occur under these circumstances. However, when a space requires heating, the coil in the terminal unit must cancel the cooling energy in the primary air. The amount of reheating that is unavoidable depends on the diversity of the space loads. If some spaces have a high cooling load at the same time that other spaces have a heating load, reheating of the primary air will occur in the spaces that require heating.

Terminal units that have changeover coils require effective drainage of the moisture that condenses on the coils during cooling operation. The design of an induction system with changeover terminal unit coils may assume that dehumidification is accomplished by the coil in the air handling unit, rather than by the coil in the terminal unit. However, conditions can still occur that cause moisture to condense on the coils. Furthermore, some of the Measures in this Subsection increase condensation on room coils.

Most induction systems operate at constant air volume. Some systems do attempt to achieve the benefits of VAV operation by throttling the primary air to the terminal units. However, the venturis in the terminal units rapidly lose their ability to induce flow of room air as the primary air flow is reduced. This minimizes any opportunity to save fan energy.

MEASURE 4.9.1 Maximize the primary air temperature.

RATINGS

New Facilities	Retrofit	O&M
		A

Reheat is the major cause of energy waste in induction systems. Reheat occurs when the primary air is being chilled and the secondary air is being heated. This is a problem that occurs in individual spaces. At any given time, reheating may be occurring in some spaces and not in others.

You can reduce reheat easily in an induction system by raising the temperature of the primary air. This Measure is similar to [Measure 4.4.1](#) in theory, procedures, and limitations. Refer to there for details.

Subsidiary [Measure 4.9.1.1](#) improves on this Measure with continuous automatic resetting of the chilled air temperature. Use manual adjustment as a stopgap method until you install automatic reset controls.

Energy Saving

Reheat wastes the most energy if the terminal unit coils provide only heating. By the same token, this activity saves the most energy in such units. There is less reheat, on average, if the terminal unit coils can switch between heating and cooling.

To illustrate the benefit of raising the primary air temperature, let's examine the effect on an individual terminal unit, under these conditions:

- primary air maximum flow: 200 CFM
- secondary flow is twice primary air flow
- space temperature: 75°F
- space conditioning load: none
- all cooling is sensible.

This table shows the energy savings that result from raising the chilled air temperature:

Energy Input, BTU/hr	Supply Air Temperature		
	55°F	65°F	75°F
conditioning energy to space	0	0	0
primary air cooling energy	4,320	2,160	0
reheat energy from terminal unit	4,320	2,160	0
total input energy	8,640	4,320	0

We have chosen these conditions to illustrate that an induction system can waste a large amount of energy even when there is no space conditioning load. The reheat energy waste is just as high any time the space requires heating, because the terminal unit must add enough energy to cancel the cooling of the primary air.

The induction system wastes energy even if the space has a low cooling load. This is because terminal unit must heat the secondary air enough to cancel the

SUMMARY

Reduce reheat losses just by turning a screw. May cause large amounts of condensate to form in the terminal unit, which makes cleaning important.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

excess cooling of the primary air. By reducing the energy content of the primary air, less energy is wasted in reheat.

In systems with changeover terminal units, the table shows that you can eliminate reheat entirely by setting the primary air temperature so high that the cooling coil in the air handling unit does not operate. In other words, the primary air temperature is set higher than the mixed air temperature returning to the air handling unit. (This is essentially the same as turning the cooling coil off, which is recommended by [Measure 4.9.2](#).) In this situation, spaces that need cooling are cooled entirely by their terminal units, while spaces that need heating are heated by their terminal units. This works when the cooling load in all spaces is so low that the coils in the terminal units can carry the entire cooling load.

The potential saving is limited by diversity among the space conditioning loads. The worst case occurs when one or more spaces require a high cooling load continuously. See [Measure 4.4.1](#) for details.

Potential Health Problems from Increased Condensate Drainage

Shifting the cooling load from the air handling system to the room units greatly increases the amount of dehumidification that is done by the room units, and correspondingly increases the amount of condensate that is formed within the room units. Make sure that this condensate be removed reliably by the drain pans inside the units. Regular cleaning of the condensate drains is essential, as recommended by [Measure 4.9.4](#). Condensate that fails to drain is a breeding site for microorganisms, which enter the room air. This can cause serious health problems.

Explain It to the Maintenance Staff

Small temperature adjustments can have a big effect on energy consumption. Install a placard at the primary air temperature control that explains clearly how to adjust the temperature of the primary air.

ECONOMICS

SAVINGS POTENTIAL: 10 to 40 percent of cooling and reheat energy.

COST: Minimal.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

See [Measure 4.4.1](#).

MEASURE 4.9.1.1 Install automatic temperature reset control for the primary air.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Most induction systems should have this control feature to avoid energy waste from reheating. This Measure is similar to [Measure 4.4.1.1](#) in theory, procedures, and limitations. Refer to there for details.

Where to Install Primary Air Temperature Reset Controls

Reset control for the primary air temperature is most valuable if all spaces have variable cooling loads, such as perimeter cooling loads in a glass curtain wall building. In such cases, a reset controller usually pays for itself quickly.

On the other hand, reset control may not be economical in systems where the primary air temperature is dictated by a constant high cooling load. This occurs in core zones, and in spaces with high internal heat gains, such as computer centers. In such cases, the reset control has little ability to raise the primary air temperature. Optimizing the primary air temperature manually is almost as efficient.

SUMMARY

Most induction systems should have this control feature. It is the only way to keep chilled air near its optimum temperature.

ECONOMICS

SAVINGS POTENTIAL: 30 to 80 percent of the energy expended for reheat; 10 to 40 percent of cooling energy. The savings potential of this Measure is limited by

TRAPS & TRICKS

See [Measure 4.4.1.1](#).

MEASURE 4.9.2 Turn off the air handling unit cooling coil when cooling is not needed.

RATINGS

New Facilities	Retrofit	O&M
		A

You can eliminate all reheat losses in an induction system for extended periods of time by turning off the cooling coil in the air handling unit. The potential saving depends on the type of terminal unit, on the climate, and on the zoning of the systems.

Energy Saving Potential

The first question is whether the terminal units have heating-only coils or coils that can change between heating and cooling. If the terminal units have heating-only coils, this method can be used only when none of the spaces has a cooling requirement. If any space that is served by the system has a continuous cooling requirement, this method cannot be used.

If the terminal unit coils can provide both cooling and heating, you can turn off the air handling unit coil at all times, except when one or more of the spaces has a cooling load that cannot be satisfied by the cooling coil in the terminal unit. You may be able to eliminate reheat in this manner for more than half the year, depending on the climate and the type of facility.

Relationship to Primary Air Temperature Reset

Automatic reset for the primary air temperature (Measure 4.9.1.1) serves the same purpose as this Measure, and it is more effective. However, even if you have reset control, consider turning off the coils seasonally as additional security against unnecessary reheat.

EXPLAIN IT: Provide clear instructions that explain when to turn off the cooling coils, e.g., when the outside air is below a certain temperature. Optimize the schedule for each air handling unit or group of units. Install placards at the air handling unit cooling coil valves.

MONITOR PERFORMANCE: This Measure is easy to forget. Schedule periodic checks of the procedure in your maintenance calendar.

MEASURE 4.9.3 Install temperature setback.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Many facilities have unoccupied periods during which it is not necessary to condition the spaces. An effective way to exploit this opportunity for saving energy is to install setback temperature control. This is a control feature that maintains normal temperature during hours of occupancy, and allows the space temperature to drift to a lower (or higher) temperature during unoccupied hours.

With most types of air handling systems, you can save energy simply by turning off the air handling systems during unoccupied hours, as recommended by [Measures 4.1.1 ff.](#) However, this does not work well with induction systems, because the terminal units have a substantial amount of heating capacity even if the fan is turned off. Setback control avoids this problem by controlling the terminal units directly.

Compared to shutting the system down completely, temperature setback has the advantage that it maintains a minimum space temperature at all times. Typically, this is about 10°F less than the occupied temperature. This provides sufficient warmth for transient personnel, such as cleaning crews, and it provides for quick warm-up if the space is needed during unscheduled hours.

Also, setback control allows the air handling unit fan to keep running, if necessary, while allowing the space temperatures to drift within set limits.

Where to Use Temperature Setback

Temperature setback saves energy in any induction system, unless the temperature of all the spaces served by the system must remain constant. Ironically, induction systems are most popular in hospitals, where a desire to maintain constant space temperatures makes temperature setback irrelevant.

Energy Saving

■ Heating Load

The heating load is approximately proportional to the difference in temperature between the inside of the building and the outside, especially at night, when there are no solar effects. Temperature setback reduces this differential. Therefore, the greater the temperature setback, the greater is the energy saving. For example, if the average space temperature can be reduced 8°F during the setback period, and if the outside air temperature during the setback period averages 40°F below the occupied temperature, then heating energy consumption during the setback period can be reduced

SUMMARY

A basic control function that saves energy during unoccupied periods. Setback can be more versatile in induction systems than in other types of reheating systems, but it may also be more complex.

Ease of Retrofit	☺ ☺

by about 20%. (This example does not include the effect of heat gains, heat storage in the building structure, and other complications.)

■ Cooling and Reheat

Setback control turns off the cooling coil during the setback period. Therefore, it eliminates all cooling energy, and it also eliminates all reheat energy waste. The only exception would occur if one or more spaces need a high level of cooling during the setback period. This would be unusual. See [Measure 4.9.1](#) for an analysis of the energy loss from reheat.

■ Conditioning Outside Air

In most cases, you can shut off outside air during the setback period. This action typically saves a large part of the conditioning load.

■ Fan Energy

The saving in fan energy is proportional to the length of time that the fan is turned off. Fan energy is especially important in induction systems because the need for high pressure at the terminal units increases the power of the fans.

How to Install Setback Temperature Control

Induction systems provide a great deal of flexibility in temperature setback because each terminal unit has individual heating capability, even with the air handling unit turned off. By the same token, exploiting the full efficiency potential of setback is more complicated in induction systems than in other types of reheating air handling systems. The following are the steps in achieving efficient setback temperature control.

■ Install a Setback Thermostat in Each Space

There are three common methods of installing setback temperature control:

- install individually programmable setback thermostats in each space
- if you have a central energy management system, program the setback schedule of each thermostat through the energy management system
- if you have pneumatic controls, program the setback schedule for the entire system collectively by using special thermostats that respond to the supply air pressure.

See [Measure 4.3.2](#) for details of each approach.

■ Turn Off the Cooling Coil in the Air Handling Unit

The setback control should turn off the cooling coil in the air handling unit throughout the setback period. This keeps the cooling coil in the air handling unit from forcing the space temperature down to the setback temperature. It also avoids reheat if the air handling unit must operate to maintain the setback temperature.

This control feature involves tricky timing. The cooling coil in the air handling unit must be turned off before the beginning of the setback periods in the individual spaces, and it must be turned on after the end of the setback periods. This requires a separate timing function. A central timing system that controls all the space thermostats and the primary cooling coil is more reliable in this respect.

■ Turn Off the Air Handling Unit Fan, If Possible

If the air handling unit fan is not needed to provide ventilation during the setback period, turn it off. This saves fan energy.

Even if heat is needed during the setback period to maintain the minimum temperature, it may not be necessary to operate the fan. The space thermostat will turn on the heating coil in the terminal unit, and the convective heat output of the terminal unit may be sufficient to maintain the space temperature. Whether this is true depends on the heat loss from the space. (The terminal unit can provide a substantial amount of heat output only if it is installed near the floor. Units installed in the ceiling cannot provide convective heating.)

To exploit this possibility, you need to install two stages of setback. First, the setback thermostat turns on the heating coil in the terminal unit. Second, a separate thermostat starts the fan in the air handling unit if the convective heat output of the terminal unit is not sufficient. You can use a single thermostat in a critical space to provide the second stage.

An unusual complication occurs if you want to maintain a maximum allowable temperature as well as a minimum allowable temperature. In this case, you

need an additional control function that turns on the fan if any space exceeds its maximum allowable temperature. This allows the cooling coil in the terminal unit to deliver cooling to the space. In extreme cases, it may also be necessary to restart the primary cooling coil (in the air handling unit) during the setback period.

■ Turn Off Outside Air Ventilation, If Possible

If the facility does not require ventilation during unoccupied hours, close the outside air dampers. In most cases, you can use the same control that turns off the primary cooling coil.

■ Provide Overrides in Each Space

In virtually all facilities, you should provide a setback override in each space that allows normal temperature to be restored during the setback period. A person who wishes to work during the unoccupied period activates the override in his space, which causes the thermostat to call for normal temperature.

The override should start the fan in the air handling unit, while leaving the cooling coil turned off. The fan is needed to provide full heating capacity from the terminal unit. Full heating capacity is needed to restore the space temperature quickly.

The override remains in effect until the next setback period, unless the occupant cancels the override. This is an efficiency weakness. It does not waste much energy if the setback override is used only occasionally. However, if the override is used often by a user who forgets to cancel the override, much of the benefit of setback is lost.

One way to overcome this problem is to use a personnel sensor to activate the override. This is not yet a standard feature of setback controls, so you have to wire it on a custom basis.

Don't Forget the Placards!

Setback thermostats require occupant action to avoid wasting energy, so they need instruction placards. Make sure that the placards request occupants to reset the temperature override after using it. See [Reference Note 12](#), Placards, for general guidance in designing and installing placards.

ECONOMICS

SAVINGS POTENTIAL: *All cooling energy and all mixing losses are eliminated during the setback period (except in unusual applications). Approximately 5 to 30 percent of heating energy during the setback period is saved. Fan energy savings are approximately proportional to the length of the setback period.*

COST: *\$100 to \$300 per space, plus several thousand dollars for system connections.*

PAYBACK PERIOD: *Several years, or longer.*

TRAPS & TRICKS

CONTROL DESIGN: Setback in induction systems is unusually complex. This invites design mistakes and missed opportunities for savings. Make sure that the control design is adapted to the particular type of induction unit, and that it accounts for all operating conditions.

SELECTING THE THERMOSTATS: If you need to add setback thermostats, select them carefully. Some programmable thermostats are difficult for occupants to use, and some setback thermostats operating with centralized systems are excessively fragile.

EXPLAIN IT: Don't forget the instruction placards. Make sure that the staff are trained to set the proper setback temperature for each location. List these temperatures in the plant operating manual.

MONITOR PERFORMANCE: Failure of the setback system is easy to ignore. Train operators to leave the controls alone unless there is a reason to adjust them. Use your maintenance calendar to schedule periodic checks and to optimize the controls.

MEASURE 4.9.4 Clean, adjust, and repair induction terminal units at appropriate intervals.

RATINGS

New Facilities	Retrofit	O&M
□	□	B

Maintaining induction terminal units consists mostly of cleaning and filter replacement. Other maintenance requirements depend on the specific design of the room units. Give these items attention at regular intervals:

- **filters, filter mountings, and lint screens.** Cleaning filters is especially important in induction units. The venturi action that induces secondary air flow through the room unit coil is relatively weak. Therefore, dirty filters and lint screens can reduce air flow and conditioning capacity substantially. Induction units tend to be used in environments that generate a lot of lint, such as hospital rooms. This reduces the interval between filter changes. A common maintenance defect is improper fit of filters into the filter holders. Unless the fit is tight, dirt bypasses the filter and collects on the coils. Check the fit.
- **coils.** The items to check are cleanliness and fin spacing. You can clean coils with a vacuum cleaner or with compressed air (in the reverse direction). In extreme cases, you need to wash out a dirty coil with detergent and a brush. Straighten bent fins with a fin rake.
- **coil condensate drain pans and lines.** If the coils in the induction units are used for supplemental cooling, condensate forms on the coils. The condensate pans tend to become clogged by debris and by slime that grows in the condensate. When this happens, the stagnant water in the pans serves as a nutritious breeding site for microorganisms. Some of these organisms are health hazards. The

SUMMARY

Basic maintenance items needed to prevent energy waste, maintain comfort, and prevent health problems.

SELECTION SCORECARD

Savings Potential	\$

Ease of Initiation	😊	😊	😊	😊

air flow through the unit disperses these organisms into the space.

This hazard may be overlooked because most of the dehumidification in induction systems is supposed to be accomplished by the cooling coil in the air handling unit. However, high humidity in the space cause substantial condensation in the terminal unit. Also, increasing the temperature of the primary air, as recommended by [Measures 4.9.1 ff](#), shifts more of the cooling load to the terminal unit, increasing condensation.

- **thermostatic controls** may be flimsy. Inspect them periodically and repair them as necessary.
- **coil valves** may leak, causing the coil to consume energy even when it is turned off. When the coil is in heating mode, valve leakage may increase the energy waste caused by mixing hot and cold air.

ECONOMICS

SAVINGS POTENTIAL: *A small fraction of conditioning energy. In induction units, maintenance is more important to comfort and health than to efficiency.*

COST: *\$3 to \$30 per unit per year, which is a routine maintenance cost.*

PAYBACK PERIOD: *Immediate. Maintenance costs less than neglect.*

TRAPS & TRICKS

SCHEDULING AND DILIGENCE: *This is simple, boring work that tends to be ignored. Schedule it in your maintenance calendar and make sure that it gets done.*

MEASURE 4.9.5 Avoid discharging conditioned air on exterior surfaces.

Keep induction units from blowing directly on exterior walls or windows. Also, keep draperies or other window treatments from trapping the discharge against exterior surfaces. Either condition increases heat loss

through the window or wall. You can usually eliminate these problems with simple changes. See [Measure 5.3.3](#) for the details.

Section 5. ROOM CONDITIONING UNITS & SELF-CONTAINED HVAC EQUIPMENT

INTRODUCTION

This Section covers a broad class of heating and cooling equipment that can be called “room conditioning units,” “self-contained units,” or “unitary equipment.” Their common feature is that each unit serves a single space or a single thermostatic zone. Each unit has a single thermostat, a single air distribution fan, and minimal ducting. These units are distinguished from the air handling units in [Section 4](#) by their lack of complexity in control and air distribution.

The approach to energy conservation with these units is largely governed by the fact that they are highly packaged and relatively inexpensive. If a unit is inefficient, the best course of action may be to replace it entirely. By the same token, it is generally impractical to change their basic design, although you may be able to upgrade components (such as motors) or add improvements (such as flue dampers). In general, the Measures of this Section involve much less engineering than the Measures in [Section 4](#). A major exception is heat pump loop systems, which are covered in their own Subsection.

How to Use Section 5

Section 5 is organized primarily by type of conditioning equipment. Go to the Subsections that apply to your facility. The Measures in each Subsection are tailored to the type of equipment. But first, go to [Subsection 5.1](#), which recommends control practices that minimize unnecessary operation of all types of unitary equipment.

As a general guide, each Subsection starts with the Measures that are least expensive and most widely applicable, and progresses to Measures that are more expensive and specialized. Measures providing exceptionally large savings are moved toward the front. Technically related Measures are grouped together.

SUBSECTION INDEX

[5.6 HEAT PUMP LOOP SYSTEMS \(ADDITIONAL MEASURES\)](#)

[5.7 DIRECT-FIRED HEATING UNITS](#)

WESINC

When should this heater operate? The unit heater is located in a transformer room that is ventilated to the outside. There is probably nothing here that is vulnerable to freezing. No people work in the space, but people enter occasionally. What space temperature should be maintained? How would the heater be turned on to accommodate people in the space? What controls or combination of controls should be used?

Minimizing Equipment Operation

The first principle of energy conservation is turning off equipment when it isn't needed. The Measures in this Subsection tailor the output of unitary HVAC equipment to actual need. These Measures often provide large savings. They are relatively inexpensive. None of them requires special skills, but all of them require careful planning.

INDEX OF MEASURES

5.1.1 Install placards at the controls of conditioning units to motivate efficient operation.

5.1.2 Assign responsibility for turning conditioning units on and off to security personnel or to those who administer the spaces.

5.1.3 Install automatic controls to turn off conditioning units when they are not needed.

5.1.3.1 Where spaces operate on regular schedules, use setback thermostats or timeclocks to control the operation of conditioning units.

5.1.3.2 In spaces with irregular usage, install timed-turnoff switches to provide user control of conditioning units.

5.1.3.3 In spaces with irregular usage, install personnel sensors to control conditioning equipment.

5.1.3.4 Connect the power to conditioning units through an appropriate light switch.

5.1.4 Install proximity switches to turn off conditioning units when doors and windows are left open.

MEASURE 5.1.1 Install placards at the controls of conditioning units to motivate efficient operation.

People cannot efficiently control what they do not understand. Therefore, install effective instruction placards on all control devices that are under the control of occupants. These include thermostats, fan control switches, heat/cool selectors switches, timeclocks, manual radiator valves, etc. Also, install placards to inform occupants about automatic controls that affect their comfort, such as timeclocks that turn conditioning on and off at particular times.

See Reference Note 12, Placards, for general guidance in exploiting placards. This Measure deals specifically with installing placards at the user controls of room conditioning units.

Where Placards are Effective

Placards provide the greatest energy savings in single-occupant spaces that have low occupant turnover and a high level of personal responsibility. If there is more than one occupant, each occupant is reluctant to turn off the conditioning unit or reset the thermostat for fear of annoying other occupants. Effective placard design can help to overcome this inhibition.

Placards are desirable in any space that has manual or automatic control of conditioning, even in spaces with many occupants. For example, Figure 1 shows a placard installed on a hotel room conditioning unit. At a minimum, they inform occupants how the conditioning in the space is controlled, which helps the occupants to deal with any comfort problems that may arise. Placards also help to create acceptance of efficient control.

Thermostat setting placards may not be useful with conditioning units that make heating and cooling available simultaneously. Such units are installed most commonly in posh environments, such a luxury hotels. With such equipment, the best thermostat setting may be ambiguous. Cheaper heating energy favors a higher thermostat setting, and cheaper cooling energy favors a lower thermostat setting. Therefore, the optimum temperature depends on the relative cost of heating and cooling energy. The occupants are not in a position to make this judgement.

If the equipment uses reheat for control of temperature or humidity, the effect of the thermostat setting on energy consumption is contrary to intuition. (Refer to Subsection 4.4 for an explanation of this behavior.) This is potentially so confusing to occupants that placards probably cannot help. Fortunately, reheat is rare in room conditioning units.

SUMMARY

A fundamental step in saving energy, but not as simple as it looks.

Energy Saving Potential

■ **Turning off the Equipment in Unoccupied Spaces**

The largest benefit of placards is motivating occupants to turn off conditioning units when they leave the space, which reduces these modes of energy usage:

- **space conditioning.** The energy delivered by a conditioning unit changes space temperature and humidity. If the spaces are unoccupied, you can usually allow temperature and humidity to drift within wide limits. The amount of conditioning energy that is wasted by unnecessary operation depends on the heat loss (or gain) of the space.
- **conditioning of outside air.** Some types of conditioning units take in outside air. Conditioning outside air requires a lot of conditioning energy. This energy expenditure usually is not needed when spaces are unoccupied. If a unit has to operate during unoccupied periods in order to maintain temperature, you may still be able to turn off ventilation.
- **auxiliary energy consumption.** Turning off space conditioning units that have fans saves the energy consumed by the fans. The fans typically are small, but the cumulative energy consumption of many small fans is expensive. For example, fans in typical room fan-coil units have a power consumption of 50 to 100 watts. The saving in fan energy depends on whether the fan runs continuously or intermittently.

■ **Minimizing Heating and Cooling in Occupied Spaces**

The amount of energy needed to heat a space, which includes conduction loss and the heating of outside air,

is directly proportional to the temperature differential between inside and outside. Lowering the heating temperature saves energy by reducing this differential. For example, if the outside temperature is 30°F lower than the inside temperature, and the inside temperature is reduced 3°F, energy consumption is reduced about 10%. (This example ignores the effect of heat gains.)

Keeping the cooling temperature as high as possible is a major energy saver in most environments. The cooling energy requirement includes conduction heat gain, outside air cooling, dehumidification, and direct solar heat gain. The first two of these are proportional to the inside-to-outside temperature differential. (The dehumidification load is loosely related to the outside air temperature, and solar gain is independent of temperature.)

The overall energy saving depends on the length of time that the system operates. During low-load conditions, resetting the space temperature may substantially reduce the number of hours that the system operates. This effect is more dramatic in mild climates, where the temperature hovers for long periods in a range that does not require either heating or cooling.

Although the absolute saving is greater in more severe climates, the relative saving is greater with milder outside temperatures, and hence is more noticeable. In addition, buildings in mild climates are often poorly insulated, so they derive larger savings from a given temperature adjustment.

(As a point of interest, the energy saving does not relate to the outside temperature *per se*, as long as there is a heating or cooling load. For example, lowering the heating temperature by 3°F saves the same amount of energy if the outside temperature is 0°F or if it is 50°F.)

What the Placards Should Say

■ Control Functions

Ask occupants to perform all of these actions for which manual controls are available:

- turn off the unit when the space is not occupied
- set the heating temperature for the lowest comfortable setting
- set the cooling temperature for the highest comfortable setting
- turn the fan to the lowest comfortable speed
- set the fan control so that the running of the fan is controlled by the thermostat (see [Measure 4.3.3.2](#))
- turn off the outside air intake when it is not needed

■ Close Windows and Doors

If the space can lose conditioning through windows or doors, ask the occupants to keep these closed while the air handling unit is operating.

■ Identify the Space being Controlled

If the controls are not mounted directly on the conditioning unit, state which spaces are covered by the controls, if this is not obvious. For example, the placard might say, “This thermostat controls the heating and cooling of the reception area.” Otherwise, occupants may not associate the controls with the conditioning of their space, or they may not know if the controls affect conditioning in other spaces.

■ Inform Occupants about Automatic Controls

Inform the occupants about the operation of any automatic controls, if this might create confusion. If you use any of the automatic control methods recommended by [Measures 5.1.3 ff](#) and [5.1.4](#), let the occupants know. For example, the placard should advise occupants if a conditioning unit is controlled by a timeclock.

■ Ask Occupants to Dress Appropriately

The way people dress has a major effect on the space temperatures they choose. Where appropriate, encourage occupants to dress warmly in cold weather, and to dress lightly in warm weather. In many environments, it is appropriate to say this on the thermostat placard.

■ Whom to Call About Problems

If there is a problem with the conditioning controls, you want to know about it as soon as possible. Therefore, provide a contact for the occupants to call. Otherwise, the occupants may seek relief by vandalizing the control.

■ An Example

In an office that is conditioned by several four-pipe fan-coil units, an appropriate placard might say:

THIS THERMOSTAT CONTROLS THE THREE AIR CONDITIONING UNITS IN THIS ROOM.

To conserve energy, please adjust the temperature setting on this control unit as follows:

- **Select HEAT or COOL on the top selector switch.**
- **If HEAT is selected, set the HEAT lever to the lowest comfortable temperature.**
- **If COOL is selected, set the COOL lever to the highest comfortable temperature.**
- **Set the FAN switch to AUTOMATIC. If you leave the room for several hours or longer, please turn the FAN switch to OFF.**

Call Ext.123 if the heating or cooling does not work properly.

Fig. 1 Hotel room conditioning unit placard These instructions are located in the right place, but they are difficult to read.

Where to Install the Placards

Install placards adjacent to the controls that they explain. If these locations are not plainly in view, consider installing additional placards at other locations. For example, if the purpose of the placard is to ask occupants to turn off equipment at the end of the day,

Fig. 2 Bad practice Transparent thermostat covers irritate people by demonstrating that they cannot control their own comfort. To add insult to injury, the lower cover has a sticker that tells occupants what temperatures to select. If you cannot trust the occupants to set the space temperature, then hide the thermostats.

install it where the occupants are most likely to see it upon leaving the space. Typically, this is at the exit.

Let the Occupants Select the Space Temperatures

Don't bother telling occupants to set specific space temperatures. This is usually not effective or desirable. Accept the fact that occupants will not make themselves uncomfortable for the sake of energy conservation.

Furthermore, it is physically impossible to maintain a fixed space temperature. Room temperature varies from one part of the space to another. The thermostat controls the temperature only at the spot where it is installed. Furthermore, the calibration of thermostat dials is not precise.

Sometimes, thermometers are installed on or near thermostats as a guide to setting the thermostats. This is usually futile, because the thermometers themselves have limited accuracy, so the thermometers and the thermostats may disagree by several degrees.

A Poor Alternative: Locked Controls

It is bad practice to try to conserve energy by making conditioning unit controls inaccessible. Good energy conservation does not reduce comfort. If thermostat limits are set too aggressively with a locked thermostat, occupants will be uncomfortable. On the other hand, if the locked thermostat is set to minimize complaints, energy efficiency will be sacrificed.

Locked thermostats that are visible within the space irritate people because they overtly prevent people from being able to control their environment. Figure 2 shows a particularly silly example. As a result, they are a magnet for tampering. Locked thermostats create an adverse attitude toward energy conservation, resulting in loss of efficiency elsewhere.

If you have to keep conditioning controls out of reach of the occupants to prevent vandalism, conceal the controls, as in Figure 3. Putting a visible box around the controls will cause the occupants to break into the box.

Eliminate Hot Spots and Cold Spots

Some occupants may complain that they are too warm, while others may complain that they are too cold. In many cases, both are right. Efficient temperature control can work only if everyone is comfortable. You may have to correct localized areas of poor temperature regulation caused by inadequate air distribution, dumping diffusers, direct sunlight, poor wall insulation, or other problems.

ECONOMICS

SAVINGS POTENTIAL: *Turning off conditioning units during unoccupied hours may save from 10 to 50 percent of conditioning energy. Optimizing thermostat settings*

WESINC

Fig. 3 Opaque thermostat cover This is better than a transparent cover, but it still tells occupants that they cannot control their temperature. These are frequently knocked off the wall. Why does this cover have a sticker that tells occupants how to set the temperature?

may save from 1 to 10 percent of conditioning cost, with the larger percentages applying to mild climates and low conditioning loads.

COST: \$1 to \$50 per placard, depending on quantity, materials, and complexity. Expect design to account for a majority of the cost of effective placards.

PAYBACK PERIOD: Less than one year, usually.

TRAPS & TRICKS

PLANNING: Use [Reference Note 12, Placards](#), as your guide. Make a tour of your entire facility and list all the conditioning units that should have placards. Design them as you make your list, then settle on a number of standard designs. Be sure to accommodate differences in equipment, occupants, or operating conditions.

INSTALLATION: Install the placards where they cannot be overlooked. Resist the temptation to use adhesives.

MONITOR PERFORMANCE: Schedule periodic checks of the placards in your maintenance calendar. Observe how well they are working. Improve the design, if necessary.

MEASURE 5.1.2 Assign responsibility for turning conditioning units on and off to security personnel or to those who administer the spaces.

RATINGS

New Facilities	Retrofit	O&M
□	□	B

If the building has a security force, consider assigning them to turn off conditioning equipment at the end of the day. Similarly, if the spaces are under the administrative control of a particular group, that group can assign an individual to turn off the conditioning units at the end of the day.

Security patrols are also effective for turning off conditioning units that are turned on by people who work after normal occupancy hours. Similarly, they can be assigned to turn on conditioning units prior to occupancy, to allow time for warm-up.

This method may be the only practical way of turning off conditioning equipment in certain environments. Both occupant control and automatic control may be unreliable in spaces that have multiple occupants, especially if space usage is irregular.

Energy Saving Potential

See [Measure 5.1.1](#).

Coordinate with Control of Air Handling Units

This Measure is identical in its administrative aspects with [Measure 4.1.1.5](#), which relates to air handling units. Accomplish both Measures together if you have both types of conditioning equipment.

SUMMARY
A cheap and powerful way to save energy, but requires effective long-term management.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

ECONOMICS

SAVINGS POTENTIAL: 50 to 95 percent of unnecessary operation of the conditioning unit, depending on the effectiveness of management. The fraction of total system energy consumption that is saved varies widely, depending on operating schedule, conditioning load, and other factors.

COST: Minimal, in most cases.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

See [Measure 4.1.1.5](#).

MEASURE 5.1.3 Install automatic controls to turn off conditioning units when they are not needed.

Human beings are not well adapted to starting and stopping equipment at precise times. Human control is especially unreliable if the starting and stopping times vary with changing conditions, such as weather. For these reasons, use automatic controls wherever possible to control the running of conditioning units. Figure 1 shows room conditioning units that are controlled automatically, and it also illustrates some of the issues that have to be satisfied to achieve efficient control.

The four subsidiary Measures provide a variety of automatic control methods:

- **Measure 5.1.3.1** uses clock controls to make conditioning available on the basis of time, and also on the basis of minimum acceptable space temperature
- **Measure 5.1.3.2** uses timed-turnoff switches to allow occupants to start conditioning at any time for a selected period of time
- **Measure 5.1.3.3** uses personnel sensors to start and stop conditioning automatically, based on the presence of people in the space
- **Measure 5.1.3.4** connects conditioning equipment through a light switch, to provide conditioning whenever the lights in the space are turned on.

Only the first of these can anticipate occupancy, allowing the space to be at normal temperature before anyone arrives in the space. On the other hand, the last three Measures allow an occupant to start conditioning at any time, and they automatically turn off conditioning after the occupants leave.

Consider combining the first Measure with one of the others for optimum control. For example, use a setback thermostat to start conditioning in the morning for the initial warm-up, and control conditioning for the rest of the day with an occupancy sensor.

Design Controls to Suit Occupants' Needs

Automatic controls for space conditioning have a poor record of reliability. They tend to be abandoned, or the occupants or staff disable them. There are two main reasons for this. One is that the occupants perceive the automatic controls as a threat to their comfort. The other is that occupants or staff cannot understand how the controls function. Therefore, to make automatic controls survive, you must make them user-friendly.

The first principle is to make conditioning available whenever people need it. Your challenge is to install controls that “know” when each conditioning unit should be running. In most applications, do not limit conditioning to fixed periods of time. Make conditioning available during unpredictable periods of space usage.

Think of regular occupants who work outside of normal working hours, and think of people who are not regular occupants, such as cleaning crews and maintenance staff.

Automatic controls are not obvious. You have to explain them so that an occupant understands how the conditioning is being controlled, as soon as he enters the space. An effective placard is your primary tool for doing this. This is especially important if the space is not at normal temperature when the occupant first arrives.

Limit Temperature Drift

Don't let the temperature wander too far when the equipment is turned off. The usual concern is letting temperature drop (or rise) to the point that it takes too long to restore comfortable temperature within the space.

WESINC

Fig. 1 Automatic control for classroom conditioning units
The classroom operates on an irregular schedule. However, the conditioning units are controlled from a central computer system located miles away. The arrow points to a computer interface. It would be more efficient and more comfortable to control the units with accessible local controls, and to make the school administration responsible for efficient operation.

In extreme cases, low temperature may cause freezing or other damage.

Temperature drift is caused by heat loss (or gain). Serious temperature drift is most likely to occur in perimeter spaces. In interior spaces that contain heat-producing equipment, the temperature may rise excessively.

Temperature drift is limited by the heat storage capacity of the building structure and contents, and by heat transfer from adjacent areas where the temperature is held constant. Even perimeter spaces may not experience large temperature drifts unless they are isolated from the adjacent spaces by closed doors.

Temperature drift usually is tolerable if the conditioning equipment can restore a comfortable temperature quickly. Temperature recovery is quick in smaller spaces because of the laws of geometry. The capacity of conditioning equipment is determined largely by the exterior surface area of the space. In contrast, the length of time that is required to bring the air temperature to a comfortable level depends on the air volume. Smaller spaces have a lower ratio of volume to exterior surface area, so the temperature of the air can be restored more quickly than in a larger space.

For example, a typical fan-coil unit in a small office may be able to restore comfortable air temperature within a few minutes, whereas a gymnasium heating unit may require an hour.

Restoring the air temperature in the space is the important part of recovering from setback, rather than reheating all the mass of the surroundings. As long as

air is flowing from the conditioning unit, air temperature is the main factor in comfort. Restoring the temperature of the surrounding mass takes much longer than restoring the air temperature, but this typically does not cause a problem. The air temperature does need to be somewhat higher than normal to compensate for the cooler surfaces. Fortunately, this tends to occur naturally, because the thermostats are attached to the surfaces. As a result, the thermostat senses a temperature that lies between the air and surface temperatures.

To limit temperature drift, start the conditioning equipment when the space temperature drifts too far. A setback thermostat (see [Measure 5.1.3.1](#)) serves this purpose. As an alternative, you can install a separate thermostat to perform this function alone.

Coordinate with Control of the Central Plant

You can also use the control methods that are recommended here to control the running of the boiler plant (see [Measures 1.1.1 ff](#)), the chiller plant (see [Measures 2.1.2 ff](#)), and the air handling systems (see [Measures 4.1.1 ff](#)). Coordinate the controls for all these types of equipment to reduce cost and increase opportunities for conservation.

Shutting off the boilers and/or chillers that serve room conditioning units is less expensive than shutting off the conditioning units individually. However, this is acceptable only if the individual spaces all operate on approximately the same schedule, and if the room conditioning units operate on the same schedule as the boilers and/or chillers. Also, this method does not save fan energy in the room units.

MEASURE 5.1.3.1 Where spaces operate on regular schedules, use setback thermostats or timeclocks to control the operation of conditioning units.

RATINGS

New Facilities	Retrofit	O&M
B	C	

If a space is occupied on a predictable schedule, you can use either timeclocks or setback thermostats to turn the conditioning units on and off. A setback thermostat is a thermostat with an internal timeclock that changes the space temperature settings at different times.

A setback thermostat normally operates through the thermostatic control circuit of the conditioning unit. A timeclock is normally installed to control the power to the entire conditioning unit. However, you could install a setback thermostat so that it controls the power to the entire unit. Or, you could install a timeclock to interrupt the thermostatic circuit alone.

Where to Use Timeclocks and Setback Thermostats

If the space served by a conditioning unit operates on a regular schedule, a timeclock or setback thermostat is usually the best method of automatically starting and stopping conditioning. For greater control flexibility, you can combine timeclocks and setback thermostats with controls that respond to other conditions, such as outdoor temperature, occupancy, etc.

Timeclocks and setback thermostats are not appropriate for spaces that operate on irregular schedules, such as conference rooms, auditoriums, and surgical suites. Unfortunately, facility managers sometimes try to schedule specific times for conditioning such spaces, most commonly through an energy management system. This inevitably leads to dissatisfaction.

Don't use temperature setback if the thermostatic control system would use energy to force the setback temperature. This limitation exists in units that provide both heating and cooling, where neither can be turned off. For example, four-pipe fan-coil units with pneumatic controls are sometimes installed with a single thermostatic element controlling both the heating and cooling coils. These are installed in some luxury hotels so that guests do not have to select heating or cooling. If a setback thermostat were used with this type of system, switching to the lower nighttime temperature would consume energy to cool the space to the nighttime temperature, and to maintain that temperature until the setback thermostat switched back to the daytime temperature.

If the conditioning unit uses reheat, study the unit's controls before using temperature setback. Setback while reheating actually increases energy consumption. (Reheat is rarely used in room conditioning units. When it is used, the purpose is usually to control humidity. To

SUMMARY

Basic and powerful energy conservation tools with great flexibility. People will sabotage them if they are not user-friendly.

SELECTION SCORECARD

Reliability	✓	✓		
Ease of Retrofit	😊	😊	😊	

minimize energy consumption for dehumidification, the reheat should be controlled by a humidistat in the space.)

Comparison of Timeclocks and Setback Thermostats

In most cases, but not in all, a setback thermostat is preferable to a timeclock. Setback thermostats behave in the same way as timeclocks, until the temperature falls (or rises) to the temperature limit that is set. The main advantage of a setback thermostat is that it restarts the conditioning unit if the temperature drops to the lower setting. This feature keeps the space warm enough for a quick warm-up, or you can use a setback thermostat as a safety feature to protect against excessively low (or high) temperature.

If the conditioning unit has a continuously running fan, using a timeclock to control the power to the unit saves fan energy, whereas a setback thermostat allows the fan to keep running. In some cases, it is fairly easy to install a setback thermostat so that it controls the operation of the entire unit.

Setback thermostats cost more than timeclocks, but the labor cost of installing a setback thermostat in the thermostat circuit usually is less than the cost of installing a timeclock in the main power circuit. On the other hand, you could install a timeclock in the thermostat circuit.

Selecting the Setback Temperature

The setback temperature is a compromise. If the setback temperature is set much lower than the normal temperature, the space may get too cold for rapid warm-up. This is a problem if people may need to occupy the space at irregular times after the space has cooled down. The warm-up time is typically much longer in larger spaces, for the reason explained in [Measure 5.1.3](#).

On the other hand, setting a higher setback temperature reduces the energy saving. This occurs if the space cool downs to the setback temperature, so that the conditioning unit operates during some of the unoccupied hours. More after-hours conditioning occurs if the space is vacated for long periods, such as a weekend. Not surprisingly, more after-hours conditioning occurs if the space has high heat loss.

Energy Saving Potential

The previous discussion shows that the potential savings vary over a wide range. The greatest savings occur when the conditioning can be turned off for a large fraction of the time and a large variation in temperature can be tolerated.

The difference between the inside and outside temperatures determines two major components of the conditioning load, the conduction load and the outside air load. Temperature setback reduces this difference. For example, if the space temperature is reduced an average of 5°F during the setback period, and if the outside air temperature during the setback period averages 25°F below the occupied temperature, then heating energy consumption during the setback period can be reduced by about 20%. (This example does not include the effect of heat gains, heat storage in the building structure, and other complications.)

How to Select the Controls

Many models of timeclocks and setback thermostats are available. Invest some effort in selecting the best one for each application. Specific features can make the difference between success and failure. The most important characteristics are ease of use, the scheduling options, and the method of override control. See [Reference Note 10](#), Clock Controls and Programmable Thermostats, for equipment features, installation practices, and operating procedures that are needed for satisfactory performance.

Where older-style time controls are presently installed, consider replacing them to take advantage of the features of newer electronic models, including internal power backup, multiple schedules, and other features.

If your facility has an energy management computer system, you might use it for starting and stopping conditioning equipment. However, such large-scale control systems tend to be unreliable, and the cost of connecting each conditioning unit to the system is high. Simple localized controls are less expensive and individually more reliable. The main advantage offered by a centralized system is the ability to re-schedule conditioning units from a central location. See [Reference Note 13](#), Energy Management Control Systems, for the complete story.

■ Occupant Override

In most applications, provide an easily accessible manual override. This allows a person to restore conditioning during hours when the timeclock or setback thermostat would normally have the conditioning turned off. This is essential for comfort. It also protects the time control. If an override is not easily available, people will eventually turn off the time control, or disable it.

Conventional overrides keep the equipment operating until the next “off” time. For example, if a conditioning unit is scheduled to turn off at 6 PM and is restarted manually at 8 PM, it will continue to operate until 6 PM of the following day. For this reason, overrides are inefficient if they are used often. Consider a conventional override to be an emergency feature rather than a routine control function.

If conditioning is often needed at odd hours, control the equipment with an interval timer, personnel sensor, or other control method that adapts to the duration of usage. These methods are covered by the Measures that follow.

Installation Options

A timeclock is usually installed to control all the power to the conditioning unit, including the fans. A setback thermostat is installed through the thermostatic control circuit. For example, a setback thermostat controlling a heat pump would control the compressor and the outside fan, but not the inside fan. With some equipment, such as convectors and hot air furnaces, there is no difference in the connections.

With small conditioning units that are powered through a receptacle, such as window air conditioners, you can plug an inexpensive timeclock into the receptacle, or use a timeclock as a replacement for the receptacle. Inexpensive timeclocks designed for such applications are common items.

Another option is to install a timeclock directly on the casing of the conditioning unit. Or, install a timeclock on a separate junction box.

To install a setback thermostat, remove the existing thermostat and replace it with the setback thermostat. Some setback thermostats are powered by the thermostat circuit itself, some are powered by a low-voltage transformer, and some are powered by an internal battery.

If the thermostatic controls are pneumatic, you can install a centralized setback system that controls all thermostats simultaneously. In this system, setback is triggered by changing the control air pressure at the air source. This retrofit requires changing all the individual thermostats, plus adding a control station at the air source to change the pressure at the appropriate times. A typical system sets the thermostats to daytime operation with 17 PSI supply pressure and to nighttime operation with 22 PSI supply pressure.

Install either timeclocks or setback thermostats where they are easily accessible to occupants, especially for override purposes.

Don't Forget the Placards!

People cannot use time controls intelligently unless you explain what they do. Refer to [Measure 5.1.1](#).

ECONOMICS

SAVINGS POTENTIAL: 10 to 70 percent of the operating cost of the conditioning units, depending on the utilization of the spaces they serve. Setback thermostats that keep the space temperature within about 10°F of occupied temperature typically save about 10 to 30 percent of heating energy.

COST: Electronic setback thermostats with a variety of features cost about \$100 to \$200. Electrical and electronic timeclock units with overrides cost from \$20 to \$100. If the control uses existing thermostat wiring, installation cost is small. Installing a timeclock on a receptacle can be done in a few minutes. Installing a timeclock in the power circuit may cost \$100 or more.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Get all the appropriate features. Select units that are easy to use. A control will become junk if it is difficult to use or if it lacks a needed feature.

INSTALLATION: Install the timeclock or setback thermostat where it is obvious and accessible to those who should set it. Keep it out of sight of other people. Make sure that an accessible and well marked override is available for anyone who occupies the space at irregular times.

EXPLAIN IT: For the occupants of the space, install a well designed placard at each timeclock or setback thermostat that states what it controls, the normal schedule, and how to use the override. For the staff who are responsible for setting and maintaining the controls, provide clear instructions about these functions.

MONITOR PERFORMANCE: Time controls have a high failure rate, mainly from tampering. Schedule periodic inspections of all your time controls to check their condition and settings.

MEASURE 5.1.3.2 In spaces with irregular usage, install timed-turnoff switches to provide user control of conditioning units.

RATINGS		
New Facilities	Retrofit	O&M
B	C	

This Measure is identical to [Measure 4.1.1.3](#) in its procedures. The spaces affected are smaller, so the savings and the costs of each installation are lower.

MEASURE 5.1.3.3 In spaces with irregular usage, install personnel sensors to control conditioning equipment.

RATINGS		
New Facilities	Retrofit	O&M
B	C	

This Measure is similar to [Measure 4.1.1.4](#) in its procedures. Personnel sensors are especially appropriate for smaller spaces because the spaces warm up or cool down quickly, and because a single sensor can monitor

the presence of people in the entire space. Because the spaces are smaller, the savings and costs of each installation are lower than for [Measure 4.1.1.4](#).

MEASURE 5.1.3.4 Connect the power to conditioning units through an appropriate light switch.

RATINGS		
New Facilities	Retrofit	O&M
C	D	

You can control the conditioning of a space by activating the conditioning through a light switch. This method guarantees that conditioning is available whenever it is needed. It provides “automatic” control of conditioning without needing special controls. However, this method works well only under a specialized set of conditions.

Where to Use This Method

Consider this method for spaces that have all these characteristics:

- **occupancy that is independent of the schedule of the rest of the facility.** For example, this method can be effective for the offices of salesmen or field inspectors, and in a police station, for the detectives’ and patrol officers’ offices.
- **low personnel turnover and a high level of personal responsibility.** The occupants have to be the kind of people who respond to a request to turn off the lights when they leave the space.

SUMMARY

Simple. Easy to use. Unconventional. Depends on people to turn off the lights when spaces are vacated.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	

- **single occupancy, or all occupants are visible to each other.** If more than one person is assigned to the space, each occupant may be reluctant to turn off the lights for fear of annoying the other occupants. Each person should be able to see that the space is entirely vacated at the time he leaves.

- **limited heat gain or heat loss.** Large temperature drift will occur in spaces with high heat losses or heat gains when the conditioning equipment is turned off. Therefore, if the climate can be extreme, limit this method to interior spaces. Occupants will tolerate an initial period of space temperature that is moderately cooler or moderately warmer than normal, especially if they are entering from the outside. However, if the temperature is too far from normal space temperature, the space will be perceived as uncomfortable. In that case, occupants will keep the lights turned on as a way of keeping the conditioning equipment running.
- **conditioning equipment that provides rapid warm-up and cool-down.** This Measure works best with fan-coil units, because these warm the air in the room quickly, making the space comfortable even before the structure and furnishings have time to warm up completely. It also works well with individual space air conditioners, because these generally have enough cooling and fan capacity to cool a small space quickly. On the other hand, you probably should not control baseboard heating with the light switch, because it warms the space too slowly.
- **at least one light fixture is always needed while the space is occupied, but not at other times.** Do not use this technique in spaces that can be lighted entirely by daylight. Also, do not use it in spaces where the lights may be turned off while the space is occupied, e.g., in sleeping quarters, or in rooms where audio-visual presentations are made.

The main competitor to this method is using personnel sensors to control conditioning ([Measure 5.1.3.3](#)). Personnel sensors are more reliable for conforming to actual occupancy. This Measure may be the best choice in spaces where personnel sensors cannot operate reliably, and in spaces where people enter and leave the space frequently during the period of time that the space is being used.

If you use security patrols to monitor the conditioning of spaces, as recommended by [Measure 4.1.2](#), this Measure makes it easier for them to do the job.

Energy Saving Potential

See [Measure 5.1.1](#).

How to Make the Connections

Select an easily accessible switch that controls a light fixture that is always required when the space is occupied. Replace it with a double-pole switch to isolate the conditioning unit power from the lighting power. Run power to the conditioning unit through the switch. If the switch is not in a convenient location, relocate it to a place where the occupant can turn it off easily when exiting.

Don't Forget the Placards!

This method is unusual. To make it acceptable, install a placard at the light switch to inform occupants that the switch also controls space conditioning. The placard should request occupants to turn off the switch whenever leaving the space for an extended period. See [Reference Note 12, Placards](#), for guidance in effective placard design.

ECONOMICS

SAVINGS POTENTIAL: 50 to 95 percent of unnecessary operation of the conditioning unit. The fraction of total system energy consumption that is saved varies widely, depending on the occupancy of the space and its conditioning load.

COST: In new construction, the additional wiring cost typically is small. In retrofit, the cost may be several hundred dollars per space.

PAYBACK PERIOD: Short, in new construction. Several years or longer, in retrofit.

TRAPS & TRICKS

CHOICE OF METHOD: The space, the conditioning equipment, the type of lighting, and the nature of the activities must all be appropriate for this method. Review all these conditions for each candidate space, and be certain that they will continue for the life of the facility.

EXPLAIN IT: Let the occupants know how the conditioning is controlled. Install an effective placard that asks them to turn off the lights, and the conditioning, when they leave the space.

MEASURE 5.1.4 Install proximity switches to turn off conditioning units when doors and windows are left open.

RATINGS		
New Facilities	Retrofit	O&M
B	B	

If a space has exterior windows and doors, they should be closed while heating or cooling the space. Unfortunately, people may leave the windows or doors open. For example, this is a common problem in motels that have sliding glass doors to provide access to patios and balconies.

To solve this problem, install a proximity switch at each exterior window and door that turns off the conditioning equipment when the window or door is opened. This simple control connection is almost foolproof. If the switch breaks or the wiring is disconnected, the conditioning unit will not function.

This control feature has two desirable effects on occupant behavior. It motivates occupants to keep the doors and/or windows closed to avoid wasting conditioning. And, it highlights that fact that occupants have a choice between using outside air ventilation and using air conditioning.

Energy Saving Potential

Opening a door or a window allows so much outside air to enter the space that the conditioning unit is kept near maximum output if the weather is cold or hot. Even partially opening a window may increase the conditioning load of a space severalfold. This Measure saves the energy that is wasted in attempting to condition the entire outdoors.

How to Install the Switches

Install a magnetic proximity switch, a mechanical contactor, or other reliable switching device to sense the opening of each door and window. Wire the switch into the thermostat circuit of the conditioning unit (if the thermostat is electrical), or use the switch to control the power to the conditioning unit through a relay.

Select the sensing device for ruggedness. Protect the switch itself and its wiring. Keep both out of sight as much as possible.

Inform the Occupants!

An integral part of this method is informing occupants that the conditioning unit will stop automatically if a door or window is opened. Install an

SUMMARY

An important control feature in spaces that have openings to the outside. Especially desirable for lodging and rental facilities. Simple. Almost foolproof.

SELECTION SCORECARD

Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

effective placard where occupants will notice it immediately, not in a location where it can be hidden by curtains or other objects. See [Reference Note 12](#), Placards, for guidance in designing effective placards.

ECONOMICS

SAVINGS POTENTIAL: 5 to 50 percent of the conditioning energy of the space, depending on the pattern of space usage.

COST: \$50 to \$200, typically, mostly for labor.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

EQUIPMENT SELECTION AND INSTALLATION: Select the switch and the installation method to be rugged enough to survive the environment. Some people become aggressive if you try to keep them from heating or cooling the entire outdoors. Don't forget the placard in each space, or you will get a lot of calls complaining that the air conditioning is not working.

MONITOR PERFORMANCE: Schedule periodic checks of the equipment, at intervals that correspond to the likelihood of damage. If you observe frequent attempts to sabotage the switches, consider a different type of switch or a different approach to controlling the equipment.

WESINC

Fig. 1 These windows need switches to turn off the conditioning. This luxury hotel is located in a climate that encourages guests to open the windows, and the ability to do so is an attraction of the hotel. The rooms are conditioned to maintain a precise temperature, so opening the windows can waste a large amount of energy.

Radiators and Convectors

The Measures in this Subsection improve the efficiency of heating with radiators and convectors. These are simple heating units in which heat is distributed solely by radiation and/or convection resulting from the surface temperature of the unit. They do not use fans, induction, or other means of distributing heat. The heating surfaces may be exposed or enclosed.

The distinction between radiators and convectors relates to their different modes of heat emission, as their names imply. Radiators have large, hot surfaces that are exposed to occupied areas of the space. This allows them to transmit a large fraction of their heat output by radiation. Radiators also release a large amount of heat by convection.

Convectors release heat primarily by convection. That is, they heat the surrounding air with fin coils, and the warm air circulates through the space by convection. Convectors typically consist of long horizontal heating elements that have sheetmetal guards. The surface temperature of the coils is too low for strong radiation of heat, and the guards block most radiation that does occur. The heating coils may be enclosed at the bottom of a tall enclosure. In this case, the enclosure acts as a chimney, increasing heat output somewhat.

The terminology is sloppy. For example, the term “baseboard radiator” is often used for convectors. A variety of names are given to different models of radiators and convectors. The distinction between radiators and convectors may be important to energy efficiency. Where this difference matters, it is discussed in the Measures.

Radiators and convectors operate with an efficiency of almost 100%, which means that virtually all energy absorbed by the units is delivered to the space as heat. Losses occur outside the space in the steam, hot water, or electrical systems that provide the energy.

Measure 5.2.1 recommends the appropriate maintenance for these units. **Measure 5.2.2** recommends installing thermostatic radiator valves on units with manual valves, a “must do” improvement. **Measures 5.2.3** through **5.2.6** recommend improvements to enclosures. **Measures 5.2.7** through **5.2.10** recommend major, expensive system modifications.

INDEX OF MEASURES

- 5.2.1 Clean and repair radiators and convectors at appropriate intervals.**
- 5.2.2 Install thermostatic control valves on units with manual valves.**
- 5.2.3 On units with manual control valves, provide easy and safe access to the valves.**
- 5.2.4 Ensure that convection and radiation are not obstructed by enclosures or other objects.**
- 5.2.5 Avoid trapping of heat output against exterior walls.**
- 5.2.6 Thermally isolate radiators and convectors from poorly insulated walls.**
- 5.2.7 With steam heating, install a vacuum condensate system to improve temperature control.**
- 5.2.8 Convert steam heating to hydronic heating.**
- 5.2.9 Replace electric resistance convectors with heating units having lower energy cost.**
- 5.2.10 Provide separate thermostatic control for each area with distinct heating requirements.**

MEASURE 5.2.1 Clean and repair radiators and convectors at appropriate intervals.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

The high efficiency of radiators and convectors does not depend on maintenance. However, inadequate maintenance may reduce the capacity of the units and it may cause conditions that motivate occupants to operate the equipment in a wasteful manner. To avoid these problems, clean or repair these components at regular intervals:

- **fins and coils.** Convectors have finned tubes that collect debris. Even cast iron radiators collect dust and dirt, especially when enclosed. The debris reduces capacity. At least once a year, arrange for your cleaning crews to suck the debris out the units with their vacuum cleaners. Supervise them when they do this.
- **manual control valves,** which are found mainly on older steam radiators. The chronic problem with these units is erosion of the valve disks and seats, which occurs rapidly when the valve is only slightly open. Typically, manual radiator valves should be overhauled every year.
Failure of the control valves wastes energy by preventing the radiators from being turned off. This leads occupants to control temperature by leaving windows open, which vastly increases heating requirements.
- **thermostatic control valves** also develop leakage by erosion of the valve disks and seats, and they waste energy in the same way. In steam radiators, expect to overhaul the valves annually. In hydronic equipment, check valve closure at the beginning of the heating season.
- **steam traps** on steam radiators fail eventually and often. A steam trap is an automatic valve that prevents steam from blowing straight through the radiator. If the trap works properly, it passes only condensate. But, if the trap leaks, it can waste a large amount of energy by short-circuiting steam into the condensate system. If the trap sticks closed, the radiator will not function. If the trap sticks in a partially open position, the radiator will have reduced capacity and will not control properly. Inspect all your radiator steam traps annually, at the start of the heating season.
- **air eliminators** are used with steam radiators to vent air that accumulates inside the units. They are automatic devices similar in construction to steam traps. If they stick open, they waste steam. If they stick closed, the radiator fills with air, loses capacity, and becomes uncontrollable.
- **damper controls** are used to modulate output in some older types of convectors. The damper may

SUMMARY

Basic maintenance items needed to prevent energy waste and maintain comfort.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊

be controlled by a manual knob, a bead chain, or a bimetallic element. Because of inexpensive construction, the dampers tend to jam. This tendency is aggravated by dirt and trash that falls into the cabinet. Maintenance consists of simple repairs, lubrication, and cleaning.

Differences Between Types

Electric units are easy to maintain, requiring only occasional coil cleaning and checking of thermostats.

Hot water radiators also require little maintenance. Be sure to check for control valve leakage. If the hot water supply system is not piped properly, air can accumulate in some heating units, mysteriously reducing capacity.

Diagnosing problems in steam radiators requires special skills related to steam equipment. Control valve operation is tricky for the reasons explained in [Measure 5.2.7](#). Steam traps have a large amount of lore that is covered in [Measures 1.10.3](#) and [1.10.4 ff.](#)

ECONOMICS

SAVINGS POTENTIAL: 20 to 50 percent of heating energy, compared to systems in which maintenance is neglected.

COST: Usually modest.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

SKILLS AND TRAINING: Electric and hydronic units require only conventional skills to check. Steam radiators require special knowledge that is disappearing as steam space heating fades into history. If you have steam radiators, study [Measures 5.2.7](#), [1.10.3](#), and [1.10.4](#). Then, train the maintenance staff. Explain the diagnosis and repair procedures in the plant operating manual.

DILIGENCE: Checking radiators is not glamorous work. In the case of steam radiators, it can be puzzling and a

source of blisters. Doing it regularly and properly is a management challenge. Start by scheduling inspections in your maintenance calendar.

MEASURE 5.2.2 Install thermostatic control valves on units with manual valves.

RATINGS

New Facilities	Retrofit	O&M
	B	

Manual control valves on older radiators and convectors, such as those in Figures 1 and 2, can cause serious energy waste. The waste occurs because manual valves require continual adjustment as conditions change. Furthermore, the heat output of steam radiators tends to be unstable at low output, for the reasons explained in Measure 5.2.7. Frequent manipulation of the valves accelerates wear and leakage.

To compound these problems, manual valves are typically awkward and uncomfortable to operate, which makes occupants reluctant to grapple with them. As a result, occupants resort to leaving the radiator valves fully open and opening windows to vent the excess heat. Thus, the window becomes the control device.

You can solve these problems by installing thermostatic valves in place of the manual valves. The thermostatic valves follow the fluctuations in space load and radiator output, keeping space temperature stable.

Some types of thermostatic valves also provide the ability to turn off heat or lower space temperature automatically during unoccupied periods. Don't overlook this capability. You can't depend on people to turn off radiators manually. If radiators are turned off, they require a long time to get a cold space warmed up.

Energy Saving Potential

If occupants use the windows to control the temperature in the space, heating the space may require several times more energy than if the windows are kept closed. Installing thermostatic valves can eliminate all or most of this waste.

If you install thermostatic valves that allow shutdown or setback of the heating equipment during unoccupied hours, the saving in unnecessary conditioning can be major. See Measures 5.1.3 ff for details.

Types of Thermostatic Radiator Valves

You have a choice of three general types of thermostatic radiator valves:

SUMMARY

Eliminates the main source of energy waste and user dissatisfaction with manually controlled steam and hydronic heating units.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% % %
Reliability	✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

- **remotely powered valves** may be pneumatic or electric. They are similar to valves used in other HVAC equipment. They require a source of compressed air or electricity, respectively, at each heating unit. This type provides the best temperature sensitivity and the quickest response. The thermostats can be installed anywhere in the space. The pneumatic or electric connections between the thermostats and the heating units can be hidden in the walls like other wiring. This is the only option that allows you to turn the radiators on and off, or to adjust the space temperatures, using a central control system. This option is the most expensive by far.
- **valves with internal self-powered thermostats** are the other extreme. They require no external control or power connections. What makes them work is a thermally expanding fluid that moves the valve disk. The temperature is set by turning a knob at the valve body. Figure 3 shows the insides of a typical self-powered thermostat. Installation is easy, consisting of removing the manual valve and replacing it with the thermostatic unit. Self-powered valves are available as direct replacements for the manual valves on both hydronic and steam heating units. In the case of steam units, they are available for both two-pipe and one-pipe systems. This option is the least expensive.

WESINC

Fig. 1 Radiator with manual control valve This radiator can be retrofitted easily with a self-contained thermostatic valve. The high position of the valve and the length of hot steam pipe under the valve make it advisable to install a valve that has a remote temperature sensor.

The major weakness of this type is the location of the thermostat, which is inside the valve. In this location, it is heavily influenced by the heat from the radiator, so it may respond poorly to the temperature of the space. Also, if the original manual valve was awkward or uncomfortable to reach, the same will be true of the thermostatic valve. This type of control has no provision for external control connections to provide automatic shutdown or temperature setback.

- **valves with external self-powered thermostats** operate on the same principle as the previous type. Figure 4 shows a typical unit. The difference is that the space thermostat is mounted remotely. The thermostat is connected to the valve on the radiator through a capillary. This type can provide good temperature control, and it is easy to use. The capillary has limited length, which may limit the thermostat locations. Also, the capillary is more difficult to get out of sight than electrical wiring or pneumatic tubing, because it cannot be snaked through walls. Retrofit is as simple as with self-contained units, and the cost is not much higher.

Provide for Turning Off Units During Unoccupied Periods

While you are planning the modification, provide for turning off the heat or lowering the space temperature when the space is unoccupied.

[Measures 5.1.3 ff](#) recommend automatic methods of turning off or reducing the heat in individual spaces.

These methods require externally controlled (pneumatic or electronic) valves.

If you use self-contained thermostatic valves, you will have to turn off the heat at the boiler, or at some point in the distribution system. For example, you could install a solenoid valve in the steam line to each radiator. However, the combined cost of the self-contained thermostatic valve and the solenoid valve, and its connections, would be as high as the cost of externally controlled electric or pneumatic control valves.

If you plan to turn off equipment during unoccupied hours, provide for overrides in individual spaces. See [Reference Note 10](#), Clock Controls, about overrides.

Thermostat Location

If the valve has a remote thermostat, install it where it will sense only the space air temperature. This means, install it to the side of the radiator or convector, so that it is not blanketed by the warm air rising from the unit. Do not locate thermostats near hot or cold objects, such as exterior walls, coffee urns, etc. Install them where they will not be in direct sunlight coming through windows or skylights at any time of day. If necessary, install a simple sun shield around the thermostat.

Location is not an option with self-contained thermostatic valves that are mounted on the radiator. These units seem to work better than one has any reason to expect, but temperature control cannot be as efficient as with a remotely located thermostat.

WESINC

Fig. 2 Group of radiators For good space temperature control, all these radiators could be controlled collectively by installing conventional control valves and a single space thermostat.

Don't Forget the Placards!

See [Measure 5.1.1](#).

Plan for Regular Maintenance

Maintenance is just as important for thermostatic valves as it is for manual valves. Automatic radiator valves do not avoid the burden of valve maintenance. The most frequent maintenance problem for both manual and automatic types is erosion of the valve seats. Both types require repair at similar intervals. See [Measure 5.2.1](#) for the details.

Consider Your Alternatives

This Measure is by far the least expensive method of providing good control. In the case of steam systems, you may want to further improve the characteristics of the system by installing a vacuum condensate system, as recommended by [Measure 5.2.7](#).

Danfoss Automatic Controls

Fig. 3 Self-contained radiator thermostat A liquid in the bellows assembly expands and contracts in response to space temperature. This motion is transmitted to a valve disk. Turning the knob changes the volume of the fluid, changing the temperature setting. The valve disk wears out and requires periodic maintenance, as with manual valves.

Danfoss Automatic Controls

Fig. 4 Self-contained radiator thermostat with remote temperature sensor The temperature is set by turning the knob, which is attached to the valve. However, the small rectangular sensor can be installed at some distance from the valve, so it avoids sensing the heat of the radiator itself. The sensor is connected to the valve through a capillary tube.

If you are planning a major renovation of the facility, consider converting a steam heating system to a hydronic system. [Measure 5.2.8](#) recommends this approach, and explains the reasons why.

ECONOMICS

SAVINGS POTENTIAL: 20 to 80 percent of the energy used to heat the space, if the occupants are using wasteful practices to control temperature.

COST: Typically \$100 to \$200 per radiator, for valves with self contained thermostats, depending on the difficulty of installation. Up to \$500 per radiator, with external thermostats.

PAYBACK PERIOD: One year to several years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Your big decision is whether to install self-contained or externally powered units. The latter are more expensive, but they make it easy to shut down heating in individual spaces. If you decide to use self-contained units, shop the market thoroughly, as performance varies widely between models. Talk with others who have used the controls for at least several years. Select a model that uses a remotely mounted thermostat.

EXPLAIN IT: People who are accustomed to manual control valves on steam radiators need to learn the virtues of thermostatic control. Make sure that occupants understand that they do not have to leave the windows open all year. Tell them how to set the thermostats. Install effective placards on the thermostats, as recommended by [Measure 5.1.1](#).

MEASURE 5.2.3 On units with manual control valves, provide easy and safe access to the valves.

RATINGS

New Facilities	Retrofit	O&M
	C	

Manual radiator valves are inherently a source of energy waste. You should get rid of them, as recommended by [Measure 5.2.2](#). Until you do that, make the manual valves as easy to manipulate as possible.

The usual problem is that it is difficult or dangerous for occupants to reach radiator valves. The surface temperature of a steam radiator may exceed the boiling temperature of water, and occupants risk burns by trying to manipulate a control valve that is not out in the open. The problem is worsened by enclosures that have been added for the sake of appearance, which usually make the valves much more difficult to reach.

Improve Access or Add a Valve Extension

You have to work out solutions on an individual basis. There are two basic approaches: modify the enclosure to provide easy access to the valve, or add an extension to the valve stem to bring the handle outside the enclosure.

You probably will not be able to modify the enclosure to make it easy to reach the original valve handle. Even if you could, keeping the valve handle inside the enclosure makes it too hot for comfort.

The better solution in most cases is to install an accessible handle on an extension attached to the stem of the control valve. Get the handle out in free air where it can stay cool. This may not be pretty, but that is the price that must be paid for good control and safety.

If you add an extension to the valve stem, include a flexible joint at the valve end. You can buy inexpensive universal joints for this purpose from industrial supply houses. If you do not add a flexible joint, the valve stem and packing will be subjected to great stress, which will damage the valve and cause leakage.

SUMMARY

An improvement that may be necessary to allow people to use manual radiator valves efficiently.

Related Enclosure Modifications

The same enclosures that cause difficulty with valve access often create other problems. Coordinate this Measure with [Measures 5.2.4](#) through [5.2.6](#), which recommend improvements to radiator enclosures for other reasons.

Don't Forget the Placards!

Instruction placards are important with any manual control. Refer to [Measure 5.1.1](#).

ECONOMICS

SAVINGS POTENTIAL: 10 to 50 percent of heating energy, if the occupants are opening windows to control temperature.

COST: \$20 to \$50 per unit, typically.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

CHOICE OF METHOD: Are you sure you want to do it this way? As long as you are going to all the trouble of reaching the valve, why not install a thermostatic valve? Go back to [Measure 5.2.2](#) and think it over.

MEASURE 5.2.4 Ensure that convection and radiation are not obstructed by enclosures or other objects.

RATINGS

New Facilities	Retrofit	O&M
	C	

The heat flow from radiators and convectors may be obstructed by enclosures that were not originally intended. Figure 1 shows an example. This causes a loss of heating capacity, and in some cases, it increases heat loss through the building envelope. The loss of capacity may waste energy indirectly, such as overheating the remainder of the facility, causing occupants to turn on excess heating units, etc.

Heat flow may also be obstructed by objects that are placed around radiators and convectors. The problem may be obstruction of the heat output of the units or obstruction of the air flow returning to the units. Figure 2 shows both problems.

Recognize the difference between radiators and convectors when dealing with obstructed heat flow. As the name implies, convectors are designed to distribute heat almost solely by convection. On the other hand, radiators are designed to distribute heat both by radiation and by convection. Radiators have the ability to project heat far into a space, even into areas where convective

Ease of Retrofit	😊	😊	

heat transfer does not occur. For example, radiators are installed high on the walls of some industrial buildings to project heat into interior space, where the heat is needed to offset losses through the roof and floor slab.

Loss of Convective Heat Output

Convection is a relatively weak force that is easily obstructed. A problem may occur when old style

WESINC

Fig. 1 Tightly enclosed radiators The mild force of convection is unable to overcome the resistance created by these decorative enclosures. Note the electric heater in front of the unit on the left. This building, located in Chicago, suffers great heat loss from the large, leaky, single-glazed windows. Upgrading the windows, and perhaps reducing their size, should be the first step in solving this problem.

radiators and convectors are enclosed to provide a more modern appearance or to keep people from being burned by the high surface temperatures. In many decorative enclosures, the convective discharge path is adequate, but a return path is lacking. In such cases, the lack of heating capacity may be puzzling.

The proper corrective action is to provide openings of ample area for both the outlet and inlet air flow. This is usually easy to accomplish.

Loss of Radiation Heat Output

Radiators become convectors if they are enclosed or obstructed. For example, if old cast iron radiators are enclosed, they lose all radiation ability. In many such cases, this does no harm. Convective heating may be satisfactory for the space, especially where it is needed mainly to offset heat loss through the walls where the radiators are installed. However, there are situations where the loss of radiation into the space causes a problem.

Heat radiation follows line of sight, so it can be blocked by almost any type of obstruction. For example,

radiation is obstructed by furniture or pallets of merchandise. Even glass stops heat radiation. (Heat radiation from radiators has much longer wavelength than the heat in sunlight, and it is almost totally absorbed by glass.)

If the radiation mode of heat output is required, the only corrective measure is to remove the enclosure. In some of these rare cases, you may have to relocate the radiators themselves or substitute a different type of heating unit.

Related Enclosure Modifications

Coordinate this modification with [Measures 5.2.3, 5.2.5, and 5.2.6](#), as appropriate. Those Measures correct other problems related to heating unit enclosures.

ECONOMICS

SAVINGS POTENTIAL: *Up to 20 percent of the energy consumed by the affected heating units. In some cases, this activity may save a large amount of money by eliminating an apparent need for additional heating capacity.*

WESINC

Fig. 2 Obstructed convectors Air return to the convectors is blocked by the file cabinets and copy machine. Discharge from the convectors is obstructed by the table at left and by an accumulation of debris. The heat that does escape from the convectors is first confined against the uninsulated exterior wall, through which a fraction is lost. Note the electric heaters that compensate for these problems.

COST: *Varies widely.*

PAYBACK PERIOD: *Typically several years or longer, if the activity is considered strictly as an energy conservation measure. If the Measure is accomplished to improve comfort, the energy saving is a bonus.*

TRAPS & TRICKS

ANALYZE THE PROBLEM: *Before starting a lot of cabinetry work, be sure that the lack of heating is caused by the enclosure. Heating problems in steam radiators can be tricky to diagnose. However, if you see that an air return path is missing, create one.*

MEASURE 5.2.5 Avoid trapping heat output against exterior walls.

Serious energy waste can occur if draperies or other window treatments are installed so they trap the heat output of the radiator or convector against an exterior wall. This is a common problem that occurs because HVAC designers and interior decorators do not communicate with each other.

The fact that the drapery or blind may be open at the top does not avoid the problem. Energy waste results from the greater temperature against the inner surface of the wall. This increase in temperature occurs near the heating unit even if air can flow freely behind the drapery.

The problem is usually caused by draperies, but other types of obstructions can cause the same problem. For example, in warehouses, tightly stacked goods may trap the heat from radiators against the wall.

Energy Saving Potential

The amount of heat loss added by trapping depends on the thermal resistance of the surface, the increase in temperature differential, the surface area affected, and the extent of heat trapping.

The thermal resistance of the wall is the dominant factor. Glass walls are the worst, with typical R-values ranging from 0.8 (single glazing) to 1.8 (double glazing with fancy coatings). At the other extreme, well insulated walls in newer commercial buildings have R-values between 10 and 20, but such buildings are exceptional. A typical uninsulated masonry wall with a furred interior surface has an R-value of about 4.

To illustrate the effect of the increased temperature differential, consider a situation where a heavy drapery hangs over a baseboard convector. If the outside temperature is 40°F and the room temperature is 70°F, the temperature of the space between the drapery and the wall could be 100°F. The greater temperature

SUMMARY

A common problem that may waste an unexpectedly large amount of energy. The worst cases involve draperies and large windows.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

differential doubles the heat loss through the covered portion of the wall.

Also, the insulation value of the drapery ceases to be an asset and becomes a liability. A typical uninsulated masonry wall has an R-value of about 4, whereas a heavy drapery and its air layers has an R-value of about 1.0. Thus, about 20% of the insulation value is lost. In addition, the drapery now retards heat from entering the space.

Reroute the Heated Air

The solution is to relocate the drapery and/or the heating unit so that the heated air does not flow between the drapery and the wall. Or, install a fixture that deflects the output of the heating unit away from the drapery.

If the drapery must hang over the convector or radiator, consider installing a sill or deflector to divert the rising heated air toward the occupied side of the drapery. Figure 1 shows a simple device that is inexpensive, easy to install, reasonably attractive, and

Fig. 1 Convection barrier This simple, inexpensive fixture eliminates the large heat loss that occurs if the heat output of the baseboard heater is able to rise between the curtain and the window.

completely effective. If the drapery goes all the way to the floor, you will have to shorten it.

If the drapery hangs over a window sill, install a retainer to keep the bottom of the drapery entirely over the sill. Go to a plastic fabrication shop and have them make attractive retainers from transparent plastic.

Related Enclosure Modifications

Coordinate this activity with [Measures 5.2.3](#), [5.2.4](#), and [5.2.6](#), as appropriate. Those Measures correct other problems related to heating unit enclosures.

ECONOMICS

SAVINGS POTENTIAL: 3 to 50 percent of heating energy, depending on the configuration and on the thermal resistance of the wall.

COST: In new construction, this usually costs little, if anything. In retrofit applications, the cost varies greatly. It becomes expensive if window treatments have to be modified.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

IMAGINATION: This is an opportunity for creativity. Look for the simple solution that causes no new problems. For example, it is more satisfying to solve a problem with a simple deflector than to spend a fortune tearing out an expensive set of draperies and replacing them with something else.

MEASURE 5.2.6 Thermally isolate radiators and convectors from poorly insulated walls.

RATINGS

New Facilities	Retrofit	O&M
	D	

Infrared photographs of the exteriors of buildings often show bright bands of heat loss through the portions of the walls adjacent to radiators or convectors. These localized areas of heavy heat loss are caused by the increased temperature differential that exists across the walls at these points. The increased heat loss is especially severe with radiators, and less severe with convectors.

It may be economical to reduce the heat loss in the vicinity of the heating units, even if it is impractical to improve the insulation of the entire wall. This Measure offers simple techniques for reducing wall heat loss in the vicinity of radiators and convectors.

Applications and Cost Saving Potential

This Measure is most valuable in buildings that do not have effective wall insulation adjacent to the radiators or convectors. A large fraction of commercial and industrial buildings fit this description. For an example, see Figure 1.

Most older buildings with masonry walls do not have wall insulation. Modern buildings with glass walls suffer from the high thermal conductivity of glass. Many modern buildings with lightweight curtain walls have little or no insulation.

As an example of the energy waste that occurs from this localized lack of insulation, consider an area of wall three feet wide and three feet high that is adjacent to a

Fig. 1 Typical wall construction adjacent to convector
 There is no insulation between this baseboard and the short wall section. The uninsulated solid wall has little thermal resistance itself. This would have been easy to correct when the building was being designed, but it would be expensive to fix now. The single-glazed window also illustrates the architect's disregard for energy costs.

SUMMARY

A small improvement that may be worthwhile in a facility with many radiators or convectors.

SELECTION SCORECARD

Savings Potential	\$	\$

Ease of Retrofit	☺	☺	

steam radiator. If the wall has an R-value of 4, and if the temperature differential across the wall is increased by 60°F during a heating season that lasts 5,000 hours, the extra heat loss is about 700,000 BTU per year. If the cost of heat delivered by the radiator is \$4 per million BTU, the annual heat loss costs about \$3. This is not a large amount, but in a facility that has several hundred radiators, it may be worthwhile to reduce this heat loss.

The increase in heat loss is lower with convectors than with radiators, and hence the potential saving is less. Convectors transfer less heat to the wall by radiation because they operate at lower temperature. They have fins that dissipate heat effectively to the surrounding air. The amount of wall heating may be strongly affected by whether a convector has a sheetmetal enclosure or backing plate. A metal surface between the convector element and the wall reflects heat radiation away from the wall. The design of the enclosure may also tend to keep the rising warm air current away from the wall.

Estimating the Extent of the Problem

You can calculate the amount of heat loss, as in the example above, provided that you know the characteristics of the wall and the interior surface temperature. You can determine the wall construction from the architectural drawings. Measure the interior surface temperature adjacent to the heating unit by holding a thermometer against the wall under a wad of insulating material. (Do this quickly, before the accumulated heat dissipates through the wall.) Or, use a remote reading (infrared) thermometer, if you have one.

An infrared scan of the building exterior can reveal whether there is aggravated heat loss near the heating units. Infrared thermographs are visually dramatic, but they do not provide an accurate indication of the rate of heat loss. See Reference Note 15, Infrared Thermal Scanning, for more about this diagnostic method.

How to Reduce Heat Loss

Consider these methods of reducing wall heating by radiators and convectors:

- **insert insulation between the heating unit and the wall**
- **insert heat reflecting material between the heating unit and the wall**
- **move the heating unit away from the wall.** This eliminates conductive heat loss, and allows a convective air layer to form as a barrier between the heated air and the wall.

The first two methods are often inexpensive, but the third is usually too expensive to be practical. The easiest approach with freestanding radiators is to insert a board of rigid insulation behind the radiators. This insulation can have a foil face to provide heat reflection.

Select insulation that is safe for interior use and that will not break down from high temperature. This excludes all or most organic foam insulations. A good choice is glass or mineral fiber insulation, in the form of blankets or rigid boards. Unfortunately, the safest types of insulation are the bulkiest, so you usually cannot get much R-value installed. However, if the wall is uninsulated, even a modest amount of insulation may prevent most of the heat loss adjacent to the heating units. (See [Reference Note 43](#), Insulation Selection, to find the best choices of insulation for this application.)

With enclosed units that are attached to the wall, you may be able to move the unit away from the wall and insert insulation behind it. On the other hand, if the unit has rigid piping connections, this approach is probably not economical.

The high surface temperature of radiators makes it possible to reduce heat loss to walls by installing heat (infrared) reflectors between them and the walls. Any polished metal plate or film is effective for this purpose, even aluminum foil. The performance of heat reflectors degrades seriously if they become dirty. In most environments, it is not practical to keep heat reflectors

clean enough to keep them very effective. If the heating unit has a sheetmetal enclosure or backing plate, that metal surface serves to reflect heat as well as any other surface in the long term.

Another limitation of heat reflectors is that they require an air gap in front of the reflective surface. Thus, it does no go good to add a foil face to insulation that is butted against the back of a radiator enclosure.

Alternative: Wall Insulation

A more complete alternative to this Measure is improving the overall wall insulation. This is covered by the Measures in [Subsection 7.2](#). In retrofit applications, improving overall wall insulation is not often economical unless the building is going to be gutted for a major renovation.

Related Enclosure Modifications

Coordinate this activity with [Measures 5.2.3](#) through [5.2.5](#), as appropriate. Those Measures correct other problems related to heating unit enclosures.

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of heating cost. The greatest savings occur with freestanding radiators, and the lowest with convectors.

COST: Typically \$5 to \$20 per unit. The cost may be much higher if it is difficult to install the insulation.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

ANALYZING THE PROBLEM: This is not a big deal. While it is annoying to see inefficiently installed perimeter heating equipment, it may not be economical to improve it. Do the simple calculations first.

MATERIALS: Avoid the temptation to use foam board insulation. It is easy to use, but it creates toxic smoke in a fire.

MEASURE 5.2.7 With steam heating, install a vacuum condensate system to improve temperature control.

RATINGS

New Facilities	Retrofit	O&M
B	C	

One reason why people tend to open windows that are located over steam radiators is that the heat output of a steam radiator is inherently erratic at low loads. Opening the window, and turning up the radiator to make up the heat loss, makes control of the radiator more stable. Also, the window is usually easier to manipulate than the radiator valve.

The erratic control of steam radiators relates to the properties of steam. Installing a vacuum condensate system allows radiators to operate in a stable manner at much lower heat output.

Other Ways to Improve Steam Heating Control

Adding a vacuum condensate system is expensive, especially in retrofit, and it does not solve other problems of manual radiator control. Installing thermostatic control valves (Measure 5.2.2) may provide adequate temperature control because they can follow the erratic behavior of radiators. If your steam radiators do not have thermostatic valves, install them before doing anything else. Then, decide whether to install a vacuum condensate system.

An alternative that is even more expensive is converting from steam to some other heat source. In retrofit applications, the most likely candidate is conversion to hydronic heating, which is recommended by Measure 5.2.8, next.

Energy Saving Potential

This Measure provides savings primarily by reducing wasteful occupant behavior in controlling steam radiators using manual valves. The savings may be large, but they cannot be calculated with precision. See Measure 5.2.2 for the range of savings.

A major deduction from the saving is the energy required to operate the vacuum pump motor. This motor may be several horsepower or larger. It must operate continuously as long as the heating system is in operation.

Why Steam Radiators are Difficult to Control

The steam in a radiator gives up most of its heat by condensing into water. The pressure at which the steam condenses depends on the temperature of the radiator surface. If the inlet valve is wide open and the radiator is at full output, the steam condenses at the supply pressure. The supply pressures for steam radiators is typically about 10 PSI, which gives a condensing temperature of about 240°F. The condensate collects in

SUMMARY

The only way to improve the inherently erratic control of steam heating units. Not cheap and not a panacea, but less expensive than system conversion.

SELECTION SCORECARD

Reliability	✓ ✓
Ease of Retrofit	😊 😊 😊

the bottom of the radiator and is forced out through the steam trap by the pressure inside the radiator.

When less heat output is required, the occupant or the thermostatic control valve throttles the steam inlet valve, causing the pressure inside the radiator to fall. As the pressure falls, the condensing temperature falls, reducing heat output. When the temperature inside the radiator falls below the boiling temperature of water (212°F at sea level), the steam pressure inside the radiator falls below atmospheric pressure.

When the pressure inside the radiator is lower than the pressure in the condensate system, the condensate cannot exit freely. This is where stability problems begin. Condensate accumulates in the radiator. It discharges erratically as the gravity pressure of the accumulated water overcomes the pressure difference at the steam trap. When the steam trap opens to discharge condensate, air enters the radiator from the condensate system, flowing backward through the steam trap. You can see a similar situation when you turn a bottle of water upside down. The incoming air, trying to fill the vacuum above the water, interferes with the flow of water through the narrow neck.

The knocking of radiators is the result of air bursting through the pool of condensate inside the radiator. The air pressure combines with the steam pressure to produce an internal pressure that approaches atmospheric. The presence of air effectively reduces the area of the condensing surface that is exposed to steam, so it reduces the heat output. The exposed surface area is also reduced by the volume of water inside the radiator.

The situation is further complicated by the need to have an air vent on the radiator, which gets rid of air at some times and lets it enter at other times. For a given valve setting, the heat output of the radiator is continually

altered by the unstable balance of air intake, air ejection, and condensate level. This makes it practically impossible to achieve satisfactory temperature control with the manual control valves that are found on old radiators.

Basics of Vacuum Condensate Systems

As the name implies, a vacuum condensate system is one in which the pressure inside the condensate piping is less than atmospheric. By keeping the pressure in the condensate system lower than the pressure inside the radiators, the condensate can drain freely at lower steam temperatures, eliminating the causes of instability.

The vacuum in the condensate system is created by using a vacuum pump to remove air from the condensate piping. The vacuum pump is located at the condensate receiver. Typically, it is part of an equipment package that includes a small condensate receiver, a separating chamber, and apparatus to minimize the loss of water vapor along with the air that is pumped out. The package may also include condensate or feedwater pumps. Figure 1 shows all these components packaged as a unit.

The vacuum that can be produced by the vacuum pump depends on the temperature of the condensate. The condensate is always cooler than the steam inside the radiator. Condensate is cooled by flashing as it leaves the steam trap, and it is cooled by conduction as it passes

through the condensate piping. Therefore, the vacuum pump is able to maintain a lower pressure than exists inside the radiator.

The vacuum pump is limited in its ability to reduce condensate system pressure, but it can produce a pressure low enough to maintain stable operation even at greatly reduced radiator output. For example, most vacuum condensate systems can sustain a vacuum of about 9 PSI below atmospheric pressure, which corresponds to a condensing temperature of about 170°F.

Other Advantages of Vacuum Condensate Systems

The oxygen in air causes corrosion of the entire steam system, including radiators, piping, and boilers. A vacuum condensate system is totally closed, so it reduces entry of air into the steam system. Also, the rate of corrosion rises strongly with temperature, so vacuum condensate systems suffer less corrosion because they operate at lower average temperatures.

The air vents in the radiators relieve steam along with air. By reducing operation of the air vents, the vacuum condensate system reduces makeup water requirements. For this reason, a vacuum condensate system reduces water treatment costs.

Other benefits are improved steam distribution at low load and improved condensate return flow at high load. These benefits usually are not significant in retrofit applications, unless there is some problem with the piping that interferes with proper steam distribution.

How to Retrofit Vacuum Condensate

The first step is to survey the entire heating system to decide whether its condition is good enough to justify an investment in new equipment. The condition of the condensate piping is especially important, because a vacuum condensate system cannot tolerate much air leakage into the system. Test the condition of the pipe in the worst portions of the system.

Installing the vacuum equipment is usually straightforward. The receiver is small enough to be brought into the building through an existing entrance. The equipment package is usually installed near the return end of the condensate system, where the original condensate receiver is located. Location is not critical, but the vacuum receiver is heavy and it must be adequately supported.

Expect to Maintain It

If there is a significant amount of air leakage into the system, the vacuum is seriously degraded. This makes it important to maintain the entire condensate piping system to prevent air leaks. Maintaining vacuum condensate systems is covered by [Measure 1.8.6](#).

Spirax Sarco, Inc.

Fig. 1 Packaged vacuum condensate receiver This unit contains all the elements of a vacuum condensate system except the pipes. In retrofits, it can easily be substituted for the existing condensate receiver, or it can be installed at a different location in the system.

Explain It!

Unless maintenance personnel are familiar with the operation of a vacuum condensate system, they are unlikely to monitor and maintain it properly. Explain the system clearly in the plant operating manual. Install an effective placard at the condensate receiver. (See [Reference Note 12](#), Placards, for details.) The placard should state the appropriate vacuum gauge readings.

ECONOMICS

SAVINGS POTENTIAL: 10 to 50 percent of heating energy, if the occupants are opening windows to control temperature. The saving is reduced by the energy required to operate the vacuum pump.

COST: Vacuum condensate receiver packages for steam heating cost from \$5,000 to \$20,000, depending on size and features.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

PLANNING: Before deciding to install a vacuum condensate system, verify that the existing condensate system is tight and in good condition. Otherwise, you will not be able to maintain the system vacuum without continual repairs.

EXPLAIN IT: The purpose of a vacuum condensate system is not obvious. Make sure that plant operators understand how it works. Describe how the system operates in the plant operating manual. Install a placard at the vacuum pump and receiver that identifies these components and states their purpose.

MONITOR PERFORMANCE: Schedule periodic performance checks in your maintenance calendar. Include a column in the plant operating log to record the condensate system vacuum at a gauge that is installed well upstream of the vacuum pump.

MEASURE 5.2.8 Convert steam heating to hydronic heating.

RATINGS

New Facilities	Retrofit	O&M
	C	

For the reasons explained in [Measure 5.2.7](#), low-pressure steam heating systems are inherently unstable in output, making thermostatic control a problem. This problem and others have led to a preference in recent years for heated water (hydronic) heating instead of steam heating. Hydronic systems are simple, reliable, and easy to control.

Existing steam heating systems can be converted to hydronic heating with varying degrees of difficulty and expense. Conversion is a drastic step. It is economically more attractive if the existing steam system is approaching the end of its life. First, consider less expensive methods of improving the performance of the existing steam heating system. The most important of these are installing thermostatic control valves ([Measure 5.2.2](#)) and installing a vacuum condensate system ([Measure 5.2.7](#)).

Energy Saving Potential

In terms of the efficiency of the equipment itself, steam heating cannot be surpassed, because it requires no parasitic energy (pumps or fans). However, as explained in [Measure 5.2.2](#), the unstable control characteristics of steam heating systems cause wasteful

SUMMARY

Not inherently more efficient than steam heating, but avoids control and comfort problems that tend to waste energy indirectly. Consider as part of a major renovation.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	😊 😊

behavior by occupants and maintenance staff. For this reason, getting rid of steam heating can provide savings as a result of more efficient occupant behavior.

This net saving is reduced by the hydronic system's need for pumps. These typically account for a few percent of the energy consumption of the system. If the operation of the pumps is not controlled well, excess pump energy consumption can become a major cause of energy waste.

If fan-powered space heating units are substituted for the present radiators, their fans typically have a rating of 50 to 100 watts per unit. This is small in relation to the amount of conditioning energy being delivered. Still, the system should be designed to minimize fan energy consumption.

Additional Benefits of Hydronic Systems

Hydronic systems are (almost) closed systems, and they operate at lower temperatures than steam systems. Therefore, if a hydronic system is operated and maintained properly, system corrosion is virtually eliminated. This provides long system life and freedom from maintenance.

Hydronic heating units do not have the knocking and whistling that are characteristic of steam radiators. However, fan-powered hydronic terminal units have fan noise.

It is easy to regulate the water temperature of hydronic systems to adapt to the heating load. During mild weather, this eliminates localized overheating, maintains stable control valve operation, and reduces valve wear.

Conversion Issues

The major components of a steam heating system are boilers, steam piping, condensate system (piping, receivers, and pumps), and radiators. You may be able to convert some of the existing steam system components to work with hot water. Your ability to do this is a major factor in economic feasibility. Here are some factors to consider.

■ Boilers

As a practical matter, don't attempt to convert a steam boiler to a hot water boiler, unless you are attracted to the technical challenge of doing it. The practical approach is to use the steam from the present boiler to make the heating water with a heat exchanger. (A heat exchanger used for this purpose is commonly called a "converter.") You can keep the original condensate receiver and condensate (or feedwater) pumps for this purpose. This is a relatively inexpensive and neat solution.

■ Piping

The pressure inside the piping of a hydronic system may be much higher than pressure inside a steam system. The maximum hydronic system pressure is the sum of the pressure due to gravity and the pump discharge pressure. For example, the gravity pressure in the basement of a 5-story building is about 30 PSI. The pump may add another 20 PSI to this to overcome system flow resistance, for a total of 50 PSI. Compare this to a typical maximum steam pressure of 15 PSI.

In most cases, even low-pressure steam piping can handle the higher hydronic pressure adequately, but

make a thorough inspection of the existing piping to be sure. Water is much denser than steam, so the original pipe sizing will be adequate for the water flow. This minimizes the pump power that is required.

■ Alternative Heating Units

If you convert from steam heating to hydronic, and you need to get the same heat output at each unit, you will need to replace the radiators with units that are designed to operate with hot water. The usual choices are:

- **baseboard convectors.** These are a favored choice for many applications because they are inexpensive, quiet, dirt-free, and unobtrusive. They use finned tubes, which provide adequate heat output despite their lower operating temperature and lack of radiation heat transfer. Convectors are limited in their ability to emit heat, so you will probably have to replace the localized radiators with long runs of baseboard convectors.
- **fan-coil units,** which use a fan to circulate air. Using a fan and finned coils provides large heat in relation to the size of the unit. Also, the same unit can be used to provide both heating and cooling.
- **unit ventilators,** which are heating fan-coil units that have an outside air intake through the adjacent wall. These are appropriate if adequate outside air intake is not available from other sources. The wall penetrations are an invitation to excessive infiltration, and to freeze problems.

■ Converting Steam Radiators

There are two applications in which you may want to retain the old radiators. One is the renovation of historic buildings. The other is using the original radiators as an item of the decor. You may be able to retain the radiators as heating units for hydronic heating if the building envelope is well insulated. Older buildings that use steam radiators typically lose most of their heat through windows that have high heat loss, both from conduction and air leakage. Installing efficient windows in such buildings may reduce window heat loss to one half or one third of its original amount.

Consider additional steps to reduce envelope heat loss, such as reducing the window area by installing insulating panels to fill part of the window openings. Also, consider improving the wall insulation, although walls usually account for only a small fraction of heat loss in buildings with a large amount of glass area. Refer to [Sections 6 and 7](#) for Measures to reduce envelope heat loss. It is a mistake to spend a lot of money upgrading the heating system without also taking economical steps to reduce heat loss.

With a certain amount of ingenuity, you can convert a steam radiator to operate with hot water. However, steam radiators lack the internal circuiting necessary to extract heat efficiently from water. Also, the heat output

from the surface of a radiator increases exponentially as the surface temperature increases. Radiators typically are rated at 1 PSIG steam pressure, which corresponds to about 217°F at sea level. In contrast, hydronic systems typically operate at a temperature no higher than about 200°F. This factor alone represents a significant loss of capacity.

A radiator that is operated with a low surface temperature loses most of its radiating ability, so it tends to behave as a convector. This is acceptable if the unit is intended to offset conductive heat loss through the wall or window where it is mounted. However, it will be a problem if the radiator is intended to emit heat deep into the space, for example, to offset the roof heat loss.

■ Pumps

Since the original steam system does not use pumps, you need to add pumps to circulate the heating water. The pumps typically are small, both in power and physical size. Connecting them into the system is straightforward.

If different portions of the facility require heating on different schedules, consider subdividing the piping system into appropriate zones, with each zone having its own pumps. You can save energy by avoiding the heating of vacant areas, and by minimizing total pump power. The Measures in [Subsection 5.1](#) recommend methods that you can use to control such arrangements.

■ Expansion Tank

The water in a hydronic system expands and contracts as its temperature changes, so a hydronic system requires an expansion tank. If you use an open, vented expansion tank, it must be located at a high point in the system. You can install a pressurized expansion tank at any level. The former approach is foolproof, the latter is not.

Air can enter the water through the expansion tank, if the air and water come into direct contact. The oxygen in the air causes system corrosion. With a vented tank, air dissolves into the water slowly. In a pressurized tank, air dissolves much more quickly. For this reason, a pressurized expansion tank should have an internal membrane to separate the air from the water.

■ Thermostatic Controls

You may be able to salvage the existing thermostatic controls, provided that they are not of the self-contained type. Make this a factor in selecting the type of heating units. It is expensive to replace thermostats and run connections between the thermostats and the heating units.

Install controls at the boiler or heat exchanger to reset the supply water temperature. This eliminates overheating during mild weather, provides stable operation of the throttling valves on the heating units, and extends the life of throttling valves by keeping them from operating in a barely-open position.

ECONOMICS

SAVINGS POTENTIAL: 10 to 50 percent of heating energy, if the existing system causes occupants to open windows to control temperature. Savings are reduced by the energy required to operate the system pumps. If fan-powered space heating units are installed, the fans add a small percentage of energy consumption.

COST: Varies widely, but expensive in all cases.

PAYBACK PERIOD: Several years or longer. The modification may be desirable largely for comfort and maintenance reasons.

TRAPS & TRICKS

PLANNING: The cost of conversion depends on the condition of the existing equipment. To be worth salvaging, the boilers and piping should have many years of useful life remaining. Be brutal in your inspection. Remove lengths of steam and condensate pipe from various parts of the system and cut them apart for inspection. Make a meticulous inspection of your existing steam boilers. If you are considering converting old steam radiators (a nice "deco" touch for some environments), calculate whether they are able to deliver sufficient heat. At the same time, consider improvements to the building envelope. It is far better to spend money to reduce heat loss than to spend the same amount for additional equipment to overcome the heat loss.

MEASURE 5.2.9 Replace electric resistance convectors with heating units having lower energy cost.

RATINGS

New Facilities	Retrofit	O&M
B	D	

Convectors with electric resistance heating elements are widely installed because the equipment and the installation are cheap. The penalty paid for this cheapness is high operating cost, unless electricity prices are exceptionally low. In most areas, electric resistance heat is much more expensive than fuel heat, per unit of heat delivered to the space.

If other available energy sources are less expensive than electric resistance heating, consider substituting another heating energy source. There are many options. The choice has a major effect on equipment and space requirements, installation cost, occupant conditions, and other factors. The selection of heating method may also affect your choice of cooling method.

Energy and/or Cost Saving Potential

Making an estimate of the savings in energy and cost is not simple. The historical record shows that the relative prices of different energy sources fluctuate over a wide range. The best long-range estimate is obtained by understanding the underlying relationships in energy prices. This is a complex matter, and it involves great leaps of assumption by even the most knowledgeable experts. See [Reference Note 21](#) for the basics of electricity pricing.

■ **If You Convert to Fuel-Fired Heating**

If you substitute fuel-fired heating for electric resistance heating, the saving results from the lower unit cost of energy. When making the cost comparison, you must factor in the efficiency of your fuel-burning equipment. Fuel-burning equipment and systems have efficiencies ranging from 55% to 90%. Losses are caused by boiler inefficiency, auxiliary energy requirements (pumps and fans, mostly), and heat leakage from distribution systems. In contrast, electric resistance heating is usually more than 95% efficient, the losses being limited to electrical distribution losses on the customer's side of the electric meter.

■ **If You Convert to Heat Pumps**

If you substitute heat pumps for electric resistance heating, the saving results primarily from reducing the amount of electricity you need to purchase. The cost of electricity is not entirely proportional to the amount used, as the price of electricity for commercial customers is usually tied to the consumption profile. Heat pumps have a higher ratio of peak consumption to average consumption than electric resistance heating, which raises the average price per kilowatt-hour.

The energy savings provided by heat pumps depend very much on climate and the type of heat pump. Air-

SUMMARY

May radically reduce heating costs. Expensive to retrofit. Be shrewd in selecting the replacement system.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return, New Facilities	% % %
Rate of Return, Retrofit	% %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	☺ ☹

source heat pumps become less efficient as the outside air temperature drops, and at a certain temperature, the heat pump ceases to operate and heating is provided by a resistance heating element. In a relatively warm climate, such as the southern United States, air-source heat pumps may save substantially more than one half of the energy consumed by resistance heating. In cold climates, such as the northern United States, air-source heat pumps save substantially less than half.

A major new market for heat pumps is being opened up by units that use alternative heat sources and heat sinks, including the earth, ground water sources, and bodies of surface water. The anticipated benefit is to increase the potential efficiency of all heat pumps and to make heat pumps useful in much colder climates. See [Reference Note 22](#) for details.

Fuel Availability

If there has not been a shortage recently, people tend to forget that fuel supplies can be cut off. In most locations, electricity is most likely to be available during an energy crisis, while oil or gas may be curtailed. Therefore, if a fuel-fired system is substituted for electric heating, give preference to systems that can burn several fuels. The combination of oil and gas is a good choice because it is unlikely that both fuels will become unavailable at the same time. The ability to burn multiple fuels also makes it possible to exploit changes in relative fuel prices.

Which fuels are available at the site to substitute for electric resistance heating? Oil is available almost everywhere. The major variable is whether natural gas is available at the site. This may not be a simple yes-or-no issue. Gas companies may be willing to install a pipeline where none exists, provided that the anticipated gas consumption is large enough. A request by a large

potential customer may motivate a gas company to extend service into the locale to serve other customers as well.

Do not overlook propane as a fuel in locations where its pricing is favorable. Transportation limitations result in propane being available at relatively low cost in the vicinity of refineries. By the same token, the price of propane is less stable.

Alternative Heating Equipment

Eliminating electric resistance heating opens up a large field of possible replacements. The most important criteria are efficiency, fuel cost, installation cost, and comfort features. Here are some key points in selecting the best replacement.

■ Air-to-Air Heat Pumps

Heat pumps provide cooling as well as heating. This is a major factor in deciding whether to make the change, and how to make it. The economic payback of this Measure may be greatly improved if heat pumps also replace cooling units that are defective or near the end of their service lives.

Air-to-air heat pumps can be expensive to retrofit. They require openings through the exterior walls. They are much bulkier than electric resistance units, so rentable space is reduced somewhat. And, they make noise. You need to provide condensate drains for both the indoor and outdoor coils. As explained previously, the efficiency and cost savings of air-source heat pumps diminish seriously in colder climates.

On the positive side, there is no need to run piping or additional wiring to install air-to-air heat pumps. The existing wiring has sufficient capacity because the heat pumps use less electricity than the resistance heaters they replace.

Select heat pumps for high efficiency in both heating and cooling. A large range of efficiencies exists in the market. [Measures 5.4.5](#) and [5.5.3](#) will help you select heat pumps.

■ Hydronic Heat Pumps

Hydronic heat pumps are similar to air-to-air heat pumps in their efficiency characteristics, but they are similar to fuel-fired systems in their installation requirements. There are two major variations in hydronic heat pumps. In one, each space has an individual heat pump, and heat is transported to or from the space units through water piping. In the other configuration, one or more large heat pumps serve the entire facility, and heat and cooling is transmitted through water piping.

The fact that hydronic heat pumps use water as a heat transfer medium allows a number of efficiency enhancements to be added to the system. These include:

- **cooling towers**, to improve cooling efficiency by exploiting evaporation
- **buried evaporators** (“earth-source heat pumps”), to improve heating effectiveness in cold climates. This feature may substantially improve efficiency, but it has serious practical difficulties. See [Reference Note 22](#), Low-Temperature Heat Sources and Heat Sinks, for details.
- **ground water sources** to improve the efficiency of both cooling and heating. This feature is proven to be effective, but increasingly runs afoul of environmental and water conservation restrictions. See [Reference Note 22](#) for details.
- **heat storage**, which is useful if a facility requires cooling during the daytime but heating at night
- **heat movement** from the core of the building for use in heating the perimeter. This is a difficult configuration to make efficient. See [Subsection 5.6](#) for details.

One disadvantage of hydronic heat pumps is that they require additional energy to operate the pumps. Pump energy consumption tends to get out of hand in some of the more elaborate designs.

Using hydronic heat pumps efficiently requires a good deal of study and analysis for each application. Hydronic heat pumps provide large efficiency gains in some applications, but they provide little benefit in other applications. See [Subsection 5.6](#) for details of these systems.

■ Hot Water Heating

Modern water boilers offer high fuel burning efficiency. Gas-fired boilers are especially efficient, if you select the condensing type. For details, see [Reference Note 30](#), Boiler Types and Ratings, and the Measures related to boiler selection.

Hydronic heating is relatively easy to distribute through small water pipes. In retrofit, the cost and difficulty of installing the pipe may be the largest part of the cost.

Hot water heating is usually done by installing some type of terminal unit in each space, which may be a convactor, a fan-coil unit, or a unit ventilator.

You can use a hydronic distribution system to distribute both heating and cooling, provided that the terminal units are suitable.

■ Forced-Air Furnaces

You can use an air distribution system for both heating and cooling. Unlike the other heating methods, forced air heating does not allow good thermostatic control of individual spaces unless you resort to unusual features. Retrofitting forced air distribution may be difficult. It is easiest in relatively open space layouts, such as manufacturing facilities and open-ceiling shopping malls.

■ Individual Fuel-Fired Heaters

Fuel-fired heaters for individual spaces take the form of overhead unit heaters, radiant heaters, freestanding

furnaces, and wall-mounted furnaces. Don't assume that fuel-fired space heaters are limited to industrial applications. Particular models may be acceptable in many types of commercial space, including offices. The major installation issues are venting the combustion products, supplying combustion air, and supplying fuel. [Subsection 5.7](#) deals with fuel-fired space conditioning units.

ECONOMICS

SAVINGS POTENTIAL: *If heat pumps are installed, 35 to 65 percent of electrical energy, with a somewhat smaller reduction in electricity cost. If fuel-fired heating is installed, the energy cost saving varies radically with fuel type and locale, and is typically from 30 to 70 percent.*

COST: *Depends on the type of equipment and the difficulty of installation. For example, gas furnaces cost \$7 to \$20 per MBH capacity, in typical sizes, plus installation. The price premium for condensing furnaces, compared to non-condensing furnaces of average efficiency, ranges from 50% to 80%. Smaller vented gas heaters for individual spaces cost from \$15 to \$30*

per MBH, plus installation. Small air-to-air heat pumps typically cost from \$25 to \$50 per MBH, plus installation, but these provide cooling also.

PAYBACK PERIOD: *Several years, or longer.*

TRAPS & TRICKS

GUESSING ENERGY COSTS: *This Measure is motivated entirely by energy cost, since nothing is more efficient than an electric resistance heater, at least when considered within the boundaries of the facility. This Measure takes at least a few years to pay off, and you want it to remain viable, so you must enter the Great Game of predicting relative energy costs and availability far into the future. This takes specialized knowledge, historical perspective, and chutzpah.*

SELECTING THE EQUIPMENT: *All conventional types of heating and cooling equipment are reliable if you select intelligently. However, unconventional equipment, such as earth-source heat pumps, is plagued by reliability problems and misrepresentation. Refer to the Measures or Reference Notes dealing with any unconventional energy sources that you are considering. By the same token, do not dismiss promising equipment just because it is unconventional. Decide how much pioneering you are willing to do.*

MEASURE 5.2.10 Provide separate thermostatic control for each area with distinct heating requirements.

RATINGS

New Facilities	Retrofit	O&M
A	D	

Convectors typically are connected end to end, allowing an unlimited length. This tempts designers and contractors to control great lengths of convector with a single thermostat. Succumbing to this temptation can prevent separately occupied spaces from being shut down individually, and it keeps them from being controlled comfortably. For example, a common problem in office buildings is that one thermostat is installed to control a great length of perimeter, and later partitioning creates separate spaces that are under the control of the one thermostat.

The discomfort within localized areas motivates occupants to set a higher average temperature for the entire area served by the convectors. Some occupants may open windows to vent the heat. Even within a single space, it may not be satisfactory to control all the heating units together. For example, control a heater located near an exterior door separately from the other heaters.

SUMMARY

A control improvement for hydronic and electric convectors that typically saves a modest amount of energy, and may substantially improve comfort.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊		

Hydronic heating units have an additional problem when a number of them are connected in series. The hot water cools as it flows from one unit to the next, so

WESINC

Fig. 1 An extraordinarily stupid thermostat installation

These thermostats control three sections of electric baseboard convectors in three areas. Installing them here, rather than in those areas, makes them useless for control. The thermostats are located next to a south-facing window, so they cut off heating when the sun shines on them. The window is single-glazed, so the thermostats overheat the spaces at other times. The locking cover makes it impossible for the occupants to adjust the thermostats to compensate.

that the downstream units produce less heat than the upstream units. This aggravates the problems.

The amount of energy waste from these causes varies widely, and it is often difficult to estimate. In general, heating units should have separate thermostatic

control if lack of separate control may cause a comfort problem or prevent shutting down an unoccupied space.

How to Provide Individual Control

The corrective measure is to subdivide thermostatic control of the convectors and radiators. Install as many individual thermostats as necessary to provide satisfactory local control of heating. Coordinate the thermostat installations with appropriate Measures of [Subsection 5.1](#) to allow heating of individual spaces to be turned off separately.

The way that thermostats are installed is important. Each thermostat should be installed where it accurately senses the temperature within the space that is being heated by its corresponding heating unit. Space air should be able to circulate freely through the thermostat. The thermostat should not be under the influence of any source of heating or cooling, such as sunlight shining on a wall, the discharge from a conditioning unit, or nearby equipment. In addition, see [Measure 5.1.1](#) about proper marking of thermostats. Figure 1 shows that some people in the heating business are thoughtless enough to violate all these requirements.

With hydronic convectors, you have to install additional piping to change the series flow to parallel flow. If a large number of heating units are served by the same supply pipe, install a reverse return to balance flow resistance without resorting to balancing valves. See [Measure 5.2.2](#) about thermostatic control valves for hydronic units.

ECONOMICS

SAVINGS POTENTIAL: Typically a small fraction of heating cost. Savings may be larger if comfort problems result in wasteful behavior, or if the Measure allows shutting down heating in vacant spaces.

COST: \$100 to \$1000 per heating unit, depending on the need for piping changes, trim changes, occupant displacement, etc.

PAYBACK PERIOD: Several years or longer.

Subsection 5.3

Fan-Coil Units

Fan-coil units are conditioning units for individual spaces that provide heating, cooling, or both. Units may be mounted in freestanding cabinets, inside walls, in ceiling plenums, or in other locations. Fan-coil units usually discharge air directly from their enclosures, although some may have rudimentary ducts for air distribution.

As the name implies, the main components of fan-coil units are a fan and one or two coils. Units may have separate heating and cooling coils, or a single water coil may be used for both functions. The coils may operate with hot water, chilled water, electric resistance, or rarely, steam. (Units with refrigerant coils are considered to be part of “split systems,” and they are covered in [Subsection 5.5](#)).

The output of a fan-coil unit can be controlled by cycling the fan, by controlling the speed of the fan, by throttling the flow of water in the coil, or by turning electric coils on and off. Units typically have control panels to allow occupants to select heating or cooling, to select the fan speed, and to control outside air ventilation, if any is available. Automatic controls may shut off flow through hydronic coils when the fan stops, and they may perform other functions. The fan-coil unit may have thermostatic controls that are entirely self-contained, or the fan-coil unit may have actuators that are powered by external thermostats.

Fan-coil units that are designed to provide a large amount of outside air ventilation are called “unit ventilators.” Unit ventilators are combined with relief air fans to provide positive control of outside air intake, maximize ventilation capacity, and direct the air flow. Consider the unit ventilator and its relief fan as an integral system.

The Measures in this Subsection improve the efficiency of fan-coil units. [Measures 5.3.1](#) and [5.3.2](#) are maintenance activities that are important for maintaining energy efficiency. [Measures 5.3.3](#) and [5.3.4](#) are improvements that apply to all kinds of fan-coil units in particular applications. [Measures 5.3.5](#) through [5.3.7](#) recommend major system modifications.

MEASURE 5.3.1 Clean, adjust, lubricate, and repair fan-coil units at appropriate intervals.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

Fan-coil units are reliable if they are not abused. The maintenance they need consists mostly of cleaning and filter replacement. Other maintenance requirements depend on their specific design. Give these items attention at regular intervals:

- **filters and filter mountings.** Letting filters get clogged reduces conditioning capacity and causes fans to operate at higher power. In time, the filter will collapse because of the pressure difference across it, allowing dirt to accumulate on the coils. A common maintenance defect is improper fit of filters into the filter holders. Unless the fit is tight, dirt bypasses the filter and collects on the coils. The person who maintains the filters has to be careful to select the proper filter, and to insert it properly. See Figure 1.
- **coils.** The items to check are cleanliness and fin spacing. You can clean coils with a vacuum cleaner or with compressed air (in the reverse direction). In extreme cases, you need to wash out a dirty coil with detergent and a brush. Straighten bent fins with a fin rake.
- **coil condensate drain pans and lines.** Condensate pans, shown in Figure 2, are clogged by debris and by slime that grows in the condensate. Condensate

SUMMARY

Basic maintenance items that prevent energy waste, maintain comfort, prevent health problems, and extend equipment life.

SELECTION SCORECARD

Savings Potential	\$ \$
Rate of Return	% %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

accumulation is a health hazard because it breeds microorganisms that are discharged into the surrounding air.

- **fan impellers** should be checked for balance, and for missing and bent blades. The cheap plastic impellers used in modern fan-coil units are easily broken by pens and other items that fall into the unit. Keep impellers clean to maintain their efficiency. Figure 3 shows a method of cleaning fan impellers. Be aware that cleaning an impeller may increase fan noise noticeably, because the dirt deadens noise.

Trane Company

Fig. 1 Filter maintenance The most important routine maintenance for fan-coil units. People hate to do it because it is awkward and messy. Failing to insert the filter properly is a common problem.

Trane Company

Fig. 2 Coil drain pan The pan must be cleaned out completely. A small amount of stagnant condensate allows colonies of organisms to grow, and these clog the drain and cause health problems.

Fig. 3 Tool for cleaning fan impellers A brush taped to the end of a vacuum cleaner crevice tool works well. Be careful not to bend or break flimsy impeller blades.

Carrier Corporation

Trane Company

Fig. 4 Outside air dampers in a unit ventilator The long, slender blades are vulnerable to damage. Be sure that dampers operate freely and that they close tightly.

- **fan motor lubrication.** If the fan motors are not permanently lubricated, oil them at appropriate intervals.
- **outside air ventilation dampers**, shown in Figure 4, have a major effect on energy consumption and comfort. Adjust them as well as possible. In many units, they are flimsy and they may fail to close properly. In some cases, the dampers may be jammed or limited in their motion by the way the fan-coil unit was installed. Correct such defects.
- **occupant controls**, such as fan speed switches and function buttons, are often flimsy. Inspect them periodically and repair them as necessary.
- **coil valves may leak**, causing the coil to consume energy even when it is turned off. In units that have both heating and cooling coils, valve leakage wastes energy by mixing hot and cold air.
- **steam traps** are used with steam coils, and they eventually fail. Inspect them annually, at the start

of the heating season. Steam traps are covered in [Measures 1.10.3](#) and [1.10.4 ff.](#)

- **air eliminators** are used with steam coils to vent air that accumulates inside them. They are automatic devices similar in construction to steam traps. If they stick open, they waste steam. If they stick closed, the coil fills with air, loses capacity, and becomes uncontrollable.

ECONOMICS

SAVINGS POTENTIAL: Usually a small fraction of conditioning energy. In fan-coil units, maintenance is more important to comfort and health than to efficiency.

COST: \$3 to \$30 per unit per year.

PAYBACK PERIOD: Short.

TRAPS & TRICKS

DILIGENCE: This kind of maintenance tends to be forgotten unless it is managed effectively. Schedule it in your maintenance calendar and make sure that it gets done.

MEASURE 5.3.2 Select high-efficiency motors in new fan-coil units and when replacing failed motors.

RATINGS

New Facilities	Retrofit	O&M
B		A

The motors used in fan-coil units typically are multi-speed shaded-pole or permanent-split-capacitor motors. The motors are small, typically drawing 50 to 200 watts, depending on the fan speed settings. Figure 1 shows a typical unit.

Small size and lack of efficiency standards make the efficiencies of these motors much lower than for larger motors. Efficiencies typically range between 25 and 65 percent. Significant improvements in motor efficiency in this size range began during the 1980's, so replacing older motors with high-efficiency units can offer improvements of 10 to 30 percent. Refer to [Measure 10.1.1](#) for more about motor efficiency.

High-efficiency fan motors have become available as an option with many models of new fan-coil units. Exploit this option when installing new fan-coil units.

It is not economical to replace a small functioning motor for the sake of improving efficiency. This is because the cost of a small motor is high in relation to the amount of energy that it consumes. Instead, let existing motors serve out their lives, and establish a reliable procedure for replacing defective fan motors with high-efficiency models.

Be Prepared Ahead of Time

Replacing failed motors with the most efficient available replacement motors is a management

Trane Company

Fig. 1 Fan motor The motor is small, but it operates for many hours. Upgrade efficiency wherever practical.

SUMMARY

High-efficiency motors for fan-coil units are an emerging option. Be ready to replace failed motors with high-efficiency units.

SELECTION SCORECARD

Savings Potential	\$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

challenge. The toughest part is ensuring that maintenance personnel remember to get the right motors at the unpredictable times when they will be needed. Otherwise, the failed motor will be replaced with any motor that fits. Don't expect the mechanic who picks up the motor to do a detailed analysis to find the most efficient model. You have to identify the appropriate replacement motor models in advance and find out where you can get them in a hurry.

If the facility has many similar fan-coil units, keep a number of high-efficiency motors as spares. This lets you order the motors for best efficiency and price, at your leisure. Also, it minimizes delay and waste of effort when making repairs.

ECONOMICS

SAVINGS POTENTIAL: From 10 to 30 percent of the energy consumed by the fan motors.

COST: Small high-efficiency motors may cost from 10% to 50% more than less efficient models. The cost premium for smaller high-efficiency motors is changing as pricing policy and efficiency standards evolve.

PAYBACK PERIOD: Several years, typically. Depends on motor size and operating hours.

TRAPS & TRICKS

TIMELY PREPARATION: In existing facilities, the main challenge is remembering to install a high-efficiency replacement motor when the time comes, and being ready to do it. Identify vendors who can provide your selected motor models on short notice. If you have many motors of a particular size and type of service, keep at least one spare in stock. Make sure that all maintenance personnel, including those who work the late shift, are aware of the procedure. Designate the selected models and vendors in the plant operating manual. State where the spare units are stored.

MEASURE 5.3.3 Keep conditioned air from discharging on windows and exterior walls.

RATINGS

New Facilities	Retrofit	O&M
A	C	

If a conditioning unit blows directly on the interior surface of a window or an exterior wall, heat loss through the window or wall is greatly increased. This is because conductive heat loss is proportional to temperature differential, and discharging directly on the wall raises the temperature differential across the wall. Also, the air blowing on the surface destroys the insulating air layer that attaches itself to the wall surface.

This problem is worst if draperies or other window treatments trap the discharge against windows. Figure 1 shows an example. Other types of obstructions can cause the same problem. For example, in warehouses, goods may be stacked tightly in front of a conditioning unit. This causes the unit to operate more intensely in order to heat or cool the space. While doing so, it increases heat loss through the wall.

If the windows allow air leakage, this may greatly increase the heat loss. The most extreme energy waste occurs if the fan-coil unit can discharge toward an open window, as in Figure 2.

Fig. 1 Discharge trapped by drapery Almost all the heating output of this unit is discharged between the drapery and a large window. Much of the heat is lost by conduction through the window, and the small insulating value of the drapery is lost.

SUMMARY
 Corrects a common, unexpected cause of heat loss. Draperies are likely to cause the problem, or to aggravate it.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	

In most cases, you can eliminate or greatly reduce these types of energy waste with simple changes.

Energy Saving Potential

■ **Conductive Heat Loss**

The additional heat loss depends on the thermal resistance of the surface, the discharge temperature of the fan-coil unit, and the amount of surface area that is affected.

If a drapery or other window treatment hangs above the fan-coil unit, it can greatly increase the area of the

Fig. 2 Discharge to an open window Much of the heating or cooling energy goes directly outdoors through this library window. And, books may block the discharge to the space. Another case where the architect did not talk to the engineer. There are several possible solutions.

wall or window that is affected. For example, if the outside temperature is 40°F and the room temperature is 70°F, the temperature differential is 30°F. Now, assume that a fan-coil unit discharges air at 140°F toward the wall. This air is trapped between the drapery and the wall, raising the surface temperature of the wall to 100°F. This doubles the temperature differential across the wall, and doubles the conductive heat loss.

In addition, the insulation value of the drapery itself is lost. A heavy drapery and its air layers has an R-value of about 1.0, which could account for a large fraction of the total thermal resistance of a window or a poorly insulated wall.

The thermal resistance of the wall determines the heat loss in absolute terms. Glass walls are the worst, with typical R-values ranging from 0.8 (single glazing) to 1.8 (double glazing with fancy coatings). At the other extreme, well insulated walls in newer commercial buildings have R-values between 10 and 20, but such buildings are exceptional. A typical uninsulated masonry wall with a furred interior surface has an R-value of about 4.

■ Loss of the Insulating Air Layer

Any vertical surface in relatively still air has an air layer attached to it that has an R-value in the range of 0.4 to 0.8. The direct discharge of a fan-coil unit is strong enough to scrub this air layer away, reducing the thermal resistance of the surface. The effect is especially significant with glazing, where the air layers on each side provide a large fraction of the total thermal resistance. With well insulated walls, the loss of the air layer matters much less than the increase in temperature differential.

WESTINC

Fig. 3 Simple, effective baffle on a fan-coil unit This piece of flat clear plastic is bent to form a flange that is screwed to the top of the unit. It keeps the unit's air discharge from blowing behind the curtain and being trapped against the window.

■ Solar Heat Gain in Window Treatments

Curtains, blinds, and other interior shading devices absorb a significant amount of heat from the entering sunlight. Some of this heat is returned to the outside by a combination of radiation from the shading device and conduction through the window glass. If the fan-coil unit forces conditioned air through the space between the window and the shading device, the air picks up much of the absorbed heat. If the space requires heating, this effect saves energy. If the space requires cooling, this effect wastes energy.

■ Air Leakage

If the windows are leaky, blowing air against them increases leakage considerably because of the velocity pressure of the air. Furthermore, since the air from the fan-coil unit is warmed (or cooled), it carries away more energy than an equal amount of air from the space.

If a conditioning unit blows toward an open window, as in Figure 2, a large fraction of the heating or cooling energy is lost directly to the outside.

How to Avoid This Problem

In new construction, if the potential problem is draperies or window treatments, you can get models of fan-coil units that extend into the room and underneath curtains. Check with the interior designer. Bear in mind that the interior decor may change over the life of the building.

If the fan-coil unit is to be installed under a window, the window design can minimize the problem. If the wall is reasonably thick and the windows are installed flush with the outside surface of the wall, this leaves a space for installing curtains or other window treatments next to the window, without extending out over the fan-coil units. (Aside from this, the window design should exploit the Measures in [Subsections 6.3, 7.3, 8.1, 8.3, and 8.4.](#))

In retrofit applications, the appropriate corrective action depends on the present installation. Most fan-coil units have louvers that control the direction of air discharge. These are usually adjustable. The trick is to fix them in position so that air does not discharge on the window or wall, and also does not cause an unwanted draft in the space. Once the louvers are adjusted properly, fasten them in place. You may be able to do this with a few sheetmetal screws.

In some cases, you may have to install an external baffle to direct the air discharge. Figure 3 shows an effective and inexpensive type of baffle that is widely applicable.

If there is a problem with heat trapping by draperies or other window treatments, use solutions similar to those recommended by [Measure 5.2.5.](#)

Comfort Dilemma with Poorly Insulated Walls

If a large fraction of the envelope surface is poorly insulated, e.g., if the building has a glass curtain wall, reducing the heating of the surface creates a comfort dilemma for occupants close to the wall. In order for a person to feel comfortable, heat loss from the person's body must be limited. Heat is lost both by conduction to the surrounding air and by radiation. If there is a large cold surface nearby, the person will feel chilly even though the air temperature would normally be comfortable. Therefore, designers locate heating units where they warm surfaces that have high heat loss.

To a certain extent, you can compensate for colder walls by increasing the space temperature. However, this makes people far inside the space too warm, and it increases heat loss elsewhere. Cold walls are an intractable comfort problem. The only solution that is entirely satisfactory is improving the insulation value of exterior surfaces. See [Subsection 7.2](#) for the methods.

(Unfortunately, cold and leaky walls are a common problem in modern architecture, proliferated by a misconception that envelope integrity is unimportant in

large buildings. Someone observed that larger buildings have a higher ratio of interior volume to surface area, so that the total heat gain of the building may be positive, even in cold weather. This may be true, but it provides no comfort for people in the perimeter zones.)

ECONOMICS

SAVINGS POTENTIAL: 3 to 50 percent of heating energy. Depends on the amount of wall or window area affected, the thermal resistance of the surface, the discharge temperature, and the extent of heat trapping.

COST: In new construction, this activity is mainly a matter of thoughtful equipment layout and selection, and it should add little cost. In retrofit, the cost is usually modest, unless you have to modify or replace window treatments.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

INGENUITY: A simple, neat solution is often possible. Make it permanent, and don't create a comfort problem.

MEASURE 5.3.4 Install thermostatic controls that allow space temperature to drift within comfortable limits.

In most HVAC applications, comfort does not require a fixed space temperature. People remain comfortable within a range of temperatures. You can save energy by using thermostatic controls that turn off

heating and cooling within this temperature range. There are several ways to do this. See [Measures 4.3.4 ff](#) for the details.

RATINGS		
New Facilities	Retrofit	O&M
A	B	B

MEASURE 5.3.5 Convert 3-pipe systems to 2-pipe operation.

In “three-pipe” hydronic systems, each fan-coil unit is provided with a separate heating water and chilled water supply. This allows each unit individually to select either heating or cooling operation. However, the system uses a single common return line for both heating and cooling water, as shown in Figure 1. Using a common return line is intended to save the cost of separate return pipes for heating and cooling.

Three-pipe systems are an extreme example of false economy. The water returning from the heating coils retains a majority of its original heat energy. Similarly, the water returning from the cooling coils retains a large fraction of its original cooling energy. This does not waste energy if all the spaces in the building are being heated, or if they are all being cooled. However, if some spaces are being heated and others are being cooled, the return heating water and return cooling water are mixed in the common return line. This cancels out a large amount of energy.

The water that returns to the boiler may be cool, creating enormous thermal stresses in the boiler. Similarly, from the standpoint of the chiller, the return water is much warmer than normal. In effect, the boiler and chiller are feeding each other through the fan-coil units.

Energy Saving Potential

Three-pipe systems waste energy only when some fan-coil units are cooling while others are heating. Typically, this situation is limited to mild weather. However, if there are large heat load differences among spaces, simultaneous heating and cooling may occur during much of the year. This situation is especially common in buildings that have a large fraction of exterior glazing, and in buildings that have core zones. Let’s look at several examples that illustrate the amount of energy waste that can be eliminated by getting rid of three-pipe operation.

First, consider a situation in which the heating and cooling loads are equal. The supply water temperature is 165°F and it returns at 145°F. At the same time, the chilled water is supplied at 45°F and returns at 55°F. A little calculation shows that the boiler load is four times higher than the actual space heating load, and the chiller load is four times higher than the actual space cooling load. In other words, three fourths of the energy produced by the boiler and chiller is wasted.

Next, consider a situation in which the heating load is ten times larger than the cooling load, with the same temperature differentials as before. In this case, the boiler is forced to produce 75% more output than the

SUMMARY

The least expensive way to eliminate the large energy waste that occurs in this type of system. Eliminates occupants’ ability to switch between heating and cooling.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	☺	☺	☺	

space heating load, and the chiller is forced to produce 850% more output than the space cooling load. This energy waste might escape attention because the boiler and chiller are both operating at relatively small fractions of full load.

Similar energy waste results when the cooling load is much larger than the heating load. Obviously, it would take only a few months per year of overlapped heating and cooling operation to double the energy cost of the facility. That’s a lot of energy wasted to save the cost of some pipe.

How to Eliminate the Energy Waste

■ **Method 1: Interlock Boiler and Chiller Operation**

The cheapest solution is simply to operate the boiler and chiller so that they do not feed the fan-coil units simultaneously. However, relying on an operating procedure alone is bound to fail. The only way to reliably avoid simultaneous heating and cooling is to connect the equipment in such a way that it cannot occur.

■ **Method 2: Abandon One Supply System**

The simplest reliable modification is to convert the three-pipe system to two-pipe operation. This is a relatively cheap solution in which one of the two supply lines is abandoned, so that all the fan-coil units are connected either to the boiler or to the chiller, but not to both simultaneously.

With luck, converting the fan-coil units should be relatively easy. The cost of the change is mostly for additional piping to connect both the boiler and chiller to the same supply pipes, plus valves to switch between the boilers and chiller.

■ **Method 3: Zone Changeover**

The disadvantage of Method 2 is that it eliminates the ability of spaces or groups of spaces to select heating

or cooling individually. This disadvantage can be eased by using zone changeover valves, as shown in Figure 2.

As in Method 2, each riser is converted to two-pipe operation. But in addition, each riser is equipped with zone changeover valves so that all the units served by that riser can provide either heating or cooling. For example, the south side of a building may be switched to cooling, while the north side is switched to heating.

Zoning with changeover valves requires additional piping and valves. The cost depends on the original piping layout, the number of zones, and the way the zones are arranged.

How to Change Between Heating and Cooling

In a building with a three-pipe system, the occupants are used to being able to select heating or cooling at any time. A two-pipe system removes this desirable comfort feature. To retain comfort, the system must switch between heating and cooling appropriately.

Changing between heating and cooling manually invites complaints. It is best to install an automatic control to make the change.

There are several methods of sensing whether to provide heating or cooling. One is to sense the outside

air temperature. The temperature setting should account for heat gains in the building. If the building has high heat gains, this method may not be satisfactory. For example, if the building has a large amount of glazing that creates high solar heat gain, cooling may be needed on a sunny day but not on a cloudy day, for a given outside air temperature.

To account for solar gain, you can install sensors that measure total heat gain from outside air and solar load. Figure 3 shows an array of such sensors oriented to control zones on each side of the building.

Another method is to control the changeover by using a thermostat that is installed in a typical space. This can be tricky. For example, if the system is providing heating because it is cold outside, allowing the space temperature to rise too much will cause the system to switch to cooling. Therefore, the thermostat must have a wide deadband range (see [Measure 4.3.4.2](#)) and it must not be adjustable by the occupants.

With Methods 1 and 2, the entire building must operate on either heating or cooling. A zone changeover system has much better comfort potential, but it needs a reliable method of selecting heating or cooling for each zone. For example, a zone facing toward the west may

Fig. 1 Three-pipe system Each fan-coil unit may select heating or cooling. However, return water from the fan-coil units is mixed in common return pipes.

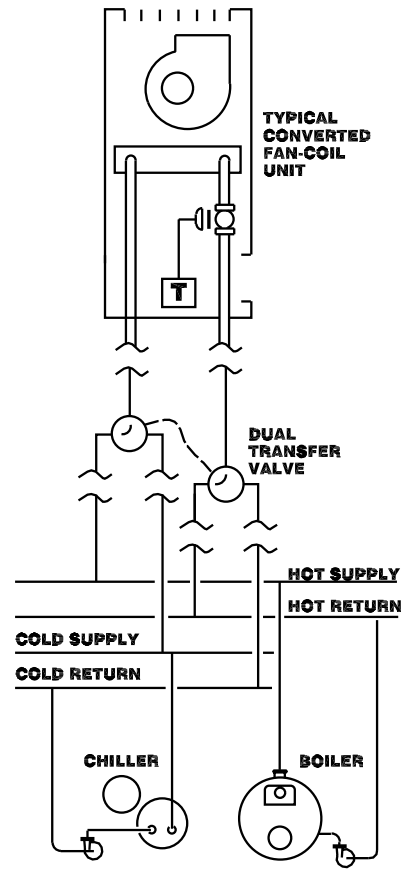

Fig. 2 Conversion to two-pipe changeover system Selection of heating or cooling by individual units is abandoned. Units grouped on individual risers, or zones, select heating or cooling collectively.

WESINC

Fig. 3 Zone cooling load sensors Each sensor simulates the combined load from outside air temperature and solar radiation. The four sensors are oriented to determine the load for each face of an office building. These provide only an approximation. A sensor located at one point cannot simulate the load at each point on the face of a building.

need heating in the morning and cooling in the afternoon. Therefore, you need sensors that determine the cooling load in each zone.

Alternative Modifications

Another possibility is to convert the system to four-pipe operation by adding a second return pipe. This approach is recommended by [Measure 5.3.6](#), next.

Three-pipe systems are so wasteful that you should consider other major modifications. For example, replacing three-pipe fan-coil units with unitary heat pumps might be justified if it is important to provide for individual selection of heating or cooling in each space. Three-pipe systems are usually found in older buildings, so you may have the opportunity to replace the system as part of a major renovation.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of heating and cooling costs.

COST: \$10,000 to \$100,000, in typical facilities.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

DESIGN: The goal is to make the changeover as foolproof as possible while providing flexibility in zoning. The main point is to design the changeover valves so that the boiler and chiller cannot feed to any zone at the same time. For each zone, use special changeover valves that have dual passages to switch the supply and return connections together.

EXPLAIN IT: Install placards on the changeover valves to explain what they do. Describe the system in the plant operating manual.

MEASURE 5.3.6 Convert 3-pipe systems to 4-pipe systems.

RATINGS

New Facilities	Retrofit	O&M
	C	

See the previous [Measure 5.3.5](#) for an explanation of 3-pipe systems.

Another way of getting rid of 3-pipe operation is to convert to 4-pipe operation. This method preserves the ability of individual spaces to select heating or cooling independently. However, it is likely to be very expensive.

How to Convert to 4-Pipe Operation

The principle is simple: add a second set of return pipes to allow chilled water and hot water to be returned

Fig. 1 Conversion to four-pipe system This system retains the ability of each fan-coil unit to select heating and cooling independently. It is expensive to retrofit.

SUMMARY

A much more expensive way of eliminating the large energy waste of 3-pipe systems. Retains the ability to switch between heating and cooling in individual spaces.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$

Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊		

separately. One return pipe goes to the chiller, and the other to the boiler. See Figure 1.

Attempting to convert existing fan-coil units is messy. The control valve and thermostatic control changes in the individual fan-coil units may be too expensive to be practical. In most cases, it makes more sense to replace the fan-coil units entirely.

Either way, piping work is needed at each fan-coil unit. Although holes already exist through floors and walls for the two supply pipes and the single return pipe, you may have to enlarge the holes to accommodate the second return pipe. Leave room to insulate both return pipes well because there is a large temperature difference between the chilled water return and the hot water return.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of heating and cooling costs.

COST: The cost is mainly in installing extra pipe. Typical materials costs are \$7 to \$12 per foot. Labor costs depend on the difficulty of running the additional pipe.

PAYBACK PERIOD: Several years, to many years.

TRAPS & TRICKS

CHOICE OF METHOD: This conversion is foolproof if it is installed properly, but it is expensive. Consider all your options.

MEASURE 5.3.7 Replace electric resistance heating units with equipment having the lowest practical energy cost.

RATINGS		
New Facilities	Retrofit	O&M
B	D	

Fan-coil units with electric resistance heating elements are widely installed because the equipment and the installation are cheap. The penalty paid for this cheapness is high operating cost, unless electricity prices are exceptionally low. In most areas, electric resistance heat is much more expensive than fuel heat, per unit of heat delivered to the space.

If other available energy sources are less expensive than electric resistance heating, consider substituting another heating energy source. There are many options. The choice has a major effect on equipment and space requirements, installation cost, occupant conditions, and other factors. The selection of heating method may also affect your choice of cooling method.

This Measure is similar in economics and procedures to [Measure 5.2.9](#). Refer to there for details.

One situation that is not covered explicitly in [Measure 5.2.9](#) is the possibility of converting fan-coil units that have electric resistance heating and hydronic cooling. In this case, you may be able to convert the cooling coil to serve as a heating coil also. This creates a 2-pipe system.

Such fan-coil units are most likely to be found in facilities that do not have a boiler plant. Therefore, you have to install a boiler, if there is none. Also, you need to make thermostatic control changes to all the fan-coil units. This configuration sacrifices the ability of individual spaces to switch between heating and cooling.

Self-Contained Air Conditioners and Through-Wall Heat Pumps

The Measures in this Subsection improve the efficiency of self-contained cooling units and heat pumps. This category of equipment includes window air conditioners, packaged terminal air conditioners (“through the wall” units), and air-to-air heat pumps. Virtually all cooling units operate on the principle of refrigerant compression. (Absorption cooling is rare and specialized in this size range.) The units include all their components in a single package. Outside air is used for condenser cooling. In the case of heat pumps, outside air is the heat source. The units typically are installed in an opening in the building envelope. They often include heating coils, which are usually electric resistance elements.

INDEX OF MEASURES

5.4.1 Clean, adjust, lubricate, and repair through-wall air conditioners and heat pumps at appropriate intervals.

5.4.2 Install high-efficiency replacement fan motors.

5.4.3 Seal through-wall conditioning units to prevent outside air infiltration.

5.4.4 In units that provide outside air ventilation by exhausting conditioned air, abolish this feature.

5.4.5 Install air conditioning units and heat pumps having the highest practical efficiency.

5.4.6 If electric heating elements are installed with air conditioners, replace them with heating units having lower energy cost.

RELATED MEASURES

- **Subsection 5.5**, for Measures that improve the efficiency of larger air conditioning and heat pump systems
- **Subsection 5.6**, for Measures that improve the efficiency of heat pump loop systems

MEASURE 5.4.1 Clean, adjust, lubricate, and repair through-wall air conditioners and heat pumps at appropriate intervals.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Modern self-contained air conditioning units are reliable throughout their service lives if they are not abused. They require little maintenance, but that maintenance is important. Give these items attention at appropriate intervals:

- **filters and filter mountings.** Clean filters at short intervals, usually every several months. In applications that generate a lot of lint, such as lodging facilities, clean the filters every several weeks. Letting filters get clogged reduces conditioning capacity substantially. If filters become too dirty, occupants are likely to remove them to restore cooling capacity, which leads to clogging of the coils.

Have a stock of spare filters. They will wear out, especially if you clean them as often as you should. If you make replacement filters from bulk material, make sure that the replacements are installed properly. Unless the fit is tight, dirt bypasses the filter and collects on the coils.

- **inside coils.** Check for cleanliness and fin spacing. In almost all cases, fouled inside coils are caused by inadequate filter maintenance. Obstructed coils block air flow, forcing the evaporator coil to run colder and the condenser coil (in heat pumps) to run hotter. This reduces the cycle efficiency of the unit, which in turn forces the unit to operate longer, increasing fan energy consumption. In addition, restricting air flow causes the inside fan to draw more power and overheat.

Fouled evaporator coils are a major potential source of indoor air quality problems. The condensate that forms on the coils keeps the dirt on the coils wet. The microorganisms that grow in the dirt are blown into the room by the fan.

Clean dirty coils with a vacuum cleaner and a stiff brush. If necessary, wash out the coils with a detergent spray and compressed air. You may need a disinfectant to eliminate the health hazard from a badly fouled evaporator coil. Straighten bent fins with a fin rake.

- **coil condensate drain pans and lines.** Condensate pans are clogged by debris and by slime that grows in the condensate. Condensate accumulation is a health hazard because it breeds microorganisms that are discharged into the surrounding air. The condensate pan should drain freely. If it does not, check the installation for proper tilt.
- **outside coils.** Outside coils are most likely to become fouled by leaves and other debris, and possibly by mud. Dirty outside coils waste energy

SUMMARY

Basic maintenance items needed to prevent energy waste, maintain comfort, and prevent health problems.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

in the same way as dirty inside coils. A brush and a water hose often suffice for cleaning. In extreme cases, use the methods given previously for inside coils.

- **fan blades** should be cleaned to keep air flow efficient. Be aware that cleaning a dirty centrifugal fan impeller makes it noisier, because dirt muffles fan noise.
- **fan motor lubrication.** If the fan motors are not permanently lubricated, oil them at appropriate intervals.
- **occupant controls,** such as fan speed switches and function buttons, are often flimsy. If occupants cannot operate the controls properly, the units will operate inefficiently and excessively. Inspect the controls often. Replace missing knobs. In environments where controls get rough treatment, as in motels, keep a stock of knobs and control panels on hand.
- **outside air ventilation dampers.** If outside air dampers are installed, check them for proper closure, connection to the occupants' control panel, and freedom of movement. A significant amount of conditioned air can be wasted if the dampers are inadvertently left open, or if they fail to close properly. See [Measure 5.4.4](#) about modifying the outside air ventilation feature of room conditioning units.
- **refrigerant charge.** Improper refrigerant charge can seriously reduce efficiency and capacity. This should be a rare problem if units are repaired properly. Assign only qualified persons to check refrigerant charge, for the reasons explained next.

How to Check Refrigerant Charge

Most self-contained air conditioners and heat pumps are hermetically sealed. This makes refrigerant leakage

an uncommon problem. Also, it is typically impossible to check the actual amount of refrigerant in the unit. For these reasons, you normally will not monitor the state of charge in air conditioning units. Your first indication of leakage is usually a loss of capacity that motivates an occupant to complain. Leakage usually occurs slowly at first, so a unit may operate at reduced efficiency for months before it loses enough cooling capacity for the defect to be noticed.

Specialized skill is needed to determine whether the refrigerant charge is low. [Measure 2.7.2](#) explains the various methods. In summary, the most reliable method is to use refrigerant gauges to measure the suction and discharge pressures. This requires the unit to have service taps, which smaller units may lack. If no service taps are installed, an experienced technician can judge whether the charge is adequate from the external temperatures of the evaporator, condenser, liquid line, and suction line. A liquid line sight glass provides a qualitative indication of low charge that is less reliable.

If the unit is low on charge, find the leak using the methods explained in [Measure 2.7.1](#).

Units can have too much refrigerant. This problem is almost always the result of attempted service by unskilled personnel. Depending on the design of the unit, excessive refrigerant may back up into the

condenser, reducing condensing efficiency, or it may be sucked into the compressor as a liquid, causing compressor damage. Diagnosing excess refrigerant charge is even more subtle than diagnosing low charge.

Refrigerant-Side Repairs Require Skill!

Any repairs that require opening the refrigerant circuit, such as replacing a compressor, require special procedures to completely remove air from the unit prior to refilling with refrigerant. Even the small amount of the moisture that is contained in air combines with refrigerant to form an extremely corrosive product. The corrosion causes leaks, electrical insulation failure, compressor bearing damage, and reduced compression. The problem is insidious because the damage may not become apparent until months or years after the repair. Furthermore, mixing air with the refrigerant results in reduced cooling efficiency.

The only effective method of removing moisture, air, and other contaminants is to attach a vacuum pump to the unit and pump it down to a high vacuum for an appropriate period of time. If this procedure is not used, the unit will fail after a small fraction of its normal service life. See Figure 1.

Even trained refrigeration mechanics may neglect purging of air before recharging because the procedure

WESINC

Fig. 1 Where air conditioners go to die The air conditioners in this large hotel typically fail within a year or two after a compressor is replaced. We can see why. There is no equipment here for properly purging the units after the repair is made.

is tedious and time consuming. Some mechanics attempt to purge units by blowing refrigerant through them. This does not work, because moisture attaches to the materials and lubricants of the equipment. Also, the older types of refrigerants (containing fluorine) that are released into the atmosphere by this practice are believed to cause serious environmental harm.

Air conditioning units are as likely to suffer from too much maintenance as from too little, especially where the persons doing the work lack training. Most units are hermetically sealed, so getting inside them is comparable to surgery. Except for routine external cleaning and occasional repairs to external controls, leave cooling units alone unless there is a clear indication of internal trouble. If the unit does require opening the refrigerant circuit, make sure that the people doing the work are effectively trained and equipped.

Extra Maintenance for Units with Hydronic Heating

If the units include hydronic heating coils, refer to [Measure 5.3.1](#) for additional maintenance items.

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of energy input. In addition, effective maintenance extends the service life of equipment.

COST: \$3 to \$20 per unit per year.

PAYBACK PERIOD: Short. The cumulative savings produced by proper maintenance greatly exceed the cost in the long term.

TRAPS & TRICKS

MONITORING: People hate to clean filters and coils, so stay on top of this. Filters need cleaning more often than commonly believed. Train maids and cleaning crews to clean filters, if possible. Check the condition of the user controls frequently, especially in transient environments. Be alert for comfort complaints that may indicate low refrigerant charge.

SUPPLIES: Keep an ample stock of spare filters, knobs, and control panels on hand. Treat these as expendable supplies. Getting spare parts on a piecemeal basis is a big obstacle to timely maintenance, and it wastes time and money.

SKILLS AND SUPERVISION: If you notice that your cooling units fail within a year or two after a repair that opens the refrigerant circuit, your maintenance people probably are not trained adequately, or they are being sloppy. Keep retraining and checking. Allow only designated technicians to do any service involving the refrigerant circuit.

MEASURE 5.4.2 Install high-efficiency replacement fan motors.

When you have to replace a failed fan motor, replace it with the most efficient motor available. This requires advance preparation. See [Measure 5.3.2](#) for the details.

The motors used in self-contained air conditioners and heat pumps are larger than the fan-coil unit motors

covered in [Measure 5.3.2](#). Your equipment may have several types of single-phase AC motors, or even 3-phase motors. Look for the opportunity to substitute a more efficient type of motor, or a more efficient model of a particular type.

RATINGS		
New Facilities	Retrofit	O&M
□	□	A

MEASURE 5.4.3 Seal through-wall conditioning units to prevent outside air infiltration.

RATINGS

New Facilities	Retrofit	O&M

With conditioning units that require an opening in the building envelope, there is a substantial gap between the unit and the window or wall opening. Seal these gaps effectively. Failing to do so wastes energy and may cause discomfort during cold weather. You can stop leakage using inexpensive materials that are available at most hardware stores.

Sealing Around the Unit

Seal units that are installed in windows by stuffing resilient foam weatherstripping into the gaps between the unit and the window.

If the conditioning unit is installed in a metal sleeve that is attached to the wall, use a durable caulking material between the sleeve and the wall. In addition, stuff resilient rubber or foam weatherstripping between the body of the air conditioner and the sleeve. The latter tends to be forgotten when the unit is removed for maintenance.

Seal wall openings on both the outside and inside. Sealing the gap on the outside prevents infiltration of outside air into the wall insulation or into the cavities of masonry blocks. Such infiltration may cool (or warm) a fairly large area of wall. Sealing the gap on the inside keeps air from leaking from the space into the wall, or vice versa.

Fill gaps with an impermeable material. Fill small gaps with a good grade of caulking compound. Fill large gaps with mortar, plastic foam, or some other solid material. Don't use fibrous insulation to fill gaps. Air passes through it easily.

Seasonal Covers for Air Conditioners

Another way to reduce leakage around air conditioners is to install an impermeable cover over the unit on a seasonal basis. Some people cover the inside of the unit, and others cover the outside. This approach works because air conditioners operate only during warm weather, and infiltration is a problem mostly during cold weather. To prevent infiltration into the wall from both sides, you would have to cover both the inside and the outside of the air conditioner. In most cases, this method is inferior to installing effective weatherstripping around the conditioning unit.

This method has the advantage that it stops leakage through the interior of the unit. However, leakage by this path is usually minimal unless internal seals have been omitted during careless repairs. If an air

SUMMARY
A simple activity that prevents air leakage heat loss around the outside of the unit.

Ease of Initiation	😊	😊	😊

conditioner is installed in a leaky window, the cover can be extended over the entire window.

A cheap, but ugly, method of covering is to use a plastic sheet attached to the adjacent wall with tape. A more attractive but expensive approach is to make a rigid cover that fits against the adjacent wall with a soft gasket. Molded plastic covers for this purpose sometimes appear on the market.

Weather covers are sometimes installed on the outside of air conditioning units. You may not be able to achieve adequate sealing against an exterior wall.

If you decide to use air conditioner covers, be sure to disconnect the power to the unit at the same time. Otherwise, someone could turn on the unit with the cover in place. This may burn out the unit.

ECONOMICS

SAVINGS POTENTIAL: 3 to 30 percent of heating costs in the affected spaces.

COST: \$10 to \$100 per unit.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING THE METHOD: Select the simplest and most reliable method that works. Permanent sealing is usually simple. Covers that require seasonal replacement are much less reliable than installing gaskets around the units. If you select removable covers, design them to be airtight, attractive, and easy to use.

FOLLOWUP AND SCHEDULING: Be sure to replace sealing materials after removing units for maintenance. If you select seasonal covers, schedule replacing the covers and disconnecting the units at the end of the cooling season.

MEASURE 5.4.4 In units that provide outside air ventilation by exhausting conditioned air, abolish this feature.

RATINGS

New Facilities	Retrofit	O&M
□	□	C

Window-type air conditioners typically have a knob to provide outside air ventilation. Turning the knob opens a small door located in the discharge path of the fan, so that a certain fraction of the cooled air is vented directly to the outside. This creates a negative pressure within the space, causing air to leak into the space from elsewhere. The weaknesses of this feature are:

- the cooling or heating energy of the discharged air is completely wasted because the conditioned air never enters the space
- the air that enters the space to replace the discharged air is probably not fresh, because it comes from elsewhere in the building
- fresh air that does infiltrate into the space from the outside is unconditioned and may therefore create discomfort
- the volume of ventilation air is limited, because the ventilation opening inside the air conditioner typically is only a few square inches in size.

How to Disconnect the Ventilation Damper

You can easily disable this feature by disconnecting the link from the control knob to the air relief door. If you do this, remove the damper control knob and label the panel to state that the unit cannot provide outside air ventilation.

Provide Ventilation

Before accomplishing this Measure, determine the outside air ventilation requirement of the space and provide an alternative source, if necessary. Ventilation requirements are controversial. See [Measure 4.2.1](#) for the details.

SUMMARY

Eliminates an inefficient feature of window-type air conditioners. Provide an alternative source of ventilation.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	✓
Ease of Initiation	☺	☺	

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of the cooling and heating energy delivered by the unit.

COST: Minimal, assuming that no alternative source of outside air must be installed.

PAYBACK PERIOD: Immediate, assuming that no alternative source of outside air must be installed.

TRAPS & TRICKS

SELECTING THE METHOD: Before doing this, make sure that the space will have enough ventilation air. If not, provide some other method of ventilation. This is rarely cheap or easy.

EXPLAIN IT: Don't forget to install the placard at each unit where you disconnect the ventilation control. Otherwise, the disconnected air dampers will be perceived as defects.

MEASURE 5.4.5 Install air conditioning units and heat pumps having the highest practical efficiency.

RATINGS

New Facilities	Retrofit	O&M
A	C	B

There are large differences in the efficiencies of different models of air conditioners and heat pumps. In facilities where air conditioning is used a lot, or where heat pumps are used for heating for extended periods, you can save a lot of energy cost by selecting highly efficient units.

This applies to retrofit applications as well as to new construction. Packaged cooling units and heat pumps typically operate for 10 to 20 years before requiring major maintenance. When major maintenance is required, the cost may be so high that replacing the unit is a reasonable option. Consider this an opportunity to save energy by substituting a highly efficient unit. The most efficient models available today are much more efficient than older models.

Usually, it is not economical to replace a unit that is still operating for the sake of the energy savings. However, if the units are operated for a large number of hours per year and if they are approaching the end of their service lives, it may be economical to replace all the existing units as part of a single project. Replacing the units as a group is especially desirable if the replacement units require some custom fitting.

Efficiency Ratings

Many factors determine the efficiency of air conditioners and heat pumps. Better efficiency has been achieved by improving all the components, including the compressor, the compressor motor, the fan motors, the heat exchangers, and the refrigerant metering devices. Heat pump efficiency has also been improved by better control of evaporator defrosting and backup resistance heating.

Fortunately, you don't have to analyze all these factors to select an efficient unit. Many countries have laws that require efficiency ratings for air conditioners and heat pumps, along with minimum efficiency requirements. In the United States, you may find these ratings being used for packaged cooling units and heat pumps:

- **energy efficiency ratio (EER)** is expressed as BTU output per watt input. The EER of a particular unit varies widely depending on the temperature and humidity, so published values are based on continuous operation at stated conditions. This does not relate well to the way air conditioning equipment is actually used, so EER is no longer used in the United States as a consumer standard.
- **seasonal energy efficiency ratio (SEER)** is the average EER of a unit measured under a standardized variety of conditions that simulate

SUMMARY

An important design issue in new construction. In existing facilities, an important option to consider when units need major repair or approach the ends of their service lives.

Reliability of Procedure	✓ ✓
Ease of Retrofit	☺ ☺ ☺ ☺
Ease of Initiation	☺ ☺ ☺

typical operation. SEER is the consumer standard used in the United States for air conditioners and for the cooling performance of heat pumps.

- **heating seasonal performance factor (HSPF)** is defined in the same way as SEER. In the United States, it is used to rate the heating performance of heat pumps. The HSPF includes the energy consumption of the electric resistance heating elements that are turned on when the outside temperature is too low for the heat pump to operate alone.

Values of the SEER's for typical cooling units range from 8 to 15. Values of HSPF's for typical unitary heat pumps range from 6 to 10.

All other things remaining the same, the efficiency of newer units is reduced somewhat by a shift to new refrigerants intended to minimize environmental damage. However, this concern has stimulated a new round of innovation in refrigeration design, so equipment efficiencies and other characteristics may improve. Shop for high efficiency ratings, and don't worry too much about how the manufacturer achieves them. One caution, as always, is to avoid new technology. You are too busy to be a guinea pig.

Where to Get Comparative Efficiency Data

The Air Conditioning and Refrigeration Institute (ARI), an industry association located in Arlington, Virginia, publishes directories of most models of air conditioners and heat pumps sold in the United States, including their capacities and efficiency ratings. These

directories are an invaluable aid in shopping for efficient units. Manufacturers' catalogs are not as useful for making your initial selection because they are limited to the offerings of a particular manufacturer or vendor. However, you need the manufacturers' catalogs to select other features.

Other Features to Consider

A variety of useful features have become available with newer space conditioning units, mostly by exploiting microprocessors. These features include accurately calibrated thermostats, time controls, temperature setback, automatic temperature reset during operation, and efficient control of fan operation. Some units allow these functions to be set with remote controls.

An especially valuable feature is turning off the evaporator (indoor) fan when the compressor is not operating. This prevents the fan from re-evaporating condensate from the coil and blowing it back into the room. This feature also saves fan energy and eliminates the noise of the fan between cooling cycles. Seasonal efficiency may be improved significantly. This function can be accomplished only with units that have their thermostats outside the unit and exposed directly to space temperature.

Cost and Size Penalties

Achieving greater efficiency requires greater weight, size, and cost. Compared to a unit of minimum efficiency standards, a highly efficient unit may be 50% larger in terms of weight and volume, and may cost 40% more.

The larger size may be the greatest impediment to replacing existing units. If you have to replace a unit in a space that cannot be enlarged, consider a unit of lower capacity, if possible. The original unit may have been oversized.

Consider Alternatives to Group Replacement

If all the conditioning units in a facility are approaching the end of their service lives, consider alternatives to replacing them. For example, consider a central conditioning system using fan-coil units.

ECONOMICS

SAVINGS POTENTIAL: 20 to 50 percent of the cost of operation of the units.

COST: Efficient units typically cost 20 to 50 percent more than the cheapest comparable units. This cost premium usually provides additional features that make the units more desirable, such as quieter operation and more accessible controls.

PAYBACK PERIOD: One year to several years, in new construction and when replacing failed units. Several years or longer, if you replace functioning units. Depends strongly on electricity costs and duration of operation.

TRAPS & TRICKS

TIMELY PREPARATION: Get a current copy of the ARI directory to help you select units for efficiency. To select for other features, you have to spend time with the catalogs. For replacing individual units when they fail, designate the selected models and identify vendors ahead of time. If you operate many units of a particular model, consider keeping a new replacement unit on hand.

MEASURE 5.4.6 If electric heating elements are installed with air conditioners, replace them with heating units having lower energy cost.

RATINGS		
New Facilities	Retrofit	O&M
B	C	

This Measure is similar to [Measure 5.2.9](#) in economics, options, and installation procedures. Refer to there for details.

Of the options presented in [Measure 5.2.9](#), air-to-air heat pumps are the most likely replacement for air conditioners that have electric resistance heating

elements. Heat pumps can use the envelope openings, power wiring, and condensate drain lines that already exist for the air conditioners. If the existing air conditioners are older units, substituting high-efficiency heat pumps substantially reduces the cooling cost as well as the heating cost.

Remotely Cooled Air Conditioning Units and Heat Pumps

The air conditioning units and heat pumps covered in this Subsection have outside heat exchangers that are separate from the inside equipment. This equipment is usually larger than the equipment in [Subsection 5.4](#). It does not require wall or window openings to provide air flow from the outside. Virtually all equipment in this class operates on the principle of refrigerant compression (not absorption).

Most commonly, units reject heat directly to the atmosphere through air-cooled condensers. They may also exploit evaporative cooling by rejecting heat through an evaporative condenser or cooling tower. Or, for greater efficiency, they may reject heat to a cooler body of water, such as well water, a lake, or even service water. Such connections require heat exchangers.

The heat pumps in this group most commonly use the atmosphere as a heat source, by using an outside air coil. Such heat pumps usually require a supplemental purchased energy source during cold weather. For greater efficiency, and to avoid the need for a purchased energy back-up source, heat pumps may draw heat from water sources or from heat exchangers buried in the soil.

This category includes a variety of configurations. The four basic components of the vapor compression refrigeration cycle — compressor, condenser, refrigerant metering device, and evaporator — can be grouped in several ways. For example, the compressor may be packaged with the inside

RELATED MEASURES

- [Section 2](#), for Measures related to central chiller plants
- [Subsection 5.6](#), for Measures related to heat pump loop systems

equipment or with the outside condenser. The most common configuration is the “split system,” which has an external package for the compressor and condenser, and an internal package for the refrigerant metering device and the evaporator. The grouping of components is based on practical considerations, such as available space, ease of installation, keeping noise outside occupied spaces, etc.

A system may have more than one of each basic element, and one element may serve several others.

For example, an external compressor/condenser unit may serve two or more inside evaporator units. Or, a single cooling tower may cool a water loop that serves any number of packaged room cooling units.

The inside equipment typically discharges conditioned air directly into the space, but some systems may have rudimentary ducts.

The inside equipment may include heating coils, which usually are electric resistance elements.

MEASURE 5.5.1 Clean, adjust, lubricate, and repair air conditioners and heat pumps at appropriate intervals.

Maintenance of remotely cooled air conditioners and heat pumps is generally similar to the maintenance of self-contained air conditioners and heat pumps, which is covered by [Measure 5.4.1](#). The differences relate to the exterior location and larger size of the equipment. Figure 1 shows the exterior condensing unit of a small split system, and Figures 2 and 3 show air-cooled condensing units of larger systems.

Also, some systems employ wet condensing units, which have a separate set of maintenance requirements.

In addition to the maintenance items listed in [Measure 5.4.1](#), make sure that these items get regular attention:

- **outside coils** have a strong tendency to collect organic debris. Clean this out regularly. Coils installed near the ground, as in Figure 2, collect leaves and grass clippings. Coils installed in locations that attract birds collect nests, feathers, the remains of prey animals, etc.
- **condenser temperature regulating valves** on water-cooled units strongly affect the efficiency of the unit. Adjust these appropriately. See [Measure 5.5.4](#) for details.
- **cooling towers and evaporative coolers** have maintenance requirements that are almost identical

Lennox Industries Inc.

Fig. 1 Air-cooled condensing unit for a residential-sized split system This is typical of units of all sizes. It contains the compressor and its accessories, a large condenser coil, and one or more fans to draw air through the coil. Refrigerant lines connect it to one or more evaporator units inside the building.

Fig. 2 Air-cooled condensing unit This unit serves a medium size public library. Being low to the ground makes it vulnerable to debris. It should be inspected from underneath and from above. The concrete slab and the surrounding fence help to keep it clean.

to those of their larger counterparts used with central chiller systems. Refer to [Subsection 2.3](#) for these procedures.

- **refrigerant lines** that connect the inside and outside equipment are sources of leaks. The major trouble spots are the connectors at the ends of the lines. Fortunately, these are localized and relatively accessible, making it easy to check them with leak detectors. Leaks can also occur where copper

WESINC

Fig. 3 What is wrong with this condensing unit? A fan failed and was never replaced. This allows air to enter through the hole and bypass the condenser coils. Efficiency and capacity are suffering seriously. A thermostatically controlled damper is installed to maintain a minimum condensing temperature. It will create the same problems if it is not working properly, or if the damper blades do not close fully.

tubing is kinked and then straightened. Also, kinked lines can limit capacity and cause erratic operation. In addition to checking these specific items, take a slow walk around each unit and observe whether

anything is wrong or suspicious. For example, the unit in Figure 3 has one serious defect and perhaps others.

MEASURE 5.5.2 Replace fan, pump, and compressor motors with models having the highest economical efficiency.

Be prepared to replace failed motors with the most efficient available models. See [Measure 10.1.1](#) for details. This Measure applies to replacing failed motors

in existing cooling units. Motor efficiency in new units is covered by [Measure 5.5.3](#).

RATINGS

New Facilities	Retrofit	O&M
		B

MEASURE 5.5.3 Install compressors or new conditioning units having the highest economical efficiency.

A basic step in designing new facilities is selecting the most efficient conditioning equipment. The market offers a wide range of efficiencies, along with a wide range of other features, such as programmable thermostatic controls.

When the compressor of an existing split-system air conditioning unit or heat pump fails, you have several ways to improve efficiency. One is to replace the compressor with a more efficient unit. Compressors of improved efficiency are becoming available in smaller sizes. The efficiency of the compressors used in air conditioners ranges from 60 to 85 percent. The compressor consumes most of the energy used in air conditioners and heat pumps, so a 15% improvement in compressor efficiency, for example, produces almost a 15% reduction in energy consumption.

An efficient compressor alone cannot produce an efficient air conditioner or heat pump. The compressor is just one of several components that have a major effect on overall efficiency. If an air conditioning unit is old and inefficient, consider replacing the entire condensing unit, including the heat exchange coil, fan, and other apparatus. Also consider replacing the entire system. Newer systems have enhanced features, such as remote control and low noise level.

Normally, the right time to improve a system is when the compressor wears out. However, if you have many similar systems and they are all approaching the end of their service lives, it may be most economical to replace all the systems as a group.

Be Ready at Repair Time

Upgrading existing systems is a management and training challenge. Before the repair is needed, identify specific replacement models of compressors or conditioning units, along with sources. If this is not done, the need for quick repair will force maintenance personnel to use whatever replacement parts are readily available. Coordinate this activity with the acquisition of other high-efficiency replacement parts, such as motors (covered by [Measure 5.5.2](#)).

If the facility has a large number of similar conditioning systems, it helps to keep a number of high-efficiency units as spares. This practice gives you the leisure to order the equipment for best efficiency and price.

Finding Efficient Equipment

Refer to [Measure 5.4.5](#) for efficiency ratings and sources of information on equipment efficiency. Ratings normally are available only for entire cooling units or

SUMMARY

An important design issue in new construction. In existing facilities, an important option to consider when replacing compressors or when conditioning units approach the ends of their service lives.

heat pump systems. For efficiencies of individual compressors, refer to the manufacturers' literature.

ECONOMICS

SAVINGS POTENTIAL: 5 to 25 percent of the energy consumed by the conditioning unit.

COST: Widely variable. The cost premium for smaller high-efficiency units is changing as pricing policy and efficiency standards evolve.

PAYBACK PERIOD: One year to several years, in new construction and when replacing failed units. Several years or longer, when replacing old units that are still working. Varies widely depending on size and operating hours.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Call ARI (see [Measure 5.4.5](#)) to get a current copy of their efficiency directory for the type of equipment you are using. Use this to select entire conditioning units. For compressors alone, you have to search the catalogs.

TIMELY PREPARATION: For replacing failed units, identify vendors who can provide your selected models on short notice. If you operate many units of a particular model, consider keeping a spare replacement unit on hand. Make sure that all maintenance personnel involved with repairing air conditioning units are aware of the procedure.

MEASURE 5.5.4 Optimize the condenser temperature setting.

RATINGS

New Facilities	Retrofit	O&M
□	□	C

The efficiency of an air conditioning unit or heat pump improves one to two percent for each degree Fahrenheit that the condensing temperature is lowered. The reason is that lowering the condenser temperature reduces the pressure against which the compressor must operate.

Many types of cooling equipment need to maintain a minimum condensing temperature, typically in the range of 65°F to 85°F (18°C to 30°C). Such units have devices to regulate the flow of cooling water or cooling air so that condensing temperature remains high enough. It is not unusual to find that the condensing temperature is kept higher than necessary, which wastes energy.

You may be able to improve the efficiency of such units by lowering the condensing temperature. This is usually a simple change to the setting of a thermostatic control element. Just don't overdo it.

SUMMARY

Increase the efficiency of some cooling units by turning a screw. Be careful to avoid equipment damage.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

How to Lower the Condensing Temperature

The first step is to find out whether the cooling unit requires a minimum condensing temperature. In case

WESINC

Fig. 1 Condenser temperature control with city water cooling In this elegant installation, the arrow points to a thermostatic valve that regulates the flow of cooling water to the condenser. Using city water for cooling creates a serious compromise between the efficiency of the cooling unit, which affects electricity cost, and the cost of the water. The water cost is substantial, as witness the individual water meter installed for the unit. With air-cooled condensers and with condensers that are cooled by evaporative heat rejection units, it pays to keep the condensing temperature near the minimum that is possible.

of doubt, pick up the telephone and call the manufacturer's engineering department. When you make this call, find out which factors determine the lower temperature limit. See [Measure 2.2.2](#) for the possible reasons. If a lower temperature setting does not pose a risk of equipment damage, but only a reduction of capacity, you may want to be more aggressive in lowering the temperature setting. Typically, lower condenser temperatures occur when the cooling load is low. A loss of capacity may not matter then.

The next step is to find all the methods of controlling condenser temperature that are used by the system. There may be several. For example, a cooling tower has a fan control and each of the individual room units served by the cooling tower may have a condenser water throttling valve. The adjustment procedure depends on the type of unit, as follows.

■ Water-Cooled Units

With water-cooled units, condenser temperature may be controlled by a thermostatic throttling valve that is installed in the condenser cooling water return line. Figure 1 shows an example. Measure the condenser water return temperature when the cooling unit is under load, and adjust the throttling valve to produce the minimum acceptable temperature. Refer to the manufacturer's literature for details.

If the cooling water is provided by a cooling tower, adjust the operation of the cooling tower fans to provide the most efficient compromise between compressor efficiency and fan energy consumption. See [Measures 2.2.2 ff](#) for details. Also, refer to [Measure 5.5.8](#), which stops fan operation when the compressors are not running.

If a minimum cooling tower water temperature is maintained by means of a bypass around the cooling tower, set the bypass valve to the minimum safe temperature.

If the unit uses city water cooling, as in Figure 1, there is a serious compromise between the water cost and the cost of operating the cooling unit. Water costs have been rising dramatically in most locations. If you have such a unit, consider eliminating the city water cooling. If you have many such units, consider installing a cooling tower. If you have only a few smaller units,

consider installing air-cooled units having the best available efficiency.

■ Air-Cooled Units

With some air-cooled units, the minimum condensing temperature is controlled by a damper that restricts the flow of air through the condenser. The mechanism that controls the damper is exposed to weather, so it is likely to be defective or seriously out of calibration, especially in an older unit. Measure the condenser cooling air discharge temperature when the cooling unit is under load during cold weather, and adjust the damper control to produce the minimum acceptable temperature. Refer to the manufacturer's literature for details.

Some larger air-cooled condensers have multiple fans that operate in stages. Adjusting such units for maximum efficiency is tricky, because increasing condenser cooling also increases fan energy consumption. See [Measures 2.2.2 ff](#) for details.

Check the Adjustment Annually

This adjustment needs to be checked occasionally. In most cases, check it annually, at the beginning of the cooling season. Schedule this in your maintenance calendar. Install a placard at each thermostatic element that states the appropriate temperature setting. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: Up to 10 percent of cooling energy.

COST: Minimal.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

PREPARATION: Be certain that you know the minimum condensing temperature that your equipment can tolerate. Don't be shy about calling the factory to find out, if necessary.

EXPLAIN IT: Install an effective placard on the thermostat that controls the condensing temperature. Explain the settings in the plant operating manual.

MEASURE 5.5.5 Turn off sump/crankcase heaters during extended shutdown intervals.

RATINGS

New Facilities	Retrofit	O&M
		D

This activity is identical with [Measure 2.1.6](#), which applies to larger chiller systems. Refer to there for the details.

MEASURE 5.5.6 Drain cooling towers and evaporative condensers during the season when they are not required, and turn off water sump heaters.

RATINGS

New Facilities	Retrofit	O&M
		B

Operating cooling towers during cold weather may waste a lot of energy if heaters are used to prevent freezing, as in Figure 1. If the cooling equipment is not needed, make it a practice to drain cooling towers during periods when freeze protection heaters may operate.

Turn off the power to any freeze protection heaters when you drain the water. Otherwise, the heaters will

WESINC

Fig. 1 Cooling tower sump heater It must operate all winter to keep the water from freezing, unless the tower is drained.

SUMMARY

A routine seasonal procedure that avoids unnecessary sump heater operation.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	
Ease of Initiation	😊	😊	😊	

turn on during cold weather even when the tower is dry. Lock open the electrical disconnects to air conditioning units and heat pumps served by the cooling tower. Tag them to say that the cooling water system must be refilled before the units can be operated.

It is good practice to drain the entire cooling water system, not just the portion exposed to freezing temperatures. Leaving water idle in the cooling system for long periods allows fouling to accumulate in the low points. Cooling tower water is dirty, so flush the system well when draining the tower.

ECONOMICS

SAVINGS POTENTIAL: All the energy used by the tower for freeze protection. In addition, water treatment and makeup costs are eliminated during the periods that the tower is shut down.

COST: Several hours of labor, mostly for flushing the system. The cost of the replacement water is small.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

SCHEDULING: The main risk is forgetting the procedure from one season to the next. Put it into the maintenance

schedule for the end of the cooling season. Describe the procedure in the plant operating manual.

MEASURE 5.5.7 Replace electric heating elements in cooling units with heating equipment that has lower energy cost.

RATINGS		
New Facilities	Retrofit	O&M
B	D	

This Measure is similar to [Measure 5.2.9](#) in economics, options, and procedures. Refer to there for details.

The modification that usually offers the quickest payback is installing heat pumps to replace air conditioning units with electric resistance heaters. Heat pumps can use the envelope openings, power wiring, and condensate drain lines that already exist for the air conditioners. If the existing air conditioners were manufactured to lower efficiency standards (which is true of most older units), replacement with high-efficiency heat pumps substantially reduces both cooling and heating costs.

Be aware that packaged air-to-air heat pumps generally rely on electric heating elements to carry the heating load during the coldest weather. For this reason, substituting heat pumps may not reduce the maximum electricity demand, although it will reduce the total amount of electricity consumed. (For an explanation of electricity demand and its effect on electricity pricing, see [Reference Note 21](#), Electricity Pricing.)

To reduce both demand and consumption, consider heat pumps that use alternative heat sources and heat sinks. See [Measure 5.5.10](#) about this.

MEASURE 5.5.8 With cooling towers and evaporative condensers, interlock the operation of the pumps and fans with the operation of the compressors.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Some systems use a cooling tower to provide condenser cooling water for a number of room cooling units. In such arrangements, the cooling tower fan and the cooling water pump typically run independently of the room units. You can save energy in these systems by keeping the pumps and fans from operating unless one or more of the room units is operating.

Some systems use an evaporative condenser. An evaporative condenser has a fan and a small pump to circulate water within the unit. You can save energy in these systems by keeping the fan and pump from running when the compressor turns off. (Evaporative condensers usually serve only a single compressor unit.)

Where to Do This

In a system with several room cooling units that are served by a single cooling tower, all the room units must turn off simultaneously in order for this Measure to save energy. If even a single room unit continues to operate, the pump and fans must keep running. For example, if one unit serves a computer room that requires continuous cooling, this Measure is ineffective. Similarly, if the climate is always warm, and a cooling tower serves many air conditioners, the cooling tower has to keep running most of the time.

Energy Saving Potential

The amount of energy that is saved depends on the facility’s operating hours, the weather, the number of cooling units, and the size of the pumps and fans.

The energy saving also depends on the cooling water temperature that the fan is set to maintain. If the temperature is set relatively high, the fan will not operate unless the compressor is running. On the other hand, if the temperature is set low, the fan will run continuously any time the wet-bulb temperature of the air is higher than the temperature setting of the fan, regardless of the cooling load. See [Measures 2.2.2 ff](#) about optimizing fan operation.

How to Control the Equipment

A simple approach is to control power to the cooling tower or evaporative condensers through a relay. This relay is connected to relays in each of the room units, so that the operation of any room unit provides power to the pump and fans. Running the wiring is the main cost of this modification. Using relays allows low-voltage wiring to be used, which reduces cost.

If the facility has an energy management computer system, you may be able to program the computer to

SUMMARY
 A simple control modification that saves a modest amount of energy.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

perform this function. In order to do this, the computer must be connected so that it senses a start signal from any cooling unit, and it must be connected so that it can control the power to the cooling tower or evaporative condenser.

Each room unit probably already has a flow switch to prove the availability of condenser water flow before the compressor is allowed to start. If this safety device is not installed, it is a good idea to install one. Virtually all compressor units are equipped with safety switches that turn off the compressors if head pressure is too high. However, these devices may allow the compressor to cycle on and off in the absence of flow, ultimately burning out the equipment.

Coordinate with Controls that Limit Equipment Running Time

To save effort, make this change at the same time that you install controls to limit the operation of the room cooling units. Refer to [Subsection 5.1](#) for those controls.

ECONOMICS

SAVINGS POTENTIAL: 30 to 80 percent of the energy consumed by the pump. 5 to 30 percent of the energy consumed by the fans.

COST: Several hundred dollars to several thousand dollars. The main cost is running the control wiring between the cooling tower and the room units.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

WHETHER TO DO IT: In retrofit, make sure that this change is worth the bother. Check the running times of

all the air conditioning units connected to the cooling tower.

EXPLAIN IT: Update the plant equipment records to record the change. Otherwise, no one will figure out the purpose of the control connections.

MEASURE 5.5.9 Recover condenser heat for preheating service water or other low-temperature heating applications.

RATINGS

New Facilities	Retrofit	O&M
C	C	

Air conditioners and heat pumps remove heat from a space, raise its temperature above the outside air temperature, and throw it away. This heat may have substantial value. Try to find an application for it.

Heat recovery equipment is fairly simple, and it operates reliably. It is available from a number of sources, typically manufacturers of specialty refrigeration equipment.

Heat recovery from smaller cooling units is usually a simpler, scaled-down version of heat recovery from large cooling units. Refer to [Subsection 2.10](#) for details about the various methods that are used in large systems.

Where to Consider Heat Recovery

Consider recovering heat from any equipment that has a condenser, including air conditioners, central chillers, refrigeration compressors, and heat pumps. (Heat recovery from central chillers, which involves a larger number of options and complications, is covered in [Subsection 2.10](#).)

The main issue in feasibility is whether there is an application for the recovered heat. The main limitation is the low temperature of the heat, which is typically in the range of 100° to 120° (38°C to 50°C). By far, the most common application is preheating service (domestic) water. Raw water typically enters the facility at a temperature of 55°F to 65°F (13°C to 18°C). The difference between the incoming water temperature and the condensing temperature allows heat recovery to provide about half of the water heating energy, assuming that enough waste heat is available.

Effect on Cooling Unit Efficiency

The condensing temperature of a cooling unit has a major effect on its efficiency. (See [Measure 2.2.2](#) for the details.) Heat recovery may improve the efficiency of the cooling unit if the liquid that is being heated (e.g., service water) is cooler than the normal condenser cooling medium (e.g., the outside atmosphere). However, the cooling unit must be able to tolerate the lower condensing temperature.

SUMMARY

A fairly simple and reliable method of recovering the heat rejected by cooling equipment.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

On the other hand, if you increase heat recovery by increasing the condensing temperature, the efficiency of the cooling unit is reduced.

Heat recovery reduces the energy consumption of the condenser fans, because they have less heat to reject.

How to Design the Heat Recovery Installation

In the simplest applications, just insert a heat exchanger between the compressor discharge pipe and the pipe carrying the liquid to be heated. This is economical, and it may work well in many applications. In other cases, there are complications. Consider the following issues.

■ **Control**

Heat recovery from cooling units may require no controls at all. The liquid being heated simply absorbs as much heat as it can, and the existing heat rejection equipment gets rid of the rest of the heat, if any. In some cases, you may have to install some simple controls, as explained next.

■ **Maintain Minimum Condensing Temperature/Pressure**

Many cooling units will operate improperly, or they will fail, if the condensing temperature is too low. (See [Measure 2.2.2](#) for the reasons.) With such equipment,

the manufacturer specifies a minimum condensing temperature. If the material you are heating with recovered condenser heat is colder than the minimum allowable condenser temperature, design the heat recovery installation to avoid trouble. A simple approach is installing a bypass valve on the liquid side of the heat exchanger that limits the liquid flow through the heat exchanger. Control the bypass valve by sensing the condensing temperature or pressure.

■ Consider Raising Condensing Temperature to Increase Heat Recovery

If the condensing temperature is a limiting factor in heat recovery, consider increasing the condensing temperature. You can do this by raising the temperature setting of the thermostat that controls the condenser cooling fans. Consult with the cooling unit manufacturer to learn the maximum allowable condensing temperature. Higher condensing temperature reduces the life of compressors and motors, but this effect should be minor if the equipment is designed for the higher condensing temperature.

Raising the condensing temperature reduces the efficiency of the cooling unit, so you should calculate the condensing temperature that provides the best compromise between heat recovery, cooling unit efficiency, and cooling unit maintenance cost.

■ Isolate from Refrigerant Contamination, if Necessary

In most heat recovery applications, the condensing pressure can be higher than the pressure of the liquid being heated. As a result, a leak in the heat exchanger could force refrigerant into the heated liquid. Common halocarbon refrigerants combine with water to form acids that are corrosive and toxic. (The properties of refrigerants are explained in [Reference Note 34](#), Refrigerants.) For this reason, cooling unit heat recovery usually requires a double-wall heat exchanger, a standard item that is only slightly larger than a conventional single-wall heat exchanger. A more expensive alternative is using a separate heat transfer loop between the refrigerant and the heated liquid.

■ Can You Benefit from a Heat Storage Tank?

If the heat is needed at a different time than it is produced, you can increase heat recovery by adding a storage tank. The tank holds recovered heat until it is needed. You need a separate storage tank, even if the application already has a tank. This allows the heat exchanger to reject its heat at the low entering temperature of the heated liquid. For most systems, a simple stratified tank is the best choice.

A storage tank provides no benefit if (1) the supply of condenser heat always exceeds the amount of heat that can be recovered, or (2) the need for recovered heat always exceeds the amount available.

Refer to [Measure 2.10.5](#) for more about heat recovery storage.

ECONOMICS

SAVINGS POTENTIAL: Typically, a large fraction of the heat rejected by the cooling unit. The value of this heat depends on the heat source that is displaced.

COST: Several hundred dollars to several thousand dollars.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

CHOICE OF METHOD: Don't fool yourself about the amount of energy that you can save. Measure your hot water requirements, and calculate the fraction of heating energy that can be provided by heat recovery.

DESIGN: Provide for isolation from refrigerant contamination, if the application requires it. If you need a storage tank, err on the side of larger capacity. Keep the condensing temperature within acceptable limits.

EXPLAIN IT: If the installation is designed properly, operation is almost foolproof. Even so, make sure that the staff understand how the system is supposed to operate. Install a placard on the heat exchanger and/or storage tank. Describe the system in the plant operating manual.

MEASURE 5.5.10 Improve cooling efficiency by using alternative heat sinks and heating efficiency by using alternative free heat sources.

The condensing temperature of an air conditioning system or heat pump determines its efficiency. (Measure 2.2.2 explains why.) With air-cooled equipment, the outside air temperature determines the condensing temperature. In comfort cooling applications, the cooling air is warmest when the cooling load is highest, so the system operates at lowest efficiency at the same time that it is consuming the most energy.

You may be able to maintain a substantially lower condensing temperature by using a heat sink other than the atmosphere. Your primary choices are the earth (soil), ground (well) water, and surface water. Figure 1 illustrates some of these heat sinks.

Similarly, the efficiency of a heat pump (while heating) depends on the temperature of the heat source. The main disadvantage of air as a heat source is that the air temperature is low when the heating load is high. In most climates, there are times when the air temperature is too low to provide satisfactory heat pump operation, and heating must be done by a separate heating unit. In most cases, the low-temperature heater is an electric resistance coil. Thus, energy cost is highest when the heating load is highest. (Reference Note 21, Electricity Pricing, explains why electricity prices are highest during peak periods.)

You may be able to improve heating efficiency by substituting a heat source that maintains a higher temperature. These heat sources are commonly called “free” or “renewable.” As before, you can use soil, ground water, and surface water.

Also, you can use solar collectors and waste heat as heat sources, but not as heat sinks (with the exception of one unusual type of solar collector).

Heat pumps are especially well adapted to this technique because the heat sink for cooling can also act as the heat source for heating. Figure 2 shows how many heat pumps in a building can be connected in this way.

Where to Consider an Alternative Heat Source/Sink

Consider an alternative heat sink for cooling if the air conditioning equipment operates for a large number of hours each year. It is especially valuable in locations where the air temperature is high for much of the cooling season.

Consider an alternative heat source for heating if heating is needed for a large number of hours per year. It is especially valuable in locations where the air temperature is especially cold during the heating season. In fact, alternative heat sources, especially soil, have made heat pumps practical in much colder climates than are suitable for air-source heat pumps.

SUMMARY

An increasingly popular way to improve the efficiency of heat pumps. Also adaptable to cooling-only equipment. May be difficult to retrofit. Each type of alternative heat sink or free heat source is a separate field of study.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊		

An alternative heat sink or heat source requires additional equipment, additional space, and connections to each conditioning unit. For these reasons, it is easier to install alternative heat sources/sinks in new construction than in existing facilities. However, there are many cases where it is practical to install an alternative heat source/sink on a retrofit basis.

Types of Alternative Heat Sources/Sinks

You may have a choice of possible heat sources and heat sinks. Start by reviewing Reference Note 22, Low-Temperature Heat Sources and Heat Sinks. You will see that each source or sink has significant advantages and disadvantages when compared to outside air and to the other sources. Each source or sink has a substantial body of knowledge that you need to learn to achieve an installation that is both efficient and reliable. This is not an activity to approach casually.

System Options in New Construction

All alternative heat sources and heat sinks are connected to the conditioning system by a water loop. Therefore, you need to select air conditioning equipment that is designed for water cooling, or select heat pumps that are designed to extract heat from a water loop and to reject heat to the water loop. The market offers a wide variety of such equipment. Any number of conditioning units can be connected to the water loop.

In selecting the equipment for efficiency, be sure that the equipment can exploit the lowest temperature of the heat sink. For reasons explained in Measure 2.2.2, some equipment maintains an artificially high condensing temperature. This negates the advantage of having a heat sink at lower temperature.

Generally speaking, using a water loop provides greater design flexibility than using air-cooled units. This is because water-cooled can be located anywhere in the facility. In contrast, self-contained air-cooled units must be installed next to a wall penetration, and split systems are somewhat limited by restrictions in refrigerant piping length.

In heat pump systems, each unit is limited to heating a small area, as with air-source units. The reason is that the heat produced by heat pumps is at too low a temperature for effective distribution over a large area. Each heat pump unit may discharge directly into the space, or it may serve a larger area through a short duct system.

In cooling systems, there is a broader choice of configurations. Individual spaces may have their own cooling units, or cooling may be distributed by air or water from larger centralized cooling units.

People tend to think of alternative heat sources and sinks as serving only smaller equipment. There is no fundamental reason for this. You can use an alternative heat sink for cooling equipment of any size. However, you may have trouble finding a heat sink of adequate capacity for a large cooling system.

Retrofit Possibilities

In some cases, it is practical to retrofit an alternative heat sink or heat source to an existing cooling or heat pump system. Again, the key point is that all alternative

heat sources and sinks are connected to the conditioning equipment by a water loop. You have to figure out how to connect the new heat source/sink to the existing system. Here are some retrofit ideas for the common types of air conditioning units and heat pumps.

■ Water-Cooled Air Conditioners

The easiest case is a system in which one or more air conditioners is already water-cooled using a cooling tower. In this case, you can connect the alternative heat sink to the existing water circuit. Operate the alternative heat sink in parallel with the existing cooling tower. Install controls that select the cooler sources. For example, the cooling tower may provide lower temperatures than well water or a cooling pond at some times of the year. Also, the control should take into account the relative costs of operating the cooling tower (fan energy) and the heat sink loop (pump energy).

■ Cooling Units Cooled with Service Water

If an air conditioning system is cooled by domestic water, the alternative heat sink may be no cooler than the domestic water. However, using an alternative heat sink may save a substantial amount of water cost. Air conditioning that is cooled by domestic water is unusual. Most such units are too small to be worth converting.

■ Air-Cooled Cooling Units

Even if an air conditioning system is air-cooled, you can still use an alternative heat sink. Install a heat exchanger in the hot gas line that leads from the

WaterFurnace International, Inc.

Fig. 1 Alternative heat sources and heat sinks These improve the efficiency of cooling by lowering the average condensing temperature, especially during periods of high cooling load. They improve the average heating efficiency of heat pumps, especially in colder climates.

Fig. 2 Alternative heat sources and heat sinks serving many heat pumps Any number of heat pumps can be served easily by means of a water loop. The ultimate limitation is the capacity of the source and sink fields.

compressor to the existing condenser coil. This may require no extra controls, except for the water loop pump. This modification may be economical with larger systems, but not with smaller air conditioners.

If you have a large number of smaller air-cooled air conditioning units, consider scrapping them and replacing them with heat pump units that are connected to the alternative heat source/sink. This may be economical if electric resistance heat is presently used, if electricity is expensive, and if the existing air conditioners are nearing the end of their service lives.

■ Air-Source Heat Pumps

In principle, you can install a heat exchanger in the external circuit of an air-source heat pump. During cooling operation, the heat exchanger takes the heat out of the compressed gas line. During heating operation, the liquid refrigerant is evaporated in the heat exchanger. This would be a very unusual modification, and you would be fortunate to make it work well. It would not be economical with the smaller heat pumps used for comfort conditioning. You may find worthwhile applications in larger industrial heat pumps.

■ Heat Pump Loop Systems

Heat pump loop systems may benefit greatly from an alternative heat source/sink, and they are easily adaptable. Heat pump loops in general are complex. [Measure 5.6.3](#) covers this modification in detail.

Common Design Issues

As we said before, each type of alternative heat source/sink involves its own body of knowledge. Use [Reference Note 22](#) as your starting point. The following points apply to all the sources and sinks.

■ Minimize Pump Power

All the alternative sources and sinks connect to the rest of the system through a water loop. Therefore, you

need pumps. Design the system to minimize the amount of pump energy required. Minimize the resistance of the heat exchangers and piping. Control the pumps to turn off when conditioning is not needed. In larger systems, consider variable-flow pumping.

■ Protect Against Refrigerant Contamination

Most cooling units and heat pumps operate with high refrigerant pressure. If ground water or surface water is used as the heat sink/source, you may have to protect the water source against refrigerant contamination that may occur if a heat exchanger leaks.

The easiest way to protect the water supply is by using a double-wall heat exchanger. In this type of heat exchanger, the heat transfer surface consists of two metal surfaces with a space between them that is vented to the outside. Thermal conduction occurs across closely spaced metal-to-metal contacts between the two surfaces.

If soil is used as the sink/source, a water loop is used to convey heat from or to the compressor, and the water loop acts to isolate the soil from a refrigerant leak.

■ Source/Sink Temperature Control

Using soil or ground water as the heat sink/source may require no additional temperature controls. Both act as essentially constant-temperature sources of heat. The refrigerant simply rejects or absorbs heat at the available temperature.

Using surface water as a heat sink may require a throttling valve in the heat exchanger to maintain a minimum condensing temperature when the water becomes very cold.

If you use solar collectors as a heat source, you will need controls to limit the temperature input to the heat pumps.

ECONOMICS

SAVINGS POTENTIAL: Cooling energy consumption may be reduced from 20% to 40%. Heating energy consumption may be reduced from 10% to 50%, depending on the climate and on which alternative heat source you choose.

COST: Open-loop surface water systems are the least expensive, the cost determined largely by the distance to the body of water. Closed-loop surface water systems are next, if the distances are not too great. Water wells are usually more expensive than these. Well designed soil heat exchanger systems are expensive, typically costing several times more than a comparable air-source system. Solar collectors are expensive as heat sources, but they are more economical in combination with heat pumps than when used to provide heat directly. Waste heat sources may be fairly inexpensive.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

SELECTING THE SOURCE: *Some sources/sinks are fairly easy to deal with, and some are tricky. Design is fairly conventional for water sources, but be sure to provide for easy cleaning of the heat exchangers. Soil heat exchangers and solar collectors involve difficult design choices. Study in detail each type of source that you are considering. Start with [Reference Note 22](#).*

SELECTING THE EQUIPMENT: *Be relentless in checking references for every component of your system, including the plastic pipe. Don't buy unproven equipment. You don't want to add one more failed or uneconomical system to the dismal collection of failures that already litter the landscape.*

INSTALLATION: *Installing a water source is fairly routine, with few opportunities for major mistakes. On the other hand, heat exchange with soil involves a large temptation to take installation shortcuts. Soil heat exchangers are vulnerable to installation damage that*

causes later leaks that cannot be repaired. Solar collectors appear to have an evil genie that causes people to install them incorrectly or in a manner that requires continual maintenance.

EXPLAIN IT: *Describe the system clearly in the plant operating manual. Install placards to identify unusual components.*

MAINTAIN IT: *Schedule inspections and maintenance at appropriate intervals. Solar collector components tend to fail from weather exposure, from high stagnation temperatures, and in poorly designed systems, from thermal expansion and contraction. Open water sources require occasional heat exchanger cleaning. All systems require occasional pump maintenance.*

MONITOR PERFORMANCE: *If your energy management control system has the ability to do trend logging, use it to record heat exchanger supply and return temperatures. Or, do this manually in the plant operating log.*

Heat Pump Loop Systems (Additional Measures)

The Measures in this Subsection improve the efficiency of heat pump loop systems. Heat pumps in general are covered in [Subsections 5.4](#) and [5.5](#). Heat pump loop systems are covered separately here because they are unique and difficult. Control is complex, selection of the heat sources and heat sinks takes you far away from the basic subject of heat pumps, and the piping can be tricky. If you deal with heat pump loop systems, budget a lot of time to work out the details and find a quiet place where you can concentrate. As you will see, it is a challenge to get these systems to provide the efficiency benefit that they promise.

GENERAL FEATURES OF HEAT PUMP LOOP SYSTEMS

In a heat pump loop system, individual air-to-water heat pumps are connected to a common water loop. Heat pumps that are cooling their spaces reject heat into the loop. Heat pumps that are heating their spaces draw heat from the loop.

Supplemental heat sources are connected to the loop to add heat at times when the total heating load of the system exceeds the total cooling load. Similarly, heat rejection equipment is connected to the loop to get rid of excess heat when the total cooling load of the system exceeds the total heating load.

In the simplest systems that are found, the supplemental heat source is a fuel-fired boiler, and the heat rejection equipment is some type of cooling tower. This type of system is shown in [Figure 1](#).

The system in [Figure 1](#) represents perhaps the most common concept of a heat pump loop system, and systems using this arrangement have been installed. Unfortunately, this arrangement is naive and wasteful. It throws away the primary advantage of a heat pump, which is to draw free energy from the environment for heating. To correct this basic flaw, a source of free energy is needed for all system operating conditions. More than one source of free energy can be included, to maximize system efficiency at different times. Such an improved system is shown in [Figure 2](#).

INDEX OF MEASURES

[5.6.1](#) Install controls to optimize the loop temperature under all operating conditions.

[5.6.2](#) Install automatic valves and bypass lines to prevent the flow of loop water through heat sources and heat sinks when they are not needed.

[5.6.3](#) Improve efficiency by substituting a heat source/sink with better temperature characteristics, or by adding a source of free heat.

[5.6.4](#) Add thermal storage to the loop system.

RELATED MEASURES

- [Section 2](#), for Measures related to chiller plants
- [Subsection 2.10](#), for heat recovery from cooling equipment
- [Subsection 5.6](#), for Measures related to centralized heat pumps in general

The overall system may have a net heating load that alternates with a net cooling load on a short cycle, usually daily. In such cases, installing a thermal storage system may improve average system efficiency. For simplicity, Figure 3 shows thermal storage added to a system that lacks the essential free heat source.

ADVANTAGES OF LOOP SYSTEMS

The water loop is the essential feature of the heat pump loop system. The water loop provides the following advantages:

- **space-to-space heat recovery.** A unique advantage of heat pump loop systems is that they allow the recovery of heat from spaces that are being cooled to provide heating for other spaces, thereby saving heating energy. The loop concept was popularized largely as a means of transferring heat from the core zones of buildings to perimeter spaces that require heating.
- **virtually any available type of heat source** can be connected to the system by means of the loop. An additional heat source is needed when the heat

Fig. 1 Naive heat pump loop system This illustrates the original concept of loop systems, which is to transfer heat from the core of the building to the perimeter. Although systems like this have actually been built, they throw away the primary advantage of heat pumps, which is their ability to draw free heat from the environment.

pumps extract more heat from the loop than they reject to the loop. Some of these heat sources are “free.” Even fuel-fired sources are typically less expensive than the electric resistance heat that is commonly used to supplement individual air-to-air heat pumps.

- **heat pump efficiency and capacity do not depend on the outside temperature**, unlike common air-to-air heat pumps. Therefore, the heat pumps in a loop system can be smaller. This advantage relates directly to the previous point. Fuel-fired heat sources and some free heat sources add heat to the loop in a way that is largely independent of the climate. (See [Reference Note 22](#), Low-Temperature Heat Sources & Heat Sinks, for more about this.)

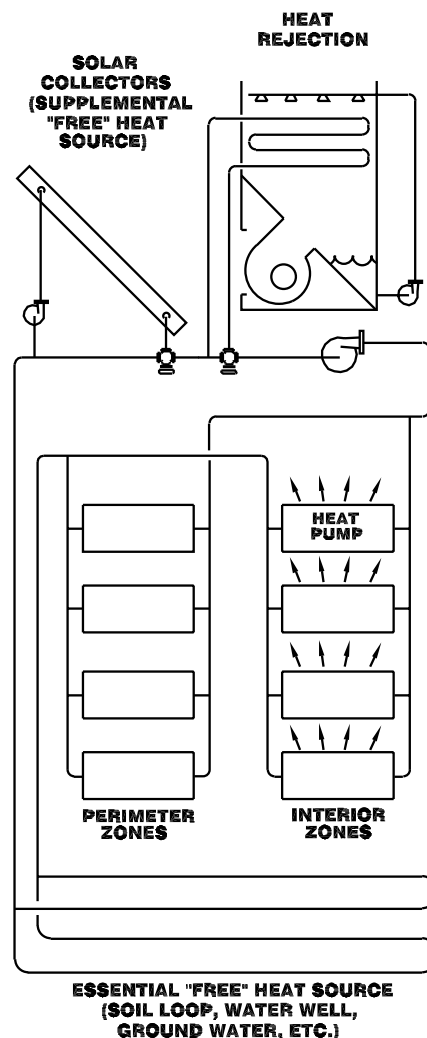

Fig. 2 Efficient heat pump loop system This system corrects the flaw in Figure 1 by adding “free” heat sources. A free heat source that is available throughout the heating season is essential. Other free heat sources, such as solar collectors, can increase system efficiency by increasing the loop temperature for heating. The reduced energy consumption of this system is related mainly to the use of free heat sources. The core-to-perimeter heat transfer is usually less important.

- **solar collectors** can be connected to a loop system at substantially lower cost than for a freestanding solar system of equal heat contribution. This is because operation with heat pumps increases the heat collection capacity of solar collectors, and because the solar collectors do not require the other components of a freestanding solar heating system. (Reference Note 22 covers this point in greater detail.) As a result, solar heating may be economical in a loop system for applications where it would not be economical otherwise.
- **thermal storage** can be added to a loop system at relatively low cost. If there is an alternating requirement for heating and cooling, e.g., heating at night and cooling during the daytime, then thermal storage can save the daytime heat to make it available for nighttime heating. Thermal storage may also be used to reduce electricity demand charges.

Note that all of these advantages, except the first, can be exploited by any individual hydronic heat pump system. However, the economics of exploiting them tends to be better in loop systems.

EFFICIENCY PENALTIES OF LOOP SYSTEMS

Heat pump loop systems have several efficiency disadvantages compared to individual air-to-air heat pumps:

- the water loop adds **another stage of heat exchange**, which increases the temperature differential across the heat pump units and reduces their efficiency
- the various **loop circulation pump(s) require additional energy** to operate
- the central heat sources and heat rejection equipment, such as boilers, cooling towers, and solar collectors, require **additional energy for their own auxiliary equipment**, such as fans and pumps.

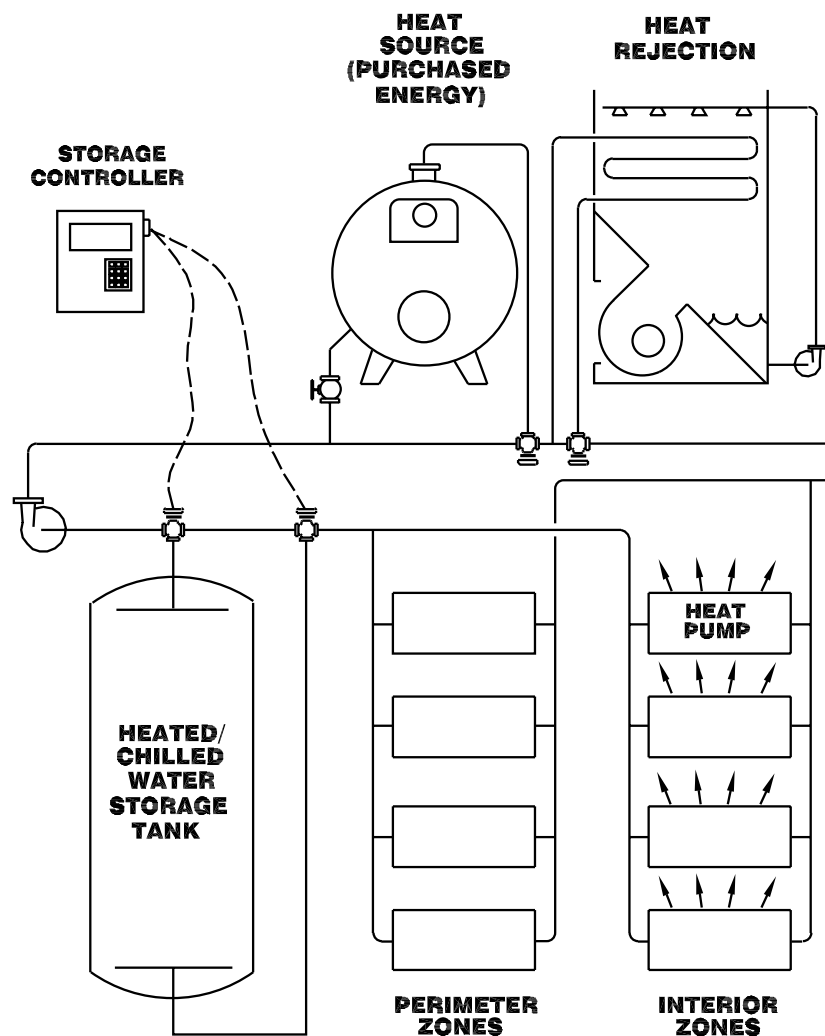

Fig. 3 Heat pump loop system with thermal storage Under some circumstances, thermal storage can improve the efficiency of a loop system. And, it allows buying electricity at times when rates are lower. This system does not show the essential free heat sources.

RELATIVE SYSTEM COST

The equipment cost for a heat pump loop system is higher than for individual air-to-air heat pumps. This is because of the extra piping and pumps, and because of the additional components that are required by the system. In all systems, these components include an additional heat source and a means of heat rejection. Optional equipment, especially thermal storage and solar collectors, raise the cost considerably. The total installation cost of all these items is typically much higher than for air-to-air heat pumps.

Using a free source of energy, such as a water well, eliminates or reduces the cost of conventional heat sources. Similarly, using the earth or a body of water as a heat sink eliminates or reduces the cost of a cooling tower or dry cooler. However, the equipment to exploit free sources and sinks is typically much more expensive to install than conventional heat sources and heat rejection equipment.

HOW VALUABLE IS CORE-TO-PERIMETER HEAT TRANSFER?

The original selling point of loop systems was their ability to transfer heat from interior spaces to perimeter spaces, and vice versa. The thermodynamic advantage

of recovering heat from inside the building is that this heat is available at a higher temperature than is available when using outside air as a heat source. Likewise, units that are cooling the interior may be able to reject heat to a loop that is cooler than the outside air temperature.

Don't overestimate this potential benefit. It may be much less important than the connection possibilities provided by the water loop, discussed previously. The saving depends on the climate, on differences in load characteristics between different zones of the building, and on the heat storage characteristics of the building's structure. Calculating the saving with any degree of accuracy usually requires a sophisticated computer program. (See [Reference Note 17](#), Energy Analysis Computer Programs, about these.)

The heat shifting potential of heat pump loops may be greatly reduced by other energy conservation measures. The interior or "core" zones of buildings require cooling year around, which provides a source of heat for perimeter areas. The amount of heat generated in the core of the building may be reduced dramatically by improvements in lighting efficiency, which are recommended in [Section 9](#). Likewise, the heat requirement of perimeter spaces may be reduced substantially by envelope improvements, which are recommended in [Sections 6](#) and [7](#).

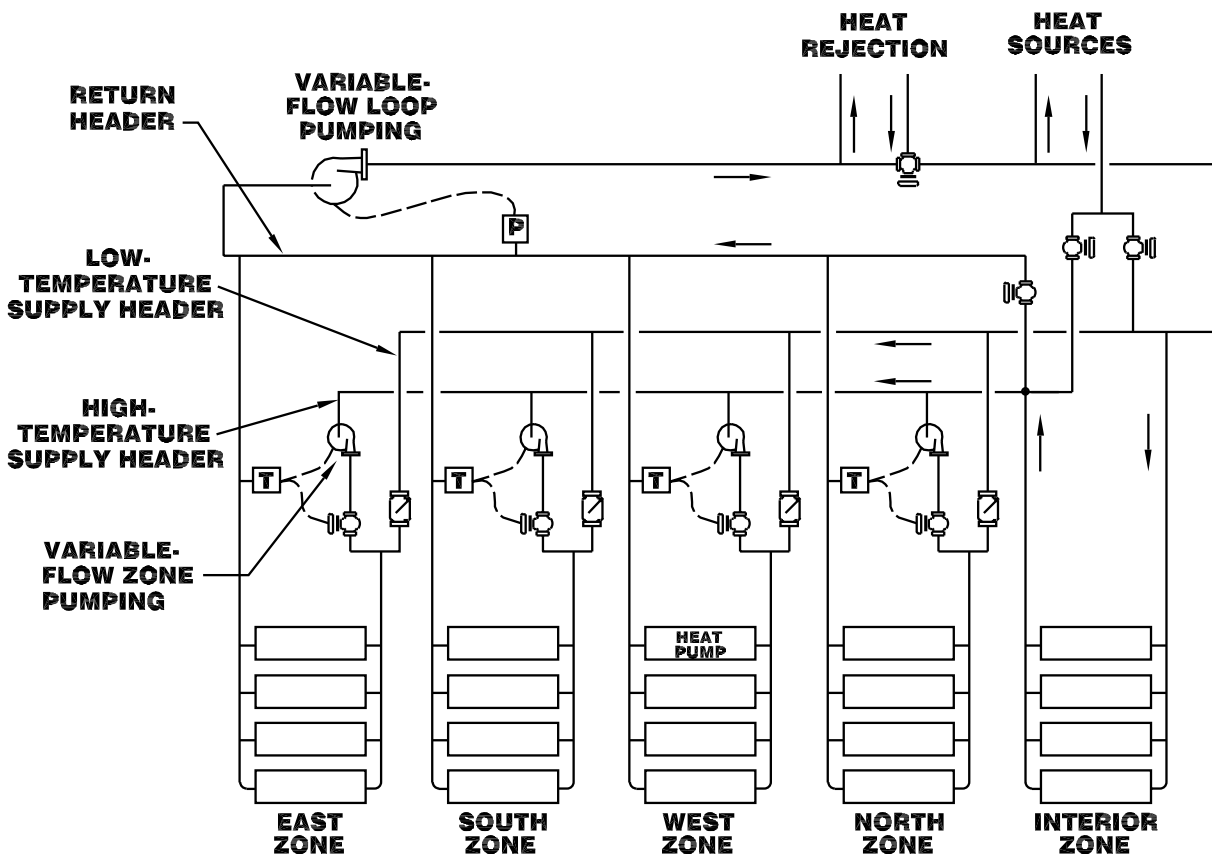

Fig. 4 Double-header heat pump loop system This system improves overall efficiency by routing warmer water to heat pumps that are heating, and cooler water to heat pumps that are cooling. All the details matter, including the sequence in which the heat pumps on different faces of the building are piped to the system.

COMMON FLAWS IN LOOP SYSTEMS

Control of heat pump loop systems is complicated by the many ways in which these systems can operate inefficiently. Overlooking any mode of operation can cause either the wrong loop temperature or improper operation of equipment units connected to the loop. Operating staffs find it difficult to understand the logic of system operation, so they cannot operate the systems efficiently. Optimizing system control is covered by [Measure 5.6.1](#).

Extensive field investigations by one expert revealed that presently installed heat pump loop systems tend to be more expensive to operate than conventional fuel-fired systems. Many existing heat pump loop systems are defective in design, i.e., they lack elements necessary to achieve their potential efficiency. It appears that the designers of these systems fail to understand the underlying theory. Or, critical components are omitted to cut cost during construction. Or, the systems are installed in applications that cannot exploit their potential advantages.

The most serious design flaw in loop systems is failing to provide a free source of heat (outside air, solar panels, water wells, etc.) for heating operation. [Measure 5.6.3](#) deals with this crucial issue.

SEPARATE HIGH- AND LOW-TEMPERATURE HEADERS

The simple loop circuit shown in Figures 1, 2, and 3 forfeits some potential efficiency because warm water (from units rejecting heat to the loop) is mixed with cool water (from units extracting heat from the loop). Greater efficiency is possible if the loop piping is arranged so that heat pumps that provide heating receive loop water that is warmed by the heat sources, while heat pumps that provide cooling receive loop water directly from the heat rejection equipment. An arrangement that does this is shown in Figure 4.

As far as is known, the arrangement shown in Figure 4 is entirely novel. If you attempt it, you will be executing an intricate concept with no experience to guide you. The details are tricky. Here are the main issues to consider:

- ***the interior zone is treated as a heat source.*** Note that the loop piping connects the interior zone in parallel with the other heat sources, and that the discharge water from the interior zone goes only to the high-temperature header (or to the return header).
- ***the exterior zones are arranged in the sequence shown.*** Each of the exterior zones may provide heating or cooling, at different times. Each is piped to the two supply headers identically. However, best overall efficiency is obtained when the exterior zones that have the largest heating loads receive the warmest water. Therefore, the high-temperature header should be piped to the exterior zones as

shown. If the internal loads are the same in all the perimeter zones, then the north zone will have the largest heating load, because it receives no direct sunlight in winter. The west zone receives no sunlight until afternoon. The east zone receives the most sunlight early in the day, when the cooling load is highest, so it needs the least heating input. The south zone typically falls between the east and west zones in average heating requirement.

- ***the main loop circulation pump is the only pump serving the interior zone.*** The main loop circulation pump is designed to provide enough flow for all the heat pumps in the system. It is designed to provide enough pressure to overcome the resistance of the heat pump coils, but only when the heat pumps are being fed in parallel. This occurs in the exterior zones only when the individual zone is being fed from the low-temperature supply header, i.e., when cooling.
- ***zone booster pumps are required for the exterior zones when heating.*** When the heat pumps of an exterior zone are providing heating, the zone is fed from the high-temperature supply header. In this case, the exterior zone heat pumps are in series with the interior zone heat pumps. This increases the total flow resistance in the water loop. To overcome this additional resistance, each exterior zone has its own booster pump for heating operation. The booster pumps should be variable-flow, because the number of heat pumps operating in heating mode within each zone will change as the heating load changes.
- ***control the operation of each zone booster pump to provide the highest overall efficiency.*** In each exterior zone, there will be times when some of the individual heat pumps are providing heating, and others are providing cooling. This is inefficient. To minimize the waste of energy, supply the zone from the high-temperature header when most of the heat pumps are heating, and supply the zone from the low-temperature header when most of the heat pumps are cooling. A simple way to make the changeover is to control the zone booster pump in response to the return water temperature in its zone. The booster pumps draw only from the high-temperature header. When the booster pump is not operating, flow from the high-temperature header is valved off, and water feeds the zone from the low-temperature header.
- ***balance the total system flow between the high-temperature and the low-temperature supply headers.*** The total supply flow from the two supply headers must equal the return flow. This does not happen automatically, but depends on the control of the various valves in the water loop. Figure 4 does not show the control details, which can be executed in several ways.

Additional variations in this design can provide further small improvements in efficiency. However, they are a nightmare of complexity.

MEASURE 5.6.1 Install controls to optimize the loop temperature under all operating conditions.

Even if a heat pump loop system has all the necessary components described in the introduction to this Subsection, it will still not provide a benefit unless it is controlled properly. Optimizing the control of a heat pump loop system is perhaps the most complex control challenge in HVAC. Stated simply, the objective of the loop temperature control is to maximize the overall system efficiency under all conditions.

To work out the controls properly, take a blank pad of paper, define all the operating conditions of the system, and calculate the optimum loop temperature for each set of conditions. To do this, you need to learn the efficiency characteristics and operating limitations of all the equipment in the system. If the system has any complications, such as thermal storage, the range of possible operating conditions expands radically.

Then, design the simplest set of controls that provide those loop temperatures. In all but the simplest cases, you need a computer to control the system efficiently. If an energy management control computer is installed, consider using that system. Or, consider using a programmable logic controller (PLC) exclusively for the loop system. Review Reference Note 13, Energy Management Computer Systems. Programming either type of computer is likely to be a daunting effort.

Consider the following issues in your control design.

The Loop Temperature Dilemma

Heat pump loop systems face a dilemma that apparently was not well understood in early systems. Namely, changing the loop temperature increases the efficiency of some components and lowers the efficiency of others. As a result, the temperature of the heat transfer loop has a complicated effect on the overall efficiency of the system. Specifically:

- **the individual heat pump units** become more efficient in the heating mode if the loop temperature is raised. On the other hand, they become more efficient in the cooling mode if the loop temperature is lowered. The fact that some heat pumps are heating while others are cooling creates a dilemma in setting the loop temperature. The efficiency (actually, the “coefficient of performance”) of individual heat pumps may vary by a factor of two with changes in loop temperature.
- **solar and “renewable” heat sources** provide more heat to the loop as the loop temperature is lowered. This effect varies considerably among different types of sources. For example, solar collectors benefit greatly from reducing the loop temperature,

SUMMARY

The controls needed to make loop systems efficient. Takes a lot of thought to get it right. Often missing in existing systems.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓		
Ease of Retrofit	☺	☺		

especially the types of collectors that have high heat loss. This is because solar heat that is not absorbed by the loop is lost to the atmosphere. In contrast, the amount of energy that can be extracted from natural water sources is not much affected by loop temperature, provided that the heat exchanger has ample capacity.

- **heat rejection equipment**, such as cooling towers and dry coolers, becomes less efficient as the loop temperature is lowered. The effect of heat rejection efficiency on overall system efficiency is much smaller than the effect of heat pump efficiency. Still, the effect is large enough that you should consider it in designing the loop temperature control. Cooling equipment that uses fans can be adjusted independently of the rest of the system to minimize waste of fan energy. Refer to Measures 2.2.2 ff for methods.
- **fuel-fired boilers** become somewhat less efficient as the loop temperature is raised. This is a minor factor within the temperature range in which heat pump loops operate. As a practical matter, you can ignore the effect on boiler efficiency. Electric boilers always operate with an efficiency near 100%, so their efficiency is not a factor in loop temperature.

The loop temperature that provides the best overall efficiency is a balance of all these factors. The balance changes continuously, depending on the relative number of units that are heating or cooling, the outside air conditions, the time of day, the amount of sunlight, the state of charge of the storage system, and other factors that depend on the specific design of the system. Another major factor is the temperature limits on heat pump operation, which we examine next.

Heat Pump Temperature Limits

Heat pump loop systems use air-to-water units that are designed to operate within a specified range of water temperatures. However, the stated temperature range may be nominal, and the manufacturer may not know how its units perform with water and air temperatures outside the stated range. Manufacturers typically design air-to-water heat pumps for a conservative range of temperatures, and may not anticipate the wide range of temperatures that may be necessary to optimize efficiency in loop systems. As a rule, heat pumps are designed with the assumption that the condenser temperature is always significantly higher than the evaporator temperature. In other words, manufacturers do not anticipate low or reversed temperature differentials across their units.

For example, consider operating a loop system in winter, with all the heat pumps providing heating. The loop heat is provided by a boiler, which can heat the loop to any temperature you choose. What should the loop temperature be? The efficiency of the heat pumps is increased by raising the loop temperature. However, as the condenser (room) temperature approaches the evaporator (loop) temperature, the pressure differential across the expansion valves in the heat pumps may drop to the point that they lose capacity. Or, the low pressure differential may allow pooling of oil away from the compressor, causing compressor failure.

If it appears desirable to operate the loop at temperatures higher or lower than those specified in the manufacturer's literature, or if no temperature limits are given, call the manufacturer's engineering department to discuss loop operation. Feel fortunate if you get a certain answer. Loop systems are still experimental, even though manufacturers and designers may not recognize the fact. Efficient operation requires pushing loop temperature control into the unknown.

While you are talking to the manufacturer, ask for verified data that shows how the heat pump efficiency relates to the water and air temperatures. You need this information to develop your schedule of loop temperatures.

Example: Loop Temperature Control in a Simple System

Consider a relatively simple loop system that has only heat pumps, a boiler, and a cooling tower. A hypothetical loop temperature schedule for this system might be:

- when the outside air temperature is less than 50°F, assume that most of the heat pumps are operating in heating mode. The loop temperature is maintained at 110°F by operation of the boiler.
- when the outside air temperature is greater than 70°F, assume that all heat pumps are in cooling mode. Keep the loop at the lowest temperature that

the cooling tower can provide without using excessive fan energy in the heat rejection equipment.

- in the range of outside air temperatures between 50°F and 70°F, the loop temperature is maintained between 110°F and 70°F using a linear reset schedule. The sliding temperature scale is based on an estimate of the relative numbers of heat pumps that are heating and cooling at each temperature.

This control schedule is purely for illustration. An evaporator temperature of 110°F for heating may not be possible with conventional heat pumps, but it illustrates an extreme that would be desirable from the standpoint of efficiency.

Adapt the Loop Temperature to the Heat Sources

Optimum loop temperature control depends on the type of heat sources installed in the system. Control with some heat sources is more complex than with others. As a rule, you can adjust the output temperature of conventional heat sources (i.e., boilers) to suit the needs of the loop system. However, the loop system temperature may have a major effect on your ability to exploit “free” energy sources.

In this Measure, we assume that your heat pump loop system includes a “free” source of energy. If this is not true, see [Measure 5.6.3](#).

Each of the following “free” heat sources has its individual loop temperature control requirements. See [Reference Note 22](#), Low-Temperature Heat Sources & Heat Sinks, for more about these heat sources.

■ Ambient Heat Sources and Heat Sinks

We define “ambient” sources as free heat available from the environment. Such sources include outside air, ground water, lakes, rivers, and deep soil. The quantity of heat is essentially unlimited, if you install enough equipment to tap it. Another major advantage of some ambient heat sources is that you can use them as heat sinks to get rid of heat when the system is primarily in a cooling mode. This is an advantage of ambient sources when compared to solar collectors or waste heat sources.

It is worth repeating that the lack of a free heat source for the loop system radically increases the consumption of purchased energy. [Measure 5.6.3](#), below, describes how to correct this problem.

Ambient heat sources and heat sinks typically provide the simplest loop temperature control. This is because the temperature of the source determines the temperature of the loop directly. Specifically:

- **ground water** and **soil** control the loop temperature at all times, always acting as either a heat source or a heat sink. The temperature of ground water and deep soil does not vary much with the time of year. Almost everywhere on earth, the ground water and

soil temperatures remain in a range that provides better efficiency than outside air for both heating and cooling. No boiler or cooling tower is required, provided that the source has sufficient capacity in relation to the system load.

- **river** and **lake** water behaves in generally the same way, except that there is a large seasonal change in the temperature of the source. When the river or lake approaches freezing temperature, it can no longer be used as a heat source, because the water freezes at the point where it gives up heat to the system. At that time, the boiler becomes the heat source and the loop is isolated from the ambient source. When the boiler is operating, control it to maintain the highest loop temperature at which the heat pumps can operate, for example, at 110°F.
- with **outside air** as the heat source and heat sink, the control schedule is about the same as with river and lake water. Most heat pump systems are able to draw heat from outside air at a substantially lower temperature than the freezing point of water. When the air temperature falls to the point that the heat pumps are no longer able to provide sufficient heating capacity, the boiler becomes the sole source of heat for the loop. At this point, the boiler is controlled to maintain the highest loop temperature at which the heat pumps can operate.

■ Waste Heat Sources

Waste heat typically is available at relatively low temperatures that keep it from being useful for direct recovery. However, most waste heat sources are warm enough to provide good recovery in heat pump systems.

The key issue in loop temperature control is whether or not the amount of available waste heat exceeds the heat requirement of the heat pump system. If the waste heat source can provide more heat than is needed by the heat pump system, then the waste heat source itself determines the loop temperature. On the other hand, if the amount of waste heat is insufficient to satisfy the loop heat requirement, the boiler operates and controls the loop temperature.

If the amount of waste heat is limited, you can increase recovery by lowering the loop temperature. For example, if a limited amount of cooling water discharge is available at 140°F, lowering the loop temperature from 110°F to 80°F would double the amount of heat that is recovered. However, this drop in loop temperature would also substantially reduce the heating efficiency of all heat pumps in the system.

To make best use of waste heat in such cases, you have to calculate a table of optimum loop temperatures based on the amount of waste heat available, the temperature of the waste heat, and the efficiency of the heat pumps at different loop temperatures. Then, you have to create automatic controls that maintain the temperature relationships that you calculated.

■ Solar Collectors

The economic limitation of solar collectors is the relatively small amount of energy that they can collect per unit of collector cost. A major collector design problem is reducing the loss of heat from the collectors themselves. For example, solar collectors used for direct space heating typically must deliver water at temperatures of 140°F or higher. At these temperatures, solar collectors suffer high losses by radiation and by conduction to the surrounding air.

These losses are greatly reduced when solar collectors are used as a heat source for a heat pump loop system. This is because the output of the collectors is useful at any temperature, down to the minimum evaporator temperature of the heat pump. As a result, the collectors can provide useful heat for a much larger number of hours per year than a conventional solar heating system. For example, on an overcast day in winter, a solar collector can provide only a minimal amount of heat at the typical flat-plate output temperature of 140°F, but it may be able to provide a substantial amount of heat at 70°F.

If the amount of solar heat is adequate to serve the heating load, the loop temperature is determined by the output of the solar collectors. Under this condition, keep the loop temperature as high as possible to maximize heat pump efficiency. If solar input starts to fall behind the heating load, the loop temperature drops as the heat pumps remove heat from the loop faster than the solar collectors add heat. If the loop temperature falls too far, the supplemental fuel-fired heat source is started to make up the difference.

Unlike other free energy sources, solar collectors can be used in parallel with fuel-fired heat sources at temperatures that provide good heat pump efficiency. This is because solar collectors can provide heat at a substantially higher temperature than other free sources.

Whenever the boiler is operating, i.e., when the solar collectors do not have sufficient output to carry the entire heating load, the boiler controls the loop temperature. In this case, the optimum loop temperature is a compromise between solar collector efficiency and heat pump efficiency. When the solar collectors are able to deliver a significant amount of heat, lower the loop temperature to maximize the output of the solar collectors. When the solar collectors cannot provide much energy (e.g., at night or during a heavy overcast on a cold day), increase the loop temperature to improve the efficiency of the heat pumps.

The output of the solar collectors can be measured directly with a BTU meter. To maximize the overall system efficiency, calculate a table of optimum loop temperatures based on the amount of solar heat available and the efficiency of the heat pumps at different loop temperatures. Then, design the system controls to maintain these temperatures.

How to Set the Loop Temperature in Systems with Thermal Storage

Control of loop temperature becomes still more complex if the system includes thermal storage. The simplest (but least efficient) case is a storage system that has no heat source other than a boiler. For this system, the basic problem is predicting how much thermal energy to store.

If the heat pumps are primarily providing cooling, they are adding heat to the loop. Should this heat be rejected to the cooling tower or saved in the thermal storage tank? The answer depends on the amount of heating operation that you anticipate. If not enough heat is stored, the boiler must operate longer to provide heating. On the other hand, if too much heat is stored, the higher temperature in the storage unit makes the heat pumps less efficient while they are still cooling.

Thermal storage in loop systems usually is limited to one-day cycles, so you can estimate the amount of heat to be stored from the outside air temperature and the cooling load. Delay turning off and isolating the cooling tower, which forces the loop and storage temperature to rise, until the latest possible moment. You can use an optimum-start controller (see [Measure 4.1.1.2](#)) to perform this control function. Alternatively, you can program an energy management computer for this.

Use the converse approach when storing cooling. Toward the end of a heating cycle, turn off the boiler at the latest possible moment that allows the heat pumps to pull down the loop temperature in anticipation of cooling operation.

In any event, don't expect to predict the load in the next cycle with much precision. Electric generating companies have full-time staffs who specialize in guessing what the cooling or heating load will be tomorrow.

If thermal storage is used in a system that also has a source of free energy, control can become even more complicated. The control sequence depends on the type of free energy source, as explained previously.

Avoid Efficiency Traps

To keep the system at maximum efficiency, optimize the loop temperature for every possible mode of system operation, at all seasons, all times of day, and with all possible combinations of heating and cooling loads. Here are some guidelines:

- **Avoid forcing a change of loop temperature with purchased energy.** Do not allow the boiler to raise the temperature of the loop as long as the temperature can be raised by the heat pumps or a free energy source. Similarly, do not use heat rejection equipment to blow away loop heat when entering a heating period.

- **Maintain a safe deadband between the operation of the boiler and the operation of the heat rejection equipment.** Otherwise, purchased energy will be expended alternately by the boiler and cooling tower to follow small fluctuations in the loop temperature.
- **Anticipate shutdowns periods when heating.** Turn off the boiler prior to shutting down the system and let the heat pumps extract the heat from the loop. Refer to the previous discussion of thermal storage. Coordinate with the controls recommended in [Measure 5.1.3](#) that limit the duration of system operation.
- **Do not keep boilers warmed up.** Design the loop temperature controls to start the boiler only when it is needed. As soon as a boiler starts to fire, the heat pumps can extract the boiler's heat output from the loop. Letting the boiler stay cold eliminates standby losses. Furthermore, a boiler that is kept hot suffers from thermal shock when cold loop water is suddenly passed through it. (In heating systems that use the output of a boiler directly, the boiler is kept warm because a high temperature is needed to deliver the heat to the system. This is not necessary in heat pump loop systems.)
- **Install control interlocks to prevent simultaneous operation of the heat sources and the heat rejection equipment.** Defects may occur that cause the heat sources and heat rejection equipment to operate simultaneously. Interlocks can prevent this. The interlocks should include alarms to alert operators to the fact that a defect exists.
- **Be careful about the location of the temperature sensors.** The thermostatic controls for loop temperature regulate the temperature only at the point where the temperature sensor is located. The temperatures at other points in the system may be radically different. Figure out carefully what you are trying to measure, and install the control sensors accordingly. If possible, try to measure the temperature at the same point in the loop for all control functions. If this does not provide enough information for good control, add multiple sensors and program the controls accordingly.

ECONOMICS

SAVINGS POTENTIAL: 10 to 40 percent of the energy consumed by the system.

COST: A few thousand dollars, at least, assuming that the system presently does not have loop temperature optimization.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

CONTROL DESIGN: Optimum control of a hydronic loop system is exceptionally challenging. It requires expertise in controls, combined with an in-depth understanding of equipment components. Unless the system is very simple, expect to need a computer-based control system to keep the loop system operating at its optimum point.

EXPLAIN IT: Once the control system has been designed, don't expect anyone but the designer to understand it completely. To keep from being stranded

when the designer moves on to his next job, insist on getting a clear description of control operation. You may have to get a competent writer to take notes from the controls expert, who may not be adept at prose. Put the control description in the plant operating manual.

MONITOR PERFORMANCE: Keep track of the loop temperature to be sure that it is behaving properly. Use the trend logging capability of your computer for this purpose. If a computer is not available, add columns to your plant operating log for the loop temperature, the outside air conditions, and other factors that determine the loop temperature.

MEASURE 5.6.2 Install automatic valves and bypass lines to prevent the flow of loop water through heat sources and heat sinks when they are not needed.

RATINGS

New Facilities	Retrofit	O&M
A	C	

The controls recommended by [Measure 5.6.1](#) should turn the heat sources and heat sinks on and off as necessary for optimum efficiency. However, controls can malfunction or they can be set incorrectly. Furthermore, heat may be able to leak into or out of the loop even if the sources or sinks are turned off.

These conditions may persist indefinitely, because they have no visible symptoms other than high energy bills. This makes it prudent to install a bypass line and automatic valves to isolate each heat source and heat sink from the loop. The loop system controls should open and close the isolation valves automatically. The system diagrams in the introduction to this Subsection show the boilers and the heat rejection equipment installed in this manner.

Isolate Boilers

Be able to physically isolate the boiler from the loop. Idle boilers act as heat exchangers. If the loop is kept warm during cold weather by other heat sources, such as solar collectors, heat can be lost from the loop by convection through the flue of an idle boiler. This problem does not arise with electric boilers, which have no flues. It is only a minor factor with boilers that have closed combustion chambers.

Plant operators may tend to keep the boiler running throughout the cold weather season, and perhaps all year. This is undesirable. The boiler should operate only when it is needed at the moment to feed heat into the loop. [Measure 5.6.1](#) explains why. Installing an automatic isolation valve at least prevents leakage of hot water into the loop when it is not needed.

SUMMARY

Prevents loss of heat through idle equipment. Also acts as an additional safety feature against improper operation.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	
Ease of Retrofit	😊	😊	😊

Isolate Heat Rejection Equipment

Bypass water around cooling towers and dry coolers when heat rejection from the loop is not required. These units are located outdoors, and they can reject a considerable amount of heat even when the cooling tower fans are not running.

The system controls should disable the fans in heat rejection equipment when they close the isolation valves. If this is neglected, the fans may continue to operate as a result of high outside air temperature or unintended operation of sump heaters.

Isolate Solar Collectors

When solar collectors are not providing heat to the loop, they can lose a large amount of heat. They are effective radiators because they are located outdoors and have large surface areas. For this reason, the controls

should isolate solar collectors from the loop whenever the collectors are not feeding heat into the loop.

Isolate Ambient Heat Sources and Heat Sinks

Some ambient sources and sinks, especially water wells and earth coils, are connected to the loop continuously, and hence they do not require isolation. Others sources are not usable when freezing occurs, so these sources should be isolated. For example, air source coils suffer heat loss in the same way as dry coolers, and they should be isolated in the same way.

Select Isolation Valves for Longevity

Select appropriate types of isolation valves. The valves should stay free of leaks over the long term, have low maintenance requirements, and be easy to maintain. In small sizes, isolation typically is accomplished with solenoid valves. In larger sizes, motorized valves of various types may be used. Plug valves and ball valves can provide tight shut-off at low cost, and they are easy to operate automatically with standard actuators.

Install the Placards

Install effective placards on all bypass valves that explain their purpose and state when they should be opened or closed. See [Reference Note 12, Placards](#), for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: *Perhaps 5 to 30 percent of system energy consumption, averaged over the life of the system. Specific savings cannot be predicted, because this is largely a safety measure to back up the operation of the system controls.*

COST: *Thousands of dollars.*

PAYBACK PERIOD: *Several years, typically.*

TRAPS & TRICKS

EXPLAIN IT: *Install an effective placard on each valve that states the conditions under which it should be open or closed. Describe the purpose of the valves in the plant operating manual.*

MONITOR PERFORMANCE: *Failure of this kind of auxiliary feature is easy to overlook. Schedule inspections of valve operation during periods when they should be closed.*

MEASURE 5.6.3 Improve efficiency by substituting a heat source/sink with better temperature characteristics, or by adding a source of free heat.

The fundamental advantage of a heat pump over other types of heating equipment is that a heat pump can draw energy from the environment, so the actual source of heating energy is free. Make sure that your heat pump loop system exploits this advantage as effectively as possible. The key is to select the most efficient free source or sources that are available.

(A heat pump needs purchased energy only to force the heat to move against the inside-to-outside temperature gradient. This is the energy that goes into the motor of the compressor.)

Loop Systems Lacking a Free Heat Source

Individual heat pumps always have a free source of heat, and this is what makes them economically attractive. In contrast, loop systems sometimes lack a free heat source, as shown in Figure 1 in the introduction to this Subsection. These systems must rely on the system’s “supplemental” heat source (i.e., a boiler) when there is a net heating requirement. It may seem inconceivable to undertake the trouble and expense of a heat pump loop system without installing a free energy source. Yet, such systems exist. Indeed, the basic design literature for engineers overlooked this fundamental feature for years after the concept was popularized. It appears that the engineering glamor of moving heat around a building distracted designers from the fact that the fundamental advantage of a heat pump is its ability to draw heat from the environment.

Without a source of free heat, a heat pump loop system consumes more energy than a conventional heating system using the same fuel. This is because the heat delivered to the space is derived mostly from the “supplemental” energy source, plus the electrical energy input to the compressor. Thus, the heat pump is not only extraneous, but adds to the energy cost. The only efficiency advantage provided by such a system is the core-to-perimeter heat transfer. Averaged over a typical operating schedule, this advantage cannot compensate for the lack of a free heat source.

With such a crippled heat pump loop system, the way to improve efficiency is to add a source of free heat, as shown in Figure 2 in the Subsection introduction. The free heat source is connected into the system through the water loop. The physical connection is typically easy to make.

Your Choice of Free Heat Sources

See [Reference Note 22](#), Low-Temperature Heat Sources and Heat Sinks, for the main characteristics of soil, well water, ground water, solar collectors, and waste

SUMMARY

A source of free energy is a fundamental feature needed to make heat pump loop systems efficient. If an existing system presently uses the atmosphere as a heat source/sink, you may be able to improve efficiency substantially by using a different heat source.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

heat as free energy sources. Each of these sources/sinks has its own advantages and disadvantages. Some of these heat sources also serve as heat sinks, providing better heat rejection efficiency than air-cooled heat rejection units. Your choice depends on the characteristics of the facility and its environment.

Also, see [Measure 5.6.1](#) about the temperature and control characteristics of free heat sources.

Along with the heat sources covered in [Reference Note 22](#), consider using outside air as the heat source and sink, even though it is less efficient in both roles than the other free heat sources/sinks. In many cases, outside air is the only available source/sink.

Outside Air as a Heat Source

The outside atmosphere is the most common heat source and heat sink for individual heat pumps. The main advantage of an air source is ready availability and low cost. You don’t have to go far to find outside air, and connections to the water loop are simple. However, the atmosphere is rarely used as a heat source for heat pump loop systems. Approach the design of an air source with the caution appropriate to a complex, innovative activity.

The main disadvantage of air as the heat source is that the temperature of the air is usually falling as the heating load is increasing. Low air temperature substantially increases the compressor power and reduces heating capacity. This makes the atmosphere the least efficient of all free heat sources. Furthermore, the heating efficiency of a loop system with an air source, when the system is providing only heating, is less than

the efficiency of individual air-to-air heat pumps. This is because the water loop needs pump energy, and because it adds an extra stage of heat transfer.

When operating at low temperatures, an air source heat pump expends energy for defrosting. At even lower temperatures, the heat pump may not be able to operate at all. For this reason, air source heat pumps often depend on electric resistance heating during cold weather.

Similarly, the main disadvantage of air as a heat sink for cooling is that the air temperature is usually high when the cooling load is high.

■ Equipment Options for Collecting Air Heat

If the system has a dry cooler to reject heat from the loop, consider using the dry cooler to collect heat from the air. The heat transfer capacity of dry coolers is about the same whether absorbing or rejecting heat. If the winter heating load is substantially higher than the summer cooling load, the dry cooler will be too small for the peak heating load, but it may still be used within its heat absorbing capacity. When the capacity of the dry cooler is exceeded, the controls should turn it off and isolate it. Then, additional heat is provided by the boiler or other existing heat source.

You can install a supplemental heat absorbing unit to provide full capacity. If this unit is used only as a heat intake for the heat pumps, try to install it where it will ingest air that is warmed by contact with a sunlit surface, such as a large, dark roof.

If the system presently has a closed-loop cooling tower, you might consider using it as a heat source. However, this would be quite a novelty. It would work only in cases where the rated cooling capacity of the tower is much larger than the peak heat collection requirement. Closed loop cooling towers have bundles of smooth coils that are kept wetted during operation. Wetting provides high heat transfer capacity, and the heat is rejected mainly by evaporation. However, the tower would have to operate dry to absorb heat, which makes its heat absorption capacity much lower than its normal heat rejection capacity. Furthermore, it would be troublesome to continually switch between dry (heating) and wet (cooling) operation.

■ Defrosting Air Heat Sources

When the system is operating primarily in heating mode, the heat pumps are mostly extracting heat from the loop, which keeps the loop temperature lower than the outside air temperature. When the outside surface of the air coil gets below freezing temperature, ice can start to accumulate on the coil. When this occurs, the fins become choked and heat transfers falls off drastically. At this point, the air source can no longer be used. The system must have a means of defrosting the coil, or a supplemental heat source (typically, a boiler) must be energized.

Defrosting a heat pump loop is problematic. Unlike individual heat pumps, a loop system cannot briefly reverse its operating cycle to provide defrosting. Instead, the system needs a separate heat source to defrost the coil. It may be possible to defrost using an external heater. A more efficient method is to circulate warm water through the coils for defrosting. This requires a separate source of warm water, a separate defrost circuit, changeover valves, and control paraphernalia. The design work is tricky.

If the system does not operate for long periods of time when coil freezing can occur, it may be more cost effective to forget about defrosting, and use the boiler as the heat source during freezing conditions.

Cost Advantage for Solar Collectors

The cost of adding solar collectors as the heat source for a heat pump loop system may be much lower than the cost of installing a solar system from scratch. This is because the loop system includes most of the expensive distribution system, and it may also include the expensive storage equipment that an active solar system needs. Further, this application can use less expensive solar collectors that are designed to operate at lower temperature.

Consider Scrapping the Loop Design

Designers have tended to become infatuated with heat pump loop systems. Despite their theoretical appeal, consider other alternatives, even with an existing system. If your loop system is flawed, get a clean sheet of paper and consider all your options, including scrapping the loop system.

You can add a free heat source to heat pumps without using a loop system. See [Measure 5.5.10](#) about this.

In many locations, using a free heat source may not be the cheapest or best way to improve the overall efficiency of heating and cooling. For example, in a mild climate, individual air-to-air heat pumps are likely to be the most efficient way to use heat pumps. In a cold climate, a system of hydronic fan-coils with fuel-fired heating and conventional cooling may be the most efficient approach.

ECONOMICS

SAVINGS POTENTIAL: *If the system presently lacks a source of free heat, this Measure saves all or most of the energy consumed by the heat sources in the original system. The saving may be reduced by increased heat pump energy consumption. However, this is true only if the free energy source operates at a temperature lower than the maximum-efficiency temperature of the heat pumps.*

If you substitute a different free source/sink for an existing outside air source/sink, expect savings in the range of 30 to 60 percent of the original energy consumption.

COST: Tens of thousands of dollars, typically.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

SELECTING THE SYSTEM: If your loop system does not have a free source of energy, it is seriously flawed. In that case, review your heating and cooling options broadly. Review the introduction to this Subsection, as well as [Measure 5.6.1](#), to appreciate what it takes to make a loop system work efficiently. If you decide to keep the loop system, start your selection of the free energy source by reviewing [Reference Note 22](#). Examine your options thoroughly. Each type of free energy source requires distinct expertise.

SELECTING THE EQUIPMENT: If you select packaged equipment or systems, such as solar collectors or earth source heat pumps, be relentless in checking references. Do not buy equipment that is not proven by long service.

INSTALLATION: Installing water sources is fairly routine, with few opportunities for major mistakes. On the other hand, heat exchange with soil involves a large temptation to take installation shortcuts. Horizontal soil fields are vulnerable to installation damage that causes later leaks that cannot be repaired. Install solar collectors for ease of maintenance, because they will need it.

MAINTENANCE: Once installed, soil heat exchangers require no routine maintenance. Water sources require occasional heat exchanger cleaning. Solar collector components tend to fail from weather exposure, from high stagnation temperatures, and in poorly designed systems, from thermal expansion and contraction. Schedule periodic checks of condition and operating efficiency in your maintenance calendar.

MEASURE 5.6.4 Add thermal storage to the loop system.

Adding thermal storage to a heat pump loop system can substantially improve the system’s efficiency and/or reduce electricity cost if certain specific conditions exist. The physical installation of the storage unit is straightforward, provided that you have sufficient space for it. In a loop system, adding thermal storage is less expensive than with other types of conditioning systems because the loop system already includes all the necessary connections.

The difficult part of thermal storage is getting the controls right. Failing to control a thermal storage system efficiently forfeits most of the savings, and may even increase energy cost. Like most aspects of heat pump loop systems, thermal storage is fraught with traps in design, installation, and operation.

A water tank is the appropriate storage unit for a heat pump loop system. Water storage is mechanically simple, it requires no additional heat exchangers, and it is suitable for both heating and cooling. However, storing heat in water requires very large quantities of water and big tanks.

Figure 3, in the introduction to this Subsection, shows a basic heat storage installation in a heat pump loop system. Be aware that this simplified diagram does not include the essential free heat sources, which are usually much more important than thermal storage.

Where to Consider Thermal Storage for a Loop System

Thermal storage may improve a heat pump system in these ways:

- **storing free energy that is not available continuously.** For example, thermal storage may increase the amount of heat that can be collected by solar collectors. This benefit occurs only if: (1) the source is not available continuously, and (2) the source provides more heat than is needed when the source is available. Thermal storage does not improve the availability of free energy if the source, such as well water, is always available with adequate capacity.
- **storing heat between alternating cycles of heating and cooling.** For example, the heat pumps may draw heat from the storage tank in the morning for heating the building, and add heat to the storage tank in the afternoon when cooling the building. In HVAC applications, this benefit occurs during the seasons of mild and variable weather. This benefit does not occur if there is a continuous net requirement for heating or for cooling.
- **reducing electricity cost.** Thermal storage allows heating or cooling energy to be produced at times

SUMMARY

Improves system efficiency, but only with certain system configurations and load conditions. Complex to control. Expensive.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓		
Ease of Retrofit	😊	😊		

of day when the cost of electricity to operate the heat pumps is lowest. See Reference Note 21, Electricity Pricing, for more about this. This benefit occurs primarily during periods of peak cooling load and/or peak heating load.

Heat loss from the storage tank limits the duration of a storage cycle to a few days, e.g., a weekend or a short weather cycle.

The tank must be large because water has limited heat storage capacity. To store a useful amount of heat, the water volume can be enormous, typically thousands of gallons for a system of modest size. The tank itself is expensive, and structural support to carry the weight may cost even more than the tank. For this reason, it is usually not economical to make the tank large enough to cover peak conditions. Analyze your needs and calculate a storage capacity that provides a good compromise between equipment cost and system efficiency.

Energy and Cost Saving Potential

Thermal storage can completely eliminate the need for fuel heating as long as the facility’s daily cooling load is larger than its daily heating load. In absolute terms, the amount of energy saved depends on the size of the heating load or the capacity of the storage tank, whichever is less. Assuming that the storage tank has enough capacity, the maximum amount of energy is saved when the daily heating load exactly equals the daily cooling load.

Using thermal storage probably reduces the average heat pump efficiency somewhat. When heat is being added to the system by a supplemental heat source, the temperature of the loop can be kept as high as desired, whereas drawing heat from thermal storage involves a significantly lower average loop temperature. On the

other hand, the cooling efficiency of the heat pumps is increased during the beginning of a cooling period, when the temperature of the storage tank has been lowered by the preceding heating period.

The potential saving in electricity cost vary widely, depending on the load characteristics of the facility, the nature of the heat pump system, and electricity pricing.

How to Design the Storage Equipment

Refer to [Measure 2.10.5](#) about storage of hot water. Refer to [Measure 2.11.1](#) about storage of chilled water. A typical heat pump loop system stores both hot water and chilled water at different times.

ECONOMICS

SAVINGS POTENTIAL: 10 to 30 percent of purchased heating energy, but only in circumstances that favor installation of a thermal storage unit.

COST: Several thousand dollars, or more.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

ESTIMATING THE BENEFIT: In most applications, estimating the potential saving is tedious and somewhat uncertain. A lot of money is at stake, so consider using an energy analysis computer program for your calculations. See [Reference Note 17](#) for details.

DESIGN: While the hardware is simple, the control design may have to be complex. Review [Measure 5.6.1](#) about the interactions between storage temperature and loop temperature. It takes a great deal of thought and patience to design for all the operating conditions that may occur in the system. Design a sensor array to accurately indicate the state of charge of the storage tank.

EXPLAIN IT: The control logic is not easy for anyone but the designer to understand. As a result, control failures or inefficient control adjustment may persist. Describe the system clearly in the plant operating manual. Install placards on the controls.

MONITOR PERFORMANCE: If your energy management control system has the ability to do trend logging, use it to record parameters that indicate how the system is operating. Alternatively, make appropriate manual entries in the plant operating log. Review these records continually.

Subsection 5.7

Direct-Fired Heating Units

The Measures in this Subsection improve the efficiency of space conditioning units that provide heating by firing of fuel within the unit itself. The types covered include direct-fired duct heaters, wall furnaces, residential-type forced air furnaces, and direct-fired heaters within air handling units.

INDEX OF MEASURES

5.7.1 Clean, adjust, lubricate, and repair direct-fired heating units at appropriate intervals.

5.7.2 Install high-efficiency heating units.

5.7.3 Install automatic flue dampers on existing heaters.

5.7.4 Set the anticipators of space thermostats to maximize the interval between firing cycles.

RELATED MEASURES

- **Section 1**, for Measures relating to larger heating plants and for all hot water heating systems

MEASURE 5.7.1 Clean, adjust, lubricate, and repair direct-fired heating units at appropriate intervals.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Direct-fired space conditioning units are generally reliable, and they require only a modest amount of maintenance. Give these items attention at regular intervals:

- **filters and filter mountings.** Clogged filters reduce the air flow through the furnace heat exchanger, causing the space air and the exhaust gases to be hotter. The higher exhaust gas temperature reduces furnace efficiency. Clogged filters also reduce heating capacity, requiring the furnace to operate for longer periods and to warm spaces more slowly. Dirty filters may be a breeding ground for microorganisms, especially if the furnace is located in an area of high humidity. The higher air temperature may cause some odors and air pollution, but only if the space air contains vapors or dusts that are changed chemically by the temperature in the heat exchanger.

- **burner cleanliness and air-fuel ratio.** Inadequate or improper burner maintenance wastes more energy than any other defect of maintenance. Routine burner maintenance consists of (1) cleaning the burner, followed by (2) readjusting the air-fuel ratio. Both of these functions require specialized equipment and techniques. See [Measure 1.4.1](#) about burner cleaning. See [Measure 1.3.1](#) about how to adjust the air-fuel ratio.

Gas-fired heating units typically require burner maintenance only at long intervals. Inspect the flame visually on a routine basis. Do a combustion gas analysis at the beginning of each heating season. If the test indicates the proper efficiency, leave the burner alone.

Oil-fired burners require cleaning and adjustment at regular intervals. Check the manufacturer’s recommendations, and also inspect the units periodically.

- **fireside cleaning.** Combustion products that accumulate on the fireside surfaces of a furnace may cause serious energy waste. Adjust your cleaning interval based on the rate of soot accumulation. Typically, clean an oil-fired heater at the beginning of each heating season. See [Measure 1.6.1](#) for details of fireside cleaning.

Gas-fired heaters that are adjusted properly may never require fireside cleaning. This is because soot burns off or spalls off faster than it can accumulate. If a heating unit accumulates soot or other fouling at an abnormal rate, the usual cause is a dirty or improperly adjusted burner.

SUMMARY

Basic maintenance items needed to maintain efficiency, comfort, and health.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	😊 😊 😊

- **automatic flue dampers** are important to efficiency. Failure of a flue damper can be a serious safety hazard, so they are made to be highly reliable and to require no maintenance. Check the operation of flue dampers visually at the beginning of the heating season. Flue dampers are covered by [Measure 5.7.3](#), below.
- **fan impellers** should be cleaned to keep air flow efficient. Be prepared for the fact that cleaning a centrifugal fan may make it noticeably louder.
- **fan motor lubrication.** If the fan motors are not permanently lubricated, oil them at the manufacturer’s recommended intervals. If motor bearings are difficult to reach for lubrication, consider installing an access plate or a remote oiler tube.
- **outside air and combustion air dampers and actuators.** These are rarely found in direct-fired heating units. If a unit has a combustion air damper, check it for proper closure, freedom of movement, proper adjustment of linkages, and proper control. A malfunctioning or incorrectly adjusted combustion air damper reduces efficiency, and it may create a serious safety hazard.

ECONOMICS

SAVINGS POTENTIAL: 2 to 30 percent of energy input, the larger savings applying to oil-fired heaters. Effective maintenance extends the service life of equipment.

COST: \$10 to \$100 per unit per year, the larger costs applying to oil heaters.

PAYBACK PERIOD: Short. The long-term saving from proper maintenance is much higher than the cost.

TRAPS & TRICKS

SCHEDULING: Post a permanent inspection checklist at each heating unit. List the dates that each item is to

be performed. Make a duplicate of each checklist for the plant maintenance schedule.

SKILLS AND SUPERVISION: Burner maintenance and adjustment requires special equipment and skills.

Nobody likes to do burner and fireside cleaning because it is messy and awkward. Make sure that it is done correctly.

MEASURE 5.7.2 Install high-efficiency heating units.

RATINGS

New Facilities	Retrofit	O&M
A	C	A

The efficiency of direct-fired heaters improved greatly in some models that became available during the 1980's. Some older heating units have seasonal average efficiencies of less than 60 percent. Modern non-condensing heaters may have efficiencies averaging around 80 percent. Condensing gas furnaces, such as the unit shown in Figure 1, typically have efficiencies better than 90 percent.

Select any new heating unit for the highest economical efficiency. The cost of the fuel burned by a heater in several years of operation may equal the cost of the heater itself. A wide range of efficiencies exists in the market, so a hasty replacement decision could waste a lot of money during the life of the new heater.

In existing facilities, consider replacing inefficient heaters even if they are still functioning. The economics are more favorable for this when:

- the existing heaters are very inefficient
- they are used for a large number of hours each year
- they are near the end of their service lives
- fuel costs are high.

How Efficient are Your Heaters?

To figure out whether it is worthwhile to replace an existing heater, you need to know the heater's efficiency. Older heaters generally were not rated for efficiency. The energy input stated on the nameplates of older heaters is nominal, so you cannot use it to calculate actual efficiency.

You can measure the combustion efficiency of a heater directly while it is operating. This is fairly easy. See [Measure 1.2.1](#) for test procedures. A combustion efficiency test accounts for these deficiencies:

- **insufficient heat transfer surface.** Cheap heaters get their capacity by increasing the size of the burner and burning more fuel. Efficient heaters get their capacity by increasing the amount of heat exchange surface to extract as much heat as possible from the combustion gases. You can detect skimpy heat

SUMMARY

The ultimate way to make heaters more efficient. Always do it when replacing old units. In some cases, it may even pay to replace a heater that is still functioning.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return, New Facilities	% % % %

Ease of Initiation	😊 😊 😊

transfer surface easily by measuring the flue gas temperature. See [Measure 1.2.1](#) for details. In older units, this factor typically wastes 10 to 20 percent of the fuel energy.

- **inability to capture the latent heat of flue gas moisture.** The latent heat of the water in flue gas represents about 10 percent of the combustion energy of natural gas, and less with oil. The heat loss is increased by the fact that non-condensing furnaces are designed to keep the combustion gases hot enough to eliminate any possibility of acid condensation on the heat exchanger. The gases are kept hot by reducing the heat transfer surface. Conversely, many modern heaters capture the latent heat of flue gas moisture by using a heat exchanger that is large enough to condense the water. These condensing furnaces are explained below.
- **incomplete fuel combustion.** This is a minor factor in all heaters as long as the burner is well

maintained. The best modern heaters have slightly better fuel combustion than older heaters.

Combustion efficiency testing cannot reveal some causes of energy waste that may be important. You can only estimate these effects, which include:

- **standby losses**, which are explained in [Measure 5.7.3](#). Efficient heaters reduce standby losses with an integral flue damper, or with a combustion gas path that has high resistance to convection.
- **continuous operation of a pilot light**, which wastes energy during periods of time when heating is not needed, and also increases standby losses during the heating season. Most modern heaters avoid this waste by using an igniter that operates only briefly to start the flame.
- **loss of conditioned space air through the flue**. This is important if the heater draws air from a conditioned space, either directly or indirectly. This

Lennox Industries Inc.

Fig. 1 High-efficiency condensing gas furnace Units of this type have two main features that enhance efficiency. A large heat exchanger made of non-corrosive material is able to cool the combustion gas sufficiently to extract the latent heat of the water in the flue gas. The resistance of the flue gas passage is so high that standby losses are eliminated when the furnace is not firing. A small fan is needed to draw the gas through the furnace.

loss is increased somewhat in heaters that require a larger percentage of excess air for proper combustion. Many high-efficiency units make it easy to connect a ducted outside air intake for combustion, which eliminates this problem.

Condensing Furnaces

The most dramatic improvement in the efficiency of gas-fired heaters occurred with the introduction of condensing furnaces. Figure 1 shows a typical unit. These heaters capture the latent heat of the water in the gases by using so much heat transfer surface that the flue gas is cooled below the condensing temperature of water. The large heat exchanger also pushes sensible heat transfer to the limit. Another bonus is that the high-efficiency heat exchanger creates high resistance to combustion air flow, which minimizes the standby losses that occur between firing cycles.

This feature raises the price of the heater substantially. The heat exchanger is larger, and the low-temperature portion is made of stainless material. Also, there are additional components and more complex controls. The resistance of the heat exchanger requires a small fan to move the combustion gases. The energy consumption of this fan is a small fraction of the heater's total energy input.

Condensing units must be connected to a sewer drain to get rid of the condensate. The condensate may be somewhat acidic, even with natural gas as a fuel, so you may have to take steps to protect sewers from corrosion. (This is unlikely to be a problem with gas fuels.)

Another possible disadvantage is that condensing furnaces deliver air at lower temperatures than do non-condensing models. The temperature rise as space air passes through the furnace may be as low as 45°F. If a space is being warmed after a prolonged period of temperature setback, air delivered by the heating unit may create a drafty sensation until the room temperature rises to normal. (Even so, high-efficiency furnaces provide air at higher temperature than heat pumps. Low heating air temperature is a persistent complaint with heat pumps.)

At present, most condensing air heaters are fired with gaseous fuels, including natural gas, propane, and liquefied petroleum gas. Gas has a larger fraction of hydrogen than petroleum fuels, so the efficiency advantage is greater than with oil. This is because the hydrogen in fuel is the origin of the water in the flue gas.

There are various impediments to burning oil in condensing furnaces. The sulfur contained in petroleum forms enough sulfuric acid to be corrosive. Also, oil contains some quantity of dirt and it forms some amount of unburned hydrocarbons. Even light oil would eventually foul the cooler portions of the heat exchanger, which typically is difficult to clean.

Efficiency Ratings of Fuel-Fired Heaters

In the United States and some other countries, laws require furnaces to be rated for efficiency. In the U.S., these ratings show where each model's efficiency lies within the range of efficiencies for that type of heater. The efficiency ratings are displayed prominently in product literature and on the equipment itself. Efficiency standards have stimulated manufacturers to pursue efficiency as an end in itself, with the result that models are available that greatly exceed minimum efficiency requirements.

Some industry associations may be able to provide lists of efficiency ratings for units of particular types, such as gas-fired furnaces.

Multi-Fuel Units

The ability to burn multiple fuels is rare in direct-fired air heaters, but some dual-fuel furnaces have been marketed. Some units have dual burners to allow switching between gas and oil. Many gas-fired heaters can be converted to burn either natural gas or bottled gas. However, you cannot make this conversion at a moment's notice.

Consider dual-fuel heaters in situations where one of the available fuels may have the price advantage at one time, and a different fuel has the price advantage at

other times. Also, consider them if you fear that the favored type of fuel may become scarce.

ECONOMICS

SAVINGS POTENTIAL: 10 to 30 percent of the fuel consumed by the heating units.

COST: \$7 to \$20 per MBH capacity, in typical sizes. The price premium for condensing furnaces, compared to non-condensing furnaces of average efficiency, ranges from 50% to 80%.

PAYBACK PERIOD: Typically about one year, in new construction and when replacing a failed unit. Several years or longer, when replacing a functioning unit. Consider the remaining life of existing units.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: High-efficiency heaters are more complex than conventional heaters, and are more prone to problems. Ask vendors for references, and talk with purchasers who have used the equipment for at least several years. Do not purchase a model that is entirely new. Purchase a popular model, so that you will be able to find spare parts in the future.

INSTALLATION: If you select a condensing heating unit, anticipate the need to drain the flue gas condensate into a sewer.

MEASURE 5.7.3 Install automatic flue dampers on existing heaters.

RATINGS

New Facilities	Retrofit	O&M
	B	

The output of direct-fired heating units is usually controlled by turning them on and off. There are various ways in which heaters lose heat through the flue during the periods when heat is not being delivered to the space. These losses are called “standby losses.” With an existing heater, you can prevent much of this energy waste by installing an automatic flue damper.

Which Heaters are Eligible for Flue Dampers

Flue dampers are appropriate for common types of heaters that have open combustion air paths and conventional flues. The heater must allow for installation of the damper at an appropriate point in the flue, as explained below.

Flue dampers are not needed with high-efficiency heating units that employ forced circulation through the combustion chamber. In such units, the resistance to convective flow is so high that heat loss is minimal when the fan is not running. Some high-efficiency furnaces include a flue gas damper.

Types of Standby Losses and Potential Savings

Flue dampers reduce standby losses. The potential for saving depends on the severity of these losses. To estimate the potential saving, examine your heating units to see whether they suffer from these types of standby losses:

- **loss of heat from the mass of the furnace.** This applies to all heaters. Combustion air continues to flow through the furnace by convection when the unit is not firing. This carries heat away from the furnace and the flue. This loss is small in direct-fired air heaters because they have lightweight construction. Also, the space air fan continues to operate after firing ceases, recovering furnace heat. The maximum loss from this cause is about four percent in air heaters. (It may be much more in hot water boilers, which have a large amount of heat stored in the mass of the water.)
- **loss of conditioned space air.** If the heater draws combustion air from a heated space, loss of space air through the flue continues by convection when the furnace is not operating. This may waste up to five percent of fuel energy. The amount is determined largely by factors unrelated to the heating unit itself, such as the leakiness of the building envelope, the outside temperature, and the effect of wind on the flue.
- **continuous operation of a pilot light** wastes most of the pilot light heat through the flue. (This

SUMMARY

A simple modification to improve the efficiency of heaters that have unrestricted flue gas flow. Not all heating units allow the retrofit.

Ease of Retrofit	☺ ☺ ☺

assumes that the inside air fan does not operate between firing cycles.) A continuous pilot light may waste up to five percent of total fuel consumption, if the heater does not operate much. In absolute terms, the energy consumption of the pilot light is small.

Flue dampers differ in their effectiveness. Expect the flue damper to reduce losses by 50 to 80 percent.

Types of Flue Dampers

Self-powered thermostatically operated flue dampers are used in smaller heaters. This type opens in response to the high temperature of flue gases. Most thermostatic dampers have a blade made of bimetallic material that changes shape when heated. After the burner lights, hot gas reaching the damper blade causes it to warp to an open position, allowing the gas to pass up the chimney. No external power or external connections are required. The advantages of thermostatic dampers are low cost and reliability.

A limitation of self-powered thermostatic dampers is that they must remain partially open so that hot gas can flow quickly to the thermostatic element as soon as the burner starts firing. Partial opening is achieved by making a hole in the damper blade, or by undersizing the damper blade. This lack of tight closure undermines the effectiveness of the damper. As a result, thermostatic dampers are limited mainly to small furnaces and boilers, where their low cost is important.

Motorized dampers typically consist of a single blade damper that is moved by an electric actuator powered from the furnace’s firing circuit. These dampers are more expensive and difficult to install than the self-powered variety, but they provide better closure of the flue. They may require additional safety controls to ensure that the fuel is shut off when the damper is not fully open.

How to Install a Flue Damper

The flue damper is installed in a short section of flue duct. A short piece of the existing duct is cut away, and it is replaced by the flue damper. Dampers are available with various diameters to match the flue diameter. Seal the connections well. The heater side of the damper is under positive pressure when the damper closes, so flue gases would be forced into the surrounding space through any leaks.

The flue damper must be installed between the heating unit and any draft hoods or draft regulating dampers (“vacuum breakers”). In other words, there can be no opening between the heater and the flue damper. Installing the flue damper on the chimney side of the draft regulator would defeat the purpose of both devices. Furthermore, it would create a safety hazard by forcing flue gases into the surrounding space. This requirement may make it impractical to install a flue damper on some existing heaters.

A flue damper should not restrict combustion air flow significantly when it is open. However, check the air-fuel ratio after installing a flue damper. [Measure 1.2.1](#) explains how to do it.

Safety Issues

Flue dampers create a safety hazard if the damper remains in the closed position while the burner is firing. If this occurs, combustion gases will back up into the space surrounding the heating unit. Approved flue dampers include safety features that deal with this possibility. Therefore, select only approved flue dampers and install them in a safe manner. Standards for flue dampers are set by various agencies. For example, the American Gas Association acts as an approval agency for flue dampers that are used in gas-fired heating units. Make sure that the flue damper has the seal of the appropriate organization.

Alternative: Install Better Heating Units

Flue dampers can save only a fraction of the energy waste that occurs in less efficient heating units. If the existing heaters are much less efficient than the best modern units, consider replacing them. See [Measure 5.7.2](#) for details.

ECONOMICS

SAVINGS POTENTIAL: 2 to 8 percent of the fuel consumption of the heating unit, depending on whether the unit has outside combustion air, a fixed pilot light, etc.

COST: Self-powered dampers cost from \$20 to \$50. Externally powered dampers cost \$100 to \$200. Installation requires one or two hours, typically.

PAYBACK PERIOD: At least several years. May be much longer.

TRAPS & TRICKS

CHOICE OF METHOD: Make sure that the heating unit allows you to do a good job of fitting the damper. Even if you can, consider whether you are trying to make a silk purse out of a sow's ear. Consider replacing an old, inefficient heater entirely, to exploit all the efficiency advantages of a new heater.

SELECTING THE DAMPER: Inspect the damper for quality before you buy it. Safety certification does not indicate reliability or efficient operation. Select a unit that closes as tightly as possible while satisfying safety requirements.

INSTALLATION: Some installations require ingenuity. Be sure that the entire flue gas passage on the heater side of the damper is well sealed. Be sure that the damper blade moves freely.

MEASURE 5.7.4 Set the anticipators of space thermostats to maximize the interval between firing cycles.

RATINGS

New Facilities	Retrofit	O&M
		C

Direct-fired heaters that control temperature by cycling on and off are subject to “standby losses,” which are explained in [Measure 5.7.3](#). The thermostats that control direct-fired heating units usually have a feature called an “anticipator.” Anticipators cause the heating unit to cycle more frequently, so they increase standby losses. [Reference Note 37](#), Control Characteristics, explains anticipators.

To reduce standby losses, set the anticipators inside the thermostat for the longest duration of heater operation that is consistent with comfort. You can adjust the anticipators in most thermostats quickly and easily. Typically, you move a small sliding contactor inside the thermostat that bypasses a portion of anticipator heating

SUMMARY

A simple adjustment that saves a small amount of energy. May affect comfort.

Ease of Initiation	😊	😊	😊	

element. Figure 1 shows the anticipator settings in a typical two-stage thermostat.

Don’t make the firing interval so long that the space temperature can become uncomfortable, either because the space becomes too warm at the end of the firing cycle, or because it becomes too cold before the next firing cycle. In the latter case, occupants will raise the space temperature, increasing energy consumption.

Where This Works, and Where It Doesn’t

This Measure is useful with conventional heating units that do not have a means of blocking the flow of combustion gases between firing cycles. It is not useful with heating units that are immune to standby losses. In particular, modern condensing furnaces (see [Measure 5.7.2](#)) have minimal standby losses. Heating units with automatic flue dampers also have reduced standby losses, so adding flue dampers (see [Measure 5.7.3](#)) eliminates most of the benefit of this Measure.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 2 percent of the fuel consumed by the heating units.

COST: Minimal.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

ADJUSTMENT: Don’t overdo it. Not much money is at stake, and energy conservation should never cause discomfort.

Fig. 1 Thermostat anticipators In this two-stage heating thermostat, each stage has its own anticipator setting. To change the setting, slide the pointer over the numbered arc.

Section 6. BUILDING AIR LEAKAGE

INTRODUCTION

New buildings can be designed and constructed to minimize air leakage at little additional cost. You can often reduce leakage in existing buildings by using methods that are inexpensive and simple. However, making existing buildings airtight is usually expensive or impractical. In any building, minimizing air leakage requires continuing maintenance.

Isn't Outside Air Needed Anyway?

Air leakage through the building envelope may or may not be a significant source of energy waste. This depends largely on ventilation requirements. For example, it makes no sense to reduce the air leakage of a garage door if the garage has a fixed ventilation requirement that is higher than the leakage rate of the door. On the other hand, you should minimize leakage around a similar door that is installed in a heated warehouse where ventilation requirements are minimal.

Occupied spaces require a certain minimum amount of ventilation. In many countries, ventilation requirements are dictated by building codes, which require ventilation rates that are fairly high. (See [Measure 4.2.1](#) for details.) In principle, air leakage can comprise part of the needed ventilation. If the leakage rate is less than the ventilation requirement, it does not “waste” energy, and there may be no economic merit in stopping it.

A building may have a high ventilation requirement when it is occupied, but little or no ventilation requirement when it is empty. This is true of most buildings intended primarily for human occupancy, such as schools, office buildings, stores, etc. Air leakage during the vacant period cools or heats the structure and contents, requiring additional conditioning energy when occupancy resumes.

Infiltration Causes Discomfort

Even if the rate of air leakage is much less than the required ventilation rate, you may still want to minimize air leakage for the sake of comfort. Unlike ventilation air that enters through the air conditioning

SUBSECTION INDEX

[6.1 PERSONNEL DOORS](#)

[6.2 GARAGE, LOADING, AND EQUIPMENT DOORS](#)

[6.3 WINDOW AIR LEAKAGE](#)

[6.4 OTHER ENVELOPE LEAKAGE](#)

system, air leakage enters the space at outside temperature and humidity. During cold weather, air leakage causes discomfort in the form of drafts that affect people located near walls, doors, and passages leading to the outside.

In addition to being objectionable from a comfort standpoint, cold drafts motivate occupants to increase heating and cooling energy consumption. If occupants bring in portable electric heaters, suspect serious infiltration.

Discomfort occurs only with infiltration (air leaking inward), not with exfiltration (air leaking outward). Many buildings maintain a positive pressure to avoid discomfort from infiltration. Positive pressure does not increase energy consumption if it is limited to occupied periods, and if exhaust fan capacity is reduced accordingly. In reality, such rational control is rare.

How to Use Section 6

The Section is organized by the envelope components where leakage occurs, including personnel doors, vehicle doors, windows, and other penetrations. The Measures in each Subsection provide specific improvements to these components. Go through all the Subsections, as some of the Measures in each Subsection apply to most buildings.

Before Getting Started ...

Read [Reference Note 40](#), Building Air Leakage, to learn about the causes of air leakage, methods of finding air leaks, and methods of calculating leakage rates.

Subsection 6.1

Personnel Doors

The Measures in this Subsection reduce air leakage through conventional personnel entrance doors. Air leakage wastes energy directly through the need to condition the entering air, and also indirectly by creating discomfort in the vicinity of the doors that motivates excessive heating of those areas. These effects vary widely, depending on the ventilation requirements and layout of the affected spaces.

INDEX OF MEASURES

6.1.1 Maintain the fit, closure, and sealing of exterior doors.

6.1.2 Install appropriate weatherstripping on exterior doors.

6.1.3 Install effective closers on exterior doors.

6.1.3.1 If manual opening of doors is acceptable, install spring-type door closers.

6.1.3.2 If manual opening of doors is not acceptable, install automatic doors or door openers.

6.1.4 Install high-efficiency doors.

6.1.5 If a pressure differential at the entrance is unavoidable, install a revolving door.

6.1.6 If a revolving door is installed, encourage people to use it instead of other doors.

6.1.7 Install storm doors.

6.1.8 Install vestibules for doors with frequent traffic.

6.1.9 Seal abandoned doors.

Related Measures:

- Measure 4.2.1, control of building pressurization
- Subsection 6.2, for Measures related to industrial doors
- Measure 6.4.2, sealing infiltration around door frames

MEASURE 6.1.1 Maintain the fit, closure, and sealing of exterior doors.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Exterior personnel doors allow a significant amount of air leakage. Leakage grows progressively worse as weatherstripping wears out, doors get out of alignment, and closers fail. When a point is reached that doors no longer close completely, the increase in air leakage becomes drastic.

To avoid this energy waste, perform these maintenance items at appropriate intervals:

- align doors for effective sealing and complete closure
- repair infiltration seals
- repair and adjust closing mechanisms.

Experience will tell you how often to schedule door maintenance. It will depend on how sturdy the doors are, and on the amount of traffic.

Related Measures

If the doors are not equipped with adequate infiltration seals, you may be able to install retrofit seals. See [Measure 6.1.2](#), next. If the doors require excessive maintenance, consider replacing them with more efficient units, as recommended by [Measure 6.1.4](#).

To save effort, coordinate this activity with maintenance of the industrial-type doors covered by [Measure 6.2.1](#).

SUMMARY
 Routine maintenance needed to prevent energy waste and maintain comfort.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓ ✓
Ease of Initiation	😊 😊 😊

ECONOMICS

SAVINGS POTENTIAL: \$10 to \$200 per year per door, depending on climate, energy cost, space layout, etc. Timely maintenance also avoids major repairs.

COST: \$5 to \$20 per year per door.

PAYBACK PERIOD: Short. The long-term saving is much greater than the cost.

TRAPS & TRICKS

SCHEDULING: Most of the challenge of door maintenance is remembering to do it. Make sure that you have an effective maintenance calendar.

PREPARATION: Keep an ample stock of spare parts on hand. Finding parts typically takes much longer than the work on the doors themselves.

MEASURE 6.1.2 Install appropriate weatherstripping on exterior doors.

RATINGS

New Facilities	Retrofit	O&M
		

Exterior personnel doors often have large gaps that you can seal using inexpensive weatherstripping. The trick is to install the weatherstripping so that it seals effectively, remains in place, and does not keep the door from closing completely.

First, Repair the Doors

It is futile to install weatherstripping on a door that is loose or out of alignment. If you do, the weatherstripping will fail quickly. Your first step is to make sure that the door is secure and moving properly. See [Measure 6.1.1](#) for door repair procedures.

How to Install the Weatherstripping

Consider each of the four sides of a door separately when you select weatherstripping. Each type of door needs its own combination of weatherstripping materials. Make the effort to find the types of weatherstripping that will work effectively with your doors.

Some types of weatherstripping are designed to create a seal by sliding, and other types are designed to create a seal by compressing. Few are effective in both ways. If you install the wrong type of weatherstripping, it will be ineffective, or it will soon be damaged, or it will break loose. Installing the wrong kind of weatherstripping may keep the door from closing properly, which will make the air leakage even worse. Here are some hints for different types of doors.

■ Single Doors with Stop Strips

Single doors that open only in one direction are commonly used in residential facilities, and as secondary doors in commercial and industrial facilities. The top and two sides of the door close against a stop strip that is installed on the door frame. The door has butt hinges. This type of door can be sealed fairly tightly.

You can seal the top and both sides of the door by using a leaf-type flexible weatherstrip. Install it on the sides of the door frame, in a way that does not interfere with the contact between the door and the stop strip. On the top and latch side, the material works as a sliding seal. On the hinge side, it acts as a compression seal. On each side of the door, select the thickness of the weatherstripping to fill the gap between the door and the frame.

This material is available in plastic and spring bronze. The bronze version is much more durable. The bronze strip is fastened with nails, so it works only with wooden door frames. A plastic version is available with a self-adhesive backing.

SUMMARY

An easy way to eliminate most air leakage around doors. Requires continuing maintenance.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, Retrofit	%	%	%
Rate of Return, O&M	%	%	%
Reliability of Equipment	✓	✓	
Reliability of Procedure	✓	✓	
Ease of Retrofit	😊	😊	😊
Ease of Initiation	😊	😊	😊

On the hinge side of the door only, if the gap is too large or too small for leaf-type weatherstripping, you can substitute a soft foam self-adhesive strip. This type is available in many thicknesses and widths. Install the strip near the hinge line, so it will create little resistance to closing the door.

Do not use compression strips between the door and the stop strip. No matter how soft the material is, it will tend to keep the door partially open, increasing leakage. A gap between the door and the stop strip does not matter, as long as the sides of the door are properly sealed to the sides of the frame. Reduce the gap by adjusting the hinges and the lock strike.

For the bottom of the door, you have a choice between installing a threshold or not. Thresholds cause people to stumble, so they are generally limited to private residences, where the residents are accustomed to stepping over them. The advantage of a threshold is that it provides a good seal without requiring a sweep on the door that contacts the floor. Door sweeps are incompatible with carpeting, they create a visible wear pattern on solid floors, they remove the varnish from wooden floors, etc.

You can buy thresholds that have an integral seal. Typically, the threshold is an aluminum extrusion, and a flexible plastic seal fits into a groove in the extrusion. These thresholds are satisfactory if the bottom of the door is parallel to the floor. However, you may not be able to find a replacement for the plastic seal when it wears out. A more reliable alternative is to install a sweep on the bottom of the door that contacts the threshold. You can easily adjust the sweep for any irregularity in the gap at the bottom of the door.

If you do not install a threshold, install a sweep strip on the bottom of the door. You can get these in the form of a plastic strip or in the form of a brush. Generally, the brush is better because it offers less resistance to opening and closing the door. A door sweep can interfere with opening the door fully if the bottom of the door gets closer to the floor as the door swings open. For this situation, try to find a brush-type sweep with very long bristles that can bend easily.

■ Double Doors with Stop Strips

Double doors that close against stop strips are found in many residential, commercial, and industrial buildings. Seal them in the same way as for single doors, discussed previously.

In addition, you have to seal the gap between the two doors. If both doors are intended to be used regularly, any seal that bridges the gap between the two doors tends to keep the doors from closing fully. The best choice in this case is a very soft brush seal, combined with a door closer that has sufficient force to ensure that the doors close fully. (See [Measures 6.1.3](#) ff about door closers.)

If one door is intended to be opened preferentially, you can install a leaf-type seal on the door that usually remains closed. In effect, this door becomes part of the frame for the other door. (This door typically can be locked in place by a latch bolt that engages strike plates in the floor and the top of the frame.)

If the doors are closed in reverse order, a leaf-type seal will tear off. To prevent this, the door that opens first needs a strip of molding over the latch side that covers the gap between the two doors. This molding keeps the doors from being closed in reverse order. (In the door business, the strip that covers the gap between the two doors is called an “astragal.”) This strip also provides protection from wind.

■ Single and Double Double-Acting Doors

A door that swings open in both directions is called a “double-acting” door. This type is difficult to seal. Any contact between the door and the frame tends to keep the door from closing fully. For this type of door, the best seal for all surfaces is a very soft brush that

contacts the opposite surface very lightly. The door should have a closer that keeps the door centered with enough force to overcome the resistance of the seal.

Double-acting doors are usually made of metal. The door may have grooves to hold custom seals. If you cannot find these seals, or if they are unsatisfactory, you can attach brush seals to the door with sheetmetal screws. Self-adhesive seals would not survive the sliding contact very long.

Expect to Maintain the Weatherstripping

Weatherstripping wears out because of continual flexing, drying of adhesives, and abuse. Therefore, expect to replace it periodically. Schedule this as recommended by [Measure 6.1.1](#).

Alternative: High-Efficiency Doors

[Measure 6.1.4](#) recommends installing high-efficiency doors. The best models have integrated door and frame systems that include effective and durable seals. These doors offer much better sealing than you can achieve by weatherstripping a leaky door, and their weatherstripping requires less maintenance.

ECONOMICS

SAVINGS POTENTIAL: \$10 to \$200 per year per door, depending on climate, energy cost, space layout, etc.

COST: \$10 to \$30 per door, including labor.

PAYBACK PERIOD: Less than one year, usually.

TRAPS & TRICKS

SELECTING MATERIALS AND INSTALLATION

METHODS: Select your weatherstripping materials for effective sealing, minimum interference with door closure, and durability. Expect to use two or three types of weatherstripping on each door. There are many sources. Keep looking until you find the right kinds.

MAINTENANCE: Weatherstripping wears out quickly compared to other maintenance items. Consider it an expendable commodity. See [Measure 6.1.1](#).

MEASURE 6.1.3 Install effective closers on exterior doors.

Leaving an exterior door open or partially open allows vastly more air leakage than even the worst leakage around a closed door. The most effect way to keep doors closed is to install door closers. The first of the subsidiary Measures deals with environments where manual door opening is acceptable, and the second subsidiary Measure deals with environments where manual door operation is not acceptable.

Alternative: Revolving Doors

Revolving doors are an expensive alternative to doors with automatic closers. They are used primarily in applications where a large pressure differential exists across the door. See [Measure 6.1.5](#) about them.

MEASURE 6.1.3.1 If manual opening of doors is acceptable, install spring-type door closers.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Most exterior personnel doors in commercial and industrial buildings should have closers. Standard models are available that fit most personnel doors.

Features to Select

The door closer market offers reliable equipment and it offers junk that is intended to look like the real thing. The cheap units fail quickly, leaving you with problems you don't need. Make the effort to select good equipment. The best units are not much more expensive than the worst. Look for these features:

- **ruggedness.** Units of good quality last much longer than less durable units.
- **adjustable closing force.** The unit should be adjustable over a wide range because the optimum closing force may not be apparent until the unit is installed. A higher closing force makes the door harder to open, while a lower closing force allows the door to hang up in a partially open position.
- **smooth closing.** Good units have a hydraulic damper that closes the door at a uniform rate and keeps it from slamming shut.
- **back check.** A back check is a damper that operates as the door reaches the full open position. It keeps the door from slamming open. This is a standard feature of most units.

Reinforce the Attachment Points

A door closer exerts a great deal of force at the points where it is attached to the frame and to the door. Check

SUMMARY

The inexpensive and proven method of keeping doors closed.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

whether you need to install reinforcements at the attachment points. The leading door closer manufacturers offer reinforcement hardware that ease the job.

A door closer creates a strong reactive force at the top door hinge. Make sure that the top hinge is sturdy. Make sure that the hinge is well anchored to the door frame, and that the door frame is well anchored to the wall.

Install Handy Door Stops

All energy conservation measures should be user-friendly. Door closers may become a nuisance when the doors have to be kept open, for example, to move packages through the door or to provide ventilation. To make the door easy to use in these instances, install an effective door stop.

Otherwise, users will jam something into the hinge side of the door. When this happens, the leverage creates an enormous destructive force on the door, hinge, and frame.

When you install a door stop, also install a placard on the door requesting people to use the door stop properly, and to keep the door closed at other times. See [Reference Note 12](#) about designing and installing placards.

ECONOMICS

SAVINGS POTENTIAL: \$20 to \$1,000 per year in heating and cooling costs, depending on climate, wind exposure, interior layout, energy costs, etc.

COST: Good door closers cost about \$100 apiece. Installation may require one to several hours, depending on the door and frame configuration.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING EQUIPMENT: Don't buy cheap door closers. They perform poorly, and fail early. Buy a model that is one grade tougher than you think you need.

INSTALLATION: Reinforce the attachment points, if necessary. Don't forget to install a door stop and placard, if the application needs it.

MAINTENANCE: See [Measure 6.1.1](#).

MEASURE 6.1.3.2 If manual opening of doors is not acceptable, install automatic doors or door openers.

Conventional door closers (recommended by [Measure 6.1.3.1](#)) require persons to overcome the spring force of the mechanism. This may be a serious impediment for handicapped persons or for persons using grocery carts, hand trucks, etc. In applications where conventional door closers are not advisable, consider installing automatic door openers. In most cases, expect to replace the entire door assembly, rather than retrofitting an automatic opener to an existing door.

Your Choices

You have two major decisions to make in selecting an automatic door, the type of door and the type of sensor to open and close it.

The two main types of automatic doors are swinging doors and sliding doors. Sliding doors are perhaps safer, because they cannot swing unexpectedly toward someone who is in the door's path. On the other hand, sliding doors require twice the width of the door opening. If you can afford separate doors for entering and leaving traffic, you can avoid the safety hazard of swinging doors by arranging the doors to open away from the traffic. In this case, use signs and railings to guide traffic through the doors in the proper directions.

The common methods of actuating automatic doors are tread switches, ultrasonic motion detectors, and photoelectric light beam sensors. See [Reference Note 11](#), Personnel Sensors, about this equipment. For most

SUMMARY

An effective efficiency feature. Also a desirable convenience, especially for handicapped persons and for persons handling articles. Expensive.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

applications, ultrasonic sensors have proven to be the best choice for opening the door. Figure 1 shows swing doors that are activated by ultrasonic sensors. In cases where a safety hazard may arise, consider installing a tread switch (weight sensor) to ensure that no one is within range of the door when it closes.

Decide Whether to Install a Vestibule

If you are willing to spend the money for an automatic door, consider making it part of an entry vestibule. A combination of an automatic door and a well designed vestibule is a powerful means of reducing infiltration. See [Measure 6.1.8](#) about vestibules.

WESINC

Fig. 1 Automatic swing doors This pair of doors is the main entrance for a large grocery. They operate hundreds of times per day, so they must be rugged and reliable. For safety, each door must swing away from traffic. This requires two doors. The sensors that open each door should be triggered only by traffic from the correct direction. These doors are activated by ultrasonic sensors, which are small, inexpensive, and easy to install. The air curtain installed here plays no significant role in reducing infiltration. It discourages insects.

ECONOMICS

SAVINGS POTENTIAL: \$20 to \$1,000 per year in heating and cooling costs, depending on climate, wind exposure, interior layout, energy costs, etc. Consider the value of increased convenience and comfort.

COST: Commercial automatic doors typically cost \$5,000 to \$10,000, including the operating hardware. There may be additional structural costs to accommodate the door.

PAYBACK PERIOD: Several years, in new construction, typically longer in retrofit.

TRAPS & TRICKS

SELECTING EQUIPMENT: Automatic doors are subject to severe use if traffic is heavy. Select units for ruggedness, ease of use, and absence of safety hazards.

INSTALLATION: Install the sensor where it will function reliably but will not open the door in response to false signals, such as people walking past the door. Install the sensor where the door has time to open fully without slowing traffic.

MAINTENANCE: Even an automatic door is an air leakage path. Keep it adjusted. See [Measure 6.1.1](#).

MEASURE 6.1.4 Install high-efficiency doors.

RATINGS

New Facilities	Retrofit	O&M
A	C	

You can buy standard doors that have minimal air leakage and good insulation. These are prefabricated assemblies that include the door itself, the frame, the threshold, and an effective sealing system.

For example, one common type uses a metal door skin and a magnetic gasket attached to a wooden frame to provide an almost perfect seal at the sides and top. The door is filled with foam insulation and has a wood thermal break at the edges, providing excellent thermal insulation.

Unfortunately, there is a compromise between effective sealing and the volume of traffic for which a door is appropriate. The most effective types of seals offer a certain amount of resistance to opening, and the seals themselves are subject to wear. Therefore, the doors with the most efficient seals are limited to applications that have relatively light traffic.

Install an Effective Closer

A high-efficiency door cannot save energy if it is left open. Consider installing an effective closer as part of the installation. See [Measures 6.1.3 ff](#) for details.

Minimize Infiltration Around the Door Frame

When you install the door, there will be a sizable gap between the door frame and the wall opening. The gap can act as a serious infiltration path. You have two ways to prevent this. One is to fill the gap with impermeable material. The other is to seal the moldings on each side of the door so that the moldings act as the infiltration barrier. See [Measure 6.4.1](#) for effective methods of sealing against infiltration.

ECONOMICS

SAVINGS POTENTIAL: \$20 to \$100 per year in heating and cooling costs, depending on climate, wind exposure, interior layout, energy costs, etc. This is in comparison to a mediocre door that has average weatherstripping.

SUMMARY

The most efficient solution for air leakage in low-traffic applications. Also provides a small saving in conductive heat loss.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% % %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

COST: In new construction, high-efficiency residential doors cost about \$300 for single units, and about \$600 for double units. Commercial doors cost from \$15 to \$30 per square foot, not including the cost of special materials and finishes. In retrofit, higher labor costs increase these prices, depending on the difficulty of retrofit.

PAYBACK PERIOD: One year to several years in new construction, several years or longer in retrofit. Consider the value of added comfort in the calculation.

TRAPS & TRICKS

SELECTING EQUIPMENT: Select doors for ruggedness, ease of use, sealing effectiveness, and durability of the seals. Inspect some installed units. Also, select an appropriate door closer, if appropriate, for installation at the same time.

INSTALLATION: Make sure that the door frame is attached securely to the wall opening, and that the leakage path between the frame and the wall opening is sealed tightly by filling gaps and caulking. Paint metal doors on arrival, as they are typically supplied with only a light primer coat.

MEASURE 6.1.5 If a pressure differential at the entrance is unavoidable, install a revolving door.

RATINGS

New Facilities	Retrofit	O&M
B	D	

Some buildings may have a considerable differential pressure at entrances. (The reasons are explained by Reference Note 40, Building Air Leakage.) Even a relatively small pressure differential can keep a conventional door from operating properly. For example, a pressure differential of 0.5 inch of water column exerts a force of about 30 pounds on the handle of a door of average size. A swing door with an automatic closer cannot close fully against this pressure. If the pressure is in the direction that tends to keep the door closed, opening the door can be inconvenient or dangerously difficult.

Revolving doors were invented to avoid these problems. The door rotates on a central axis. The pressure differential acts symmetrically on both sides of the door axis, so operation is not affected by the building pressure. A revolving door also acts as an air lock, never allowing outside air to flow directly into the building.

Most revolving doors are moved manually, which requires considerable force to overcome the inertia of the door and the friction of infiltration seals. Revolving doors are built heavily to survive rough handling, and

SUMMARY

The most effective method of limiting air leakage at entrances with a large pressure differential. Expensive and inconvenient.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺

to resist the pressure differential on the door panels. Motorized revolving doors are becoming increasingly popular, but these may invite accidents. The revolving doors in Figure 1 are motorized.

Where to Consider a Revolving Door

Revolving doors are the most effective means of minimizing air leakage in applications with heavy traffic.

WESINC

Fig. 1 Powered revolving doors These doors are intended to minimize infiltration through the main entrance of a tall office building. They turn automatically in response to ultrasonic motions sensors. Users can choose to slow the rotation rate by pressing a button, visible here on the right-hand door. Even so, this pedestrian is using the manual door that is alongside the revolving door. Many of the people who use these doors are visitors. The installation lacks effective signs to tell them how to use the doors efficiently and safely.

Unfortunately, they are awkward and expensive. Their cost limits them to larger buildings where a pressure differential at the entrance is unavoidable.

You Still Need a Conventional Standby Door

Revolving doors should have a conventional door nearby for safety, for high volume traffic during an emergency, for delivery of items that cannot be carried through a revolving door, and for access by handicapped persons. Try to discourage people from using the conventional door. See [Measure 6.1.6](#), next.

Alternative for Low Traffic

If traffic through the door is light, or if traffic is limited to short periods of time, consider using a powered sliding door. Even more effective is a long vestibule with a powered sliding door at each end. See [Measure 6.1.8](#) for details. Neither of these options is as effective as a revolving door, but they may be easier to install in retrofit applications. Also, they provide easier access, which is important for handicapped persons and for moving goods through the door.

ECONOMICS

SAVINGS POTENTIAL: *Thousands of dollar per year, typically, in applications where a high pressure differential exists at the entrance. Improved comfort in the vicinity of the entrance is a major benefit.*

COST: *The revolving door itself costs \$15,000 to \$30,000. This range includes powered units, but not exotic materials or finishes. In addition, a revolving door requires a separate conventional door, and the structure to support both.*

PAYBACK PERIOD: *In new construction, 1 to 10 years, depending on the climate, the height of the building, energy costs, etc. In retrofit, several years to much longer.*

TRAPS & TRICKS

CHOICE OF METHOD: *Balance the advantage against the disadvantages. Nothing else can stop air leakage as well as a revolving door. However, it is awkward, it needs a conventional standby door, and it is expensive. Do not try to cut costs by installing a lightweight unit, which will eventually leave you with a mess.*

MEASURE 6.1.6 If a revolving door is installed, encourage people to use it instead of other doors.

RATINGS

New Facilities	Retrofit	O&M
	A	

Where a revolving door is installed, a conventional door is usually installed nearby. The conventional door is an important safety feature, so it must not be locked or obstructed. Because the revolving door is more awkward to use, people are inclined to use the conventional door instead, which defeats the purpose of the revolving door. Figure 1 in the previous Measure shows this occurring.

To minimize this problem, install large, permanent, attractive signs on the conventional doors that say, "Please Use the Revolving Door," along with a large arrow pointing to the revolving door. This sign is a prominent part of the decor, so get someone with taste involved in designing it.

SUMMARY
A simple step to protect the benefit of revolving doors.

PAYBACK PERIOD: Less than one year.

MEASURE 6.1.7 Install storm doors.

RATINGS

New Facilities	Retrofit	O&M
		

If the existing doors are especially leaky, you can reduce infiltration significantly by installing storm doors. Storm doors are especially effective for doors exposed to wind. The storm door dissipates the velocity pressure of the wind, greatly reducing infiltration through the inner door, even if the storm door itself is leaky. A storm door also protects an expensive inner door from rain damage.

The main advantage of storm doors is that they are relatively easy to install. Typically, you buy a complete assembly that consists of the storm door installed in a lightweight frame, perhaps with a primitive closer. The assembly is screwed into place over the existing door frame. Figure 1 shows a unit at the high end of the quality range.

WESINC

Fig. 1 Storm door This is a storm door of much better than average quality. Still, it is fragile compared to a conventional door, and it costs more. Note the closers at top and bottom.

SUMMARY

Storm doors are clumsy and fragile, only cheap substitutes for a really good door. Usually limited to privately owned residences.

SELECTION SCORECARD

Savings Potential	\$ \$
Rate of Return	% %
Reliability	✓ ✓
Ease of Retrofit	☺ ☺ ☺

Storm doors have serious disadvantages. Fundamentally, they are cheap. They exist primarily as a cheaper alternative to installing a good primary door. They are lightweight, so they are vulnerable to damage from rough handling and from being slammed open by wind. They have cheap closers. Eventually, the storm door gets out of alignment and hangs open, which defeats its purpose. Also, they are awkward to manipulate, since the user must manipulate two doors at the same time.

Where to Consider Storm Doors

Storm doors remain open as long as the primary door, so they are effective only in applications where the doors remain closed most of the time.

Storm doors are weak, so they are suitable only for environments where everyone who uses the door has an interest in protecting it and closing it fully. This tends to limit storm doors to privately owned residences.

Features to Seek

The price of storm doors is proportional to their quality. The cheapest units cannot survive long. Expect to spend almost as much for a good storm door as for a good primary door. Remember, the only major advantage of the storm door is ease of retrofit. Look for these features:

- **rigidity.** The door must resist twisting and sagging to remain as airtight as possible. No storm door is really rigid enough, but some are better than others.
- **strong hinges and attachments.** The hinges should be strong enough to keep the door from shifting in its frame over time, which will prevent it from closing. The door and frame should be reinforced at the points where the hinges attach.
- **a durable latch.** The latch should be durable and easy to use. An aluminum frame needs a steel strike plate. The latch should allow for a certain amount

of shifting of the door in the frame. The latch should work with minimum closing force, or it will hold the door open.

- **effective weatherstripping.** The purpose of the storm door is to block infiltration, so it needs effective weatherstripping to do its job. The weatherstripping should be durable and easy to repair, and it should not require a large closing force. Get an adjustable sweep to minimize leakage at the bottom.
- **a good closer and back check.** No storm door comes with a really good closer, but get the best you can find. A storm door must have an effective back check or shock absorber, because wind tends to destroy storm doors by slamming them open.

Install Them Carefully

To achieve the most benefit, be careful to install the frame of the storm door in a way that minimizes leakage all around. This requires snug contact between the storm door frame and the frame of the main door. If necessary, insert weatherstripping or filler pieces between the two frames.

Better Alternatives

If you want to install a storm door because your main door is leaky, consider installing a better main door. This is more expensive, but it avoids the awkwardness of multiple doors. This alternative is also more reliable and more enduring, and it resists conductive heat loss as well as air leakage. See [Measure 6.1.4](#).

If you want to create an enclosed space between entry doors, consider installing an entry vestibule. (In houses, this may be called a “mud room.”) See [Measure 6.1.8](#), next.

ECONOMICS

SAVINGS POTENTIAL: \$10 to \$100 per year per door, depending on climate, energy cost, space layout, etc.

COST: Different models cost from \$50 to \$200. Installation typically takes less than one hour.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

CHOICE OF METHOD: Stop and reconsider before selecting this approach. Although storm doors are common, they are not very desirable. A storm door is just a cheap, flimsy door. It may not survive long enough to pay for itself, and it is a nuisance in the meantime.

SELECTING THE EQUIPMENT: Ordinary storm doors are too flimsy. Go out of your way to find sturdier units. Expect them to cost more. Check for all the important features.

INSTALLATION: Install weatherstripping between the storm door frame and the opening, to prevent leakage around the frame. Adjust the frame so the door closes crisply, with no tendency to hang partly open. Install the closer so it works effectively. Adjust all the sealing features.

MAINTENANCE: When the storm door gets out of alignment, fix it. A defective storm door saves little energy.

MEASURE 6.1.8 Install vestibules for doors with frequent traffic.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Entry vestibules are effective in reducing infiltration where wind is a major factor. The outer structure of the vestibule dissipates the velocity pressure of the wind, reducing infiltration through the inner door. Even when both doors of a vestibule are open, the vestibule may reduce infiltration significantly, provided that the outer door is not facing into the wind.

Where to Consider a Vestibule

Vestibules are more expensive than most other methods of reducing door infiltration. A vestibule may pay for itself in energy savings if the application has all these characteristics:

- **there is a lot of pedestrian traffic.** An open door is a big hole in the building envelope. If there is considerable traffic, a vestibule can reduce the effective length of time that the hole exists.
- **wind is a major factor in infiltration.** A vestibule may dissipate the velocity pressure of wind at the doors, greatly reducing the rate of infiltration. The orientation of the vestibule’s openings with respect

SUMMARY

Most effective in reducing infiltration where wind is a major factor.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

to the wind is a critical factor in the vestibule’s effectiveness.

- **there is enough space to install the vestibule.** The vestibule must be wide enough to allow people to pass each other comfortably. Size is especially important if the vestibule may be used as a waiting area. In retrofit applications, consider installing a

WESINC

Fig. 1 Typical vestibule This vestibule is so short that the inner and outer doors are open simultaneously for a period of time when a person passes through. These doors are operated manually. The situation would be worse if the doors had automatic openers. The only solution is to make the vestibule much longer. This vestibule is heated, which attests to its lack of effectiveness in preventing infiltration.

vestibule either outside the existing doors or inside them, depending on the building layout and appearance considerations.

Even if a vestibule cannot meet the first two conditions enough to be economically desirable, it may still be desirable to minimize discomfort to occupants located near the door. For example, entry vestibules on restaurants prevent discomfort to patrons seated near the doors during cold weather, and the vestibule also acts as a protected area for patrons waiting to enter.

If people are transporting goods through the doors, make sure that a vestibule would not impede this traffic. For example, note how grocery stores have vestibules that allow customers to move shopping carts through them easily.

Distance Between the Vestibule Doors

If practical, make the vestibule long enough to allow the outer door to close before the inner one is opened, or vice versa. When both doors are open simultaneously, air flow into (or out of) the building can increase radically. Figure 1 shows a vestibule that is too short. Figure 2 shows how to install a vestibule of adequate length.

Automatic door openers keep doors open longer, increasing the separation required. Unless the vestibule is long, both doors will be open simultaneously for a large fraction of the door operating cycle.

Heating Vestibules

If the vestibule space itself is not heated, it always saves energy. However, heating the vestibule itself invites energy waste. The pressure inside the building makes a big difference.

■ Vestibules with Negative Indoor Pressure

If the area of the building adjacent to the vestibule has negative pressure, outside air flows through the vestibule toward the inside of the building. In this case, a vestibule heater improves comfort in the area of the building adjacent to the vestibule. To keep puffs of cold air from entering the building, the vestibule must be long enough, and the heater must be powerful enough, to heat the outside air before it reaches the inside door.

In this situation, a vestibule heater does not increase energy consumption very much. Most of the vestibule heating energy moves indoors, reducing the heating load on the interior heating systems.

■ Vestibules with Positive Indoor Pressure

If the area of the building adjacent to the vestibule has positive pressure, indoor air flows through the vestibule toward the outside. In this case, a vestibule heater is wasteful because the heat in the vestibule is contained only by the outer door. As a result, the

vestibule heater tends to run at full output during cold weather.

In this situation, a vestibule heater is not necessary for comfort inside the building, because outside air does not flow into the building. Furthermore, the flow of air from inside the building tends to keep the vestibule warm.

If the building has positive pressure, a vestibule heater is valuable only if the vestibule is used as a waiting area. To avoid the energy waste, try to design the area so that people can wait inside the building. If the people are waiting for rides, provide a window so that people waiting can see vehicles outside.

If you decide to install a vestibule heater, consider a radiant type. Radiant heaters heat the occupants and the mass of the space, rather than heating the air directly. As a result, they waste less heat to the outside, although they do not feel as cozy. If a radiant heater would require

WESINC

Fig. 2 Effective vestibule This vestibule for a large grocery is very long. It is built along the front face of the building. It accommodates people with shopping carts. The doors are operated automatically by ultrasonic sensors. Entering and leaving traffic are separated by a railing inside the vestibule, which expedites movement.

a more expensive energy source, calculate whether the saving in energy provides a saving in cost.

Alternative: Install a Revolving Door

In most cases, revolving doors are more effective than vestibules in preventing infiltration, but they have serious disadvantages. See [Measure 6.1.5](#).

ECONOMICS

SAVINGS POTENTIAL: *Hundreds of dollars to thousands of dollars per year in typical applications, depending on climate, energy cost, building orientation, etc. Consider the value of improved comfort.*

COST: *Thousands of dollars.*

PAYBACK PERIOD: *Typically several years, in new construction. Several years or longer, in retrofit.*

TRAPS & TRICKS

DESIGN: *Invest some time in studying vestibules, noting their good and bad points. Remember that you are trying to mimic the performance of an air lock. Make the vestibule long, if possible. Using automatic doors affects the way you should lay out the vestibule. If the building has positive pressure, try to avoid installing a heater. If you must have a vestibule heater, consider a radiant unit.*

MEASURE 6.1.9 Seal abandoned doors.

RATINGS

New Facilities	Retrofit	O&M
	B	

Abandoned doors may be in poor condition, allowing a considerable amount of air leakage. If the door does not have to remain as an emergency exit, render it completely immobile and seal the air leaks. In effect, make it part of the wall. Mark the door plainly to state that it is no longer in use.

Since the door does not have to be opened, it is easy to select sealing materials. You can probably do the entire job with soft foam weatherstrips. With the door open, install self-adhesive foam strips on the hinge side of the door frame. After you close the door, stuff foam strips into the remaining gaps with a putty knife. Then, fasten the door rigidly on all sides.

If the door must continue to serve as an emergency exit, maintain it as you would any other door. See Measures 6.1.1 and 6.1.2. Mark the door boldly, stating that it is to be used only as an emergency exit.

ECONOMICS

SAVINGS POTENTIAL: \$10 to \$200 per year per door, depending on climate, energy cost, space layout, etc.

SUMMARY

Corrects a source of energy waste that is overlooked in older buildings.

Ease of Retrofit	☺	☺	☺

COST: \$20 to \$100, typically.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

MAKE IT STRONG: Unless the door is blocked closed in an obviously strong way, some ignoramus will try to force it open. Make sure that the door is well secured. Mark it on both sides.

Garage, Loading, and Equipment Doors

Industrial doors are immense holes in the building envelope, through which the heat and cooling inside a building easily spills into the outdoors. It is virtually impossible to maintain normal temperatures in a space that has a large door that is kept open. Even reduced levels of conditioning are very expensive to maintain. To avoid this energy waste, you need efficient doors, and you need to keep them closed. The first three Measures recommend maintenance and improvements for exterior doors. The fourth Measure recommends installing new high-efficiency exterior doors.

Large doors operate slowly, so they tend to be left open for long periods. This wastes the efficiency benefit of the door. The fifth Measure deals with this problem by using quick-acting doors that are installed inside the primary exterior doors. These can remain closed most of the time without interfering with traffic. The last Measure minimizes infiltration at loading docks by installing special seals between the building and the vehicle.

INDEX OF MEASURES

6.2.1 Maintain the fit, closure, and sealing of industrial-type doors.

6.2.2 Install infiltration seals on existing doors.

6.2.3 Install powered door operators.

6.2.4 Install efficient exterior doors.

6.2.5 Install lightweight quick-acting doors to supplement exterior doors and to separate interior spaces.

6.2.5.1 Install strip curtains.

6.2.5.2 Install fabric swing doors.

6.2.5.3 Install impact doors.

6.2.5.4 Install powered quick-acting vehicle doors.

6.2.6 Install dock-to-truck seals.

RELATED MEASURES

- [Measure 4.2.1](#), control of building pressurization
- [Subsection 6.1](#), for Measures related to personnel doors

MEASURE 6.2.1 Maintain the fit, closure, and sealing of industrial-type doors.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Vehicle, loading dock, and other large exterior doors receive severe use. They require periodic maintenance to effectively minimize infiltration. You have to decide how often to inspect the doors, based on their type and usage. The adjustments and repairs you need to make are usually obvious when you inspect carefully. Check these conditions at appropriate intervals:

- repair and adjustment of infiltration seals, curtains, etc.
- operation of automatic closing mechanisms
- alignment of doors for effective sealing and complete closure.

Related Measures

Coordinate this activity with maintenance of personnel doors, which is covered by [Measure 6.1.1](#).

ECONOMICS

SAVINGS POTENTIAL: Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.

COST: \$5 to \$100 per year per door.

SUMMARY
 Routine maintenance needed to prevent energy waste and maintain comfort.

PAYBACK PERIOD: Short. The long-term saving greatly exceeds the maintenance cost.

TRAPS & TRICKS

SCHEDULING: The hard part is remembering to do it. Make sure that you have an effective maintenance calendar.

PREPARATION: Keep a full stock of spare parts on hand. Otherwise, searching for parts can be more bother than the maintenance work itself.

MEASURE 6.2.2 Install infiltration seals on existing doors.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
	B	

It is especially important to keep industrial doors well sealed because they are so large. Unfortunately, industrial doors tend to be leaky because their large weight and size require mounting systems that are difficult to seal.

Sealing large garage and industrial-type doors is a challenge because sealing systems may make it more difficult to open and close the doors. Still, you may be able to substantially reduce the infiltration of existing doors by using methods that do not excessively interfere with the operation of the door. You can create effective seals by using standard weatherstripping materials and by creative carpentry. Also, you can buy specialized seals for industrial doors.

First, Repair the Doors

Don't bother trying to seal a door that is loose or out of alignment. Your sealing methods will be ineffective, or they will wear out quickly. Your first step is to make sure that the door is secure and aligned properly. See [Measure 6.2.1](#).

How to Install the Weatherstripping

Make the effort to find the types of weatherstripping that will work effectively with your doors. The top, the sides, the bottom, and the gaps between individual panels each require different sealing methods. Each type of door needs its own combination of sealing materials. Study how your door operates before buying your materials. [Measure 6.2.4](#) describes the characteristics of the main types of doors.

Select your methods for durability and for minimum interference with the operation of the door. Here are some guidelines for different types of doors.

■ **Roll-Up Doors and Overhead Segmented Doors**

These two types of doors may allow serious infiltration. They have large clearances at the top and sides that are difficult to seal effectively. The gaps between the segments provide many infiltration paths.

Both types slide vertically in tracks on each side of the door. If the segments are narrow, they may slide in the track directly. If the segments are wider, each segment may have wheels that roll in the track, as in Figure 1. The only difference between the two is that the roll-up door is stored on a spool at the top of the door, while the overhead door slides on its track to an overhead position. The roll-up door has narrower segments, and it takes up less ceiling space.

SUMMARY

An inexpensive method of reducing air leakage, but not effective with all doors. Expect to search for the best sealing devices.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

There are two ways to deal with the large number of gaps between the door segments. If each segment butts against the next, try to install self-adhesive soft foam strips between the segments. The foam is pinched between the segments when the door is down, creating an effective seal. This is the most durable method. It may last several years.

If you cannot use this method between the segments, use a strong, flexible tape to cover the gaps on the inside of the door. The main weakness of this method is the life of the adhesive. Expect to replace the tape every year or two.

The sides are the most difficult to seal because of the need to maintain a clearance for the door to slide in its track. Various types of seals are offered to deal with this type of door. People keep inventing better types of seals, so make a search to find the best that are currently available. If the door is installed inside a jamb, you may be able to install brush seals on the outside of the door to contact the jamb. This method creates significant resistance, so limit it to doors that have motorized operators. You can reduce the resistance by arranging a brush seal on the door to mate with a "knife edge" installed on the jamb, or vice versa.

A less effective method is to install a rail on the wall, inside the door, that covers the gap. This still leaves a gap, but the rail greatly reduces the effect of wind.

To seal the top of the door, install a flexible or hinged flap that spans the space between the wall and the upper surface of the door. The door must slide underneath this seal, so make sure that it does not jam or create excessive friction. In the case of a roll-up door, the seal must be able to move over a wide range as the door winds and unwinds on the spool.

The bottom of the door is usually easy to seal. Use a soft compression gasket. Several types are readily available.

■ Overhead Panel Doors

This type of door has a single large panel that swings down from the ceiling. It closes with a motion that is a combination of sliding and compression.

If the door fits within a frame, try to use a sliding seal for the sides. A plastic or rubber leaf seal, which is a larger version of the bronze seals used on older residential doors, works well and provides the least resistance.

If the door does not fit inside a frame, install brush seals on the wall to mate with the top and sides.

For the bottom of the door, use a soft, compressible gasket material that can tolerate sliding against the floor.

Don't rely on compression weatherstripping with this type of door. To be effective, compression weatherstripping requires a clamping pressure all around the perimeter of the door. This is not possible with a conventional operator. Conventional operators apply their closing force at one or two points, and the door would distort away from an all-around seal at other points.

■ Sliding Doors

Sliding doors have large surface areas in relation to their edge length. In principle, this provides for low infiltration. However, the edge gaps are large to provide clearance for the panels to move. Sealing a sliding door requires ingenuity and custom fitting.

To seal the gaps between the panels, install interlocking channels at the sides of each panel. Arrange the channels so that an edge of one channel seats in a very soft foam gasket in the channel of the adjacent door.

To seal between the end panels and the door frame, install a deep channel or pocket on the door frame that surrounds the edge of the end panel. Use a brush-type seal on the channel that seats against the inside surface of the door. Arrange the seal so that the panel does not contact the seal until the panel has entered the channel. To reduce the resistance of the seal, install it at a slight angle to the edge of the panel, from top to bottom. In this way, the panel pushes through only a portion of the seal at any point in its travel.

To seal the bottoms of the panels, install a limp curtain-type seal on each panel that drags across the floor with minimal resistance.

The top of a sliding door assembly is the most difficult to seal. One way is to install a horizontal shelf extending from the wall over the top of the panels. Install brush seals on top of each panel to contact the bottom of the shelf.

The total resistance of all these seals may make it impractical to operate the door by hand, forcing you to install an operator. See [Measure 6.2.3](#) about door operators.

■ Vertically Folding (Bi-Fold) Doors

Bi-fold doors have the potential of sealing tightly. They have a low ratio of edge length to surface area. All sides of the panels may be relatively easy to seal.

There are two hinged joints, between the two panels and at the top of the top panel. You can seal both these joints tightly by installing a soft foam gasket in each joint so that it is pinched when the door is closed. Make the gaskets very soft so they do not interfere with closing the door.

Seal the bottom of the door using standard rubber weatherstripping that is widely available for installing on the bottoms of garage doors.

A sliding seal is best for the sides of the panels. If the door is installed inside a jamb, install the seals inside the jamb. If the door butts against the outside wall, install a channel along each side of the door, and install sliding seals between the channels and the sides of the panels. The side seals will increase the difficulty of closing the door fully. Make sure that the door operator is rigged to provide sufficient closing force.

WESINC

Fig. 1 Track for an overhead door The rollers hold the edge of the door away from the wall. You can seal the sides of this door with a fixed seal that slides against the face of the door opposite the rollers. Sides seals must be very flexible to accommodate looseness in the track and to minimize resistance to opening and closing.

■ Horizontally Folding Doors

Horizontally folding doors consist of a series of hinged panels. The center of each panel is suspended from an overhead track. There may be one set of panels that closes across the entire door opening, or two sets of panels may close toward the center of the door.

Seal the hinged joints by installing a soft foam gasket in each joint so that it is pinched when the door is closed. Make the gaskets very soft so they do not resist closing the door.

If there are two sets of doors that close from opposite sides, install a channel at the end of one panel, such that the opposing panel enters the channel when the doors close. If the channel fits fair snugly, there is no need for additional sealing at this location. If there is only one set of panels, install the channel on the jamb.

Probably the best way to seal the top of the door is to install brush seals at the top of each panel. These contact the track as the door closes. The seals tend to keep the door from closing fully, so install them so they create as little resistance as possible.

To seal the bottoms of the panels, install a limp curtain-type seal on each panel that drags across the floor with minimal resistance. The door may have a bottom track to guide the bottom of the door and add strength. If the track is raised, most of the bottom seal will not contact the track until the door reaches a closed position. At that point, the bottom seal tends to keep the door from closing fully.

■ Swing Doors

Large swing doors are rare because they require a large clearance area, and because they place a great deal of stress on the hinge and wall.

Seal the hinged sides of the doors by installing soft foam gaskets that are pinched when the doors close. Make the gaskets very soft so they do not interfere with closing the door.

To seal the tops of the doors, install leaf seals, if possible. However, to get good results with a leaf seal, the gap needs to be uniform and stable in width. A leaf seal is destroyed quickly if the door can shift in its frame. If you cannot use a leaf seal, install a strip of molding on the outside of the door to cover the gap. This is

effective for blocking wind, but does not provide much resistance to other infiltration.

If there are two doors, sealing the gap between them is tricky. The seal must offer little resistance to closing. It must bridge the gap and accommodate changes in the gap dimensions. It must work well regardless of the sequence in which the doors close. The best choice in most instances may be a very soft brush seal. Installing a strip of molding over the gap (an “astragal”) requires users to close one door before the other.

To seal the bottoms of the doors, install sweeps. Select sweeps that are very limp, to minimize resistance.

Keep the Seals Maintained

All types of seals wear out. Consider them to be an expendable commodity that you expect to replace occasionally. Wear is aggravated by changes in the gap dimensions caused by shifting of the building, flexing of the doors, etc. See [Measure 6.2.1](#) about scheduling door maintenance.

Alternative: High-Efficiency Doors

Some doors cannot be sealed reliably or economically. Consider installing an efficient new door in such cases. See [Measure 6.2.4](#) for details.

ECONOMICS

SAVINGS POTENTIAL: Typically hundreds of dollars per year per door, depending on climate, fuel cost, space layout, etc.

COST: Several hundred dollars, typically.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

STUDY THE SITUATION: Invest enough time to figure out a method of sealing your doors that is effective, reliable, and easy to maintain. Being clever at the beginning will save a lot of energy and effort later.

MAINTENANCE: Weatherstripping wears out quickly compared to most other maintenance items. Consider it an expendable material that you have to replace periodically.

MEASURE 6.2.3 Install powered door operators.

RATINGS

New Facilities	Retrofit	O&M
B	B	

A powered door operator provides two benefits. One is providing the physical effort of opening and closing the door. The other is the option of installing an automatic control that keeps the door closed when it is not being used. Install an operator if the door is difficult to move manually or if people are likely to leave the door open unnecessarily. Most vehicle doors should have operators because a manually operated door would require the vehicle operator to dismount to operate the door.

Types of Door Operators

The typical door operator consists of a motor and a mechanism to convert the rotation of the motor into linear motion. Door operators use a variety of mechanisms for this purpose. The most common are:

- a chain traveling on a guide rod
- a threaded shaft driving a nut along a guide rod
- a pinion gear on the motor driving a rack (a rod with teeth)
- a cable wound on a drum or rod.

Also, you need a control device to start and stop the motor. Some operators include their own controls. For example, garage doors are offered with radio controls to open and close them. Other operators require you to design the control separately. A variety of operators and control devices are available as standard items.

How to Connect the Operator to the Door

Some doors have operators that are an integral part of the door assembly. With others, you have to figure out the best way of installing the operator. Here are some tips for different types of doors.

■ **Overhead Panel and Segmented Doors**

For these types of doors, the operator is usually one that provides a straight-line motion, and the operator is attached to the top of the door. The operator is usually installed on the ceiling, providing an easy connection.

Be especially careful in the way you attach this type of operator to the door. The operator pulls horizontally because it is mounted on the ceiling, while the top of the door initially moves vertically in its track. If the operator is attached to the center of the door, it applies a bending force to the top of the panel. Figure 1 shows the problem. This inward force may deform the upper door panel, making it impossible to seal. You can avoid this bending force by attaching the operator to both sides of the door with rigid rods. This requires installing the operator farther inside the building.

SUMMARY

All doors that handle traffic, or that are difficult to operate, should have powered operators. Standard units are reliable and modestly priced.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$

Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

If you cannot install the operator at the proper orientation on the ceiling, you can use a system of cables to operate the door. You need one set of cables to open the door, and another to close it. An advantage of using cables is that you can operate them from a compact motorized winch.

■ **Sliding Doors**

If a sliding door has only one panel, or if it has two panels that open in opposite directions, installing an operator is fairly simple. The most compact solution is a simple cable system operated by a winch.

You can extend this method if the sliding door has more than one panel opening in each direction. For example, consider a set of three panels, all of which open in one direction. The cable opens one panel first. When the first panel completely overlaps the second panel, a stop on the second panel keeps the first panel from going past it. This causes the first and second panels to move as a unit until they overlap the third panel. Then, a stop on the third panel keeps the second from going past. From that point, the three overlapping panels move together to a fully open position.

The door closes in a similar manner. From the fully open position, the cable pulls the first panel toward the closed position. The first panel moves alone until its outer edge latches to the inner edge of the second panel, so the cable pulls the two panels in train. Then, the outer edge of the second panel latches to the inner edge of the third pane, and the three panels move in train until the door is fully closed.

Design the installation to provide effective sealing when the door is closed. You can do this by using interlocking channels to latch each panel to the next when it closes. See [Measure 6.2.2](#) for details.

■ Horizontally Folding Doors

The panels in horizontally folding doors are connected. Therefore, opening and closing the door requires only a single connection to the end door. A simple cable system operated by a winch can do the job.

For sealing purposes, note that simply pulling the door closed does not force the panels tightly into alignment. With this type of door, the laws of trigonometry reduce the aligning force to zero as the door is pulled fully closed. You can overcome this problem with some fancy linkages, but you probably don't need to bother. As explained in [Measure 6.2.2](#), you can effectively seal the gap in the panels and the gap underneath the door even when the panels are not aligned. However, sealing the top of the door requires the panels to be closed almost completely. By using a wide brush plate, as recommended in [Measure 6.2.2](#), you can seal the top gap even if the door panels remain somewhat staggered.

■ Vertically Folding (Bi-Fold) Doors

Opening a bi-fold door requires lifting the entire weight of the door, so a bi-fold door usually has a powered operator. You can reduce the lifting force on the operator by using counterweights to balance the weight of the door. Bi-fold doors are almost always operated with a cable system. Cables are attached to the bottom of the door at several points, which keeps the lower door panel from bending excessively. The winch is typically installed on the door itself, which makes the installation neat and compact.

Bi-fold doors close by gravity. When the door approaches the fully closed position, the closing force on the sides of the door becomes zero. As a result, bi-fold doors tend to hang slightly open. This allows a substantial amount of infiltration if the door is installed outside the door opening, rather than inside a frame. Manual latches may be installed to complete closing the door, but manual latching tends to be ignored if the door is opened and closed frequently. Some manufacturers offer automatic latches. Get this feature.

■ Roll-Up Doors

Roll-up doors typically have an integral geared motor. They are difficult to retrofit with an operator. If you have a roll-up door that lacks an operator, see if you can attach a cable reel to the existing spool. As an alternative, consider replacing the door with another type that seals tightly.

■ Swing Doors

Probably the best way to operate a large swing door is to use a straight-line operator. Install the operator at a suitable location on the ceiling of the space. Attach a rod from the operator to the top edge of the door. Install a spring link on the rod so that the door is spring-loaded when it is closed.

How to Control the Operator

Select the most efficient type of control to open and close the doors. First, consider the way the door is used. Do vehicles pass entirely through the door, allowing the door to close behind them? Is the door at a loading dock, where it may have to be open for part of the time that a vehicle is present, but not all the time? Does the door have to be opened in a way that does not relate clearly to the traffic through it, as in an aircraft maintenance hangar? Adapt the method of control to keep doors closed as much as possible, subject to usage requirements. These are your control choices:

- **manual switches.** These are desirable at loading docks, where a truck may linger for long periods without needing the door to be open. The truck driver or warehouse personnel can open the door when needed. However, this is an unreliable method of keeping doors closed. A loading dock door that seals tightly to the vehicle body is a better alternative in many cases. See [Measure 6.2.6](#) for this approach.
- **driver-actuated remote controls.** These are commonly used for garages. The most popular type is a handheld radio transmitter that can be used from inside a vehicle. These are actually manual controls that operate over a distance. They suffer from the main disadvantage of manual control, which is that

WESINC

Fig. 1 Common door operator problem The arrow points to the link between the door operator and the top of the door. When the door starts to open, the link pulls horizontally, whereas the door can only move vertically. This creates a strong bending force on the center of the top panel. You can avoid this problem while using the same operator by using two long links between the operator and the sides of the door.

the driver can neglect to close the door. This type of control offers security because the signals are coded.

- **induction loops** that are buried under the pavement near the door. These are sensitive to the height of the vehicle chassis above the floor. For example, a sensor that is set to be triggered by a forklift truck may not be triggered by a tractor trailer.
- **motion detectors.** Ultrasonic motion detectors and photoelectric light beams are capable of restricting their sensing range to a localized area in front of the door. Other types of motion sensors, such as infrared units, are likely to be triggered by activities that are unrelated to the door.
- **card access controls** are used primarily for security against unauthorized entry. The driver inserts a card into a card reader to open the door, and a proximity sensor of some type closes the door after the vehicle passes through.
- **time delay controls** are used in combination with other controls to keep the door open for a minimum period of time. Time delays are used in applications that have heavy traffic, to reduce excessive cycling of doors.

If you install automatic or remote controls, consider installing an additional manual control at the door. This allows emergency exiting and provides backup if the automatic control fails.

Decide whether your application makes it desirable to stop the door at a partially open position. If so, provide controls that make this possible.

Placards

To avoid confusion and enhance safety, tell users how the doors work. Do this with a conspicuous sign. If the door is controlled manually, install a sign to remind users to keep the door closed. See [Reference Note 12, Placards](#), for guidance in placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: *Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.*

COST: *The equipment costs \$200 to \$500 for smaller standard systems, up to several thousand dollars for heavy or complex equipment. Installation costs vary widely, being higher in retrofit applications.*

PAYBACK PERIOD: *One year, to several years.*

TRAPS & TRICKS

SELECTING THE EQUIPMENT: *Powered doors and door openers are subject to severe use if traffic is heavy. Select units for ruggedness, ease of use, and absence of safety hazards. Select a control method, or a combination of methods, that is appropriate for the nature of the traffic.*

INSTALLATION: *If you use an automatic door opener, select a sensor appropriate for the type of traffic. Install it where it will function reliably, but will not open the door in response to false signals, such as people walking near the door. If doors are controlled manually, install conspicuous placards that tell users how to operate the controls.*

MAINTENANCE: *Even an automatic door is an air leakage path. Keep it adjusted. See [Measure 6.1.1](#).*

MEASURE 6.2.4 Install efficient exterior doors.

RATINGS

New Facilities	Retrofit	O&M
B	C	

In new construction, select the most efficient doors you can find. Much better doors have come on the market in recent years, but the old inefficient types still prevail, so you will have to select critically. You may have to adapt the design of the structure around the door opening to accommodate efficient doors. Doors that are well sealed and well insulated do not raise the overall price of the building very much, and they save a large amount of money.

In existing buildings, you have to decide whether to improve the existing leaky doors or replace them entirely. Some doors cannot be modified effectively to resist air leakage. Also, you may not be able to insulate some existing doors. These weaknesses are worst in doors that consist of many segments. The gaps between the segments cannot be sealed in a permanent way, and leakage between the door and the guide rails is difficult to seal at best. With such doors, the only possible remedy is to replace the door with a more efficient type.

This Measure deals with big doors that have good long-term resistance to outside weather conditions, including wind, precipitation, and sunlight. These doors are physically strong, so they also act as effective security barriers.

At present, all large doors that have these good durability characteristics are limited to slow opening and closing speeds. If you need doors that open and close quickly, and if you are willing to make compromises for speed, consider the types of doors covered by Measures 6.2.5 ff.

Types of Large Exterior Doors

The genius of humanity has devised many ways to cover a large entrance in a building. These are the main types of exterior doors that are used at present:

- **sliding panel doors.** This is the simplest type of large door. Individual panels hang from an overhead track. The panels overlap when the door opens. This type is used primarily in medium and large sizes, including the largest doors in the world. See Figure 1. Sliding doors are easy to insulate, but somewhat difficult to seal against infiltration.
- **horizontally folding doors.** This type is made of large panels that are suspended from an overhead track. The sides of the panels are hinged together, so the door folds open in accordion fashion. This type is similar to sliding doors in insulation and infiltration characteristics. It is typically used in medium sizes.
- **bi-fold (vertically folding) doors.** As the name implies, bi-fold doors consist of two panels. The

SUMMARY

There are major differences in the sealing and insulation capabilities of large doors. You have a wide range of choices in efficiency and other features.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% % %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

door folds vertically, usually toward the outside. This type has the potential to be well insulated and to provide good resistance to infiltration. Figures 2 and 4 show typical examples. The structure of bi-fold doors, shown in Figure 5, makes them expensive. Also, they require structural bracing of the top of the door opening. They are becoming increasingly popular in the medium size range.

- **roll-up doors.** This type consists of short segments that roll up vertically around a spindle. This provides a compact door installation. Figure 3 shows a typical unit. However, the short segments cannot be insulated effectively, and the design is difficult to seal against infiltration. It is typically used in sizes that accommodate individual vehicles.
- **overhead segmented doors.** This type opens by rising in a track that bends to a horizontal position underneath the ceiling. The door is made in hinged segments to accommodate the bend in the track. The number of segments keeps this type from being well insulated, and the track mounting makes it difficult to seal against infiltration. It is typically used in widths that accommodate one or two vehicles.
- **overhead single-panel doors.** This type consists of a single panel that swings upward to an overhead horizontal position. It can be well insulated, but sealing against infiltration is difficult. It has fallen out of popularity because the mounting hardware is awkward and the door sweeps through interior space when opening. It is typically used in single-vehicle sizes.
- **swinging doors.** This type is limited to smaller sizes because of the space that is swept when the door opens, the potential for slamming by wind, and the large loads on the hinges. Too bad, because

swinging doors can be well insulated and they are easy to seal against infiltration.

How to Select Your Doors

In the past, you could expect that some types of doors would be better or worse than other types from an efficiency standpoint. This is true no longer. Interest in energy efficiency has spurred manufacturers of all types of doors to try to make their products more efficient. Therefore, do not limit your search to a particular type of door.

Although efficiency is important, it is not the only factor to consider. A large door is a major cost item, and it may have a major effect on the facility's activities. Make the effort to recognize every aspect of your

application that affects your door selection. Use the following as a checklist.

■ Infiltration Sealing

The door should have an effective method of sealing each edge of each panel. Each edge is a separate design challenge for the manufacturer. Examine how the manufacturer deals with the top, the bottom, and the sides. With segmented doors, examine the sealing between segments. If the door closes from both sides, examine how the manufacturer closes the gap between the two halves. With sliding doors, look for a reliable method of sealing between the panels that does not make it awkward to close the door.

All seals eventually wear out from flexing and abrasion. Check that the seals are installed in a way

Kalwall Corporation

Fig. 1 Sliding doors At the top of the size range, sliding doors are about the only choice. In large sizes, it is easier to provide them with effective weather sealing and powered operators. Note how the structure at the top of the door is designed. This door is so big that it has two sizes of smaller doors at the bottom. The center panels in this door are box structures made of translucent material.

that makes them easy to replace. If the seals are specialized, you will be dependent on the manufacturer to provide replacement seals in the future.

The bottoms of vertically moving doors are usually sealed with a thick compression seal. These work well.

If the door moves horizontally, any type of seal that contacts the floor causes drag that makes the door difficult to close. Therefore, horizontally operating doors may lack bottom seals. Minimizing infiltration with such doors requires careful installation to minimize the size of the gap. If you plan to install a powered operator, select one that has enough force to overcome the drag of sweep seals, which you can add to the bottom of the door.

Another problem area in sliding and folding doors is the top of the door. These types are suspended from rollers that ride in a track or group of tracks. Examine how the door design minimizes leakage through the track.

Overhead segmented doors have a similar leakage problem at their side tracks. Some manufacturers of segmented doors offer side sealing that is much better than the products of others.

■ Adjustment and Reliability of Operators

If the door has a powered operator, examine how it affects infiltration sealing. With some types of doors, such as rolling and bi-fold types, the adjustment of the

linkage between the operator and the door may not be critical.

Other types, such as sliding and folding doors, may need a complex linkage to provide effective sealing, and the adjustment of the linkage may have to be just right. To minimize air leakage in the long term, avoid linkages that may tend to get out of adjustment.

■ Insulation

Large doors have enough surface area to allow substantial heat loss by conduction. All types that have large panels can be insulated well, but this requires careful design by the manufacturer, or careful installation in the field. Effective insulation requires thickness, an unbroken surface area, and snug contact between the insulation and the door.

Doors with many small segments cannot be insulated well. This applies to rolling doors and overhead segmented doors. Insulation can be placed inside each segment, but the metal frames of segments comprise a large path for heat loss.

■ Dead Space for Open Door and Operating Hardware

Some types of doors take up a considerable amount of side space when they are open. Sliding doors are the worst in this regard. If the door must open to the full width of the building, the track must be extended beyond the sides of the building on an outrigger. This

Schweiss Distributing, Inc.

Fig. 2 Bi-fold door Almost all vertically opening panel doors consist of two panels, as shown here. A truss is needed at the bottom edge to resist bending from the weight of the panel. This model also has a truss at the center, which protects against wind loads when the door is closed. It is easy to install windows or a person door in the panels.

arrangement is very vulnerable to wind, and it impedes traffic around the sides of the building.

Folding doors waste relatively little end space when open.

Overhead segmented doors require ceiling space, which may interfere with lighting and ductwork.

Most bi-fold doors block a significant fraction of the upper part of the door opening. However, at least one manufacturer uses side braces that allow its bi-fold doors to open almost to the full height of the opening. This type is shown in Figure 4.

The operating hardware also takes up space. For example, overhead doors need tracks that extend into the space. Cable-operated doors need connections between the winch and the door. Models with self-contained actuators ease this problem. For example, some bi-fold doors have the motor, winch, and cables mounted on the door assembly itself. Figure 5 shows a compact operator installation.

■ Clearance While Operating

When the door opens, it sweeps a certain amount of space, which must be left clear. For example, horizontally folding doors require clear space inside and outside the door opening. Swinging doors require a large clear path, which is one reason why they are rarely found in large sizes.

The sweep area of the door reduces storage space somewhat, but this issue is usually minor. More important, it requires people to anticipate the opening of the door and to keep the space clear. By the same

Fig. 3 Roll-up door The main virtue of this type of door is compactness. It can be motorized easily. The large number of segments make it impossible to insulate well. Some models seal against infiltration fairly well, and some do not.

token, the sweep of the door is a safety issue, especially if the door has an automatic operator.

If you install a door that sweeps through an area that may be occupied by people or vehicles, install a prominent placard, guide lines, guard rails, or other means to avoid danger from the door.

■ Speed of Operation

All types of large exterior doors operate slowly, but some are faster than others. Higher speed creates less of an impediment to traffic. It also reduces the amount of heat that is lost while the door is open. If the door cannot open quickly, it is likely to be left open.

If there is frequent traffic, consider installing one or more quick-acting interior doors to supplement the exterior door. See [Measure 6.2.5.4](#) for specialized doors that open quickly.

For loading docks, consider installing seals between the building and vehicles that are being loaded or unloaded. See [Measure 6.2.6](#) for the details.

■ Ease of Operation

People are more likely to keep a door closed if it is easy to operate. This is a factor if the door is operated

Fig. 4 A bi-fold door that wastes a minimum of height This proprietary design allows the door to open almost completely by using integral jacks at each side of the door. Most bi-fold doors cannot open fully because the lower panel must act as a brace against the door frame.

manually. Any type of door can be easy to operate if you install a powered operator. Even then, select a method of controlling the door that is most efficient for the type of traffic. See [Measure 6.2.3](#) for the details about operators.

■ Strength

Make sure that the door, the frame, and associated hardware are able to withstand all the forces that occur in the application.

Large, flat door surfaces are vulnerable to deformation by wind. The door is usually strong enough to withstand the force of strong winds, but slamming caused by wind may damage the door, the frame, or the building structure. Select and install the door to limit slamming forces. This means that the door should be held firmly while it is in any position.

In some cases, the closing and opening forces of the operator may be strong enough to deform the door. You can avoid this problem by the way you install the operator linkage. See [Measure 6.2.3](#) for details.

Some types of doors, especially bi-fold doors, are subjected to large gravity loads that deform the doors when they are opened. Manufacturers of bi-fold doors offer additional bracing as an option. The bracing consists of horizontal trusses installed at the bottoms of

the two panels. The trusses may be installed on the inner or outer sides of the door.

Conventional doors generally are not designed to resist impact, as from vehicles. If the application involves a risk of impact, consider supplementing the primary exterior doors with an inner door that is designed to tolerate impact. See [Measures 6.2.4 ff](#) for these doors.

■ Safety Features

If the door has a powered operator, you may wish to install safety devices to stop the door if something is in the door's path. Such features are unusual on large exterior doors, but you can probably find them if you search long enough. A common type of safety device is a light beam that stops the door if anything interrupts the beam. Another safety device is a "reversing edge," which stops the door if anything contacts the leading edge of the door. These devices are common with the types of quick-acting doors recommended by [Measure 6.2.5.4](#). Refer to there for the details.

■ Ability to Install Windows and Personnel Doors

Some types of exterior doors offer windows as an option. These can provide natural lighting to a space that lacks it. Similarly, you can get a small personnel door installed in the larger door. This allows easy access without opening the large door itself. Windows and

Schweiss Distributing, Inc.

Fig. 5 Construction of a bi-fold door All bi-fold doors require a bottom truss to resist the strong bending forces that occur when the door is being opened. Similarly, a continuous line of hinges is needed to carry the top edge of the door, and the top of the door frame must be reinforced to carry this load. Bi-fold doors need operators, which can be installed in a compact manner. The edges of the door panels can be sealed against air leakage fairly easily.

personnel doors are offered in bi-fold, sliding, and horizontally folding doors. Windows are offered in overhead segmented and single-panel doors.

■ Security

The same factors that contribute to physical strength and to infiltration sealing also contribute to security. In addition, get appropriate locking devices.

■ Ease and Cost of Installation

Consider the price of the door itself, its accessories, installation labor, and any required strengthening of the building structure. For example, bi-fold doors typically require substantial bracing of the upper part of the door opening structure.

Which Type is Best?

Okay, now that we have gone through all that, which door is best for your application? For doors that are very wide or very tall, your choice is limited to doors that hang by gravity. Sliding doors are used in the largest sizes. Their main disadvantage is the difficulty of sealing the edges from air leakage. They also require a substantial amount of extra opening width. Folding doors probably deserve greater attention for large openings, because they are better in both respects.

In smaller sizes, swinging doors provide the best potential for insulation and sealing. Their major disadvantages is the swing clearance they require on opening. An overhead door may be the best choice for a relatively small opening. Infiltration sealing in overhead doors has improved considerably in recent years, but examine the sealing design carefully before you buy.

For the middle size range, from about 20 to 50 feet (7 to 16 meters) in width, bi-fold doors probably have the best efficiency potential. They can be made to seal tightly, and they can be well insulated. Bi-fold doors have other advantages. They fold outward, so they require no internal space, and they require no internal clearance to operate. This type initially came into widespread use for aircraft hangars, and they are gaining in popularity for other applications.

The main disadvantage of bi-fold doors is their relatively high cost. The door assembly itself is expensive, because it requires a lot of structure and an operator. And, it is custom-built at the site. Prefabricated bi-fold doors have not yet made an appearance on the market. The building structure must be braced to withstand the stress that the open door exerts on the top of the door opening.

ECONOMICS

SAVINGS POTENTIAL: *Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.*

COST: *\$2,000 to \$20,000 in typical sizes.*

PAYBACK PERIOD: *Several years, or longer.*

TRAPS & TRICKS

SELECTING THE EQUIPMENT: *Select doors for ruggedness, ease of use, sealing effectiveness, and durability of the seals. Inspect some installed units. Select the operator, if one is needed, for reliability, ease of use, and tight closing.*

INSTALLATION: *If the door has an automatic operator, install the sensor in a manner that is appropriate for the nature of the traffic. See [Measure 6.2.3](#).*

MEASURE 6.2.5 Install lightweight quick-acting doors to supplement exterior doors and to separate interior spaces.

All the types of exterior doors covered by [Measure 6.2.4](#) are inherently slow. That is, they cannot accommodate the rapid movement of vehicles and people. As a result, they are typically left open as long as frequent traffic may occur. You can solve this problem effectively by installing quick-acting interior doors to block infiltration.

You can choose from a variety of types, which differ in features and price. They are all made of light materials. The light weight allows users to push the door open easily, or it allows a powered actuator to operate the door quickly. You can find an infiltration door to fit virtually any size of door opening.

The subsidiary Measures cover the spectrum of contemporary quick-acting doors. In order of increasing price, the most common types are:

- **strip curtains**, covered by [Measure 6.2.5.1](#). These are popular, primarily because they are cheap and simple. They are the least effective type, they are annoying if they touch people, and they soil clothing.
- **fabric doors**, covered by [Measure 6.2.5.2](#). These are a compromise design that is moderately satisfactory for both people and vehicles, if the people can tolerate soiled clothing. They are simple, safe, and relatively inexpensive, but they do not seal well.
- **impact doors**, covered by [Measure 6.2.5.3](#). These are effective for equipment handling, and less satisfactory for people. They are simple, reliable, and relatively inexpensive. They may pose a safety hazard.
- **powered quick-acting vehicle doors**, covered by [Measure 6.2.5.4](#). These are the most effective type for resisting infiltration. Unlike the previous types, they require no contact with the vehicles or people passing through the door. Their main disadvantages are high initial cost and more expensive maintenance. [Measure 6.2.5.4](#) covers the types of powered doors that are currently on the market.

There are other types that fit between these categories, and there are some relatively unusual types that combine features from several of these categories. If you study these four basic types, you will learn about the others also. The subsidiary Measures explain the advantages and disadvantages of each type. Often, several types are competitors for the same applications. It's your decision to make the compromise between efficiency, other features, and cost.

Comparison with Exterior Primary Doors

To date, nobody has invented a strong, durable type of exterior door that handles frequent traffic well. The doors covered by this Measure handle traffic well, but they cannot serve as primary exterior doors in most applications. In your planning, take into account these distinguishing characteristics of the quick-acting doors covered by this group of Measures:

- **little or no delay in passing through the door.** These doors are intended to keep traffic moving. Unpowered types are simply pushed aside by the user, either a vehicle or a person. Powered types have actuators that operate very rapidly.
- **designed to withstand impact.** These doors are designed to be hit. Unpowered types tolerate impact because they are light. Powered models are also relatively light, and they may have breakaway features that limit damage if the door is hit.
- **need for recurring maintenance.** All types of doors have components that wear out occasionally from repeated cycling, impact, and weather. The doors are (or should be) designed for quick repair.
- **minimal insulation value.** The primary benefit of these doors is minimizing infiltration. Most have little insulation value, because they are light and thin. Some types do have a limited amount of insulation value, which can be important for some applications.
- **minimal security.** The light weight of these doors keeps them from serving as an effective barrier to forced entry. A small vehicle could drive through any of them.
- **limited resistance to outdoor conditions.** Unpowered types have virtually no resistance to wind. Powered types can resist varying wind speeds, depending on the model. Strong sunlight would weaken the plastic materials within a few months or years and make them brittle. The mechanisms of powered types may be vulnerable to precipitation.
- **specific temperature ranges.** Temperature affects the flexibility of plastic materials. Flexibility is important for the operation of door types in which the fabric folds, rolls, or bends in operation. Flexibility is also important for impact resistance. Select a material that is suitable for the lowest temperature at which the door will operate.

Where to Install Quick-Acting Doors

In general, consider installing a quick-acting door if there is frequent traffic between a conditioned space

and another space that is at different temperatures. These are common applications:

- **as a supplement for an exterior door.** This allows the primary door to remain open during hours of heavy traffic. Depending on the type of primary door (see Measure 6.2.4 for details), you may be able to install the infiltration door close to the primary door, taking up little additional space.
- **as the inner door of a vestibule.** If possible, try to create a vestibule between the primary door and the infiltration door. This blocks infiltration more effectively during the times when the primary door

is kept closed. For example, at a truck dock, install the infiltration door between the dock and the rest of the building. In this way, the entire dock acts as a vestibule. (See Measure 6.1.8 for vestibule design issues.)

- **for refrigerated spaces.** If practical, install an infiltration door between any interior spaces that differ substantially in temperature. For example, in a commissary building, install an infiltration door between the meat storage freezer and the warmer part of the refrigerated space. In addition, install an infiltration door at the truck docks.

MEASURE 6.2.5.1 Install strip curtains.

RATINGS		
New Facilities	Retrofit	O&M
B	B	

Strip curtains consist of overlapping strips of flexible plastic material that hang by gravity. They are used most commonly with loading vehicles, such as forklift trucks. Lighter versions are available for use by people. The strips are usually transparent, which is a valuable safety feature. Figure 1 shows how strip curtains work.

The main advantage of strip curtains is their low cost to install and to repair. The transparency of the plastic allows vehicles to approach the curtain safely and to drive through the strips without stopping. The curtain material is so light and supple that it does not pose a safety hazard when someone blasts through the door.

Strip curtains can be annoying in applications where people, rather than vehicles, push through the door. The transparent plastic cannot be reinforced, so the strips must be fairly heavy to survive. The plastic strips drag against exposed skin, which is especially unpleasant if the strips are stiff and cold. Also, the strips become soiled, so strip curtains are not appropriate for people wearing formal clothing. For this reason, don't use strip curtains as personnel doors except in rugged environments.

Strip curtains can be made in any width. All you need is a structural element or a suspended bar from which the strips can be hung. Strip curtains can also be fairly tall. However, long strips tend to twist, allowing more air leakage.

The transparent plastic is not crystal clear, and it becomes less clear with wear and soiling. To aid in guiding vehicles through the proper part of a strip

SUMMARY

A popular type that is inexpensive, simple, safe, and fairly effective. Annoying if the curtain touches people. Cannot resist wind.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

curtain, you can install one or more colored strips among the transparent strips.

How to Install Strip Curtains

If the strip curtain is made of plastic, fabric, or any other organic material, try to install it out of sunlight. The ultraviolet component of sunlight causes plastic to become weak, stiff, and dark.

Select the plastic material for the temperature range in which it is used. Plastic becomes stiffer as it becomes colder. If the plastic is much colder than its normal temperature, it becomes brittle enough to break easily. If you have a choice, install the strip curtain in a location where the temperature varies least.

Try not to install the strip curtain where it is subject to strong wind. Wind flows easily through strip curtains if it is strong enough to blow the curtain partly open. If

Rite-Hite Corporation

Fig. 1 Strip curtains This is the least expensive kind of quick-acting door. It is foolproof in operation, and fairly safe. Because of the large amount of edge length, sealing against air leakage is relatively poor. They are annoying to walk through, especially with clean clothes. Different weights and widths of plastic can be used for vehicles and people. In this example, a colored strip of plastic is used to separate vehicle traffic from pedestrian traffic.

possible, install the strip curtain in combination with a vestibule (see [Measure 6.1.8](#)).

Keep Them Repaired

Strip curtains tempt some vehicle drivers to drive through them aggressively. Try to dampen their enthusiasm by installing a large sign on each side of the door that says, “CAUTION: Drive through the door SLOWLY.”

The plastic strips eventually stiffen. This keeps them from closing properly, and pieces break off. Expect to replace strips as they break or lose their transparency.

Keep spare strips on hand to repair individual ones that become damaged. Keep the spares flat, in a dark, cool location. The strips are easy to replace, but they are also easy to overlook. Include maintenance of strip curtains as part of the regular door maintenance program recommended by [Measure 6.2.1](#).

Roll-Up Strip Curtains

A hybrid type of door is available consisting of a strip curtain that rolls up on roller, which is usually motorized. This type avoids the annoyance of having to push through the strips. To keep the strips from jamming along the side of the door when the curtain rolls up, the strips are cut in a tapered shape. This type of door is not as effective as the tightly sealing roll-up doors recommended by [Measure 6.2.5.4](#), but it is less expensive. The tapered shape of the strips sacrifices

sealing at the sides of the door, and the door may not be well sealed at the top.

ECONOMICS

SAVINGS POTENTIAL: *Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.*

COST: *Several hundred dollars, for a strip curtain large enough to pass a forklift truck. Roll-up strip curtains typically cost several thousand dollars.*

PAYBACK PERIOD: *Less than one year, to several years.*

TRAPS & TRICKS

CHOICE OF TYPE: *Install strip curtains if you can afford nothing else. Their low cost gives them the best cost-benefit ratio of all the door types, although they are less efficient. Use a better type of door if the location is windy, or if the door is used often by people on foot.*

INSTALLATION: *If you have a choice, install the strip curtain where it is protected from sunlight, wind, and large temperature variations. Install a highly visible placard that asks vehicle drivers to drive through the door slowly.*

MAINTENANCE: *Replace broken strips and strips that become too stiff to close properly. Schedule inspections in your maintenance calendar.*

MEASURE 6.2.5.2 Install fabric swing doors.

RATINGS

New Facilities	Retrofit	O&M
C	B	

Fabric doors are soft swinging doors. They are usually installed as a double door, which makes them easier to use. The door surface is heavily reinforced fabric, which hangs from a pivoting bar at the top of the door. The lower part of the door is reinforced to withstand the impact. Typically, a window of clear plastic is installed in each door. Figure 1 shows one in action.

The door is opened by people or vehicles pushing through the door. The door is closed by a self-centering closer. Typically, the bar at the top of the door falls by gravity into a V-notch on the hinge, as shown in Figure 2 of Measure 6.2.5.3.

The characteristics of fabric doors lie between those of strip curtains (covered by the previous Measure) and rigid impact doors (covered by the next Measure). They are a close competitor to both types in many applications.

Fabric doors have several advantages over strip curtains. One is that they do not drag over persons passing through the door, although a person on foot must

Rite-Hite Corporation

Fig. 1 Fabric swing door This door is installed inside a rigid freezer door. It consists of heavy fabric suspended from two swinging arms. Use is somewhat awkward. Here, the cargo has already passed through the doors, but the upper arms have not yet opened against the centering force. This model has windows and reinforced bumper bottoms.

SUMMARY

A compromise design that is effective for vehicles and people, especially for people moving goods on hand trucks. Inexpensive, simple, and safe. Does not seal well.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% % % %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

push his way past the door edges. Fabric doors are more durable than strip curtains because they can be made of stronger materials. Changes in the pliability of the material with temperature and age do not matter as much as they do with strip curtains.

Fabric doors also have several disadvantages. They are more expensive than strip curtains, although they are much less expensive than powered doors. Unlike strip curtains, they require a rigid frame, including a strong side frame for mounting the hinges. Fabric doors sweep open, which poses a safety hazard. However, the material is flexible and light, which minimizes the hazard. By the same token, if the object passing through the door is narrow or short, the door tends to stay closed, while the edges of the doors drag across the object or person.

Fabric doors are limited in width, but they are available in widths sufficient to pass all typical vehicles.

Fabric doors do not seal as well as rigid impact doors. The edges of the doors are thin and the material is pliable, so the edges typically do not meet closely at the center of the door. Also, fabric doors cannot resist significant wind or pressure differential.

You can order some models of fabric doors with enhanced insulation value, but this hardly matters in view of their relatively high air leakage.

Caution Drivers

Try to keep vehicle drivers from driving through fabric doors aggressively. This minimizes the safety hazard and extends the life of the door. Install a large sign on each side of the door that says, "CAUTION: Drive through the door SLOWLY:"

ECONOMICS

SAVINGS POTENTIAL: Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.

COST: About \$1,000.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

CHOICE OF MEASURE: Consider fabric doors if the primary traffic is people with hand trucks. Don't expect good sealing. For somewhat more money, you can get an impact door that provides much better sealing.

INSTALLATION: Install a highly visible placard that asks vehicle drivers to drive through the door slowly.

MEASURE 6.2.5.3 Install impact doors.

Impact doors are lightweight rigid swing doors that are pushed open by a person or by a materials handling vehicle. Most impact doors are installed as double doors, which makes them easier to use. The doors themselves are typically made of plastic sheet materials over a light metal frame. The doors are installed in a strong frame that withstands the transmitted impact forces. Figure 1 shows an impact door in action.

To minimize air leakage, the door can be equipped with effective seals on all sides. They can also be insulated to a limited extent. Doors that seal tightly provide a significant amount of noise isolation.

Impact doors can be used by both people and vehicles. However, the door must have a fairly strong closing force to overcome the resistance of the seals. The closing force may be an impediment to some people on foot.

How to Select An Impact Door

Impact doors are simple devices. Still, there are significant differences between models. Consider these features:

- **closing and centering force.** The door must have a centering force that is strong enough to overcome the resistance of the seals, and to resist wind and pressure differential. Most impact doors are centered by gravity. In the closed position, a cam on the door side of the hinge rests in the bottom of a V-notch fitting that is installed on the frame. See Figure 2. When the door is opened, it rides up the side of the notch. When the door is released, gravity pulls the door back into the center position. A spring may be installed on a hinge rod to increase the centering force. Some manufacturers allow the purchaser to select the centering force by providing

SUMMARY

A popular type that is simple and fairly inexpensive. Good models provide the best resistance to air leakage and the best insulation of all types of quick-opening doors. They can also provide better security than other types. Can be used by powered vehicles and by people on foot. The swing of the door poses a safety hazard. Limited to smaller door sizes.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	😊

notch fittings of different depth or springs of different stiffness.

- **swing pattern.** By using a hinge installed on the corner of the frame, some models can open as much as 180° in one direction. In other words, the door folds flat against the wall. The door can open 90° in the other direction. See Figure 3. If the wider opening angle is in the direction of the vehicle's travel, the vehicle can make a turn even before it clears the door. This can be a valuable feature, especially in tight quarters.
- **sealing features.** The edge seals of the door are an important factor in stopping air leakage. Look at all four sides of the door. Manufacturers use several

types of seals, all of which can block infiltration almost completely. The gap between the two doors is typically closed with soft hollow tube seals. Figure 4 shows typical seals for the door gap and the hinge side. The top seal is a special design because the door rises as it opens. This requires clearance between the top of the door and the door frame. To fill this gap and minimize resistance, many models have a soft seal on the top of the door that mates with a soft seal installed in the top of the frame. The bottom of the door can be sealed effectively with a rubber sweep. The door rises as it opens, so the sweep seal does not drag on the floor except when the door is near the closed position.

- **visibility.** Impact doors have enough weight and stiffness to be dangerous if they are slammed open. The primary safety feature of an impact door is a large window that allows vehicle drivers to see that the space on the other side of the door is clear. Unfortunately, the window cannot extend below the top of the bumper portion of the door, which is typically at about half the door height. This leaves the danger of hitting a low object on the other side

Rite-Hite Corporation

Fig. 1 Impact door As the name implies, this type of door is designed to open by being pushed. The door survives by being light and strong. Plastic bumpers at the bottom of the door absorb much of the shock. The safety issues are obvious here.

WESINC

Fig. 2 Centering hinge This is the most common type of centering device for impact doors. The weight of the door is carried by a roller fitting, which falls by gravity into a V-notch. This aligns the doors accurately enough to engage the infiltration seals. The hardware has virtually unlimited life. The infiltration seal on top of the door must accommodate the rising of the door as it opens.

of the door. Get the largest window that does not interfere with the strength of the door.

- **resistance to impact.** Impact doors use bumpers to absorb the shock of vehicles running into them. Select bumpers that are appropriate for the severity of the application. Select the height of the bumpers for the nature of the vehicles and goods passing through the door. For example, a stack of goods that is being carried on a forklift truck may strike the door before the truck itself. At the same time, do not make the bumper so tall that it interferes with visibility through the window.
- **insulation.** Impact doors are relatively small, so conductive heat loss through the door is not a major problem. Even so, it is worth insulating the door. You can get models that are filled with foam insulation. Typical door construction allows for somewhat more than one inch (about three centimeters) of insulation, which provides an overall insulation value of about R-4.

Rite-Hite Corporation

Fig. 3 Swing pattern An impact door mounted with the hinge on a corner of the wall opening can open flat against the wall in one direction. This allows materials handling vehicles to make a tight turn away from the door.

- **security features.** Impact doors can be made strong enough to provide a moderate degree of security. They cannot use conventional locks, because the thick seals between the doors create too much of a gap between the strong parts of the doors. The doors can be latched to the top of the frame and to the floor with sliding bolts. (These are commonly called “cane bolts” in the door trade.) The most common method of locking impact doors from the outside is to chain the doors together. To make this possible, order doors that have holes with bushings for the chain.
- **mounting features.** A vehicle slamming into an impact door transmits a large force to the adjacent wall. Therefore, the door needs a strong frame, and the frame needs to be attached strongly to the wall. In some cases, you may have to reinforce the wall itself. The bottom hinge absorbs more impact than the other hinges. For this reason, some models provide the option of bolting the bottom hinge to the floor.
- **ease of repair.** Select a door that is easy to repair. In particular, expect to replace the seals and bumpers occasionally. The windows should be easily replaceable, because they can be broken, and they will become obscured in time.

Rite-Hite Corporation

Fig. 4 Infiltration seals for door gap and hinge side

The center gap seal works by being big and soft. This door is made of a single sheet of rigid material. Many impact doors have a box construction, which maintains better alignment.

Caution Drivers

Safety is an issue with impact doors because they swing open. The best safety features are a large window and persuading vehicle drivers to go through them slowly. Less aggressive driving also extends the life of the door. Install a large sign on each side of the door that says, “CAUTION: Drive through the door SLOWLY.”

ECONOMICS

SAVINGS POTENTIAL: Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.

COST: \$1,000 to \$2,000.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

CHOICE OF MEASURE: Impact doors are a good choice from the standpoint of energy efficiency. They resist wind and pressure differentials better than the types in the previous subsidiary Measures, but not as well as powered doors. Powered doors, covered next, offer better safety and ease of operation, but at much higher cost.

SELECTING THE EQUIPMENT: You have lots of choices among impact doors. Make sure that you fit the door to the application.

INSTALLATION: Impact doors require a strong installation. Reinforce the wall, if necessary. Consider bolting the lower hinge to the floor. Install highly visible placards that ask vehicle drivers to drive through the door slowly.

MEASURE 6.2.5.4 Install powered quick-acting vehicle doors.

RATINGS

New Facilities	Retrofit	O&M
B	B	

The previous subsidiary Measures recommended doors that are pushed open by the people or vehicles who pass through them. In some applications, the requirement to push the door open is unacceptable, or at least undesirable. In such cases, you can minimize heat loss by installing powered quick-acting doors. Quick-acting doors are designed to open so rapidly that they do not delay traffic significantly. They are usually operated by sensors that detect approaching vehicles and open the doors automatically.

There are several types of quick-acting doors on the market. Each type has significant advantages and disadvantages. Within each type, different models may have important differences. This Measure describes the types that are available, and spells out the characteristics that distinguish them.

The primary advantage of quick-acting doors is that they avoid contact with people and vehicles. They resist wind and strong pressure differentials better than all types of push-through doors. However, they are probably no better than good impact doors for resisting small pressure differentials and ordinary convection.

Quick-acting doors are not foolproof, and they require maintenance that is more complex. They pose a safety hazard primarily when closing, in contrast with push-through doors, which pose a safety hazard when opening. Most types are designed to break loose when hit, so they do not provide strong security. All quick-acting doors are much more expensive than push-through doors.

Types of Powered Quick-Acting Doors

All quick-acting doors achieve high operating speed by using materials that are light in weight and by using a powerful motor. These are the main types:

- **vertical roll-up.** This type rolls up vertically on a spindle, like a roller blind. The material for this type of door is a fabric-reinforced plastic or rubber sheet. The door typically includes a plastic window. Figure 1 shows a typical unit in action.
- **horizontal roll-up.** This type typically consists of two doors, each of which rolls up on a spindle at the side of the door opening. The material is similar to that used in vertically rolling doors. The doors typically have plastic windows. Figure 2 shows a typical unit.
- **horizontally folding.** This type typically consists of two doors, each of which folds to the side in accordion fashion. The material can be thicker and tougher than that used in rolling doors. The doors typically have plastic windows. Models are

SUMMARY

Powered quick-acting doors create the least obstruction to traffic, are easy to use, have the best wind resistance, and are relatively safe. Some models offer limited insulation value. They do not offer a significant efficiency advantage over impact doors, except in windy locations. Much more expensive than the previous types.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

available that include a thin layer of insulation. These are sometimes called “freezer doors,” because they are favored for cold storage applications. Figure 3 shows a unit, with particular features highlighted.

- **overhead sectional.** This type is a quick-acting version of overhead sectional doors that are used for exterior purposes (which are covered in Measure 6.2.4). The differences are faster operation, greatly reduced infiltration, and tolerance for impacts. Models are available with insulated panels, as shown in Figure 4.

How to Select a Powered Quick-Acting Door

The different types and models of quick-acting doors provide you with a broad choice of features. Their relative advantages and disadvantages may not be obvious, so pay attention to the details. Consider the following characteristics of quick-acting doors in relation to your particular applications.

■ **Speed of Operation**

Quick-acting doors typically operate at a speed of one to three meters per second (three to nine feet per second). Quick operation is important to minimize interference with traffic and to reduce the chance of hitting the door.

The door may close more slowly than it opens. Opening quickly is more important than closing quickly, so the door may have a spring to assist the motor in opening the door. When the door closes, the motor must

overcome the force of the spring. Some vertically rolling doors close by gravity, whereas the other types require power to close.

Slower closing may be important for safety, since the closing cycle poses more of a danger than the opening cycle. Slower closing allows more heat loss, but this effect is minimal at the high speeds at which the door operates.

■ Infiltration Sealing

The door should have an effective method of sealing each edge of each panel or sheet. Each edge is a separate sealing problem. Examine how the manufacturer deals with the top, the bottom, and the sides. In the case of double doors, examine how the manufacturer closes the gap between the two halves. In the case of segmented doors, examine the sealing between segments.

All seals eventually wear out from flexing and abrasion. Check that the seals are installed in a way that makes them easy to replace. If the seals are specialized, you will be dependent on the manufacturer to provide replacement seals in the future.

The bottoms of vertically moving doors are usually sealed with a large, hollow cushion seal. These work well. The bottoms of folding doors usually have sweep seals. These work fairly well, but the seals wear on an

uneven floor, and the drag of the seals tends to keep the door from closing fully near the bottom. Horizontally rolling doors may have no bottom seals. Minimizing infiltration with this type of door requires careful installation to minimize the size of the gap.

With double folding or horizontally rolling doors, look for an effective seal where the doors meet. Some doors rely on a large, soft edge seal. This method may not seal well, because the edges may not meet properly. Some models have magnetic seals installed in the edges to provide effective closure.

With rolling doors, pay attention to the manufacturer's method of minimizing air leakage where the edge of the sheet slides in the track. This part of the door design is a compromise between air leakage, reducing a tendency to jam, and breakaway during impact. Also, make sure that there is an effective seal between the door frame and the roller.

With folding doors, look for effective closure at the top and bottom. Some folding doors have a curtain of lighter fabric that seals the gap between the top of the door and the sliding track. The bottom of the door should have effective sweep seals.

With overhead segmented doors, examine the method of sealing the top and sides. It is a challenge

Rite-Hite Corporation

Fig. 1 Vertically rolling quick-acting door The motor that rolls up the door is on the upper right side of the frame. A large window is needed for safety. The driver has a view of the complete width of the floor on the other side as soon as the door starts to open.

for the manufacturer to combine good side sealing with effective breakaway.

■ Resistance to Wind and Pressure Differential

Wind and pressure differentials exert a strong force on large doors. In applications where wind or a strong pressure differential may act on the door, select a model designed to maintain effective sealing under these conditions.

Overhead segmented doors have the greatest ability to resist wind and air pressure. At the other extreme, horizontally rolling and folding doors have the least resistance, tending to blow apart where the two halves meet in the middle. Magnetic seals can substantially improve sealing by these types, up to a point where the magnets cannot hold the two halves of the door together. Vertically rolling doors resist wind and pressure up to a point, but they jam or blow open above their maximum pressure tolerance. Some models of vertically rolling doors offer limited reinforcement to resist pressure.

■ Insulation

Rolling doors have minimal insulation, because the door segments must be thin. Some horizontally rolling doors have double rollers and a double surface, so the air layers that adhere to the inside surfaces provide additional insulation. This may give the door an overall insulation value of about R-1.

With folding doors, the fabric can be padded with a thin layer of insulation. Insulated models are bulkier.

Segmented doors are much thicker than the other types, so a fairly large amount of insulation can be installed inside each panel. However, this advantage is partially cancelled by heat conduction through the many metal frames of the panels.

■ Durability

Durability is a primary factor in selecting a quick-acting door. All types have components that are subject to many cycles of flexing. The door should be designed to minimize stress on flexible components, and to make it easy to replace them when they fail.

Rite-Hite Corporation

Fig. 2 Horizontally rolling quick-acting door This type quickly provides clearance for tall, narrow loads. The bottom edges of the doors are not restrained, so the struts seen in front of the door are installed to hold the center edges in alignment.

The door is subject to moisture from condensation, and perhaps from blowing rain or snow. Moisture corrodes steel parts and it causes mildew on plastic and fabric components. The materials should resist this damage. (You can avoid condensation by heating the door, as described below.)

The ultraviolet radiation in sunlight harms all plastic and fabric materials. If the door is exposed to direct sunlight, these materials may fail prematurely. This is a factor with rolling and folding doors, where the plastic materials carry load and are subjected to flexing. Such applications may favor a segmented door, in which the loads are carried by metal parts.

Make sure that plastic components are rated for the temperature range of your application. Flexible materials become brittle when they are too cold.

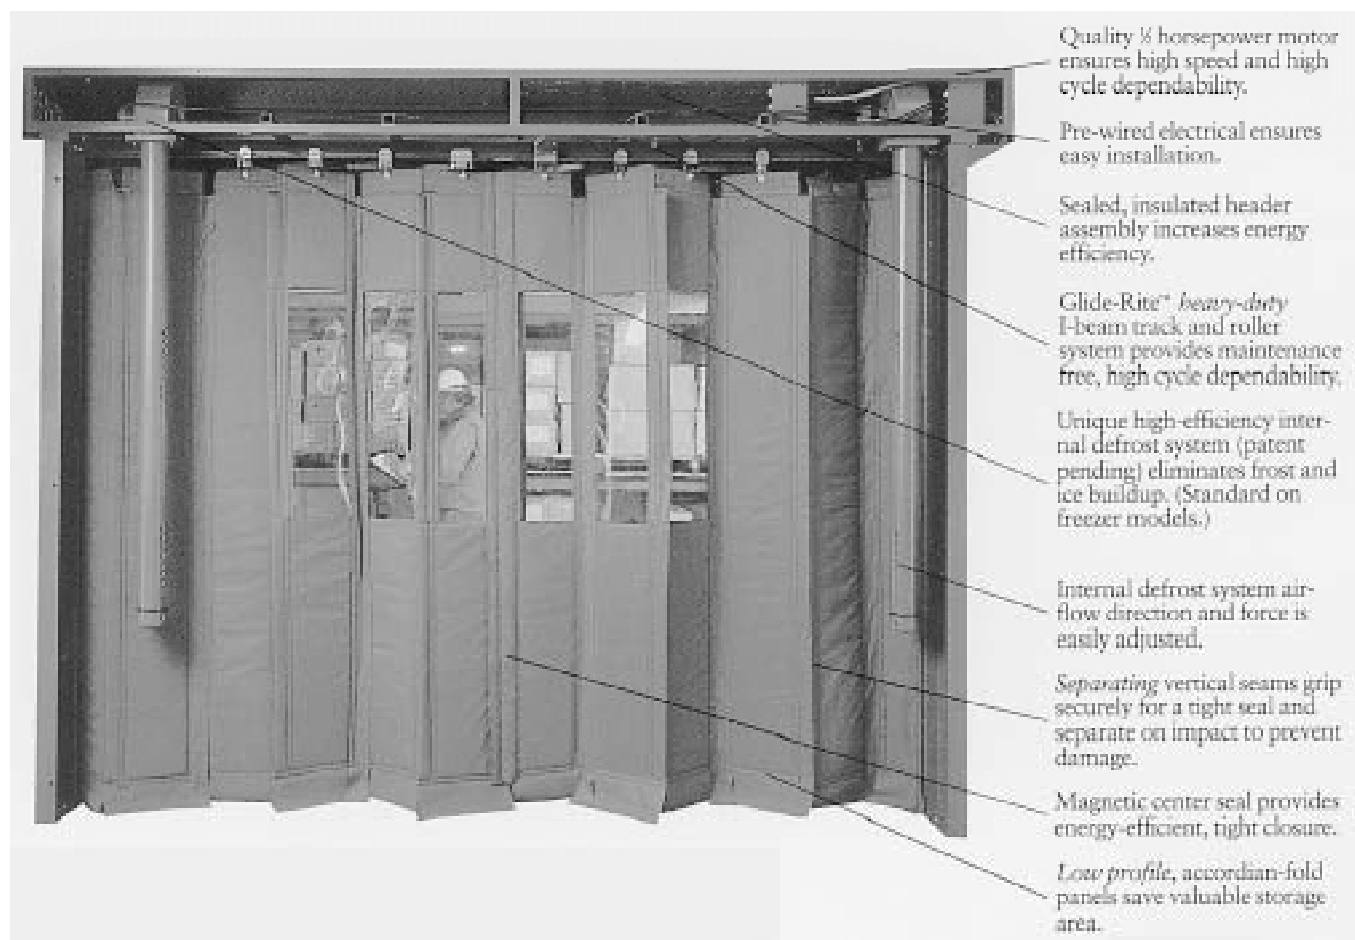

■ Impact Resistance and Ease of Repair

Severe damage may occur if a vehicle strikes the door. Impacts occur because the door cannot open quickly enough, or because a sensor fails to detect the presence of the vehicle. To avoid or minimize damage,

most quick-acting doors are designed to be hit occasionally. The material of rolling and folding doors is intended to absorb light impacts.

To protect against impacts where the vehicle continues through the door opening, the door may be designed to come apart without breaking, as shown in Figure 5. Such breakaway features are offered with all types. However, the breakaway ability of horizontally rolling doors is limited. With folding doors, the individual folds may have magnetic or hook-and-loop tape attachments that separate. With vertically rolling doors, the fabric door material may pull out of the side guides. With segmented doors, the lower segments may pop out of the side frames. Or, the frame itself may separate or open on hinges, releasing the door.

When a breakaway door comes apart, the local staff must put it back together. If the door is well designed, this can be done quickly. If the door cannot be repaired quickly, it is likely to remain out of service for a long time, wasting energy.

Rite-Hite Corporation

Fig. 3 Horizontally folding quick-acting door The door has two halves that fold to the sides. This model is designed for low-temperature cold storage. It highlights the features that one manufacturer offers for this application. The material of folding doors retains its flexibility better at low temperature than the material of rolling doors. Also, this type of door can be lightly insulated. Magnets provide a tight closure between the two halves of the door when it is closed. This door is made in vertical strips that are held together by hook-and-loop tape, which separate non-destructively in the event of a heavy impact.

Some doors make it easy to replace the window separately from the rest of the door. This is a valuable feature if the window is not expected to last as long as the door. However, the window attachment should not compromise the strength of the door.

■ Safety Features

The purpose of quick-acting doors is to allow traffic to keep moving. The motion of the traffic and the rapid action of the doors pose safety hazards. Different models of doors deal with safety in various ways. Investigate how the door deals with each of these three aspects of safety in your application:

- **visibility to the other side of the door.** A danger with any type of door is a collision between the moving vehicle and something on the other side of the door. To avoid this, the driver needs full

visibility ahead of the vehicle. Rapid opening is the most effective way to provide safe visibility.

Doors that open horizontally provide full-height visibility through the door as soon as they start to open, but they do not provide a view of the entire door width until the door opens fully. Doors that open vertically immediately provide a full-width view of the floor area on the other side. However, the load in front of the driver obstructs the view of the center area until the door opens a large part of the way.

A large, clear window in the door is valuable in most applications. However, windows cannot cover the entire opening, and the plastic material becomes obscured over time.

- **danger when opening.** Rolling doors do not sweep through any additional space as they open, so they

Rite-Hite Corporation

Fig. 4 Overhead sectional quick-acting door This is a variation of the common garage door. In addition to a powerful motor, the main differences are lighter weight, effective seals on all sides, and breakaway panels. The panels can be insulated.

Rite-Hite Corporation

Fig. 5 Breakaway feature Most quick-acting doors protect themselves against major impacts by breaking free of the frame. The design of the door should allow it to be replaced in the frame quickly when this occurs.

are relatively safe when opening. Segmented doors rise into space that is normally kept clear.

Folding doors pose some hazard when they open. You can minimize the hazard by selecting a folding door that has a larger number of folds, so that the folds do not stick out as far. Also, you can select a folding door that has soft folding edges. And, you can install guards to keep people away from the sides of the door.

- **danger when closing.** Quick-acting doors close rapidly, so their edges can be a serious hazard. A common solution is to install a “reversing edge” on the door. This is a lightweight strip that is installed in the extreme edge of the door. When the strip touches an object, it makes an electrical contact that stops or reverses the door. (You commonly find reversing edges on elevator doors.) Some vertically rolling doors rely on a yielding edge for safety. For example, one rolling door model that closes by gravity has an edge that consists of a pocket filled with small gravel. Figure 6 shows this feature.

Other doors use a breakaway edge. This is an edge that contains a weak link. Soft edges and breakaway edges protect the door itself from impact from any direction, as well as reducing the danger when closing.

Any type of door can be equipped with a sensor that holds the door open as long as anything is within the path of the door. Light beams are commonly used for this purpose. Some models

offer light beam switches as an integral feature. Figure 7 shows a typical installation.

■ Preventing Condensation and Frost

If the space on one side of the door is much colder than the space on the other side, condensation or frost is likely to form on the warmer side of the door. For example, this is a common problem in freezer applications, but it can occur in any application if the warmer space has high humidity. Condensation blocks visibility through the window, and it may harm the door materials. Frost may accumulate enough to interfere with the operation of the door.

Condensation occurs first on the window, because it is a single thickness of plastic that has minimal insulation value. You can keep the window clear by using a separately mounted heater to warm the side that faces the warmer space. You can use either a forced-air heater or a radiant heater. In either case, minimize the energy required by focussing the heater narrowly on the window portion of the door. Be careful to avoid overheating the plastic window or door material.

Some models offer a forced-air heater that is an integral part of the frame assembly. This is compact, and saves you the additional design and installation effort.

If the need for heating is not continuous, save energy by controlling the heater with a humidistat. Use a humidistat, not a thermostat, because condensation is related to the relative humidity in the warmer space. Install the humidistat in the warmer space at a distance from the door, so that the humidistat is not affected by the operation of the heater. Install a placard on the

Rite-Hite Corporation

Fig. 6 Yielding edge This model of roll-up door uses a lower edge that is filled with gravel. The gravel also provides weight for closing the door by gravity. A common alternative is a “reversing edge,” which has a contact switch that causes the motor to open the door. Some doors have a lower edge made in segments, with links that yield when the edge is struck.

humidistat to explain its operation. (Measure 5.1.1 tells how to design an effective placard for this purpose.)

You can minimize condensation on the rest of the door by selecting a door that has as much insulation as possible, and by avoiding a door that has metal conductive paths through the door. Fabric folding doors are perhaps the best in this regard. Selecting an insulated door minimizes the need to warm the entire door.

■ Avoiding Drillage

With doors that open vertically, debris and moisture picked up from the floor by the bottom edge can fall on people and goods as they pass through the door. This can be a hazard for sensitive goods, and it can be an annoyance to people using the door.

Horizontally opening doors avoid this problem completely. If you use a vertically opening door, you can reduce edge drippage by installing a threshold or by raising the floor under the edge. Make the threshold gradual enough to avoid jogging vehicles excessively as they pass through the door. This is most important with vehicles carrying tall loads.

■ Security

Plastic and fabric doors offer little security. An intruder can cut through them. Most rolling and folding doors have breakaway features, so an intruder can use a vehicle to push through the door.

Overhead sectional doors offer considerably more security, although not as much as a conventional exterior doors. However, the breakaway features make them vulnerable. In many models, the door can be locked to

WESINC

Fig. 7 Light beam safety switch This safety device holds the door fully open as long as the light beam is interrupted.

the frame with sliding bolts (cane bolts). The number of bolts increases with the number of panels that break away.

The staff must remember to insert the bolts during periods when the facility is not operating, and to remove them before traffic starts. Some manufacturers may offer doors with automatic bolts that unlock when the door is activated.

Installation Issues

Install the door so that it provides safety, efficient traffic flow, and reliability. Consider the following issues when deciding how to install the door.

■ Sensors for Opening and Closing

The type of sensor you install, and the way you install it, can make a big difference in the performance and the longevity of the door. You need one set of sensors to open the door reliably, and you may need another set of sensors to close the door safely.

For opening the door, the main point is to sense an approaching vehicle early enough so that the door is open enough to avoid damage by the time the vehicle reaches it. Calculate the appropriate distance between the sensor and the door by using the door opening speed and the maximum expected vehicle speed.

For example, consider a door that opens at the rate of eight feet per second. It is used by forklift trucks that require a vertical clearance of eight feet. Therefore, the door requires an opening time of one second to provide adequate clearance. If the maximum expected speed of the truck is ten feet per second (about seven miles per hour), then the sensor must start opening the door while the truck is at least ten feet from the door.

For closing the door safely, you need additional sensors that verify the absence of objects in the door safety zone. For example, an induction loop cannot sense a person standing underneath an open door. To keep the door from closing on the person, you need sensors that will detect anything within the door area itself.

In general, you can use any type or combination of sensors with any type of door. The sensor installation may be entirely separate from the door assembly. It's up to you to select a sensor that will work reliably in your application. The types used most commonly with quick-acting doors are:

- **induction loops.** An induction loop is a coil of wire buried in the floor that creates a magnetic field. It senses the presence of steel. The loop must be selected for the mass of steel in the vehicle, and for the height of the steel chassis above the floor. Induction loops are perhaps the most common type of sensor used to open quick-acting doors for vehicles.
- **ultrasonic motion detectors.** Ultrasonic sensors are fairly reliable as long as the person or vehicle keeps

moving toward the door, but they fail if the vehicle has to stop near the door. They can “see” the entire path to the door. By the same token, they are susceptible to false triggering from activity near the door. See [Reference Note 11](#), Personnel Sensors, for details about this type.

- **photoelectric cells (light beams, electric eyes).** These are commonly used for keeping the door open because the beam can be aligned closely with the operating path of the door. Some models offer them as an integral part of the door assembly for this purpose. Electric eyes can also be used to sense approaching vehicles or people.

Especially with materials handling equipment, you have to install the sensors so that they can accommodate differences in the vehicle configuration and loading. For example, an induction loop may be able to sense the fork of a forklift truck while it is lowered, but not when it is raised.

Even if vehicles are the primary traffic, expect that the door may be used by pedestrians. If the sensors necessary for vehicles cannot sense people reliably, install a separate manual control for pedestrian traffic. Install the manual control within the safety zone of the door, so the safety sensors keep the door open as long as people are nearby. Controls for pedestrian traffic are not needed if there is a separate personnel door that is located nearby. However, the door safety sensors should still protect against people attempting to scurry through the vehicle door.

Doors can also be operated by remote control. This is usually a security measure that is used outside of normal operating hours.

■ Mounting in the Wall Opening

Quick-acting doors are light, so they generally do not exert a strong reaction force on the wall when they operate. Typically, the open and closing forces are contained with the frame assembly.

As with any door, make sure that the gap between the door frame and the wall opening is sealed to prevent infiltration. Don't just stuff the gap with porous insulation. Fill the gap with solid material, such as wood and mortar, and finish it off with real caulking compound.

■ Door Guards

As we said before, the primary means of protecting the door from damage is to make sure that the door is fully open before a vehicle can reach it. In addition, it is prudent to install guards that protect the door from collision while it is in the open position. These should be heavy. Anchor them to the floor or to the wall, not to the door frame.

■ Traffic Pattern and Traffic Guides

For safety, and to avoid confusing the sensors, consider using guard rails or barriers to create an area on each side of the door that excludes people and vehicles that are not going to use the door.

Caution Drivers

Some vehicle drivers seem to view it as a challenge to ram the door before it opens. Try to dampen their enthusiasm by installing a large sign on each side of the door that says, “CAUTION: Drive through the door SLOWLY.”

Keep Them Repaired

In the environments where quick-acting doors are used, some damage is almost inevitable. Establish a routine for getting the doors repaired as quickly as possible. Otherwise, energy will be wasted and refrigerated products may be spoiled.

ECONOMICS

SAVINGS POTENTIAL: *Hundreds of dollars to thousands of dollars per year per door, depending on climate, fuel cost, space layout, etc.*

COST: *In typical sizes, powered quick-acting doors cost from \$10,000 to \$20,000, installed.*

PAYBACK PERIOD: *One year to several years.*

TRAPS & TRICKS

CHOICE OF TYPE: *Do you really need a powered door? How important is ease of operation? Would a swinging door create a safety hazard? Impact doors provide comparable or better efficiency at much lower cost, unless there is significant wind or pressure differential. They also provide better security than most types of quick-acting doors.*

SELECTING THE EQUIPMENT: *The differences between the various types of powered doors may be important for your application. Also, the details of particular models may make a big difference in ease of maintenance.*

INSTALLATION: *Follow the manufacturer's instructions closely. Seal the gap between the frame and the wall. Install a highly visible placard on each side of the door that asks vehicle drivers to drive through the door carefully.*

MAINTENANCE AND SUPERVISION: *A powered door saves no energy while it is out of service. Teach the relevant people how to repair a door that has been knocked loose. Use your maintenance calendar to schedule periodic inspections.*

MEASURE 6.2.6 Install dock-to-truck seals.

RATINGS

New Facilities	Retrofit	O&M
B	B	

Most of the world’s goods are transported at some time by trucks and tractor trailers. Many of these are loaded and unloaded at enclosed truck docks. When a truck pulls up to the dock, the gap between the vehicle and the dock is a major path for air leakage. In fact, the gaps along a line of vehicles in effect convert an enclosed truck dock to an outdoor space. This greatly increases heating requirements in the loading dock and adjacent spaces during cold weather. When loading to and from refrigerated trucks and spaces, the air leakage radically increases refrigeration cost.

You can prevent most of this loss by installing sealing systems on the outside of the truck dock wall that mate with the vehicles. These systems are commonly called “dock seals.” Figure 1 shows a truck dock that uses dock seals effectively.

Dock seals have become popular. They continue to evolve, so get the latest catalogs.

SUMMARY

Greatly reduces infiltration into enclosed truck docks. Essential for cold weather, and when loading to and from refrigerated spaces.

Types of Dock Seals

Contemporary dock seals come in two basic type. We will call these “butt seals” and “side seals,” although

Rite-Hite Corporation

Fig. 1 Truck dock equipped to minimize infiltration Each entry has a tightly sealing door for times when it is not being used. To seal the gap between the trailer and the dock, butt-type seals are installed. Simple alignment marks are attached to the butt seals to help the driver mate the trailer to the seal properly. Dock levelers are installed to accommodate variations in trailer height. The dock leveler at left is in its vertical stowed position, where it acts as a safety feature to keep people from driving off the dock. A latching mechanism for the trailer’s ICC bar is installed below the dock leveler. The trailer at right is being held in place by wheel chocks. The entire assembly is protected from precipitation by the roof overhang.

Rite-Hite Corporation

Fig. 2 Types of dock seals The type at left is a sliding seal, which contacts the sides of the trailer, seen here from above. The type in the center is a butt seal, which contacts the rear of the trailer. The type at right is a hybrid of the other two that seals the gap between the open door and the side of the trailer.

standard names for these types do not yet exist in the industry. Figure 2 shows both types. Each type has advantages and disadvantages in particular applications. There are variations within these two types.

With butt seals, the rear of the truck or trailer butts against thick pads on the outside of the wall opening, squeezing the pads between the vehicle and the wall. By far the most common seal of this type is made of a spongy rubber material, covered with a wear-resistant surface.

WESINC

Fig. 3 Inflatable dock seal The upper part of the seal is inflated, the sides are not. Note the guide post, the bumpers to keep the trailer from backing too far into the seal, and the stoplight. Correct alignment is essential for sealing and for protecting the seals.

Less commonly, a butt seal may consist of an inflatable bladder. The bladder is inflated with a small high-pressure fan. This type is more adaptable, but more expensive. Figures 3 and 4 show this type.

Some docks seals may use an accordion seal made of rubberized fabric. This type is unusual.

The other major type, side seals, slide along the sides and roof of the vehicle. These consist of a more flexible rubberized material. The top seal may consist of a heavy curtain of adjustable height that drapes over the top of the truck.

Dock seals should be sheltered from precipitation. Otherwise, they will collect water, rot the wooden structure, leak into the wall, and suffer freeze damage. If the building does not provide adequate shelter, as in Figure 1, you can buy appropriate hoods from dock seal manufacturers, or from other sources. The hood may

WESINC

Fig. 4 Inflatable seal deflated The small fan at the top of the unit provides all the pressure that is needed for effective sealing.

be separate from the dock seal, or it may be an integral part of some dock seal assemblies.

The seal along the floor of the vehicle is a special problem. The floor height varies from one vehicle to another, and the height varies as the vehicle is loaded and unloaded. If the floor height remains close enough to the dock height, a simple butt seal may suffice. This can be used in combination with butt seals or side seals for the sides and top of the vehicle.

An adjustable ramp, called a “dock leveler,” is commonly installed in the floor of the loading dock. Figure 5 shows a typical unit. The dock leveler adjusts to changes in the height of the vehicle floor. Unfortunately, the space underneath the dock leveler is a large path for infiltration. Dock levelers may be equipped with side guards, as shown in Figure 5.

The side guards are intended as a safety feature, and to keep things from falling into the dock leveler pit. They may substantially reduce infiltration, especially from wind. One of these days, dock leveler manufacturers will realize that these guards can easily be augmented to make them effective infiltration seals. If you get dock levelers, make sure they have this feature.

Dock levelers are made of steel, so condensation and ice tend to form on the ramp when the outside air is cold. This is dangerous. To avoid this problem, you can order insulation as an option on the dock leveler. Get this feature. It also saves a small amount of heat loss.

An older method of minimizing infiltration at truck docks is to attach a short tunnel to the outside of the building. It is effective primarily against wind, rather than convective heat loss. The tunnel must fit the vehicle body closely to be effective. This requires that all vehicles have the same dimensions, and it is more

WESINC

Fig. 5 Dock leveler This is a steel ramp that is moved by a hydraulic jack. The metal skirts on each side are intended as a safety feature. They also reduce infiltration from underneath the trailer into the space.

difficult to back the vehicle into position properly. The availability of effective dock seals has made this method obsolete.

How to Select a Dock Sealing System

Dock sealing systems are another example of an important energy conserving action that is simple in concept, but that requires careful planning. Consider these issues before you buy:

- **adaptability to different vehicle dimensions.** Truck or trailer dimensions will eventually change, even in fleet operations, where dimensions may be standardized. One day, your standard dimensions will change. Butt seals are more adaptable than side seals to differences in vehicle width. Major differences in vehicle height require a curtain-type seal to contact the roof of the vehicle.
- **adaptability to height change in loading.** The vehicle changes height at the dock as it is loaded and unloaded. Butt seals and sliding seals can accommodate these changes in height. However, the vertical movement tends to wear out the pads of butt seals. Different manufacturers address this problem in different ways. One method is to use pleats in the surface material, so the pleats slide as the vehicle height changes. If you use a dock leveler to accommodate changes in vehicle floor height, be sure to include effective seals in the dock leveler.
- **adaptability to vehicle tilt.** At many loading docks, the vehicle ramps has an upward or downward slope. Most side seals can accommodate the tilt without special provisions. With butt seals, you have to order side pads that are tapered from top to bottom, as shown in Figure 6. Butt seals have only limited ability to deal with variations in the vehicle tilt. Inflatable seals are more adaptable than solid butt seals. If the ramp does not have a constant slope, vehicles may come to rest at different degrees of tilt, depending on the distance between the front and rear wheels.
- **adaptability to different types of vehicle doors.** Butt seals are efficient with all types of doors that swing completely out of the way of the rear face of the vehicle. Ordinary side seals have a problem with doors that swing open. The gap at the door hinge creates a channel between the open door and the side of the vehicle that is a path for infiltration. A variation of side seals, shown in Figure 2, has extensions that cover this gap at the rear of the vehicle. However, this type of side seal cannot accommodate much variation in vehicle tilt.
- **resistance of seal to damage from goods and loading equipment.** The opening between the pads of a butt seal must be narrower than the width of the vehicle. This makes the pads vulnerable to

damage as goods are being loaded and unloaded. For example, a forklift truck carrying pallets into a trailer can sideswipe the seal. This problem does not exist with side seals.

- **resistance of wall to damage from vehicle pressure.** The seal should be designed so that the pressure of the vehicle is exerted primarily on the dock floor, not on the wall of the building. The force of a vehicle backing against a wall is enough to damage it. This is true of all wall types, even concrete block. (Concrete has great compression strength, but no significant tensile strength. The wall is held together by the weight above each block. A side load can buckle a concrete block wall fairly easily.) Side seals transmit much less force to the wall than butt seals. If you need a butt seal, consider an inflatable type. Alternatively, brace the wall or the door frame.
- **compatibility with dock doors.** Each opening in the truck dock needs a door, as shown in Figure 1. The door is normally installed on the inside of the wall, while the sealing system is normally installed on the outside of the wall. However, there may be interference between the two, especially if the sealing system must be bolted through the wall.
- **latching the vehicle to the dock.** Safety may require a system that latches the truck or trailer to the dock. The latch is below the level of the truck floor, as shown in Figure 1. In the United States, trucks and trailers must have an “ICC bar.” This is a fender bar that is attached to the rear of the vehicle to keep following automobiles from riding under the truck or trailer in a collision. Some manufacturers offer systems that latch the ICC bar to the dock. Make sure that the sealing system does not interfere with the latch, or vice versa. An alternative is installing automatic chocks for the rear tires of the vehicle, which are also shown in Figure 1. These do not interfere with the dock seal.
- **durability and ease of repair.** The sealing system must withstand slamming by vehicles that weigh tons, sliding stresses from changing vehicle height, and uneven pressure on the pads. All dock seals have components that wear out and require

Rite-Hite Corporation

Fig. 6 Butt seals must be tapered to accommodate sloping ramps

occasional replacement. Nobody likes maintenance, so repairs tend to be neglected. To minimize heat loss over the long term, select seals that last for a long time and are easy to repair.

- **ease of installation.** Labor is a large part of the total cost of a dock seal. Especially in retrofit applications, look for a sealing system that can be installed easily to the existing dock.

Align the Vehicles with the Dock

With butt seals, it is important to align the vehicle perpendicular to the dock. With side seals, it is important to position the vehicle laterally within the seal. Provide guides to aid drivers in aligning their vehicles.

An inexpensive method is to install painted stripes on the dock face to help drivers to align visually. For night operations, install reflective tape or position lights. Figure 1 shows simple alignment marks made of reflective tape that are attached to the face of a butt seal.

A more positive method is to install guide rails for the tires. With butt seals, make the rails long enough to guide both the front and rear tires. To prevent tire damage, make the rails rounded. Large steel pipe is effective for this purpose. Figure 3 shows guard posts that are installed near the dock seal.

Coordinate with Dock Doors and Interior Doors

Truck-to-dock seals are useless if the adjacent dock doors are left open to the outside. Make sure that you have good dock doors that close effectively and easily. See the [Measure 6.2.4](#) about exterior doors. Also, see [Measures 6.2.5 ff](#) for interior doors that you can use to isolate the truck dock from the rest of the building.

ECONOMICS

SAVINGS POTENTIAL: Thousands of dollars per year, typically. Depends on climate, fuel cost, space layout, etc.

COST: Butt seals and sliding seals typically cost \$1,000 to \$2,000, installed. Inflatable seals may cost twice this much. Additional sealing features for dock levelers may cost about \$500.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Shop the market to find all your options. If you have several dock doors, consider installing one sealing system on a trial basis. Talk to other operators about their systems.

EXPLAIN IT: Install large placards that tell drivers how to engage the sealing system.

MAINTAIN IT: Expect to replace parts from time to time. Keep spares on hand. Schedule inspections in your maintenance program.

Window Air Leakage

Windows can be a major path for air leakage, especially in older buildings. Windows also affect energy consumption in several other ways. There are three Subsections that deal with different aspects of window efficiency. The Measures in this Subsection reduce air leakage through windows and window frames. [Subsection 7.3](#) recommends improvements to windows that deal specifically with their insulation value. [Subsection 8.1](#) deals with windows as a source of heat gain, and it provides the most detailed coverage of window characteristics. Become familiar with all the window-related Measures in these three Subsections before you make any major changes to your windows.

INDEX OF MEASURES

[6.3.1 Maintain the fit, closure, and sealing of windows.](#)

[6.3.2 Install weatherstripping on openable windows.](#)

[6.3.3 Install supplemental \(“storm”\) windows.](#)

[6.3.4 Install high-efficiency windows.](#)

RELATED MEASURES

- [Measure 4.2.1](#), control of building pressurization
- [Measure 6.4.2](#), sealing infiltration around window frames
- [Subsection 7.3](#), for window modifications to reduce conductive heat loss
- [Measure 8.1.3](#), installation of high-efficiency windows

MEASURE 6.3.1 Maintain the fit, closure, and sealing of windows.

RATINGS

All openable types of windows allow some air leakage. Modern versions of all types of windows have much less leakage than old models. However, even modern windows have serious infiltration when the weatherstripping wears out. With hinged windows, air leakage may become especially severe if the movable panes get out of alignment with the frame. Inspect all your windows periodically to check for air leakage, and maintain the sealing features.

Even fixed windows should be checked periodically. Thermal expansion causes relative motion between the glazing and the frame. This motion and the effects of weather and sunlight destroy sealing materials.

How often should you check the windows? It depends on the window type and the severity of usage. The main items to check are:

- **the integrity of the glazing.** Replace any panes that are broken, or that do not fit properly in the frame.
- **the integrity of glazing compounds and gaskets.** Glazing is held in the frames by rubber seals or by glazing compound. These need to be replaced over long intervals as they wear out.
- **the condition of infiltration seals.** All openable windows should have infiltration seals between the fixed and movable frame elements. These are made of flexible materials that deteriorate with time and usage. Replace them as necessary.
- **proper fit of movable elements.** Make sure that movable elements fit properly within the fixed frame, and that they move easily. Bad alignment defeats infiltration seals and wears them out.
- **operation and adjustment of latches.** Make sure that window latches operate easily and securely. A latch that is not adjusted properly can prevent the window from sealing properly.

SUMMARY

Routine maintenance needed to prevent energy waste and maintain comfort.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	
Ease of Initiation	😊	😊	😊

What If the Windows are Inherently Leaky?

If windows lack adequate infiltration seals, you can usually improve them with weatherstripping. See [Measure 6.3.2](#), next. If you cannot seal your existing windows adequately, consider replacing them with more efficient units, as recommended by [Measure 6.3.4](#).

ECONOMICS

SAVINGS POTENTIAL: Up to 50 percent of heating and cooling costs. The saving depends on the type and size of windows, space layout, etc.

COST: Usually minor.

PAYBACK PERIOD: Short. Serious window leakage can cost much more than routine maintenance.

TRAPS & TRICKS

SCHEDULING: Most of the challenge of window maintenance is remembering to do it. Schedule it in your maintenance calendar.

PREPARATION: Keep a full stock of spare parts and glazing materials on hand. Searching for specialized window hardware can be more bother than the actual maintenance work.

MEASURE 6.3.2 Install weatherstripping on openable windows.

RATINGS

New Facilities	Retrofit	O&M
□	□	B

Older openable windows tend to have serious air leakage. The worst leakage occurs with older hinged windows. These include casement (hinged on the side), hopper (hinged on the bottom), and awning (hinged on top) types. Old double-hung windows are also very leaky. Weatherstripping can reduce the air leakage of existing windows considerably, if you install it properly. However, it usually cannot provide the leakage resistance of modern efficient windows.

A given window may require several types of weatherstripping. The first step is to find out the types of weatherstripping that are available. Weatherstripping is available that you can use for most types of openable windows. Most weatherstripping is generic, so you have to figure out how to use it effectively on your windows. You will need a different combination of weatherstripping materials for each window type.

Weatherstripping is designed either to slide or to be compressed. Any particular type of weatherstripping will not work well unless it is used in the intended manner. Compression weatherstripping is the most important type for hinged windows. Select the thickness of compression weatherstripping carefully. If it is too thick, it will keep the window from closing fully, which may increase air leakage.

Weatherstripping for sliding windows is more specialized. Weatherstripping for old double-hung windows must be capable of sliding, and it must also fill the large gaps between the movable part and the frame.

Self-adhesive weatherstripping is convenient, but it has limited life because the adhesive eventually dries out. It tears off quickly if it is installed in a way that places stress on the adhesive.

Expect to Replace It Periodically

The major limitation of retrofit weatherstripping is that it does not last long, usually a couple of years at most. Weatherstripping is not an effective solution unless you can keep replacing it periodically. See [Measure 6.3.1](#) about maintenance.

SUMMARY

May greatly reduce window air leakage. Requires careful installation and periodic replacement.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓
Ease of Initiation	☺ ☺

Alternative: High-Efficiency Windows

To achieve the lowest air leakage and minimize maintenance requirements, as well as gaining other major benefits, install high-efficiency windows. The best modern windows have effective and durable sealing systems. Needless to say, this change is expensive. See [Measure 6.3.4](#).

ECONOMICS

SAVINGS POTENTIAL: 3 to 60 percent of heating and cooling costs, depending on the type and size of windows, space layout, etc.

COST: \$1.00 to \$10.00 per movable element, most of which is for labor.

PAYBACK PERIOD: Typically less than one year.

TRAPS & TRICKS

PLANNING: This work requires thought, mostly in selecting the materials and in figuring out how to install them. Select your materials and methods to provide effective sealing, minimum interference with window closure, and durability.

MAINTENANCE: Consider weatherstripping to be an expendable material that you have to replace periodically. Check your installation methods by observing how long the weatherstripping lasts.

MEASURE 6.3.3 Install supplemental (“storm”) windows.

In existing facilities, installing supplemental glazing can be a powerful way of improving the efficiency of windows. (Common “storm windows” are supplemental glazing, but the concept can be extended much further.) Supplemental glazing can eliminate infiltration almost

completely. If the existing windows are single-glazed, a single sheet of supplemental glazing can almost triple the insulation value. There are good ways and bad ways to install it. See [Measure 7.3.2](#) for the details.

MEASURE 6.3.4 Install high-efficiency windows.

High-efficiency windows eliminate several major causes of energy waste. Installing high-efficiency windows is a fundamental, economical energy conservation measure in new construction. It is also an important improvement in existing facilities, although

the economics are not as favorable. Selecting high-efficiency windows involves a variety of potential benefits, problems, and interactions with other aspects of the building design. See [Measure 8.1.3](#) for the complete picture.

Other Envelope Leakage

The building envelope consists of the parts of the building that separate the inside from the outside. The envelope is a complex structure. In addition to walls and roof, it includes many surfaces that are hidden from view. Examples are elevator shafts, enclosed ceilings in loading docks, vented pipe chases, etc. All these surfaces may include paths for air leakage. In many cases, air leakage may occur along a long path inside the envelope structure. The envelope also includes specific components, such as hatches and smoke vents, that may become defective, allowing considerable air leakage. The Measures in this Subsection correct these leaks. Each Measure focuses on a specific type of envelope leakage and the particular methods used to correct it.

INDEX OF MEASURES

6.4.1 Seal gaps in the envelope structure.

6.4.2 Install gaskets at wall switches and receptacles that allow outside air leakage.

6.4.3 Install roof and attic hatches that close tightly and reliably.

6.4.4 Adjust and repair space air vents periodically.

6.4.5 Ventilate elevator shafts rationally.

RELATED MEASURES

- [Subsection 7.2](#), for envelope insulation
- [Measure 4.2.1](#), control of building pressurization

MEASURE 6.4.1 Seal gaps in the envelope structure.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

The building envelope is a complex system that is intended to provide structural strength, protection from the elements, and good appearance. Designers may leave the details of sealing the envelope structure against infiltration to the builders. However, builders are not in the business of devising reliable sealing methods in the midst of construction. Also, materials used for sealing the envelope may have shorter life than the building as a whole. As a result, most buildings have air leakage paths that should be sealed.

Where Envelope Air Leaks Occur

An air leak can occur anywhere that the skin of the building has an opening. In most buildings, the wall has an outer skin and an interior finish surface, with various layers of structure between the two. Outside air enters at an opening in the outer skin, travels through the envelope structure, and enters the interior of the building at a gap in the interior finish surface. Air may travel a long distance inside the envelope. Envelope air leakage typically occurs in certain areas of the structure. To organize your search, focus on the following sites.

■ **Clearances Around Window and Door Frames**

Windows and doors are installed after the wall is built. Therefore, the wall openings are made larger than the windows and doors. This leaves substantial gaps between the frames and the wall, as shown in Figure 1.

WESINC

Fig. 1 Typical window installation All window and door assemblies are surrounded by a gap. The gap should be filled with an effective sealant, but this is rarely done. In many cases, the molding around the door or window is the only barrier to air leakage.

SUMMARY

Typical buildings have many envelope leaks. You need one set of skills to find them, and another to fix them.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Initiation	😊	😊		

If the building is well constructed, these gaps are filled when the windows and doors are installed. However, this rarely happens. Instead, the frames are shimmed into place, and the gaps are covered with molding.

If the molding is installed well, it acts as an effective infiltration seal. However, the molding may not be well attached, or it may loosen with age. If the molding is the infiltration seal, it should be tight on both the inside and outside. Otherwise, air can enter the wall structure through the molding.

■ **Curtain Wall Structures**

A “curtain wall” is a non-load-bearing exterior surface that is attached to a load-bearing steel building structure. The curtain wall is made of panels sized to be convenient for shipping and installation. Typically, each panel is attached to the steel frame with a small number of clips. There may be little or no obstruction to air movement inside the wall structure.

The primary barrier to air leakage in curtain walls is sealing material between the exterior panels. This may be done with pre-formed gaskets, or the gaps may be sealed with an elastomeric (rubbery) caulking material. Look for gaskets or caulking that may have been omitted. If the panels are not fitted closely, the sealing material may not close the gap between panels. In older buildings, the sealing material may have deteriorated to the point that it loses effectiveness.

A shoddy practice that is common in curtain wall construction is attempting to join the backing sheets of batt insulation to form a barrier to air leakage. Much of the tape fails immediately, and all of it fails eventually. The weight of the insulation causes it to collapse, as shown in Figure 2. Even if the exterior building surface is well sealed, air that is cooled by heat loss through the thin exterior surface is able to flow freely to the interior of the building, rendering the insulation useless.

■ Soffits

A soffit is an exposed underside of a structure. Soffits occur under the eaves of roofs and under overhanging floors. A soffit may form the roof of a loading dock or other entrance. The soffit is not exposed to precipitation and it carries no load, so it may be covered with a flimsy surface that allows considerable infiltration. In many buildings, the structure that is covered by the soffit has no provision to stop infiltration. Or, the air space inside the soffit may connect with the interior of the building, by way of ceiling plenums or curtain wall spaces. Figure 3 shows an example.

There are two general solutions to soffit infiltration. One is to install an infiltration barrier inside the soffit. The other is to use the soffit itself as the infiltration barrier. If you choose the latter approach, you may have to strip off the existing soffit material and replace it with a strong, impermeable surface.

■ Roof-to-Wall Joints

The heavy load of the roof is transmitted to the building structure by connecting the roof joists or rafters to the load-bearing columns. In this method of construction, the spaces between the roof joists are open to the spaces between the wall columns. To keep air leakage from traveling from the roof structure to the wall structure, or vice versa, the gaps between the joists or columns should be closed. However, this may not be

done, as there is no structural need. Infiltration at this point is especially likely if the roof overhangs the wall, forming a soffit.

In smaller buildings, the roof joists may rest on the top of the wall structure. In this case, the horizontal member that forms the top of the wall is called a “plate.” The plate is an effective barrier to infiltration into the top of the wall if it is installed properly. However, there is still an infiltration path into the space between the joists. Failing to close the gap between the joists is a common oversight. In this type of construction, the roof or attic joists commonly overhang the wall, creating a soffit. Sealing this arrangement is complicated by the need to vent the attic space to prevent condensation.

■ Foundation Plates

The top of a concrete foundation is an irregular surface. A steel beam or a wooden board is attached to the top of the foundation to act as a connector to the wall structure above. This connector is called a “plate” or “sole plate.” There is an irregular gap between the plate and the top of the foundation. There may also be a gap between the plate and the wall. Figures 4 and 5 illustrate the problem.

If the building is built well, the gap below the plate is filled by installing a strip of compressible material on top of the foundation before installing the plate. Similarly, if the wall rests on the plate, compressible material should be installed between the two. In many buildings, this gap sealing material is missing. This creates an infiltration path all along the top of the foundation, or along the top of the sole plate.

■ Expansion Joints

In larger buildings with rigid exterior surfaces (especially concrete and masonry), expansion joints must be installed in the exterior surfaces to allow for thermal expansion and contraction. These are potentially long infiltration paths. Expansions joints typically are filled

WESINC

Fig. 2 Air leakage superhighway This is the scene behind the opaque portions of the curtain wall of a new glass box office building. The insulation was joined by tape. The tape quickly fails, causing the insulation to collapse. Air cooled by the exterior surface of the curtain wall freely circulates to the interior of the building, rendering the insulation useless. Shoddy practice like this is common in glass box buildings.

WESINC

Fig. 3 Inside a soffit over a loading dock The bottom surface, exposed to the outside, is loose fitting ceiling tile. The air space connects to the ceiling plenums and curtain wall spaces of the building. Several heaters are installed to keep water pipes in the space from freezing.

WESINC

Fig. 4 Foundation plate, from outside A layer of insulation material is used to seal the gap between the concrete wall and the rim joist. Although sold commercially for the purpose, this is the wrong type of material for the job.

with gaskets or with very flexible caulking materials. All these materials have a life span that is long, but only a fraction of the life of the building.

■ Parapet Flashing

In buildings with flat roofs, the exterior wall structure typically extends above the roof level, forming a parapet. The wall structure typically is hollow, allowing a large chimney effect to move air inside the wall. To close the top of this potential chimney, a cover is installed over the top of the wall. In modern construction, this cover is typically sheetmetal called “flashing.”

The flashing is not merely a decorative item. In most cases, it is an important infiltration barrier. To be effective in this role, it must be tightly sealed to the top of the wall. Commonly, the flashing is not installed in a manner that can keep it sealed over the life of the building.

■ Gaps in Structures

The people who build the structure may not have knowledge or interest about preventing infiltration. As

WESINC

Fig. 5 Foundation plate, from inside Daylight shows where air can leak into the building. There are large gaps at the foundation plate and around the end of the center beam.

a result, air leaks are common in structures. For example, when concrete block is laid around structural steel, the bricklayers will not fill in the gaps that will occur. Figure 6 is a typical case.

Gaps may also occur after the building is built. For example, someone may remove a block to inspect hidden equipment, and neglect to replace the block. Figure 7 shows an example.

■ Penetrations

Any building envelope has a large number of penetrations. These include vent stacks, drain pipes, flues, exhaust ducts, power and telephone cables, etc. Most of these will be properly sealed. Some will not be. For example, if there is a flue pipe inside a chimney structure, air may be able to enter or leave the building through the space between the flue and the chimney.

How to Find Envelope Air Leaks

See [Reference Note 40](#), Building Air Leakage, for the tools to use for finding air leaks. Most of these are simple and cheap.

To organize your search, focus on the areas discussed previously. Equip yourself with a set of as-built drawings to reveal concealed areas where leakage may occur. You can find some potential leak sites on the architectural drawings (e.g., expansion joints), some on the mechanical drawings (e.g., vent stacks and ducts), and some on the electrical drawings (e.g., power cables).

Don't overlook air leakage through the walls of internal spaces that are open to the outside, such as pipe chases and ventilation air shafts. Also, consider leakage

WESINC

Fig. 6 Gap around structural steel Inside this elevator shaft, concrete block had to be fitted around steel beams. The masons filled the gap with clay bricks, the smallest material they had on hand, leaving a gap that is still large.

WESINC

Fig. 7 Missing block The block was removed by a plumber to gain access to a pipe fitting. Since the plumber is not a mason, he did not replace it. While this provides a home for birds, it also allows major air leakage into the building.

through the walls of spaces that are not heated to normal temperature, such as garages, loading docks, unheated storage spaces, unheated equipment rooms, crawl spaces, and voids.

If the facility is large, use a camera to help you make the survey. Film is cheaper than time, and photographs record conditions that you could not possibly describe verbally.

How to Seal the Leaks

Sealing an air leak is usually a simple procedure, but take the time to do it right. The trick is to seal the gap in a way that endures. These are the important points:

- **Seal the gap from the outside wherever possible**, to block leakage of outside air into the wall cavity.

Sometimes, this requires removing exterior sheathing to gain access to a gap that is hidden.

- **Close large gaps with structural material before caulking.** Fill large gaps with wood, masonry, mortar, sheetmetal panels, etc. Fasten this material securely to make it part of the structure. Then, caulk any small gaps that remain.
- **Use caulking materials**, rather than stuffing insulating materials into gaps. Air can flow easily through porous insulation.
- **Force the caulking material into the gap**, rather than merely over the gap. Caulking materials harden and shrink as they age. Install the caulking material so that the interior surfaces of the gap hold the caulking in place as it ages.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. See [Measure 4.2.1](#).*

COST: *Low, unless you have to remove surfaces to gain access to gaps.*

PAYBACK PERIOD: *Less than one year, to several years.*

TRAPS & TRICKS

SELECTING METHODS: *Don't expect to fix all envelope leaks with a single method or material. Treat each leak as a separate engineering task, in which your goal is to find a sealing method that will last as long as the building. Combine caulking material with filler pieces for large gaps. Plastic foam applied with a spray can is versatile, but don't try to fill big holes with it. Large expanses of caulking material are ugly, and they will eventually crumble and fall away. Use silicone caulk and a small nozzle for most smaller gaps. Start with rubber strips and other flexible material in expansion joints and other gaps that may move over time.*

MEASURE 6.4.2 Install gaskets at wall switches and receptacles that allow outside air leakage.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
	B	

Among the many gadgets invented during the energy crisis of the 1970's are gaskets designed to be installed behind electrical switch plates and receptacle covers. These stop leakage between the inside of the wall and the space. The gaskets are precut to fit switches or receptacles snugly. They are available for common switch and receptacle configurations. They are cheap and easy to install.

Switch and receptacle gaskets provide a benefit if the outside of the wall is penetrated. For example a typical application is for a switch that is wired to an outside light fixture, where air can enter along the wiring. Gaskets are also helpful for switches and fixtures installed in an outside wall that has a large cavity. In this case, gaskets block the entry of convection currents from the inside of the wall.

The gaskets do not keep air from entering the wall on the outside. Air leakage into the wall can reduce the effectiveness of the wall insulation, even if the air cannot enter the interior spaces. Therefore, it is more efficient to seal any wall penetrations from the outside, as [Measure 6.4.1](#) recommends.

The easiest way to check for incoming air leakage at the receptacle or switch is by feel. Use a smoke pencil to check for outward leakage.

SUMMARY

A cheap and easy way to stop minor air leaks along electrical wiring that feeds receptacles and wall switches.

SELECTION SCORECARD

Savings Potential	\$				
Rate of Return	%	%	%	%	%
Reliability	✓	✓	✓		
Ease of Retrofit	😊	😊	😊	😊	😊

ECONOMICS

SAVINGS POTENTIAL: Typically about one dollar per year per gasket.

COST: About \$0.10 per gasket. Preparation and installation take a few minutes.

PAYBACK PERIOD: About one year.

TRAPS & TRICKS

CHOICE OF METHOD: Consider this an auxiliary activity of [Measure 6.4.1](#). Used alone, this method is much less effective than sealing leaks from the outside.

MEASURE 6.4.3 Install roof and attic hatches that close tightly and reliably.

RATINGS

New Facilities	Retrofit	O&M
A	B	C

Roof hatches are potentially a serious path for air leakage because chimney effect is strong at the top of the building. During cold weather, chimney effect forces the warmer interior air through any defects in the hatch and through any gaps in installation. Hatches in older buildings are often damaged so badly that they cannot close effectively. These are the steps in avoiding this problem:

- purchase hatches of good quality
- seal them well
- make them easy to use
- ask users to keep the hatches closed
- keep the hatches maintained.

Get Good Hatches

Strong roof hatches with effective gaskets are commercially available as prefabricated units. Many styles are available. Figure 1 shows a typical unit. Select a style for each application that is easy to operate by all users, including those burdened with tools and equipment.

Get an opening mechanism that operates easily. Unless the door is very light, get a model that is counterbalanced.

In new construction, good hatches add virtually nothing to the cost of the building. In older facilities, you can usually find a prefabricated unit that installs fairly easily as a replacement for a shabby older hatch.

WESINC

Fig. 1 Roof hatch A leaky roof hatch can waste a considerable amount of heat energy, especially in a tall building. For perspective, the hatch will waste much less energy than the adjacent fan, if the fan is left running unnecessarily.

SUMMARY

Hatches may be a severe source of air leakage. Install them to stay airtight.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

Install Them Properly

When a hatch is installed, make sure that it is sealed tightly against air leakage between the hatch assembly and the roof structure.

Install a gasket of ample thickness between the hatch and the curb or other structure. To keep the gasket from slipping out of position during installation, staple it in place before mounting the hatch.

Do not warp the frame of the hatch during installation. This would keep it from closing easily and sealing properly.

Make Hatches Easy to Use

Hatches are most likely to be damaged if they are difficult to open or close. Put yourself in the position of a mechanic trying to get through a roof hatch while teetering on a vertical ladder and trying to hold equipment. If you are concerned about your safety, you are unlikely to be tender with the hatch.

Anything that eases passage through the hatch reduces the likelihood of damage. For example, if a hatch is installed at the top of a vertical ladder, consider installing a shelf at a convenient place just below the hatch. This allows users to place articles on the shelf while they open or close the hatch.

Even better, do not use awkward, dangerous vertical ladders to get to hatches. In new construction, design the access to the roof using a conventional stair and door. A hatch at the top of a tall vertical ladder indicates a lack of awareness by the architect.

Ask Users to Close Hatches

Install an effective placard on the inside that asks users to keep the hatch closed. Stencil a similar large sign on the outer surface of the hatch. See [Reference Note 12](#) for guidance in effective placard installation.

Maintain Them

In existing facilities, check all accesses to roofs and attics for tight closure. Hatches are typically out of sight and in awkward locations, so they tend not to be repaired. If you find that a hatch is damaged, question why. If necessary, make it easier to use.

If the hatch is leaking around the edges, you may be able to take it off, seal it, and reinstall it properly without too much effort.

ECONOMICS

SAVINGS POTENTIAL: Hundreds of dollars to thousands of dollars per year in heating costs.

COST: Good hatch assemblies typically cost several hundred dollars. Retrofit installation cost, including

features to make the hatch easy to use, may be several hundred dollars. In new construction, installing a hatch effectively adds little to cost.

PAYBACK PERIOD: One year, to several years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Select hatches for ruggedness and ease of use. If possible, select an unit in which the hatch is integral with the frame. A strong and user-friendly closing mechanism is essential. Get a balance spring to minimize the lifting force required to open the hatch.

INSTALLATION: Check the installation to ensure that the frame is well sealed at the time of installation. Don't forget the placards.

MEASURE 6.4.4 Adjust and repair space air vents periodically.

RATINGS

New Facilities	Retrofit	O&M

A building may have a variety of dampers and louvers that vent air through the building envelope. Some have fans, and some do not. These may be intended for natural ventilation, for venting the warm

WESINC

Fig. 1 Open roof vent Daylight reveals an open vent here, probably a ventilation fan with a damper that does not close properly. A permanent leak of this sort can waste a large amount of heating energy.

SUMMARY

Leaky vents can waste a lot of energy. You may have more than you realize.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	
Ease of Initiation	😊	😊	😊

air that accumulates under skylights, or for venting smoke in the event of a fire. A vent that is open or leaky can waste a large amount of heating energy because of chimney effect.

Vents may be located in obscure places, such as the tops of stairwells or the perimeters of skylights. Sometimes, vents are completely hidden above suspended ceilings. Figure 1 shows a roof vent that is almost impossible to see from below. Make a careful search to find and inspect all envelope vents. If you find a leaky vent damper, repair it or replace it with a unit that is capable of sealing more tightly.

Fire-Related Dampers

As a rule, dampers installed as part of fire control systems should remain tightly closed under normal

circumstances. The dampers should be held snugly in the closed position by springs in the release linkages. The dampers may be released in the event of a fire by fusible links, signals from a computer, or other means.

Theories of fire protection keep changing in fundamental respects. Figures 2 and 3 show vents that probably have something to do with fire protection, but their purposes are not clear. In any case, do not alter or adjust fire-related vents without expert knowledge. If in doubt, have a fire safety expert review all your smoke relief vents. You may want to update your fire control systems at the same time.

Label the Purpose of Vents

The purpose of a vent may not be obvious. The uncertainty keeps maintenance personnel from repairing leaky conditions. Correct this problem by stating the purpose of each vent on an adjacent placard. See [Refer Note 12, Placards](#), for tips on doing this effectively.

WESINC

Fig. 2 What are these vents? They have manual chains, apparently intended to release the dampers. They are probably part of a fire protection system. Only an expert could guess with any certainty. Since their appearance invites action, they need a clear placard to explain what they do, and how they should be used.

WESINC

Fig. 3 Mystery vent This roof vent with a cheap, leaky gravity damper is installed at the top of a stairwell in a tall building. On a cold day, the damper opens, venting warm air from the building. Someone has placed a piece of lumber over the damper, apparently to hold it shut. It still wastes energy by leaking air through the bent blades, but it can no longer do whatever it was intended to do.

ECONOMICS

SAVINGS POTENTIAL: Hundreds of dollars to thousands of dollars per year in heating costs, if leakage is severe.

COST: Variable, but usually low.

PAYBACK PERIOD: Usually short.

TRAPS & TRICKS

SCHEDULE IT: This kind of maintenance is always forgotten unless the facility has an effective maintenance scheduling system. Make sure you have one, and include vent maintenance in it.

EXPLAIN IT: Be especially detailed about adjusting vents that are part of safety systems.

MEASURE 6.4.5 Ventilate elevator shafts rationally.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Elevator shafts are conditioned spaces. They are conditioned by air that enters when the elevator doors open, and they may have their own conditioning systems. The conditioned air can be lost to the outside through vents, as shown in Figure 1. They can also lose air through elevator cable openings between the top of the elevator shaft and the elevator machinery room.

Elevator shafts have maximum chimney effect, which tends to force air out of the elevator shaft into vents and penetrations at high points in the elevator shaft. The air may be lost directly to the outside, or to the elevator equipment room.

The motion of elevators has a piston effect which drives air out of the shaft ahead of the elevator rises, and sucks air into the shaft behind the elevator. The strength of this effect depends on how closely the elevator fits within the shaft. The effect is greatly reduced if more than one elevator rides in a shaft.

Fig. 1 Elevator shaft ventilation The melting snow shows that a lot of heat is being lost from this elevator shaft, which has a number of vents this size.

SUMMARY

Use good sense with a serious leakage path.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

The question is, how much ventilation does an elevator shaft need? Ventilation may be required for respiration, in the event that the car becomes disabled. Or, it may be needed for some fire protection purpose. Or, it may be needed to minimize discomfort resulting from the piston effect. In any event, find out how much ventilation the shaft needs, and do not exceed a reasonable amount of ventilation.

Various types of seals are commercially available from elevator companies to seal around the cables. If the building lacks such seals, or if the present seals are not effective, ask your elevator contractor to install efficient seals. The seals should be designed to resist wear while allowing for sidewise motion of the cables. However, if the required ventilation rate is greater than the rate of leakage through the cable openings, then don't bother installing a seal.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely, but several hundred dollars per year per elevator is a typical figure.*

COST: *Typically modest.*

PAYBACK PERIOD: *Less than one year, to several years.*

TRAPS & TRICKS

BE SURE OF THE REQUIREMENT: *If the shaft seems to have an excessive amount of ventilation, try to find out if there is a reason. Talk to your elevator expert and check the building codes.*

Section 7. BUILDING INSULATION

INTRODUCTION

In new construction, good insulation is probably the best bargain in energy conservation. Furthermore, improving insulation requires only conventional skills, and no unknown risks. There is enormous room for improvement in contemporary insulation practice. It is amazing how poorly buildings are still being insulated, given the ease and low cost of good insulation. You can do much better.

In existing buildings, improving insulation costs much more than in new construction. It also involves serious risks of damage to the structure that you have to be careful to avoid. Still, you can often greatly improve the insulation of existing buildings, making them more comfortable as well as more efficient.

How to Use Section 7

The Section is organized by the envelope components where you can improve insulation. The Subsections deal with roofs and attics, walls, and glazing, respectively. Each of these areas requires different insulation techniques. There are Measures in each of the Subsections that apply to most buildings.

This Section does not cover conductive heat loss through doors. Doors usually waste much more energy through air leakage than through heat conduction, so they are covered in [Subsections 6.1](#) and [6.2](#).

Before Getting Started ...

For a quick refresher on insulation principles, see [Reference Note 41](#), How Insulation Works, and [Reference Note 42](#), Vapor Barriers.

For specific types of insulation and for insulation selection criteria, see [Reference Note 43](#), Insulation Selection

For tips on installing insulation properly, see [Reference Note 44](#), Insulation Integrity.

To decide how much insulation to install, see [Reference Note 45](#), Insulation Economics.

SUBSECTION INDEX

[7.1 ROOFS AND ATTICS](#)

[7.2 WALLS AND SOFFITS](#)

[7.3 GLAZING INSULATION](#)

Roofs and Attics

Roofs or attics make up a large fraction of the total surface area of most buildings. Their large size and their orientation make it important to insulate them well. Roof heat loss is especially severe during cold weather because the roof faces the night sky, allowing maximum radiation loss. The roof is exposed to precipitation and wind, which carry away any heat that makes its way to the outer surface. And, the interior temperature is highest inside the roof or attic.

Roof insulation is especially important for reducing solar heat gain during warm weather. Roofs have especially high solar gain because of their orientation and because roofing surfaces tend to be absorptive.

Roofs and attics have large, unbroken surfaces that offer relatively easy access for installing insulation. Therefore, they often provide the most economical opportunity for reducing heat loss and heat gain. In new construction, good roof insulation adds little to overall cost. In retrofit, improving roof insulation may be your only opportunity for improving the building's insulation on a large scale. You can usually find a way to improve roof or attic insulation without having to disrupt other building components.

The Measures in this Subsection cover the various methods that you can use to insulate roofs. Each has important advantages and drawbacks. They are alternatives to each other.

INDEX OF MEASURES

- 7.1.1 [Increase the quantity of attic insulation.](#)
- 7.1.2 [Add rigid insulation to the top surface of roofs.](#)
- 7.1.3 [Apply sprayed foam insulation to the top surface of roofs.](#)
- 7.1.4 [Install insulation on the underside of roofs.](#)
- 7.1.5 [Install a suspended insulated ceiling.](#)

RELATED MEASURES:

- [Subsection 8.2](#), for methods of reducing cooling load on roofs and attics

MEASURE 7.1.1 Increase the quantity of attic insulation.

RATINGS

New Facilities	Retrofit	O&M
A	C	

An attic is an unheated space between the roof and the highest occupied space. If a building has an attic, installing insulation on the floor of the attic is usually the best way to block heat conduction to and from the top of the building. Figure 1 shows a favorable application for attic insulation.

The attic space is almost always vented to the outside. In this way, the exterior roof acts as a sun shade, greatly reducing the cooling load. (In order for this to work properly, the attic needs good ventilation. See [Measure 8.2.3](#) for details.) Since the attic is ventilated, the roof provides little reduction of heat loss during cold weather. Heat loss is blocked mostly by the attic insulation, which must be installed so that the air currents through the attic do not get under the insulation.

In new construction, a simple increase in the amount of attic insulation can make a major improvement in the thermal efficiency of the building at relatively modest additional cost.

Most existing buildings that are suitable for attic insulation already have some, but the amount may be scanty. Typically, you can easily add any amount of insulation that makes sense. However, the economic rate of return decreases sharply with the amount of existing insulation. Also, the cost of adding insulation may be raised considerably by the need to work around

SUMMARY

Usually the best way to minimize heat loss from the top of the building. Inadequate preparation or poor workmanship can degrade insulation performance and create safety hazards.

equipment and other obstructions. Figure 2 illustrates this.

Appropriate Types of Insulation

See [Reference Note 43](#), Insulation Selection, for comparative insulation characteristics. For most attic insulation applications, the best materials for attic insulation are glass fiber or mineral fiber. Cellulose insulation is also used widely for attic insulation.

WESINC

Fig. 1 Uninsulated hospital attic with concrete deck The hospital is located in a climate that has cold winters and hot summers, so attic insulation can reduce both the heating and cooling loads considerably. The concrete slab is a good base, and the equipment in the attic is installed above the slab, providing clearance for installation. But, why is this attic not already insulated? There may be concern about intake of fibers or microorganisms into air handling systems, or there may be insulation already installed under the slab. These questions need to be resolved first.

Cellulose insulation has been controversial because the raw material requires treatment to avoid certain problems that are explained in [Reference Note 43](#). Loose fill, blankets, and batts are appropriate for attics. The choice depends on the configuration of the attic and the capabilities of the installer.

Loose fill is widely used in retrofit applications. It is favored by contractors because it is inexpensive to install. That does not mean that you should choose it. On the positive side, loose fill has much less tendency than batts to leave voids under wiring and other attic clutter, especially when it is installed properly. However, by the same token, it will easily fall into spaces where it does not belong, such as eaves and flue chases, and it is more likely to block proper venting of hot equipment.

How to Install Loose Fill

Loose fill insulation is commonly installed in large attics by blowing, because this method involves low labor costs. For smaller applications, the insulation can be poured from bags.

Preparation is important. Cover any deep cavities, such as the tops of interior walls or flue chases, into which the insulation may fall. Alternatively, install dams to hold back the insulation.

Similarly, keep loose fill away from any hot equipment, such as flues, incandescent light fixtures installed in the ceiling, and space heaters installed in the ceiling. If such equipment is covered with insulation, it may become hot enough to start a fire. Odd bits of loose fill may block vent holes in equipment, which may create a fire hazard or damage the equipment. For example, recessed light fixtures that are installed in ceilings must be vented.

Loose fill tends to settle, so add an extra amount of insulation to compensate. Rake the insulation after pouring it.

The Cellulose Insulation Manufacturers Association (Dayton, Ohio) publishes a pamphlet, “Standard Practice

WESINC

Fig. 2 Police station attic over drywall ceiling This attic is insulated, but with a meager amount of material. The arrows point to places where insulation is missing over gaps that lead to the interior of the building. The ductwork and other obstructions will make it difficult to add insulation properly.

for Installing Cellulose Building Insulation,” that spells out practices for installing cellulose insulation. Much of this information applies to all types of loose fill insulation. This document is valuable both for building staffs doing their own insulation, and for owners to ensure that a proper job is done by insulation contractors.

How to Install Blankets and Batts

The major challenge with blanket and batt insulation is to avoid the formation of voids between the insulation and the ceiling. This problem is especially severe if the attic is filled with wiring, piping, and ductwork. The only solution is careful fitting of the insulation. This means cutting the blankets or batts to allow wiring to pass through it, or fitting the insulation under obstructions piecemeal.

If you use multiple layers of blankets or batts, crisscross successive layers to minimize convective heat loss.

Blankets and batts contain a small amount of combustible material to act as a binder. Also, dust that collects on the insulation over time is flammable. Therefore, even if the insulation is made from inert materials, avoid contact with hot equipment.

How to Install the Vapor Barrier

See [Reference Note 42](#), Vapor Barriers, for an explanation of vapor barriers. With attic insulation, the primary purpose of a vapor barrier is to protect the insulation itself, and to a lesser extent, to protect the structure and equipment located above the insulation. In a cold climate, attic insulation that lacks a vapor barrier may become loaded with frost.

If possible, install an unbroken vapor barrier of plastic film under the insulation. In many attics, equipment clutter makes this impractical.

A poor second choice is to use insulation that has a kraft paper or foil vapor barrier attached. The weakness of this approach is that water vapor can escape between adjacent batts.

Vent Moisture from the Attic

Vent the space above the insulation to allow moisture to escape. Moisture can enter the attic either from below, as a result of the vapor barrier being imperfect, or from above, as a result of roof leaks and piping leaks.

It is tempting to close off the attic to reduce heat loss during cold weather. Resist this temptation. The insulation stops most of the heat loss, not the roof surface or attic space. Furthermore, if the attic space is closed during the long daylight hours of the cooling season, the attic will become an oven, perhaps doubling or tripling the temperature differential across the insulation.

Protect the Insulation from Physical Damage

If people need to enter the attic, such as for equipment maintenance, protect the insulation with walkways that are elevated above the top of the insulation.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

ECONOMICS

SAVINGS POTENTIAL: Insulating a bare attic typically reduces heat loss through the attic by 70 to 90 percent. It may reduce heat gain by 30 to 70 percent, depending on how well the attic is vented. This may be a large fraction of the total building heat gain or loss. In retrofit, the benefit depends on the amount of insulation previously installed.

COST: In new construction, a good quantity of blow-in insulation costs from \$0.50 to \$1.00 per square foot. Poured insulation averages about \$2.00 per square foot. The cost of batt insulation varies widely, but averages

perhaps \$4.00 per square foot. In retrofit, blown-in insulation and poured insulation are not much more expensive than in new construction. Batt insulation may cost two or three times more.

PAYBACK PERIOD: One year, to many years, depending primarily on the original insulation value of the ceiling and attic structure.

TRAPS & TRICKS

PLANNING: Use [Reference Note 43](#), Insulation Selection, as a guide in selecting the most appropriate materials. Figure out good ways of installing both the vapor barrier and the insulation. Refer to [Reference Note 42](#) if you are unclear about vapor barriers. Make sure the installer knows how you want the job done. In retrofit, start by surveying the attic areas in detail, looking for voids, wiring, light fixtures penetrating the ceiling, and other problems.

INSTALLATION: Monitor the installation. The quality of the workmanship determines the effectiveness of the insulation. Also, you want to catch any potential safety problems.

MEASURE 7.1.2 Add rigid insulation to the top surface of roofs.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Installing rigid insulation on the exterior roof surface is often the best method of insulating a roof, provided that the building has no attic. This method has several significant advantages:

- **ease of installation.** Roof deck insulation does not run afoul of obstructions from piping, ductwork, suspended ceilings, and other clutter that resides under the roof surface.
- **no physical restrictions on thickness.** The sky is the limit.
- **no separate vapor barrier is needed.** The insulation itself or its bonding layer form an unbroken impermeable surface.
- **does not interfere with a decorative ceiling surface.**

In retrofit, the major disadvantage of this method is that the existing roof covering must be stripped off, and a new roof covering installed over the insulation. This method gains appeal when the existing roof covering is due for renewal.

Each type of insulation, and each method of installation, involves its own set of details. These details are important. Follow the manufacturer's instructions

SUMMARY

An effective method for insulating roofs of buildings without attics. In retrofit, requires stripping the existing roof surface.

SELECTION SCORECARD

carefully. This Measure covers the key issues for all methods of insulating the top surfaces of roofs by using rigid board insulation. Make sure that each of these issues is covered in adequate detail by the manufacturer's instructions, and that the installer pays attention to these issues.

Do not use this method if there is a vented attic space below the roof.

Fig. 1 Rigid insulation applied to a flat roof This insulation is applied in layers. Snug fit is essential, and it is achieved by using many fasteners. The top layer is tapered to provide drainage. However, the small amount of slope provided by tapered insulation does not provide reliable drainage unless the top surface membrane is applied carefully. Even then, the roof drains must collect all water reliably, or the water will work its way underneath the bottom layer of insulation.

Dow Chemical Company

Fig. 2 Rigid insulation applied to a sloped roof Foam board insulation is applied under cedar shingles, allowing any desired amount of insulation value to be combined with a rustic appearance. With this common method of installation, any water that leaks through the shingles will be trapped by the horizontal battens, channeling the water between the joints of the insulation boards and through the nail holes into the underlayment.

Types of Insulation

Many manufacturers offer rigid roof insulation. Types range from simple blocks of insulation to interlocking composite panels. The material must be rigid enough to withstand compression from people walking on it. Plastic foam insulation is common. The types are covered in [Reference Note 43](#), Insulation Selection. Even semi-rigid fiber can be used if it is bonded to a rigid surface. See Figures 1 through 4.

Plastic foam insulation may be acceptable from a fire safety standpoint in above-roof applications, especially if the insulation is installed on top of a concrete slab or steel pan. Make sure that occupants cannot be trapped by a roof fire. It is probably not a good idea to install plastic foam insulation on a wooden roof deck. Such a combination could burn fiercely.

Roof insulation is available that is bonded to a nail base, such as plywood. This is needed for applications where the outer roof surface consists of shingles, metal sheet, or other material that requires fasteners. The bonded nail base allows you to specify a less dense insulation, because the nail base distributes external compression loads.

Another composite insulation material provides a vented roof. In this type, a nailing surface is attached to the insulation board by spacers, providing a gap of about one inch (several centimeters) between the top surface and the insulation. This reduces the temperature differential across the insulation. This type works on a pitched roof, and it requires a continuous vent along the lower edge and the ridge of the roof.

Celotex Corporation

Fig. 3 A sample selection of rigid insulation and composites Many types of rigid insulation are available. Many combinations with other structural materials are available as standard items, including insulation that is bonded to wood underlayment, to gypsum board, to interior and exterior finish surfaces, and to reflective foil. The composite on the bottom right allows circulation of air between the nailer surface and the insulation, for sloped roofs. Many variations of tapered insulation are available. All organic foam insulation is combustible in some manner, and it should be selected accordingly.

Celotex Corporation

Fig. 4 Insulation system that provides roof venting This system is available as prefabricated units that include the insulation, underlayment, and spacers. This configuration reduces the temperature differential across the insulation from solar heat gain, and it reduces the tendency to form ice dams in winter. In order to work well, it must be vented well at the top and bottom.

Reliable Drainage

Water is the enemy of roof insulation. If the insulation is permeable, water will soak it and destroy its thermal resistance. If the insulation is impermeable, water will conduct heat around it. Therefore, good drainage is a critical part of roof insulation.

The key to correct drainage is understanding a fact that has been forgotten in schools of architecture, namely, that water flows downhill. If the roof surface has enough slope and is smooth enough to prevent the formation of puddles, soaking will not occur as long as the top membrane remains intact. On the other hand, if the roof is flat, water will seek to go downhill through the roof structure itself, and it will eventually succeed.

With flat roofs, an easy way to achieve drainage is to install tapered insulation. Design the installation so that the insulation is thick enough at its thinnest point to provide good thermal resistance. Doing this may result in the insulation being thicker than is economical at the high points. On the other hand, tapered insulation is so easy to install that the saving in labor cost is likely to compensate for the additional material cost.

Other methods of protecting insulation on flat roofs are more expensive. About the only other reliable method is to construct a slanted structure on top of the roof to shed water.

Make sure that the deck or slab on which the insulation is installed has an effective drain system. All water that drains off the insulation, or through it, has to

be carried away before it can waterlog the insulation. Good drainage also avoids freeze damage.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

ECONOMICS

SAVINGS POTENTIAL: Insulating a bare roof typically reduces heat loss and heat gain by 70 to 90 percent. This may be a large fraction of the total building heat gain or loss.

COST: In new construction, a good quantity of exterior roof deck insulation may cost from \$8 to \$20 per square foot. In typical retrofits, increase these figures by about 30%.

PAYBACK PERIOD: One year, to many years, depending primarily on the original insulation value of the ceiling and roof structure. The payback period in retrofit is improved if the roof surface is due for replacement.

TRAPS & TRICKS

DESIGNING OR SELECTING THE INSULATION SYSTEM: You can choose from a variety of established roof deck insulation systems. Start by studying all the available standard types. Most are reasonably good, but they are oriented heavily toward low cost and installation with unskilled labor. Even standard systems

may fail to deal with drainage, but instead attempt to create an impermeable basin. This approach inevitably limits service life. Tapered insulation provides good drainage, if it is installed properly. In retrofit, it can be a problem to slope insulation toward the existing roof drains. A custom-engineered roof can solve all these problems, but the cost is usually much higher.

INSTALLATION: With any type of roof, the quality of installation affects service life. This is especially true of membrane roofs intended to hold standing water. When installing tapered insulation, ensure continuity of the slope and effective runoff into drains.

MEASURE 7.1.3 Apply sprayed foam insulation to the top surface of roofs.

If the roof surface is flat or gently sloped, sprayed foam insulation can be applied to the upper surface. This type of roof insulation can be installed quickly by contractors who have specialized equipment for the work. In terms of installation, this method is almost the opposite of the multi-component roof systems covered previously by Measure 7.1.2.

There are various materials and application methods that are used for sprayed roof insulation. Each type of insulation, and each method of installation, involves its own set of details. These details are important. Make sure that the installer follows the insulation manufacturer’s instructions carefully. This Measure covers the key issues for all methods of insulating the top surfaces of roofs with sprayed foam. Make sure that each of these issues is covered in adequate detail by the manufacturer’s instructions, and that the installer pays attention to these issues.

As with all roof insulation, do not use this method if there is a vented attic space below the roof.

Advantages

Sprayed foam roof insulation is a radical departure from other types of external roof insulation. It has several significant advantages:

- **no separate outer membrane** is required. The foam itself, and an opaque coating, are the weather surface.
- **no separate vapor barrier** is needed. The insulation itself forms an unbroken, impermeable surface.
- **ease of installation.** Installation does not run afoul of the clutter of piping, ductwork, etc. that obstructs internal insulation.
- **no physical restrictions on thickness.**

SUMMARY

A method for flat or gently sloped roofs that combines major advantages with major disadvantages.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%		
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

Disadvantages

Sprayed foam is not widely used, despite its important advantages. The reason is that it also has significant disadvantages:

- **uncertain longevity.** Foam is destroyed rapidly by sunlight, so a durable opaque coating is needed. Foam also shrinks and cracks. The long-term performance of external sprayed foam insulation is not well established.
- **vulnerability to traffic.** The foam does not have sufficient compression strength to resist footsteps. The foam surface is irregular, so it is not practical to apply flat sheathing to protect the foam. You may have to install independently supported walkways for protection.
- **puddling.** The method of application produces a lumpy surface that puddles water. At a minimum, this is messy. As the foam ages and cracks, puddled water penetrates the cracks, undermining the effectiveness of the insulation and destroying it with freeze and thaw cycles.

The disadvantages limit this type of roof insulation to retrofit applications where existing conditions make other approaches more difficult or much more expensive.

Installation Precautions

Some water will eventually penetrate the insulation. Therefore, install the insulation so that water penetrating the insulation is led to the roof drains.

Plastic foam is vulnerable to sunlight, so cover it with a completely opaque coating that will endure for the life of the foam. In fact, the coating will largely determine the life of the foam. In warm and moderate climates, make the coating as reflective as possible, to minimize heat gain and to prevent degradation of the foam from high temperature. (Do not use metallic paints for this purpose. Although they reflect light, they do not radiate heat well.)

Do everything you can to minimize puddling. Discuss this issue with potential contractors. If necessary, establish a slope on the surface of the foam, which requires additional material. Monitor the installation to make sure that this is handled properly.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

ECONOMICS

SAVINGS POTENTIAL: *Insulating a bare roof typically reduces the heat loss and heat gain through the roof by 70 to 90 percent. This may be a large fraction of the total building heat gain or loss.*

COST: *In typical retrofits, a good quantity of exterior sprayed foam roof deck insulation may cost from \$5 to \$10 per square foot.*

PAYBACK PERIOD: *Several years or longer, depending primarily on the original insulation value of the roof.*

TRAPS & TRICKS

SELECTING THE METHOD: *The appeal of this method is its speed and its apparent adaptability. Beware that the installer may deal with problems by burying them in foam, and the emphasis on speed causes important preparation to be ignored. If you select this method, have a clear agreement about how the job is to be done, and have an enforcer at the site.*

MATERIALS: *There is a common misconception that foam insulation is weatherproof. The opposite is true. Foam is destroyed by sunlight, and therefore requires a durable, opaque surface coating. It is also vulnerable to oxidation, and it is destroyed by freezing and thawing like any other material. A sprayed roof will probably have a shorter life than any other applicable type. A long-term warranty is likely to be meaningless, because a specialty applicator faced with many claims will disappear.*

MEASURE 7.1.4 Install insulation on the underside of roofs.

In many existing buildings, the only economical way to improve the thermal resistance of the roof is to install insulation against the underside of the roof surface. This method has a number of major advantages, but one potentially disastrous disadvantage.

You can use various types of insulation underneath roof decks, including boards, batts, and spray-applied materials. Each type of material and each method of installation involves its own set of details. These details are important. Follow the manufacturer's instructions carefully. This Measure covers the key issues for all methods of insulating underneath roof surfaces. Make sure that each of these issues is covered in adequate detail by the manufacturer's instructions, and that the installer pays attention to all of them.

As with all roof deck insulation, this method should not be used if there is a vented attic space below the roof.

Advantages

This method has several significant advantages:

- **ease of installation.** In many buildings, the underside of the roof is the only reasonably accessible surface for installing insulation.
- **unrestricted thickness.** There is typically plenty of space to add as much insulation thickness as you want.
- **low cost.** Cost is relatively low because of the ease of installation, and because it is not necessary to remove and replace other roof components.
- **longevity.** The insulation is well protected from sunlight, weather, and impact.

Risk of Moisture Damage

The overwhelming disadvantage of this method is the risk of serious moisture damage if the building is located in a climate where the outside temperature can be much colder than the inside temperature. In such locations, the insulation must have an effective vapor barrier on its inner surface. (Reference Note 42, Vapor Barriers, explains the problems of moisture in insulation.) If the outer roof surface is also impermeable, a region is created between the outer roof surface and the vapor barrier that can trap and hold moisture. Persistent moisture will eventually destroy any type of roof structure, and may even cause structural collapse. You may not be able to provide drains and/or vents that are adequate to get rid of trapped moisture.

Because of this potential problem, this method of insulation is safe only if you can design a reliable

SUMMARY

May be the easiest way to add roof insulation to an existing building, but risks serious moisture damage. Safest in a warm, dry climate.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%		
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

moisture venting for the space above the insulation, or if the outside air dew-point temperature is always higher than the inside temperature.

This method of insulation is least likely to have trouble in climates that are warm and dry, where the insulation is used primarily to reduce cooling load.

How to Avoid Moisture Damage

Insulation installed underneath the roof is much better protected from precipitation than insulation installed on top of the roof. However, even under-roof insulation is vulnerable to water damage from roof leaks. Expect any roof to leak occasionally during its life. Moisture inside the insulation may do more damage to the roof structure than to the insulation itself.

The best protection against roof leaks is to use insulation that is highly permeable, such as glass fiber board. This allows any moisture to evaporate freely and escape through the vents.

If you decide to install under-roof insulation in a colder climate, you face a serious challenge in avoiding moisture damage. In that case, two things are needed:

- **a very reliable vapor barrier.** You must keep water vapor from entering the insulation from the inside of the building. Use a very effective, reliable vapor barrier, such as thick plastic film with overlapped, taped joints. If you cannot be sure of the vapor barrier, do not use under-roof insulation. The exception is climates that are warm and dry, where it may be desirable to omit the vapor barrier.
- **a path to vent any accumulated moisture to the outside.** Aside from the issue of roof leaks, no vapor barrier can completely block the flow of water vapor into the insulated space. The installation must provide a path for water vapor to vent to the outside before it reaches a concentration that allows it to

condense. In a cold climate, the insulated space must vent to the outside of the building, not to the inside.

Adequate venting to the outside is not possible with typical commercial flat roofs that use an impermeable outer membrane. The best case occurs with a highly permeable outer roof surface, such as tiles on a sloped roof. However, standard practice involves laying an impermeable base under the tile. Even if an impermeable base does not presently exist, one may be installed later during a renovation. Adequate venting may occur with a corrugated or channeled sheetmetal roof, in which the channels act as vapor vents. This requires keeping the channels open to the outside at the top and bottom. But again, an impermeable underlayment under the sheetmetal will block adequate venting.

Attach the Insulation Snugly

Make the insulation fit snugly against the roof surface. Otherwise, air will leak from the roof surface to the space, bypassing the insulation. Use a tight fastening that is reliable and will not work loose. Seal around the edges of each panel of insulation.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

ECONOMICS

SAVINGS POTENTIAL: *Insulating a bare roof typically reduces heat loss and heat gain by 70 to 90 percent. This may be a large fraction of the total building heat gain or loss.*

COST: *In typical retrofits, adding a good amount of under-roof insulation may cost from \$4 to \$10 per square foot, using conventional insulation materials. The unit cost varies with the size of the job and difficulty of access.*

PAYBACK PERIOD: *Several years or longer, depending primarily on the original insulation value of the ceiling and roof structure.*

TRAPS & TRICKS

CHOICE OF METHOD: *Approach this method with great caution. It is a challenge to design under-roof insulation in a manner that is thermally effective while avoiding moisture problems throughout the life of the building.*

MEASURE 7.1.5 Install a suspended insulated ceiling.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Installing a suspended, insulated ceiling can reduce heat gain and heat loss from the ceiling and the upper portions of walls. Possible configurations range from a standard suspended grid ceiling tile system to a rigid, permanent ceiling. A suspended ceiling does not have to be horizontal.

This is generally a retrofit method. If you are designing a new building, the other Measures provide better ways of insulating the top surface of the building.

A suspended ceiling is most favorable in applications where cooling is the primary conditioning load, and there is little heating load. Unlike roof insulation, this method works even when the space below the roof is vented.

If heating is a major conditioning load, consider this a method of last resort. This is because a suspended ceiling is not a very reliable thermal barrier. For example, you might install an insulated suspended ceiling if the inner and outer surfaces of the roof are so cluttered that it is not practical to install insulation on them, or if you cannot insulate the inner roof surface because of the moisture problems explained in [Measure 7.1.4](#).

Cooling-Only Applications

Suspended ceilings are most favorable in applications where cooling the space costs much more than heating it. They are especially effective where a hot roof radiates heat down into the occupied portion of the space, or where circulation fans move warm air from the upper portions of a tall space into the lower areas.

In cooling applications, the suspended ceiling performs two functions. One is creating a physical barrier to vertical air circulation. This enhances the natural tendency of cooler, denser air to stay in the lower part of the space, avoiding contact with the warmer surfaces in the upper part of the space. The other function is to block heat radiation from the upper part of the space into the lower part.

Both these functions could be performed by any thin, opaque material, even a sheet of paper. Insulation is needed only because the suspended ceiling itself is warmed by radiation and conduction from above. The insulation keeps the suspended ceiling itself from radiating heat into the space. The temperature rise in the ceiling space is relatively small, so only a small thickness of insulation is needed. Ordinary acoustical tile is satisfactory for most applications.

In these situations, the ceiling does not have to be tightly sealed. Stratification helps to keep the lower cool air separated from the upper warm air. If fans are

SUMMARY

A retrofit method of last resort. Better for reducing heat gain than heat loss.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% %
Reliability	✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

used to circulate air within the cooled space, these are located below the suspended ceiling, so they do not mix air between the upper and lower spaces.

Applications involving cooling alone do not require a vapor barrier in the suspended ceiling. The lower, occupied space usually has the highest absolute humidity. The relative humidity is lower inside the ceiling insulation, and above the ceiling, because these areas are warmer.

For the suspended ceiling to be most effective, the space above the suspended ceiling should be well vented to the outside. This minimizes the temperature differential across the ceiling, and keeps the warm air above the ceiling from expanding into the occupied space.

However, if the space is heated at certain times, venting the space above the suspended ceiling poses the risk of serious heat loss, a problem that we will now explore.

Heating Applications

If heating is the primary need of the space, it is more difficult to make a suspended ceiling effective. The major challenge is creating an unbroken barrier to convective heat loss through the insulation. If the space is heated, the warmed space air tends to rise. Only an unbroken surface from wall to wall can prevent this. With lightweight ceilings, such as suspended grid systems, this is virtually impossible to achieve, so some convective heat loss occurs.

Similarly, it is difficult to create an effective vapor barrier, which is needed unless the space above the suspended ceiling is well vented to the outside. (See [Reference Note 42](#), Vapor Barriers, for details.)

Both these considerations argue in favor of installing a rigid, permanent ceiling, instead of a suspended ceiling tile system. One way to install a rigid ceiling quickly is to use prefabricated panels that include insulation and a vapor barrier.

If there are air returns in the upper part of the space, a suspended ceiling cannot be used.

Reduce the Volume of the Space?

Suspended ceilings can be used to reduce the conditioned volume of a space. This was a popular energy conservation concept during the 1970's. However, space volume, by itself, does not consume energy. A suspended ceiling reduces the conditioning load only if it reduces the area of exterior surface, or if it reduces the rate of heat loss through exterior surfaces.

An example that illustrates the greatest advantage of installing a suspended ceiling is a poorly insulated metal building with a tall roof. The reduction in volume and the change in the shape of the space:

- **reduces the surface area for heat loss and heat gain**
- **minimizes stratification.** In a tall space, there may be a difference in air temperature between the top and bottom of the space of 10°F (6°C) or more. The higher air temperature at the top of the space increases conductive heat loss.
- **minimizes convective circulation.** Tall spaces have a great deal of convective heat loss if the insulation is poor. Buoyancy forces warmer air to the top of the space, where it is cooled by contact with the cold roof. The chilled air then falls to the bottom of the space, promoting air circulation and accelerating the heat loss. Reducing the height of the space greatly reduces this effect.
- **allows an attic space to be created above the conditioned space.** The space remaining above the suspended ceiling acts as an attic. The roof blocks solar radiation. If the space above the ceiling is well vented, the temperature differential across the ceiling is greatly reduced, compared to the differential that would exist if the insulation were installed against the roof.

These are important benefits. However, the suspended ceiling makes the space above the ceiling inaccessible. This space is now filled with suspension wires for the ceiling. Furthermore, all the lighting must be changed. In most cases, it would be more desirable to install a generous amount of insulation on the roof and walls, rather than install a suspended ceiling.

Persuade Occupants to Leave Ceilings Intact

A problem with suspended ceilings is the ease with which they can be rendered ineffective, especially as a barrier against heat loss. Suspended ceilings are vulnerable to openings created by the occupants and maintenance staff. For example, an occupant may prop up a ceiling tile in the hope of getting better ventilation.

Let everyone know that the insulated surface has to be kept unbroken. One possible method is installing placards in appropriate locations. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

ECONOMICS

SAVINGS POTENTIAL: *Adding a suspended ceiling to a space with an uninsulated roof may reduce heat gain by 60 to 90 percent. Heat loss may be reduced 60 to 80 percent, but this saving is less reliable. In retrofit, the benefit depends on the amount of insulation previously installed in the roof and walls.*

COST: *In retrofit, installing a suspended ceiling may cost from \$2 to \$6 per square foot, depending on the difficulty of installation.*

PAYBACK PERIOD: *Several years, or longer, depending primarily on the original insulation value of the ceiling and roof structure.*

TRAPS & TRICKS

CHOICE OF METHOD: *Are you sure that this is the best approach for your application? The other Measures are more expensive, but they are also more reliable.*

SELECTING MATERIALS AND INSTALLATION METHODS: *There are many ways to install a suspended ceiling. Start by getting familiar with all the types of insulation materials you might use. Select a type that has a good fire safety rating.*

Walls and Soffits

Heat loss through the opaque portions of walls contributes a large fraction of heating cost, except in buildings where large amounts of glazing dominate heating cost. Wall heat gain is typically a lesser factor in cooling load, but it can be important in many buildings.

The time to minimize this heat loss is while the building is still being designed. In new construction, improving wall insulation costs little. In fact, it may reduce overall construction cost by reducing the heating and cooling capacities required. Good wall insulation may even allow you to eliminate perimeter heating systems.

Improving wall insulation on a retrofit basis is practical primarily in buildings that have large areas of opaque wall. You can usually find a way of increasing the insulation value of walls, but the cost may be high in relation to the economic benefit.

The labor cost of retrofitting small or irregular wall areas is prohibitive in most cases. When improving the thermal performance of walls, consider where the heat loss is occurring. In buildings with a large fraction of window area, most of the heat loss and heat gain occurs through the glazing, so concentrate your attention there, using the Measures of [Section 8.1](#).

The Measures in this Subsection cover the various methods that you can use to insulate walls. Each has important advantages and drawbacks. They are alternatives to each other.

INDEX OF MEASURES

- [Section 5](#), for modifications to perimeter heating systems

MEASURE 7.2.1 Insulate wall cavities.

In most new buildings, except shell buildings, wall insulation is an internal component of the wall structure. You can do a much better job of insulating the opaque portions of the walls than is conventional practice, and you can do it at modest additional cost. This does not require new techniques or materials. It requires only a modest increase in wall thickness to accommodate more insulation, along with attention to good installation practice.

Figure 1 shows a few common methods of installing insulation inside stud wall structures. All these methods are satisfactory, provided that enough insulation is installed to provide ample insulation value for the climate. Figures 2 and 3 show a common method of installing insulation inside masonry wall structures.

The main challenge is to install the insulation so that it will continue to be effective for the life of the building. This means avoiding convection paths around the insulation. If you use compressible insulation, such as glass fiber batt, the reliable installation method is to fill the wall cavity entirely and snugly. If you use rigid insulation, it is critical to fasten the insulation snugly to a strong wall component, and to permanently seal the gaps between the insulation boards. Figures 2 and 3 show the details.

With any type of wall insulation, you must provide a satisfactory vapor barrier and provide for venting any moisture that gets into the wall or insulation.

In many existing buildings, you can improve wall insulation by filling the cavities in the walls. Any type of wall that contains unfilled spaces is a candidate for cavity insulation. As a retrofit activity, filling the wall cavity has the advantage that there is less disturbance of the interior and exterior surfaces than with other methods. The practical question is whether you can gain access to the cavities to install the insulation at reasonable cost.

To help you select the best type of insulating material, see [Reference Note 43](#), Insulation Selection. For retrofit installation, the type of insulation and the method of installing it are determined by the wall construction, especially by the obstacles that you can expect to encounter inside the wall. We discuss these issues for existing stud walls and masonry walls.

Energy Saving Potential

See [Reference Note 45](#), Insulation Economics about the balance between energy savings and costs when increasing the amount of insulation.

SUMMARY

Usually the preferred method of insulating walls in new construction, where it is relatively inexpensive. In retrofit, it is limited by the width of the wall cavity and by internal obstructions.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

In new construction, the cost of additional wall insulation is almost inconsequential. The major cost is changes to the wall structure to accommodate the greater thickness. A clever designer should be able to minimize this cost premium.

In retrofit applications, filling the cavity completely is the only practical approach. You can rarely overdo this. Typically, you can increase the R-value of a wall from 3 to 10 points by adding cavity insulation. The R-values of typical uninsulated walls range from 3 to 6, depending mostly on the number of layers in the wall section. Thus, filling wall cavities with insulation may double or triple their thermal resistance.

Retrofit Insulation for Stud Walls

In a stud wall, the inner and outer surfaces are attached to slender vertical members (“studs”). Studs may be made of wood or sheetmetal. In low buildings, the studs may carry the weight of the building above. In steel frame buildings, the studs only give thickness and rigidity to the wall surface.

The interior of a stud wall is mostly empty space. This space is oriented vertically, allowing a large amount of heat transfer by convection. Heat is also conducted through the studs themselves. However, the low thermal conductivity of wood studs and the thin cross section of steel studs limit this heat loss. In an uninsulated stud wall, most the of the heat transfer occurs in the space between the studs, as a result of convection.

In new construction, it is relatively easy to insulate a stud wall, although workmanship is a limiting factor. (See [Reference Note 44](#) for details.) In existing buildings, the large gap inside stud walls is an attractive target for retrofit insulation. The problem in existing

Fig. 1 Various methods of insulating stud walls All these methods can provide good results, provided that you install enough insulation, avoid convective circulation around the insulation, and prevent moisture problems. Beware of methods that use impermeable sheathing on the cold side of the wall in combination with cavity insulation, as this invites moisture problems.

Celotex Corporation

buildings is that the stud spaces may contain obstacles to insulation, which we now discuss.

■ Obstacles in Stud Walls

The main obstacle to retrofit insulation in stud walls is “fire stops.” Fire stops are horizontal pieces that span from one stud to the next. Their purpose is to keep the empty stud space from acting as a chimney, hastening the spread of fire. In order to work, fire stops must block the stud space completely. They make it impossible to fill the wall with insulation by pouring into an opening at the top of the wall.

You are most likely to encounter fire stops in types of construction where the stud space is not interrupted at each floor. These methods of construction are called “balloon frame,” “post and beam,” etc. In these types of construction, fire stops may be located anywhere. In construction where the stud starts at each floor (“platform” construction), fire stops typically are installed half way up the wall.

Not all stud walls have fire stops. They are not common in platform construction, or where non-flammable wall materials are used, such as metal studs and gypsum board. In case of doubt, check for the

presence of fire stops by drilling access holes into some stud spaces and probe to determine whether the cavity is clear from top to bottom.

Window frames pose a problem similar to fire stops, except that there is no doubt where they are located.

Wiring in the walls can cause pouring insulation to fail to fall into the space below, especially if the insulation is fluffy. If the insulation is held up by wiring but later settles, a void will form at the top of the wall.

■ Access and Installation Methods

Loose insulation is usually injected into walls with blowing equipment that carries the insulation in a stream of air. This requires making holes of significant size in each stud space. Insulation contractors use specialized plugs to close access holes after the insulation is installed. The amount of refinishing work needed to cover the plugs varies widely, from none to prohibitive.

Some contractors claim that the holes can be located anywhere in the stud space, but be skeptical of how well the insulation fills the cavity if it is blown from below. Try to insert the insulation into the wall from the top. The top of a wall may be accessible from inside the attic, perhaps by drilling holes in the top plate of the wall.

Dow Chemical Company

Fig. 2 Rigid board insulation inside a wall cavity Using rigid board insulation may be the most reliable way to install insulation inside a masonry wall. The big challenge with rigid insulation is avoiding convection paths between the boards, and between the boards and the wall. Note the eyes installed in the mortar joints for holding the boards snugly against the wall. This requires good workmanship.

Any type of pouring insulation will leave an uninsulated void space at the top of the cavity because of settling. Also, the completeness of filling is dependent on the proficiency and honesty of the installer.

Another method of gaining access to the inside of stud walls is to remove either the exterior or interior skin. This is most likely to be economical when major renovation work is done. For example, if the siding of residential units needs to be replaced, it may be simple to remove the exterior sheathing, install batt insulation, and replace the sheathing. Figures 4 through 6 show an example. At the same time, seize the opportunity to eliminate air leak sites that become accessible.

■ Insulation Materials for Stud Walls

The choice of insulation materials is easiest when you insulate a wall by removing the skin. In this case, use glass or mineral fiber batts fitted between the studs.

If the insulation is to be installed by pouring or blowing, the choice involves compromises:

- **glass fiber** and **mineral fiber** have excellent thermal and safety characteristics. It tends to snag on anything inside the cavity, so a vigorous method of filling the cavity is required.

- **cellulose** insulation is vulnerable to moisture damage and settles more than other types. It also tends to snag.
- **perlite** and **vermiculite** pour well, but have a lower R-value than other types of insulation.
- **plastic foam beads** have excellent characteristics for pouring. However, their fire characteristics make them unsafe in most stud walls enclosing occupied spaces.

If the material consists of small particles, it will leak out of any crevices on either side of the wall, such as the gaps around electrical boxes.

Retrofit Insulation for Masonry Walls

Masonry walls may have several types of cavities. The concrete blocks themselves, and other types of masonry units, typically have large cavities that allow strong convective heat loss. Often, the cavities can be filled with insulation, which kills the convection. However, the insulation cannot reduce conductive heat loss, which occurs through the webs of the blocks. ASHRAE data show that filling the cores of masonry units typically doubles their effective thermal resistance.

Dow Chemical Company

Fig. 3 Details matter The long-term reliability of this insulation job depends on holding the boards snugly against the concrete block wall. Note the clips installed for this purpose. Also, note the sealant that is installed between the joints. We hope that the sealant was installed between the boards, not just skimmed over the top.

Fig. 4 Retrofitting stud wall insulation from the outside, first step The exterior siding and sheathing are removed. Porch light wiring penetrations in the wall are sealed.

Fig. 5 Second step The old single-glazed window is replaced with a new double-glazed window. The stud wall cavities are entirely filled with insulation, being careful to leave no voids.

Fig. 6 Third step Strong exterior sheathing is installed, each panel caulked and nailed to the studs. This method of installation does not allow a satisfactory vapor barrier to be installed inside the wall, so impermeable paint is applied inside the house.

This still results in R-values ranging only from 2 to 5, depending on the type of block.

If a masonry wall consists of a block core and an outer veneer of brick or other material, there is usually a gap of an inch or two (several centimeters) between the block the veneer. This gap is worth insulating, especially if the wall has no other insulation.

The space between the block and any interior finish surface is usually too narrow to insulate on a retrofit basis. Filling the narrow gaps would be difficult or impossible, and the economic benefit would be small.

■ Obstacles in Masonry Walls

The space between the inner and outer elements of a masonry wall is filled with wall ties. Wall ties hold the veneer in place, and improve the strength of the total wall structure. Wall ties can take many forms, such as heavy wire grids, steel rods, and bricks laid sideways across the gap.

The gap surface of block and brick walls is covered with hardened mortar squeezed from the joints. While not bridging the gap, the mortar snags insulation.

The wall cavity may also contain wiring, piping, and other equipment that causes the same problems as in stud walls.

■ Insulation Materials for Masonry Walls

Consider the same types of insulation as for stud walls. Foam beads are especially favorable in masonry walls, provided that they are installed outside a heavy, fireproof structural element, such as concrete block.

■ Access Methods for Masonry Walls

Try to fill the wall from the top. If the wall extends upward to an exposed parapet, removing the parapet flashing provides access to the interior of the wall. Or, chisel out blocks in the upper part of the wall, and cement them back into position after installing the insulation.

Fire Safety

Before selecting the type of insulation, survey the wall for potential fire hazards, such as wall-mounted heaters. The objectives are to keep from igniting the insulation and to keep from overheating the equipment itself. Insulation may catch fire even if it contains only a small amount of combustible material, such as the binder used in glass fiber blanket insulation. Even dust can fuel a fire. Isolate all electrical connections from contact with insulation. Electrical fires typically start when an electrical connection corrodes or loosens, creating resistance that acts as a heating element.

Vapor Barriers

[Reference Note 42](#), Vapor Barriers, explains the need for a vapor barrier. In most cases, you can create a satisfactory vapor barrier with a reasonably impermeable

surface inside the space, such as vinyl wall covering or a thick coat of latex paint. But, keep in mind that the interior finish may change during the life of the building. Leave an explanation in the building's permanent records that an impermeable interior finish is required to protect the wall structure, and hope that somebody reads it at the proper times. It is far safer to build a permanent vapor barrier into the wall structure.

ECONOMICS

SAVINGS POTENTIAL: 40 to 70 percent of the heat loss and heat gains through the insulated portions of the wall.

COST: In new construction, a good thickness of fibrous wall insulation costs from \$0.50 to \$1 per square foot. Plastic foam insulation costs \$1 to \$2 per square foot. In retrofit, filling wall cavities with fiber insulation may cost from \$2 to \$5 per square foot, depending on the difficulty of access.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

SELECTING THE MATERIALS AND INSTALLATION

METHOD: Specific installation methods are used with specific types of materials as a system. Each system has its own contractors, who usually specialize in that system alone. It is your responsibility to understand all the advantages and disadvantages of each system, and to make the best choice for your facility.

MEASURE 7.2.2 Insulate the inside surfaces of walls.

RATINGS

New Facilities	Retrofit	O&M
B	C	

If the wall structure itself does not provide enough space for adequate insulation, your remaining choices are to install the insulation outside the wall or inside the wall. Installing the insulation on the inside protects it from the elements. Also, the insulation may integrate well with an interior finish surface.

In many existing buildings, adding insulation to the inside surface of a wall is the only practical way to improve the wall’s thermal resistance. Installation is easiest with industrial buildings that do not require an interior finish. However, the method works with almost any kind of wall by installing an appropriate cosmetic covering over the insulation.

Figure 1 shows a variety of methods for insulating the inside surface of a masonry wall using rigid board insulation. In retrofit, the same methods could be used with any kind of existing wall.

Figure 2 shows methods of insulating below-grade walls, both above and below floor slabs. Below-grade walls pose a much more difficult problem because of the possibility of soaking the wall from the outside. When insulating below-grade walls, the preparation of the outside of the wall matters as much as the insulation methods inside the wall.

Interior installation has one potentially serious disadvantage, which is a risk of serious moisture damage to the wall structure. Examine your situation closely to determine whether this can occur with your climate and your type of wall. If so, you need to take steps to prevent the problem.

Insulation Types to Consider

Glass or mineral fiber is best for most applications because of its fire safety and ease of attachment. For flat surfaces where no interior finish is needed, semi-rigid board works well. If a surface finish is needed, fiber insulation is available bonded to plywood, gypsum board, and other materials. Blankets or batts may be the best choice if the wall surface is irregular, or if there are many obstructions, such as structural elements, wiring, and piping. Review [Reference Note 43](#), Insulation Selection, before making your final decision.

Each type of insulation, and each method of installation, involves its own set of details. These details are important. Follow the manufacturer’s instructions carefully. The most important issues are preventing moisture damage and convective heat loss.

SUMMARY

Applicable to many building types. Becomes complicated if you need to add features to avoid moisture damage.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

How to Avoid Moisture Problems

To prevent moisture problems with any method of insulation, you have to provide two features: (1) a good vapor barrier on the warm side, and (2) a path on the cold side for venting any moisture that may get into the insulation. See [Reference Note 42](#), Vapor Barriers, for more about vapor barriers. See [Reference Note 44](#), Insulation Integrity, for an explanation of venting paths. You have to make a special effort to satisfy both of these requirements when installing insulation on the inside of the wall.

If the wall includes any elements that block the passage of water vapor, such as a sheetmetal skin, a region is created between that surface and the vapor barrier that traps moisture. To avoid this problem, create a gap on the outer (cold) side of the insulation for venting moisture. The existence of an impermeable trapping layer in the wall increases the importance of having an unbroken vapor barrier.

The climate and the permeability of the wall determine how critical the vapor barrier is. For example, in a building with concrete block walls that is located in a dry climate, it may be satisfactory to attach insulation board having an integral vapor barrier directly to the wall.

If the climate is fairly dry and the outer wall is corrugated aluminum, which does not corrode rapidly, the corrugations may serve as channels for venting moisture.

How to Avoid Convection Losses with Permeable Walls

Convection currents in walls can seriously reduce the effectiveness of wall insulation. This problem is

Celotex Corporation

Fig. 1 Methods of installing rigid board insulation on the inner surface of a wall These methods could be used inside a wall of any type, not just concrete block. The minimum gypsum board thickness is required for fire protection when using flammable insulation material.

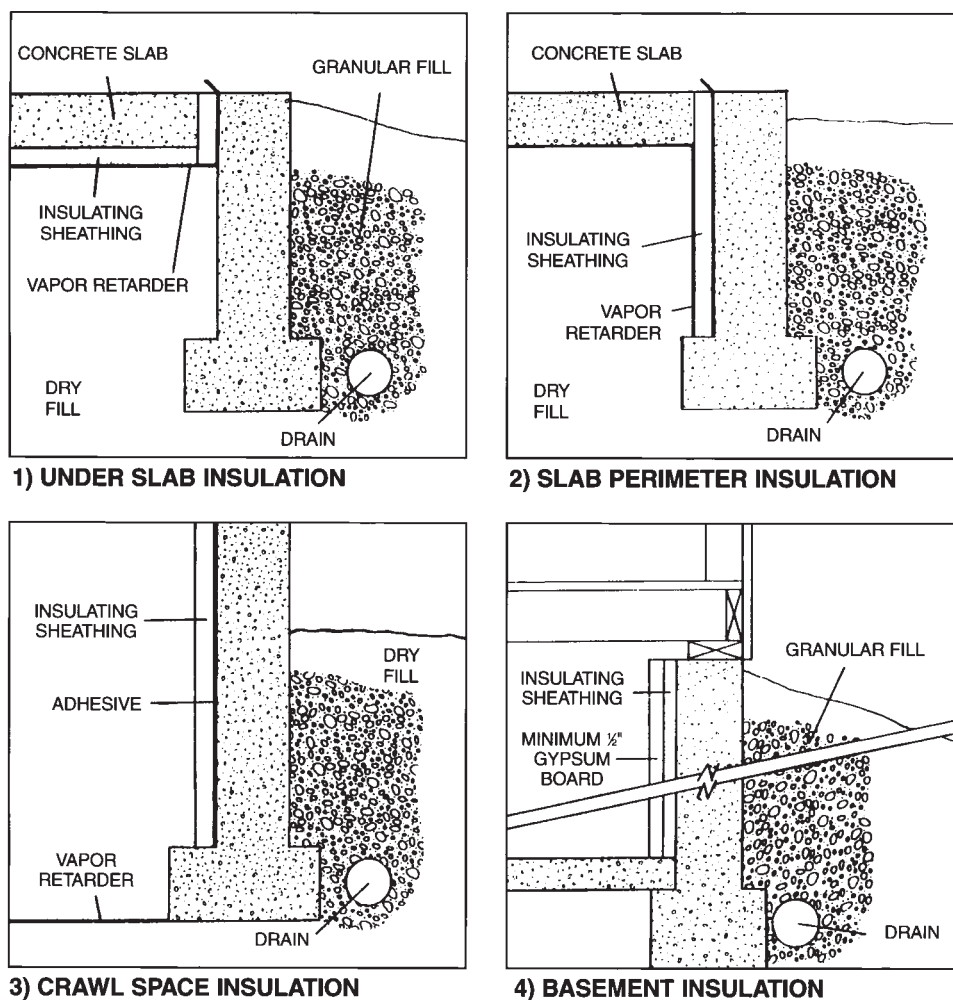

most serious in walls because they are oriented vertically, creating a chimney effect. The way to minimize convection currents is to install the insulation snugly against an unbroken surface. This keeps convection currents from bypassing the insulation. Also, it minimizes the harm done by any air leaks through the insulation (from cable penetrations, etc.)

If the wall is permeable enough to act as its own vent path to the outside, you can install the insulation directly on the inside surface of the wall. This is satisfactory with most masonry walls, provided that the wall cannot be soaked by precipitation from the outside.

If the wall is flat enough so that you can use board insulation, attach it by using plenty of mechanical

fasteners and by caulking the joints of each panel, both to the wall and to the adjacent panels. See Figure 3.

Figure 4 shows a method of insulating the inside of a wall using studs and batt insulation. Use batt insulation that has an attached vapor barrier, and fasten the vapor barrier to studs or furring strips. This method is adaptable to all types of walls. Batt insulation is generally fluffy enough to accommodate irregularities in the wall surface. To achieve the optimum R-value and to ensure snug contact with the wall, use a nominal batt thickness that is somewhat greater than the depth of the stud space. For example, if the stud space is 3.5" deep, install batt insulation that is rated for a stud space 5.5" deep.

Celotex Corporation

Fig. 2 Methods of installing rigid board insulation on the inside surfaces of below-grade walls No common insulation material is able to function properly in a soaked condition. Therefore, the preparation outside the wall is as important as the installation methods inside the wall. The dry fill and drain tile shown here are necessary to deal with underground water sources, if any. The best protection against precipitation is a continuous downhill slope away from the wall. This can usually be accomplished easily and attractively by building a mild berm against the side of the building.

An important advantage of this method over rigid insulation is that the materials used are less dangerous in a fire. Fire safety should be primary issue when installing insulation inside a building.

Poor attachment is a common problem with insulation. Figure 5 shows an example. Tape and adhesives dry out with age. This releases the insulation and destroys the effectiveness of the vapor barrier. Therefore, use attachment methods that do not place a load on adhesives. If you must use taped joints to apply the insulation, use a method of installation that holds the joints together permanently. For example, install insulation between battens (furring strips) or cover the joints with battens. The battens then serve as an attachment for the interior finish surface.

Broad-head nails are commonly used to attach insulation board to walls, but this method is not always satisfactory. Unless the wall surface holds the nails well, the nails tend to come loose. This is a common problem when insulating masonry walls.

Do not use the wall as the mounting surface if it is so irregular that the insulation cannot contact the wall at all points, or if there is any equipment that prevents the insulation from lying snugly against the wall. In those cases, use the following general approach.

How to Avoid Convection Losses with Impermeable Walls

If the wall is not permeable enough to vent moisture under the climate conditions that exist at the site, avoiding convection becomes more complicated. Venting requires an air gap on the outer (cold) side of the insulation. To create the gap, you must attach the insulation to an interior surface that is strong enough to carry the insulation. The entire wall surface must be sealed from top to bottom, and from side to side, so that air cannot leak through the insulation.

One way to create an interior mounting surface is to use insulation that is bonded to a rigid backing, such as plywood or gypsum board. This material can also serve as an interior finish surface. Such composite material can be secured with screws, nails, or other permanent fasteners. If an air gap is needed on the cold side of the insulation, you have to mount the rigid boards on studs or other structural elements to separate them from the outer wall surface. Since the boards are rigid, you can achieve an unbroken interior surface with caulked or taped joints, provided that you support the joints properly.

Do not use batt insulation if it is not supported on both sides. If the side of batt insulation facing a vent space is unsupported, it will sag and tear loose, largely as a result of rough handling at the time of installation. This problem will be invisible, and it will be virtually

impossible to fix. The torn insulation will also interfere with venting.

Minimize Air Leakage Into the Vent Space

If the insulation is installed in a way that leaves a vented air gap on the outer side of the insulation (whether deliberately or not), any penetration of the insulated inner surface will allow air leakage into the space. Therefore, if penetrations are needed for electrical wiring or other purposes, install stuffing boxes or take other steps to avoid air leakage. This is unconventional, so it is unlikely to succeed unless you work out the details and supervise the installation.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

Celotex Corporation

Fig. 3 Attaching rigid insulation inside a concrete block wall Rigid insulation works best when the wall surface is flat enough to provide a snug fit between the insulation board and the wall. Battens are an effective method of attachment, provided that plenty of fasteners are used and that the fasteners hold well in the wall. An important item missing from this picture is the caulking gun. Each insulation panel should be caulked to the wall and to adjacent panels.

WESINC

Fig. 4 Method of attaching batt insulation to the inside of a wall This works well with any type of wall, including the walls of old buildings. Note how the window openings are boxed, with flanges that attach to the wall to block infiltration. The batts should be somewhat thicker than the stud depth.

WESINC

Fig. 5 Irresponsible insulation job This batt insulation in a big, new office building was simply suspended by the paper backing sheet, and adjacent batts were taped together. The batt in the middle has fallen down already, and the rest will follow within a few years.

ECONOMICS

SAVINGS POTENTIAL: 60 to 95 percent of the heat loss and/or heat gain through the wall.

COST: In new construction, adding a good amount of insulation to the inside of the wall structure costs \$2 to \$5 per square foot. In retrofit, the cost is typically several times higher because of difficulty of access.

PAYBACK PERIOD: One year, to many years, depending mainly on climate and on the original insulation value of the wall.

TRAPS & TRICKS

DESIGN: The details are important. Work out a method of attachment appropriate for the insulation material. Do not depend on adhesives for attachment or sealing. Provide adequate moisture venting on the cold side. Select a vapor barrier material that will survive rough handling during installation.

INSTALLATION: Plan to supervise the installation. You will probably have to take some special steps to get a good job. Installers will resist any deviations from their usual procedures, no matter what it says in the contract.

MEASURE 7.2.3 Insulate the outside surfaces of walls.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Adding insulation to the outside of a wall is a method that is becoming increasingly popular. The development of plastic foam board insulation was a breakthrough for this method.

Exterior installation has these advantages:

- ***ease of installation.*** Installation from the outside is usually less hampered by obstructions. Foam board can be cut and fitted quickly to any wall configuration that consists of flat elements, even if the wall area is broken up by windows, ledges, etc. It can be attached to the structure directly. It is easy to protect from the elements.
- ***unlimited insulation value,*** in most applications. Plastic foam has high R-value per unit of thickness, and exterior application allows any desired thickness to be installed, within reason.
- ***complete coverage.*** Other methods of wall insulation cannot prevent heat loss through floor slabs, studs, and other structural elements that span the width of the wall. In contrast, exterior insulation covers the entire opaque area of the wall. The insulation can be extended below grade to any desired depth.
- ***avoidance of moisture problems.*** When the interior of the building is being heated, installing the insulation on the outside keeps the entire wall warmer than the dew point. When the interior is being cooled, the low permeability of plastic insulation (or of any insulation using a good vapor barrier) blocks moisture migration into the wall structure. If installed properly, exterior insulation also shields the wall from rain soaking.

Installing plastic insulation on the outside of the building minimizes the danger posed by its nasty fire characteristics. Of course, there may be cases where the fire hazard of petroleum-based foam insulation is unacceptable even for external applications.

Exterior insulation must be protected from sunlight and impact. If the insulation is located away from the possibility of contact with people and equipment, a coat of stucco is sufficient. Board insulation is available with various surfaces to attach the exterior finish surface. For example, board insulation is available that is bonded to a plywood nail base. You can achieve almost any desired exterior appearance using available materials.

Insulation Types to Consider

For most exterior applications, the appropriate type of insulation is some type of rigid, relatively impermeable foam board, such as extruded polystyrene or polyisocyanurate. In principle, any type of insulation

SUMMARY

Has significant advantages over other insulation methods, and is less prone to trouble. The insulation can be covered with almost any type of decor.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return, New Facilities	% % %
Rate of Return, Retrofit	% %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

can be installed externally. However, porous or permeable types are more difficult to install satisfactorily, especially from the standpoint of avoiding moisture problems.

Sprayed foam insulation is in development. Even if it comes to market, it probably will be a secondary choice, except for curved or irregular surfaces. Application of sprayed foam to vertical or slanted surfaces will be difficult to control, resulting in uneven thickness and roughness. On-site mixing of the materials will be subject to mistakes that may reduce the quality of the material.

Each type of insulation, and each method of installation, involves certain steps to achieve a good installation. These steps are important. Follow the manufacturer's instructions carefully. Make sure that all the important issues are covered in adequate detail by the manufacturer's instructions, and that the installer pays attention to them.

How to Avoid Convection Losses

Install the insulation snugly against the wall's exterior surface. Otherwise, outside air will bypass the insulation. If insulation boards are used, apply a bead of caulk around the entire perimeter of each board before sticking it to the wall. In addition, seal each board to the adjacent ones with caulk.

Try to select an exterior finish that holds the adjacent edges in position with respect to each other. For example, install the boards vertically, and install decorative battens over the joints.

Plastic insulation becomes weak and brittle with age, so install it in a manner that can keep it physically intact over its useful life. Adhesives are unreliable over the long term because they dry out and separate from the

foam and from the wall. In most cases, mechanical fasteners are best. However, the broad-head nails commonly used to attach insulation to masonry may perform poorly in certain materials. Test your method of installation beforehand to make sure that it will remain secure.

How to Avoid Moisture Problems

A major advantage of using plastic exterior insulation is that it usually does not require additional steps to avoid moisture problems, in either cold or hot climates. If you use board insulation, seal the joints between the boards to create an unbroken vapor barrier. This involves the same methods you use to prevent convection, which we just discussed. Keep both purposes in mind when you decide how to install the boards.

See [Reference Note 42](#), Vapor Barriers, about the importance of blocking moisture movement through the envelope.

How to Protect the Insulation

In all external applications, plastic foam requires a completely opaque covering to block sunlight. Sunlight can destroy plastic insulation much more quickly than other environmental factors. Any lightweight surface can be used to cover the insulation for decorative

purposes and sunlight protection. The insulation material can be covered with a heavy paint or with a veneer, such as metal siding. A stucco appearance can be achieved by attaching a glass fiber mesh to foam boards with mechanical anchors and then applying a coating over the mesh and boards. Plastic foam can be bonded to a wide variety of surface materials, which speeds installation and aids attachment.

Lightweight plastic foam is easily dented and crushed. Protect vulnerable areas from impact, especially if appearance is important. If potential impacts are light and spread out, you may be able to get enough strength by using foam of higher density. To resist sharper impacts, you can use foam that is bonded to an impact resistant surface material. Manufacturers offer many types of resistant surfaces on insulation boards, including wooden nail base, rigid plastic skins, and metal.

Plastic insulation can be degraded by long exposure to moisture. However, if you protect the surface finish from excess exposure, the insulation underneath will be adequately protected. Moisture damage is a concern primarily with below-grade installation. Only certain types of insulation should be used underground, and even these types require special installation methods to protect them from waterlogging. See Figure 1.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics.

Celotex Corporation

Fig. 1 Exterior below-grade insulation This is a desirable method of insulating below-grade walls and foundations. However, no available material retains its insulation value when soaked, so protecting the insulation from moisture is critical.

ECONOMICS

SAVINGS POTENTIAL: 60 to 90 percent of the heat loss and/or heat gain through the wall.

COST: In new construction, a good amount of exterior foam board insulation may cost \$2 to \$5 per square foot, including the surface finish. In retrofit, the cost may be 50% to 100% higher.

PAYBACK PERIOD: One year, to many years, depending mainly on climate and on the original insulation value of the wall.

TRAPS & TRICKS

DESIGN: Work out a secure method of attachment that will last as long as the building. Do not depend on adhesives for attachment or sealing. Make sure that the insulation is protected from sunlight and impact. Provide for drainage of moisture that may get behind the insulation. When insulating the outside of existing buildings, exploit the opportunity to give the building a better appearance.

INSTALLATION: Supervise the installation details, which can have a major effect on longevity and insulation effectiveness.

MEASURE 7.2.4 Increase the thermal resistance of the panels in curtain walls.

RATINGS

New Facilities	Retrofit	O&M
A	C	

A large fraction of commercial buildings constructed since the 1950's, especially highrise buildings, use curtain wall construction. The structural strength of the building comes from a rectangular steel frame. Most of the wall surface consists of lightweight panels and/or glazing that are inserted in the spaces between the

WESINC

Fig. 1 Curtain wall construction This building uses several types of surface treatment over the same basic structural frame. This is the time to make the envelope efficient. However, in existing buildings, it may be possible to remove the exterior panels with surprising ease, providing an opportunity to improve the insulation, control sunlight, and update appearance.

SUMMARY

An easy, powerful improvement for new buildings. In retrofit, a radical method, but often the only way to substantially reduce heat loss. Lets you completely update the building's appearance. Keep this in mind for the day when an energy shortage makes your glass box energy hog uninhabitable.

SELECTION SCORECARD

Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	😊 😊

exterior columns and beams. These panels are strictly fillers, with no structural purpose, even though they may be surfaced with materials such as brick or stone. Figure 1 shows all the phases of curtain wall construction in a large building.

In new construction, the designer has almost unlimited ability to increase the thermal resistance of the opaque portions of the curtain wall panels. (Improvements to glazing are covered by [Measure 8.1.3.](#)) Indeed, failing to exploit this opportunity is one of the worst oversights of modern architecture.

Another oversight is the potential for dramatically improving the thermal characteristics of existing curtain walls. Opaque curtain wall panels are usually attached with clips and bolts, so it may be fairly easy to remove them from existing buildings. This makes it practical to improve the thermal characteristics of the wall by exchanging the panels. Consider changes to the size and configuration of windows at the same time. With careful planning, the external appearance of an old building can be changed in ways that are limited only by the imagination of the designer. Figures 2, 3, and 4 show an example.

Improving wall panels involves two separate activities: (1) fabricating new panels or modifying the old ones, and (2) all the other work needed to remove and re-install the panels. The first activity is done by a fabricator who specializes in making curtain wall components. The second may involve a variety of contracting work. In the easiest cases, you may be able to upgrade the panels without seriously disturbing the

interior finish and systems. In other cases, you may have to remove wallboard and move piping and equipment. The cost and feasibility of the modification are determined largely by whether you can remove and replace the panels without other expensive work.

Judging Whether Retrofit is Feasible

The first step is to examine the wall construction in detail to see how it is put together. Study the architectural details drawings (shop drawings) of the wall structure.

This will tell you how much insulation you can add, and how much effort is needed to take the wall apart.

Examine the mechanical and electrical drawings to find out if there is equipment that will interfere with modifying the wall panels.

If your examination of the drawings suggests that it may be feasible to upgrade the wall panels, select one or more representative areas of the wall as test subjects. Completely remove the curtain panels from these areas, and visualize the steps needed to make the changes. This

WESINC

Fig. 2 Curtain wall upgrade The original exterior, above, was replaced with the one below. Although they appear similar, the new curtain wall has much better insulation value and somewhat less glazing area. The improvement made it possible to abandon the original perimeter heating units, rather than replacing them.

will allow you to calculate the cost of the modification with some precision.

Insulation Types to Consider

In most applications, the appropriate type of insulation is glass or mineral fiber. Avoid plastic foam insulation because of the fire hazard. This is true even if the insulation is encapsulated within the panel. In a fire, plastic foam inside a sealed panel will melt, boil, and blow out the panel.

Panel Insulation Design

In most cases, you will want to fill the panels entirely with insulation to maximize the thermal benefit and to avoid convection.

Make sure to avoid moisture problems. See [Reference Note 42](#) for the important issues. In summary, you need an impermeable surface on the warm side of the insulation and moisture vents on the cold side. In a humid climate where heating and cooling alternate, vent both sides of the insulation and use panel materials that resist moisture damage.

Seal the Panels to the Structure

Stop air leakage at the edges of the panels, using a method that will survive as long as the building itself. Relatively small air leaks can wipe out much of the benefit of the insulation. If necessary, use the modification to improve the design of the panel sealing system. Replace aged and defective sealing components.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics, about calculating the optimum amount of insulation. In most cases, the best approach is to install as much insulation as the existing structure allows.

Consider Other Improvements at the Same Time

In many curtain wall buildings, it makes sense not only to improve the R-value of the opaque wall components, but also to replace superfluous glazing with insulated panels. There is no type of glazing that has an insulation value even close to the R-value of a well-insulated opaque panel. Therefore, reducing the glazing area may substantially reduce heat loss. Also, reducing the area of glazing that is exposed to sunlight greatly reduces solar heat gain, which is the strongest component of cooling load. See [Measure 8.1.5](#) about this.

At the same time, consider other improvements. Consider installing windows that can be opened. Consider sun shades. And so forth. This is a major opportunity for creativity.

WESINC

Fig. 3 Curtain wall clips The clip on the right held the original curtain wall panels in Figure 2. The clip on the left is for the new panels. There is a mature industry that is capable of making all the necessary components for replacement curtain walls.

ECONOMICS

SAVINGS POTENTIAL: 60 to 90 percent of the heat loss and/or heat gain through the wall.

COST: In new construction, the cost for additional insulation may be \$0.50 to \$1 per square foot. In retrofit, the cost of replacing the curtain wall panels may range from \$20 to \$40 per square foot.

PAYBACK PERIOD: In new construction, the payback period for improved insulation may be relatively short. In retrofit, the payback period is many years. Consider the value added to the building by the improvement in appearance.

TRAPS & TRICKS

BE CREATIVE: Let your imagination roam free. This is the place to fix the flaws of modern envelope design. Even in retrofit, consider improving the windows, reducing their size, and adding sun shades. Design for effective sealing against air leakage and effective rain shedding. This improvement may radically reduce heat loss and heat gain through the walls, giving you an opportunity to eliminate or modify the perimeter conditioning systems. Make the building beautiful. Some inexpensive detailing on the exterior surfaces can make the building a showpiece.

INSTALLATION: Installation details are important for avoiding air leakage. Be actively involved in removing and installing the panels.

Subsection 7.3

Glazing Insulation

Glazing is responsible for much more heating load and much more cooling load, per unit of surface area, than other envelope components. Glazing includes windows, skylights, glass enclosures, glass doors, and any other transparent or translucent surfaces. Modern buildings tend to have large amounts of glazing, and therefore to have high energy loads from heat loss and heat gain.

The Measures in this Subsection reduce the heat loss of glazing during cold weather. The Measures of [Subsection 8.1](#) reduce the heat gain of glazing. In many environments, it is important to reduce both heat gain and heat loss. For such cases, consider the Measures in this Subsection and in [Subsection 8.1](#) together. Glazing improvements are expensive, so you want to optimize both aspects at the same time.

MEASURE 7.3.1 Install high-efficiency glazing.

RATINGS

New Facilities	Retrofit	O&M
B	C	D

Installing high-efficiency windows, skylights, and other glazing is a powerful energy conservation measure because it can eliminate several major causes of energy waste. The heat loss of the best contemporary glazing

is only a fraction of the heat loss from glazing that was conventional several decades ago. Before making any changes, consider all your options for improving the windows. See [Measure 8.1.3](#) for the full story.

MEASURE 7.3.2 Install storm windows or supplemental glazing.

RATINGS

New Facilities	Retrofit	O&M
D	C	D

A common way of reducing both heat loss and air leakage through windows is installing supplemental windows, or “storm windows,” outside the existing windows. A typical installation is shown in Figure 1.

A less common method is installing supplemental glazing inside the existing windows. This method is usually more efficient, and it may be easier to install in some cases. Figure 2 shows the features of a window with removable interior glazing.

SUMMARY
 A retrofit measure primarily for buildings with single-glazed windows. Substantially reduces heat loss and air leakage.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%		
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

ASHRAE

Fig. 1 Storm window A storm window will approximately double the insulation value of a single-glazed window, if it is installed properly. It is not as effective as installing new windows, but it is much less expensive. This version has a movable pane for ventilation, which is generally not a good idea in storm windows.

Energy Saving Potential

■ **Conductive Heat Loss**

The thermal resistance of a window depends mostly on the number of panes. Adding one additional pane to a single-pane window more than doubles the insulation value of the window, cutting heat loss to less than half.

Most of the thermal resistance of a pane of glass results from an air layer that attaches itself weakly to each surface of the glass. With a single-glazed window, both the inner and outer air layers are weakened by wind and air currents. If you add a second pane, you create two additional air layers that are well protected. A single-glazed window has an R-value that varies around 0.8. Adding a supplemental window increases the total R-value to about 2.0. You can make similar calculations for any other combination of original and supplemental glazing. Refer to [Measure 8.1.3](#) for the details.

■ Air Leakage

Supplemental glazing eliminates all or most window air leakage, whether caused by wind, building pressurization, or chimney effect.

Exterior or Interior?

At present, the most common type of supplemental glazing is single-pane “storm windows” that are installed outside the existing windows. The prevalence of this type is due to the fact that they have the lowest installed price. Price is a dominant consideration in the residential market where storm windows are usually sold.

There is no inherent reason to limit supplemental glazing to residential applications or to single panes. In locations that have a significant amount of cold weather, consider double-pane supplemental glazing, even when the existing windows are double-glazed.

Also, there is no inherent reason why supplemental glazing must be installed outside the existing windows. On the contrary, installing supplemental glazing from the inside offers an efficiency advantage. The advantage stems from the fact that internal supplemental glazing does not have to be vented to prevent condensation. If the existing windows are very leaky, installing supplemental glazing inside the existing windows may be the only method that avoids serious condensation.

Both internal and external installation require careful fitting of the supplemental glazing to the existing window frame or to the adjacent wall.

How to Prevent Condensation

Condensation is a potential problem with any window that has more than one pane. If the air inside the building can leak past the inner pane, the moisture it carries may condense on the outer pane during cold weather. The condensation is unsightly and causes moisture damage. If the temperature is low enough, frost forms on the inside of the outer pane, obscuring the view.

To avoid condensation, be sure that the inner pane has substantially less air leakage than the outer panes. Stated differently, the outer panes must have significantly more leakage than the inner pane. If this condition is met, any moisture that makes its way between the panes will vent to the outside before it reaches a concentration high enough to condense. For this reason, externally mounted storm windows have small vent holes at the bottoms of their frames. This is also a reason why it is better to install supplemental glazing on the inside of existing windows that are leaky.

The same principle applies with any number of panes. Each pane must be sealed more tightly than the one outside of it. If the window ends up with more than

WESINC

Fig. 2 Corner of window with interior removable glazing
The inner pane is held in place by the clips. The hole at left vents the space between the panes to the outside. These windows were installed as part of the original construction. Nowadays, in new construction, you would select a sealed double-glazed window. However, this arrangement shows the features that are important when retrofitting interior supplemental glazing.

two panes, you must vent each air space to the outside. As an alternative, you can install a sealed multiple glazing unit as the inner glazing. The second approach has greater efficiency potential, but it is heavier and more expensive.

The vent holes in external storm windows cause some loss of efficiency, but the penalty is fairly small. If the vent holes are kept small, air currents do not disrupt the air layer that is attached to the inside surface of the glass, which is the source of windows' insulation value. By the same token, the vent holes must be at the bottom of the frame so that convection currents will not arise in the space between the panes. Even if the original windows are leaky, the vent holes are so small that they do not allow much air leakage.

How to Provide Ventilation

Supplemental windows interfere with opening the original windows for ventilation. There are two ways to keep the ability to open the windows.

One way is to remove the supplemental windows seasonally. This requires labor and storage space. It also requires a removable frame system for the supplemental windows. Such systems invite a considerable amount of air leakage unless the supplemental windows are sealed carefully every time they are reinstalled.

The other way is to install supplemental windows that can be opened themselves. Such storm windows are usually unsatisfactory. Storm windows are light and flimsy in order to be competitive in cost with total window replacement. Openable versions soon become deformed to the point that they cannot close properly, which makes them worthless. Occupants find it clumsy to manipulate both the original window and the storm window. Hence, occupants become the agents of the demise of the storm windows.

Another possibility is abandoning the ability to open all the windows. For example, supplemental glazing may be installed on all the windows, except for two windows at opposite ends of the space that are left to provide cross ventilation.

Windows that open for ventilation require insect screens. Either install supplemental windows that do not interfere with the screens of the original windows, or install supplemental windows that have their own screens. Screens should be easy to remove and they should fit securely. Many commercial units lack these qualities.

How to Install Supplemental Glazing

The effectiveness of supplemental glazing depends on eliminating leakage all around the edges. This requires snug contact between the edges of the supplemental glazing and the frame of the original window. If necessary, insert weatherstripping or filler pieces between the two frames. But, make sure that the small vent holes at the bottom of the frames remain open.

If you install supplemental glazing inside the original windows, fit it to the existing window frame or to the adjacent area of the wall. If you expect to remove the supplemental windows seasonally (to allow opening the primary windows), spend some time designing a gasket surface that will remain effective as the supplemental glazing is reinstalled each season. Also, you need to design secure clips to hold the gaskets snugly. In most cases, the easiest approach is to install a jamb for the supplemental windows inside the existing window frame.

Comparison to Total Window Replacement

All the Measures of this Subsection are potential alternatives to supplemental glazing. In a majority of applications, the choice is between adding supplemental glazing and replacing the existing windows. (But, don't ignore the other possibilities.) Between these two alternatives, the main advantages of supplemental glazing are lower cost and relatively easy installation, without major disruption of normal activities.

Supplemental glazing is not able to provide the same efficiency as the best modern windows, which exploit tight sealing, insulating gases, infrared reflecting films, and other features. The efficiency advantage of primary windows has increased substantially in the past two decades as a result of new technology, and their efficiency advantage continues to grow. Refer to [Measure 8.1.3](#) for details.

Total window replacement avoids the problem of seasonal removal of supplemental glazing. It also provides the opportunity for improving the appearance of the building.

ECONOMICS

SAVINGS POTENTIAL: *About 35% to 65% of conductive heat loss, depending on the number of original panes and the number of supplemental panes. Supplemental glazing can eliminate most heat loss due to air leakage.*

COST: *\$100 to \$300 per window, for windows of typical size.*

PAYBACK PERIOD: *5 to 15 years.*

TRAPS & TRICKS

CHOICE OF METHOD: *Supplemental windows are expensive, somewhat unattractive, and clumsy to open. Before deciding to use this approach, consider completely replacing the windows ([Measure 7.3.1](#)), replacing the windows with insulating panels ([Measure 7.3.3](#)), or if you are an innovator, installing thermal shutters ([Measure 7.3.4](#)). Whichever approach you choose, consider the need to open the windows and to install reliable insect screens. Decide in haste, and you may repent at leisure.*

SELECTING THE EQUIPMENT: *Commercial storm windows are rarely as rugged as they should be. Openable storm windows would have to be as rugged as regular windows in order to survive. With removable storm windows, examine how well the sealing system will survive 10 or 20 years of use. Use only aluminum alloy frame materials, as plastic will crack within a few years.*

MEASURE 7.3.3 Reduce the area of glazing.

A powerful method of reducing the high heat loss of windows is to replace all or part of the window area with insulating panels. It is easy to fabricate panels that have much better insulation value than windows. This approach is widely applicable because of the excessive

use of glazing in modern architecture. Obviously, this modification has a major effect on the appearance of the building, and it has other advantages and disadvantages.

Refer to [Measure 8.1.5](#) for the full story.

MEASURE 7.3.4 Install thermal shutters.

“Thermal shutters” and “movable insulation” are general terms for methods of insulating windows and skylights during hours of darkness. The concept of thermal shutters first gained prominence in the context of passive solar heating, which requires large expanses of glazing. Thermal shutters prevent the serious heat loss that the passive solar collectors suffer at night.

Thermal shutters are especially important with non-vertical glazing, which has substantially lower thermal resistance than similar glazing would have if installed in a vertical orientation.

Thermal shutters are a novelty, still more of a concept than a practical type of equipment. Many configurations are possible, and none is yet free of major disadvantages. Use [Reference Note 47](#), *Passive Solar Heating Design*, as a design guide.

At this point in time, start by considering thermal shutters in the form of rigid external panels, which may be moved in a variety of ways. This general type offers high insulation value, requires only simple materials and fabrication techniques, and is easiest to seal against air leakage. On the other hand, large panels are clumsy to manipulate. If a panel is designed to pivot away from the glazing, it must be constructed and mounted very strongly to resist wind.

Security Benefit

Thermal shutters can provide effective security for buildings that are left unoccupied, such as seasonal warehouses. With little additional effort, thermal shutters can be made an effective barrier to human entry.

SUMMARY

Still more of an innovative concept than a practical reality. Can radically reduce heat loss. May also be an effective security measure.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%		
Rate of Return, Retrofit	%	%		
Reliability	✓	✓		
Ease of Retrofit	😊			

They also protect the glazing and building interior against hail damage and strong winds.

Comparison with Storm Windows

The most direct competition to thermal shutters is supplemental glazing ([Measure 7.3.2](#)). Thermal shutters have the advantage of much higher insulation value in the closed position, while supplemental glazing provides its insulation benefit at all times. As noted before, thermal shutters can be used to provide security if they are designed for this purpose.

The relative disadvantages of thermal shutters are higher cost, the need for custom engineering, the need to operate the thermal shutters on a daily basis, and odd appearance.

ECONOMICS

SAVINGS POTENTIAL: 60% to 80% of heat loss through the affected glazing.

COST: From several hundred dollars to several thousand dollar per window or skylight.

PAYBACK PERIOD: Expect the payback period to be longer than ten years, in both new construction and retrofit, until standardized shutter units are developed.

TRAPS & TRICKS

DESIGN: Thermal shutters are at the frontier of efficient building design. Anyone can come up with a variety of designs. The challenge is to design thermal shutters that are practical. They should be durable, they should continue to seal tightly over the years, they should open and close easily, they should not be too difficult to install, and they should not be too ugly.

MEASURE 7.3.5 Use window films that reflect heat back into the building.

Retrofit window films are primarily a device for reducing cooling load. Some types of films offer a secondary advantage of reducing heat loss. They accomplish this with a low-emissivity (“low-E”) coating that faces the interior of the building. The coating reflects the long-wavelength infrared radiation that is emitted by the warm interior of the building. Without the coating, this heat radiation would be absorbed in the glass, and a certain fraction of the heat would be lost to the outside by conduction.

In the past, low-E coatings were offered as an optional feature of films sold primarily to reduce solar

heat gain. Now, some low-E films are being marketed primarily for reducing heat loss. Unfortunately, the benefit of such films is too limited to make them economical for this purpose alone. This is because heat radiation from the interior of the building represents only a small fraction of total heat loss. Other techniques, such as supplemental glazing, are much more effective for reducing heat loss. However, if you are considering window films for reducing the cooling load, consider the low-E option also.

See [Measure 8.1.4](#) about the full range of window film types, including their heat reflecting properties.

Section 8. CONTROL AND USE OF SUNLIGHT

INTRODUCTION

This Section deals with sunlight, both as a source of unwanted cooling load and as a potential energy source for daylighting and heating.

The most glaring deficiency of modern architecture is failure to deal with the enormous amount of energy that falls on buildings in the form of sunlight. This amount of energy is enough to satisfy all or most of a typical building's energy requirement. At present, much of this potential is unavailable because of a lack of certain critical equipment, and because of the high cost of using available methods and materials. However, a large fraction of the solar energy that could be tapped economically with current technology is being overlooked, while careless architectural design allows too much uncontrolled sunlight into the building. The penalty paid by building owners for the first oversight is purchasing energy that could be obtained free. The penalty paid for the second oversight is purchasing still more energy to eject the unwanted solar energy.

Sunlight is a difficult energy source to harness. It is thinly distributed. It varies continuously in location and intensity. It is unavailable half the time, and it cannot be stored. Even during the daytime, it is unreliable. Using sunlight for one purpose, such as heating, may be difficult to reconcile with using sunlight for another purpose, such as lighting. As a result of these vexing characteristics, contemporary building design has thrown up its hands and ignored sunlight.

Nonetheless, a great deal of research and conceptual design relating to solar energy has been done, and there have been a few periods of intense commercial promotion. Specialized areas of interest have evolved from this experience, each with its own theory and methods.

SUBSECTION INDEX

**8.1 REDUCING COOLING LOAD:
WINDOWS & SKYLIGHTS**

**8.2 REDUCING COOLING LOAD: OPAQUE
SURFACES & OVERALL**

8.3 DAYLIGHTING

8.4 PASSIVE SOLAR HEATING

The applications of solar energy that are summarized under the following headings deserve your attention in current and foreseeable building applications. This Section covers the application areas that are introduced under the first three headings. These three areas are grouped in this Section because of their heavy interaction with each other, and with the adjacent [Section 7](#) (envelope insulation) and [Section 9](#) (electric lighting). The remaining four application areas are summarized in [Reference Note 23](#), where they are grouped with other “free” energy sources. These last four areas do not require difficult interactions with the building envelope design.

■ Reducing Solar Cooling Load

Ironically, the most important energy conservation aspect of solar energy for many buildings is keeping sunlight out. Since the advent of modern architecture, with its vast expanses of bare glazing, designers have failed to deal effectively with the enormous increase in cooling load that is caused by such design. As a result, reducing solar cooling load is a top priority for heavily glazed buildings, even those located in cooler climates. Consider almost any building as a candidate for the Measures that reduce solar cooling load, even if it has only a modest amount of glazing.

Reducing solar heat gain is covered by [Subsections 8.1](#) and [8.2](#). Most of the methods given in these two Subsections are fairly well proven, although some of them need to be applied more intelligently than is common in contemporary architecture. In new construction, you can always design the building to control cooling load effectively at modest cost, although ideal control may be beyond reach. In retrofit, your choices are much more limited, and the economics are not as favorable.

All methods of controlling solar gain must be tailored closely to the structure and its surrounding conditions. Failure to provide this attention, rather than cost, has been the reason why this important area has been neglected.

The effect of cooling load on electric utilities has made this aspect of solar energy even more important to facility owners from an economic standpoint. Air conditioning causes generating loads that are large and of short duration. It is uneconomical and troublesome for electric utilities to satisfy such a demand profile. Utilities respond

by creating strong financial incentives for reducing cooling loads. These include severe demand charges and providing subsidies for customer activities, such as installing thermal storage, that reduce cooling load. (See [Reference Note 21](#), [Electricity Pricing](#), for an explanation of electricity demand charges.)

■ Passive Solar Heating

In contrast with the previous, the objective of passive heating is to bring a large amount of solar heat into the building. The term “passive” solar heating contrasts with “active” solar systems, which collect solar heat outside the building and move it indoors. Passive solar heating is covered by [Subsection 8.4](#).

The energy density of sunlight is sufficient to satisfy all or most of the heating requirements of typical buildings. However, passive solar heating has virtually never been successful in contemporary architecture. The main challenge is not collecting the heat, but avoiding adverse side effects.

Practical passive solar is probably just within reach for new construction, but it requires much more than the usual amount of brain work to design. In most existing buildings, you can exploit passive solar heating only to a limited extent.

■ Daylighting

The amount of sunlight falling on a building, even on a cloudy day, is theoretically sufficient to provide all lighting requirements. The practical challenge is distributing sunlight throughout the building. At present, daylighting is limited to perimeter areas and to interior areas that can be served by skylights. New methods and equipment are needed to approach the full potential of daylighting in all buildings.

Daylighting design is exceptionally complex, but this fact is not yet recognized. The result is that most contemporary attempts are failures. Daylighting must be integrated with control of solar gain, with passive solar heating, with control of artificial lighting, and with esthetic considerations. Each of these is complex in itself, and combining all of them effectively is a mind bending challenge.

[Subsection 8.3](#) offers a limited number of daylighting Measures that you can accomplish without making a career of the subject. See

[Subsection 9.5](#) for the methods that you need to control electric lighting in response to daylighting.

■ Active Solar Space Heating

From a design standpoint, collecting sunlight with an active solar system is relatively simple. This is because an active solar system has no effect on direct solar heat gain into the building, and it has no effect on daylighting. The main problem is equipment cost, which is high in relation to the value of the energy that is recovered. Governments heavily subsidized the development and installation of active solar space heating during the 1970's and 1980's.

Unfortunately, this epoch served mainly to demonstrate that active solar systems have a poor rate of return, in terms of both economics and energy recovery. Most active solar systems have not survived long enough to break even. This dismal record is not just the fault of the weak energy content of sunlight. There is something about solar energy that causes people to underestimate its practical requirements, leading to failures from sloppy design, installation, and maintenance.

■ Active Solar Heating of Domestic Water and Process Applications

Using solar collectors for low temperature process heat recovery may be much more economical than using solar collectors for space heating. Low-temperature process applications allow solar collectors to collect more heat, they use collector capacity more economically, and they do not need an expensive distribution system.

■ Solar Cooling

To date, solar cooling systems have consisted of active solar systems driving conventional absorption cooling machines. Thus, their economics are even worse than the economics of active solar heating. Solar cooling probably cannot become practical until someone invents a cheaper method of getting cooling from sunlight.

■ Photovoltaic Electricity Generation

Photovoltaic electricity generation is well proven technically. It is widely used in specialized remote applications. Also, many demonstration

sites have proven that it can be technically successful in large arrays. It is simple and reliable. Unfortunately, it is not yet efficient enough or cheap enough to provide energy for typical building and plant applications. However, there is promise of major improvements in both areas.

How to Use Section 8

Go to [Subsections 8.1](#) and [8.2](#) to reduce the cooling load of almost any building. Even if your building does not have mechanical cooling, the Measures in these Subsections will improve comfort during warm weather.

[Subsections 8.3](#) and [8.4](#) exploit sunlight for illumination and for heating, respectively. Be prepared to get deeply involved with these subjects if you want to exploit them effectively. You are on the frontier of building design when you exploit daylighting and passive heating.

The Measures of this Section have a high degree of interaction with each other, even from one Subsection to another. Before you commit to any of them, identify all the Measures that apply to each situation. Then, apply them in a coordinated way.

Before Getting Started ...

Since this Subsection is all about sunlight, start by reading [Reference Note 24](#), Characteristics of Sunlight.

Before you start with daylighting, review [Reference Note 46](#), Daylighting Design, and [Reference Note 51](#), Factors in Lighting Quality.

If you want to plunge into passive heating, read [Reference Note 47](#), Passive Solar Heating Design.

NOTE FOR READERS IN THE SOUTHERN HEMISPHERE

To keep the discussion simple, compass directions in the text assume locations in the northern hemisphere. The corresponding situations for the southern hemisphere are obvious. Simply substitute "south" where the text says "north," and vice versa.

Reducing Cooling Load: Windows & Skylights

Control of solar heat gain has always been a blind spot of Western architecture, but architectural practices in recent decades have made this oversight a major cause of energy waste. In the past, limited window size, massive walls, and tall ceilings were able to limit overheating without the expense of cooling. However, the vast expanses of unshaded glazing in modern architecture make cooling a major building operating cost. By the same token, the popularity of mechanical space cooling allowed architects to remain oblivious to the problems caused by their extravagant use of glazing. As a result, a large fraction of modern buildings are candidates for improvement.

The heat content of direct sunlight is about 240 BTU per hour per square foot (about 0.7 kilowatts per square meter), measured perpendicular to the direction of the sunlight. Vertical glazing oriented east, west, or south receives roughly 1,000 BTU per square foot (about 3 kilowatt-hours per square meter) per day in clear weather. This figure applies to all middle latitudes, and it does not change much as the seasons change.

As a result, in warmer climates, reducing the cooling load is the most important energy conservation measure related to glazing. Even in northern climates, heat gain through glazing may cause a large fraction of annual energy costs, especially in heavily glazed buildings. In recent years, electricity demand charges have risen steeply as utilities seek to avoid building new power plants. Solar cooling load typically is the largest cause of high electricity demand charges in commercial buildings.

INDEX OF MEASURES

[8.1.1 Install external shading devices appropriate for each exposure of the glazing.](#)

[8.1.2 Install internal shading devices.](#)

[8.1.3 Install high-efficiency glazing.](#)

[8.1.4 Install solar control films on existing glazing.](#)

[8.1.5 Reduce the area of glazing.](#)

RELATED MEASURES:

- [Measure 8.2.4](#), tree shading, which can be an effective method of shading windows
- [Measure 8.3.2](#), light shelves, which must be integrated with exterior or interior shading devices
- [Section 4](#), for modifications to air handling systems to make them respond more efficiently to reduced cooling load
- [Subsection 6.3](#), for reduction of air leakage through windows
- [Subsection 7.3](#), for reduction of conductive heat loss through glazing

From a practical standpoint, this is an important area of conservation because feasible methods exist to reduce solar heat gain in virtually all types of buildings. However, be careful. You may have to use unfamiliar methods, and unfamiliar methods may cause unexpected adverse effects.

Selecting a method of controlling sunlight is complicated by interactions with other important issues that involve glazing, including:

- **building heat loss.** If clear glazing is replaced with reflective glazing to reduce heat gain (Measure 8.1.3), the glazing can also be selected to reduce conductive heat loss during cold weather. Reducing the amount of glazing (Measure 8.1.5) may radically reduce both heat gain and heat loss. Other sunlight control methods offer only a minor improvement in heat loss.
- **passive heating.** Reducing solar heat gain during warm weather also reduces beneficial solar heating during cold weather. You can design shading (Measures 8.1.1 and 8.1.2) to reject sunlight during warm weather and to allow it into the building during cold weather. Other contemporary sun control methods do not provide this option.
- **daylighting.** All methods of reducing solar heat gain reduce the amount of visible sunlight. External shading (Measure 8.1.1) is the only method of reducing cooling load that can be combined with effective daylighting.
- **view.** Glazing treatment (Measures 8.1.3 and 8.1.4) and some types of external shading (Measure 8.1.1) may improve occupants' view. Other sun control methods interfere with view to some extent.
- **appearance.** Virtually anything you do to improve the efficiency of glazing affects the appearance of the building. If executed well, these Measures may substantially improve the appearance and value of the building. But, if you don't pay enough attention to appearance, you can make the building ugly.

As you can see, good sun control tries to kill several birds with one stone. This requires a great deal of thought and study. The responsible approach is to reduce the solar cooling load while exploiting other opportunities to conserve energy while

minimizing adverse effects. Daylighting and passive heating are covered in Subsections 8.3 and 8.4, respectively. Consider all the Measures of Section 8 together if you want to push efficiency to the economical limit.

With all methods of reducing cooling load, an important guideline is to stop sunlight as far outside the space as possible. Once sunlight is absorbed, it becomes heat, which requires cooling energy to remove. External shading is the most efficient method of blocking sunlight, and internal shading is the least efficient. If you use coatings on glazing to reduce heat gain, install the coatings on the outer surfaces as much as possible. If you use internal shading devices, keep them close to the glazing.

Expect to customize your sunlight control methods to each orientation of the glazing, and also to localized shading conditions. Reference Note 24, Characteristics of Sunlight, explains how the sun moves through the sky. The way the sun moves with respect to each face of the building determines the techniques that you should consider for each face. This depends on the orientation of each face and the latitude of the site. The weather profile is also an important factor. If the sky is usually clear, you want different shading techniques than if the sky is usually cloudy. The yearly temperature profile is also a primary factor.

Big money is at stake with these Measures if a building has much glazing. Make accurate estimates of savings and costs. Sunlight is a complex energy source and shading interacts with other aspects of conservation, so consider using an energy analysis computer program to make your estimates. See Reference Note 17 if you are unfamiliar with these programs.

Finally, make sure that the building's HVAC equipment will respond efficiently to improvements in glazing. If the HVAC system uses reheat for temperature control, glazing improvements will fail to yield the anticipated benefits. Refer to Section 4 for Measures to improve the efficiency of such systems.

All the Measures of this Subsection are alternatives to each other, and each has major advantages and disadvantages. Tree shading, recommended by Measure 8.2.4, shades both glazed and opaque areas of the building. Consider it along with the Measures in this Subsection.

MEASURE 8.1.1 Install external shading devices appropriate for each exposure of the glazing.

Well planned external shading is the most effective method of reducing solar heat gain. In addition, it offers possibilities for incorporating daylighting and passive heating. Some types of external shading interfere with view, while other types make it possible to exploit view that would otherwise be impossible because of solar glare.

External shading is much easier to integrate into the design of a new building than it is to retrofit. External shading has a major effect on the appearance of the building, and it must be anchored strongly to the building structure to resist wind loads. In retrofit, both of these factors are serious challenges.

Each face of a building requires a different shading treatment because sunlight strikes each side from different angles. A south face is best shaded with horizontal shading. East and west faces require shading that blocks sunlight entering at low angles. A north face can often be left unshaded.

Where to Consider External Shading

External shading is useful in almost all situations where direct sunlight through glazing increases the cooling energy requirement substantially. Shading can be adapted to virtually all sizes of windows and skylights. The most common limitations are high cost and the effect on the building’s appearance.

If an existing building has glass that is treated to reduce solar heat gain, adding external shading is not likely to be economical from the standpoint of energy efficiency. External shading does reduce the temperature of the glass, improving comfort in some cases. (Exposed absorptive glass may become quite warm in the absence of wind.) See [Measure 8.1.3](#) for details.

Energy Saving Potential

Effective external shading blocks all or most direct sunlight, although it admits indirect light from the sky. It typically reduces solar heat input by 80% to 90%. In buildings where solar load dominates the cooling requirement, shading may reduce a building’s total cooling load by as much as half.

In new construction, this large reduction of cooling load may allow the capacity of the cooling equipment to be reduced by a similar amount. The saving in cooling equipment cost may pay for the shading, or a large part of it.

SUMMARY

The most effective method of controlling solar heat gain. Each orientation must be designed separately. All new buildings should have it. In retrofit, it is expensive and often impractical.

Shading Methods

External shading is a general technique that you can accomplish with many different types of hardware or architectural features. Shading may be fixed or movable. These are most of the types of external shading that you will encounter today:

- **projecting horizontal shelves.** These can be a primary method of shading south faces. They have little value elsewhere. They must be built into the building’s structure, and hence they are limited to new construction. To be effective, they must be much wider than the windows, in the direction along the wall, to account for the sun’s motion from east to west. Typically, they are installed above the level of the windows, as in Figure 1. If the windows are closely spaced, shelves typically are installed along the full width of the south face. They are vulnerable to strong wind forces, and in northern climates, to snow loads. Smaller shelves can also be built into tall windows at various levels, as in Figure 2.
- **balconies.** These have the same effect as horizontal shelves, but more so. They are deep enough to provide significant shading even if they do not face in a southerly direction. Figure 3 shows a variety of examples. They provide major additional value as usable space and as an ambiance feature. The shelves in Figure 1 also serve as balconies. They are limited to new construction.
- **eaves and overhangs,** which can provide effective shading for the floor level directly under the eave. They merit strong consideration as shading devices,

and they can provide major additional value in protecting the wall finish and reducing below-grade moisture problems. Figure 4 shows a typical residential installation, and Figure 5 shows an installation for a public library. They are limited to new construction.

- ***inset windows***. In effect, the entire wall acts as a shading device around the window, as shown in Figure 6. This is obviously a feature that is limited to new construction. It is usually done as a stylistic element, rather than as a rational approach to controlling sunlight. As a method of shading, it is very expensive and wasteful of occupiable space. However, it can be effective if it is used properly, namely, on southerly exposures at low geographic latitudes.
- ***fixed louvers*** may be useful on any exposure of a building, except north. The best orientation for the louver blades depends on the direction that the glazing faces. On the south side, the blades should be horizontal. For the north side, louvers are vertical. For other directions, they may be tilted. Louvers can be arranged in a horizontal array, like a shelf. Figures 7, 8, and 9 show examples. Or, they can be arranged in a vertical array, like a venetian blind. Figures 10 and 11 show examples. Or, they can be installed at an angle, like an awning. Figures 12 and 13 show examples.

The choice of installation geometry depends on the issues discussed below, and perhaps on additional considerations, such as using the shading devices as storm shutters.

Louver blades can take many forms, including flat blades, airfoil shapes, and egg crates. They are easier to install than shelf-type shading because they have less wind resistance and they accumulate less snow load. Therefore, they can be much lighter and easier to attach. They can be attached to the wall, as in Figure 14, or they can be mounted on columns that carry their weight to the ground, as in Figures 9 and 15.

Louvers interfere with the view if they are installed in the line of sight, but they may not block the view entirely. For example, a vertical stack of horizontal louvers in front of a window interferes with the view upward and horizontally, but they are not too bad when viewing downward.

- ***vertical fins*** are useful for shading north faces from summer sunlight early and late in the day. Figure 16 shows a building with fins molded into the wall surface.
- ***awnings***, which project downward over the windows. Figure 17 shows a typical installation. These may be fully effective on south faces, and provide partial shading of windows on east and west faces. A common mistake is making awnings to fit

Fig. 1 Horizontal shelves These can be every effective for reducing cooling load on the south side of a building. As seen here, sunlight gets under the shelves on other orientations. These also serve as balconies, a nice touch that is rare in office buildings. They make window washing much easier, protect the glazing, and protect the surroundings from falling glass.

the width of the window. Such awnings are too narrow, allowing an excessive amount of sunlight to enter from the sides.

- **miniature fixed-louver materials** are supported in frames and installed directly over glazing. They are useful on all faces. One product is made from aluminum sheet punched to create tiny louvers. Another product consists of tiny bronze strips woven into a louver with wires. Within limits dictated by the manufacturing process, the manufacturer may offer a variety of louver spacings and tilt angles. Some fixed louver materials can be

Vistawall Architectural Products

oriented vertically for use in east-west shading, or to any other angle.

- **mesh materials** are loose weave fabrics made of materials such as glass fiber and plastics. They are largely non-directional, although some directional characteristics can be achieved by altering the pattern of the weave. The principal merit of these materials is low cost.
- **movable louvers**, which operate like venetian blinds. They are expensive because they must be rugged enough to survive the outside environment. They may be controlled manually or with sun tracking controls. Movable louvers can be installed in any orientation for shading of any face.
- **roll-up external blinds**, which typically are made of aluminum. These are widely used in Germany, for example. They provide security as well as sunlight control. Like internal roller shades, they are non-directional, and they do not offer good lighting quality.

Design and Selection Issues

Exterior shading requires more thought and innovation than most energy conservation techniques because you have many choices, but not a well established doctrine for using them. A wide variety of prefabricated shading devices have appeared on the market. For most applications, external shading is fabricated on a custom basis by a manufacturer who specializes in particular materials and fabrication techniques. Shading devices can be made from metal, wood, fabric, or any opaque material. There are well established companies that can fabricate almost anything you want, but they cannot tell you the best solution for your building. You have to design the installation. As you do, consider the following factors.

■ Shading Effectiveness

Simply hanging shading devices over windows may not provide much benefit, as shown in Figure 18. Overall shading effectiveness depends on the performance of the device at all sun positions. For example, a window awning on a south face may provide complete shading at noon, but poor shading in the morning and afternoon.

■ Effect on View

Shading always blocks a part of the view. As a minimum, it blocks the portion of the sky where the sun travels. On south faces, you can usually arrange window shading in a way that preserves the view of the surrounding landscape. On east and west faces, fixed shading may eliminate the view toward the south, or they may limit the view to a downward angle. Movable shading on the east and west can restore views during the portion of the day when the sun is on the other side of the building.

WESINC

Fig. 3 Balconies Buildings in this summer resort use many kinds of balconies to reduce the cooling load and to provide pleasant space for occupants. These buildings face the ocean toward the east, so the balconies are effective for controlling sunlight mainly around the middle of the day.

■ Daylighting Potential

External shading provides the potential of daylighting in perimeter areas, provided that the shading never allows direct sunlight to fall inside the space. If the shading method allows direct sunlight to enter the space even occasionally, occupants will resort to closing curtains or blinds. Daylighting is difficult to accomplish effectively, and it requires automatic light switching. See [Subsections 8.3](#) and [9.5](#) for details.

WESINC

Fig. 4 Eaves and porches Roof overhangs have long been used to keep buildings cool in warm climates. The trees help, also.

WESINC

Fig. 5 Roof overhang The shadow pattern shows that the roof overhang of this library is effective in keeping direct sunlight out of the windows. The open windows show that natural ventilation is cooling the building, assuming that the air conditioning has been turned off.

Fig. 6 Inset windows The shadow patterns show that deeply inset windows reduces solar heat gain. However, it cannot create satisfactory daylighting by itself.

■ Passive Heating Potential

Early in the project, read [Reference Note 47](#), *Passive Solar Heating Design*. Effective shading kills passive heating. You can reconcile shading and passive heating by moving or removing the shading device when passive heating is desirable. For example, movable louvers and roller blinds provide shading when needed while allowing passive heating at other times.

On the south face of a building, you can achieve passive heating even with fixed shading. This is an important opportunity. The sun's path through the sky is much lower in winter. As a result, you can design horizontal shading over southerly windows so that it shades the windows in summer but allows sunlight to enter in winter. This fact has long been exploited in the architecture of various cultures, including pueblo Indians and the Zulu. For example, at a latitude of 40° (Philadelphia, Denver, Beijing, Madrid, Ankara, Wellington), the noonday sun is about 70° above the horizon in the middle of summer, while the noonday sun is about 30° above the horizon in the middle of winter. See [Reference Note 24](#) for more about solar motion.

You can shade south faces either with a single shelf installed over the window, or with a set of louvers in front of the window. If you use a single shelf, it must project outward a distance that is proportional to the height of the windows. Therefore, this method is easiest to accomplish with windows that are not tall. In new construction, you can exploit this shading possibility by installing balconies along the south face.

Fixed shading used in this manner gives only crude control of solar heat input. It cannot adjust to changes in the intensity of sunlight or to internal heat gains. Also, the outside temperature lags behind seasonal solar motion, typically by four to eight weeks.

■ Appearance

External shading has a major effect on the appearance of a building. If the building is highly stylized (e.g., neoclassical or glass cube), it may be impossible to reconcile external shading with the original style. In such cases, the style of the building has to change.

A stylistic advantage of external shading is that you can make it have any color or surface finish without increasing heat gain. Very little of the heat that is absorbed by the shade is transmitted to the building interior by thermal conduction. Because of its exposed location, the shade is cooled by the atmosphere.

■ Longevity

Try to make external shading device last as long as the building. Generally, it is a mistake to use materials that have limited life outdoors, such as fabric and plastic.

Fig. 7 Horizontal louver shading This building is located at a latitude of 30 degrees. The louver arrays greatly reduce the cooling load. On the south side, they also provide effective daylighting by keeping direct sunlight out of the windows at all times.

Airolite Company

Fig. 8 Shadow pattern of horizontal louvers These are working well, except at the corner. We infer that the wall at right faces in a southerly direction. A double row of louvers is used to reduce the outward distance required. The louvers are attached to vertical stringers, which are bolted to the wall.

Airolite Company

Fig. 9 Egg crate louvers The egg crates block sunlight from all directions. They are supported by the columns, rather than being attached to the wall. This rather massive construction and the irregular placement of the louvers may have been motivated by an appearance concept as much as by sunlight control.

Why inflict the cost and effort of periodic replacement on future owners and operators? Also, such materials soon lose their sparkle and start looking shabby.

■ Attachment to the Building

Attaching external shading devices to the building can be a design challenge. Shading devices are subject to strong wind forces because they have a large surface area. Some shading is subject to snow loads. If the building envelope does not have easily accessible strong points for attachment, you have to create them.

In new construction, you can make some of the shading features described previously an integral part of the structure. This is generally very strong.

Separate shading devices can be bolted to the wall. However, do not assume that an existing wall is strong enough to withstand the weight and wind loads. You may have to reinforce the wall at the attachment points, and doing this may be awkward.

You can also attach shading devices to columns or vertical stringers. If the latter are attached to the wall, as in Figure 8, they distribute the weight of the devices along the wall, while minimizing bending loads that tend to tear attachments out of the wall.

If the attachment columns can extend to the ground, they can relieve the gravity load on the wall. In some

installations, the columns are freestanding, except for a steady attachment at the top.

■ Removable Shading

Try to avoid shading devices that have to be removed on a seasonal basis. Stowage is a major problem, and operating personnel hate to bother with this kind of chore. Such shading tends to be abandoned within a few years.

■ Method of Control

Movable shading may be operated manually or automatically. Automatic control is necessary to achieve efficient results in most applications. Controls based on some form of sun position sensor can be simple and reliable. Such controls are unconventional, so you have to make sure that they are installed properly.

Manual control is reliable only if people become uncomfortable in an obvious way when they fail to control the equipment efficiently. For example, manual control may work for a louver shade that allows glare when it is not adjusted to keep out sunlight. However, this method of control is not pleasant for the occupants, and it is not effective for exploiting passive heating.

Airolite Company

Fig. 10 Vertical array of louvers These provide effective shading of full-height windows across a narrow walkway. They are high enough to avoid obstructing the view.

WESINC

Fig. 11 Vertical louvers for a house These provide effective light and ventilation for the southeast side of a house located in southern Florida. Provides a limited downward view.

WESINC

Fig. 12 Louvers installed as awnings These simple louver assemblies on the south side of a modest commercial building provide effective shading, along with a moderately good view of the street below. They have been lengthened to hide air conditioners installed below the windows.

*Construction Specialties, Inc.*

Fig. 13 Louvers arranged in a curved array The curvature is strictly for appearance. The designer has to work a little harder to figure out the louver dimensions that keep direct sunlight from striking the window.

*Airolite Company*

Fig. 14 Shading louvers attached to wall by brackets

■ Envelope Penetrations

Avoid actuators for movable shading that require significant envelope penetrations. These become sources of air leakage.

■ Fire Egress

Windows may be potential escape routes in the event of fire, or points of entry for firefighters. Do not install shading devices in a way that interferes with emergency use of windows.

■ Property Lines and Setbacks

If a sun shading device would extend beyond a property line or beyond the limit of a construction setback, make arrangements beforehand to use the adjacent air space.

Orientation is Critical

Some shading methods are extremely specific to compass orientation (azimuth). For example, fixed horizontal shading may leak sunlight into the building during the morning or afternoon unless it is used on a face that is oriented almost exactly due south. The same is true of vertically oriented shading that is installed on east and west faces.

Do not assume that a north face does not require shading. See Figure 16. In summer, the sun rises and sets well to the north of due east and due west, respectively. Shading of the north side is simplified by the fact that the sun is low by the time it gets around to

the north face, except at low latitudes. North faces that are oriented slightly toward the east or west experience a significant increase in solar gain during summer mornings or evenings, respectively.

■ Determine the Azimuth Accurately

If you are going to retrofit shading to an existing building, you need to know the actual orientation of the building faces within an accuracy of about 10°. The compass roses on most building drawings are not precise, and hence are worthless for shading design. Instead, work from a surveyor's plot plan that has an accurate north arrow. Use directions based on true north, rather than magnetic north. True north and magnetic north may differ by 30° or more. If you cannot find an accurate plot plan, use a surveyor's magnetic compass and set it up away from any ferrous objects (including buried pipe, pavement reinforcement steel, and the magnetized screwdriver in your shirt pocket). Correct the magnetic compass reading to find the true orientation.

Construction Specialties, Inc.

Fig. 15 Shading louvers supported by columns

WESINC

Fig. 16 Vertical fins Fins are cast into these concrete wall panels. They are too shallow to keep sunlight off the north windows during summer. They do keep the wall cool by shading most of the surface area.

Account for Reflection from Surrounding Features

Reference Note 24, Characteristics of Sunlight, points out that a substantial amount of solar radiation may arrive by reflection from features that surround the building. Some of these features may be too big to ignore, such as the lake on the south side, or the glass box building next door. Reflected sunlight that arrives from an unexpected direction is likely to get past your shading devices. So, don't assume that all sunlight comes directly from the sun. Take a careful look around your property.

Account for Shading by Surrounding Features

The lower portions of tall buildings may be shaded effectively by adjacent buildings and other features. Don't spend money unnecessarily to shade these portions of the building. However, external shading may still be desirable in such cases to eliminate glare for the purpose of preserving a good view.

WESINC

Fig. 17 Awnings Canvas awnings provide effective shading for the rooms of this hotel in a warm, sunny climate. The wall to the right faces east. As you can see from the shadows, the narrowness of the awnings allows some direct sunlight to enter the windows. This could be minimized by tapering the sides of the awnings outward. The awnings provide an important decorative accent for this plain rectangular building. However, fabric has a rather short service life.

Airolite Company

Fig. 18 Shading or deco? Look at the shadow patterns. The windows on the right face southeast, and most of the sunlight is getting into them now, at mid-morning. Fixed horizontal shading works well only on a south face. If horizontal shading wraps entirely around a building, only a part of it will be very useful. Given the limited outward reach of these shades, how far south must the building be located for the shading to be effective, even on the south side?

ECONOMICS

SAVINGS POTENTIAL: 70% to 95% of the cooling load caused by the shaded glazing.

COST: \$2 to \$20 per square foot of window area.

PAYBACK PERIOD: In new construction, may be immediate if the cost of shading reduces the cost of the cooling equipment by an equal amount. May be several years, in other cases. In retrofit, the payback period is several years or longer.

TRAPS & TRICKS

PIONEERING: If you want to attract attention, this will do it. For better or worse, sun shading radically changes the appearance of a building. A major decision is whether to use fixed or movable shading. Fixed shading cannot completely block direct sunlight while preserving an open view unless it faces directly south. Movable shading requires custom engineering, custom fabrication, and maintenance. Make sure that the structural attachments have sufficient strength to withstand the strongest wind loads. Consider the effects on fire safety, window cleaning, etc. Make a study of other facilities that use sun shading, but do not expect to find perfect shading performance on all sides of a building. If you achieve it, you will be making architectural history.

EXPLAIN IT: If you install movable shading devices, tell the staff how it is supposed to operate. Describe the system in the plant operating manual. Install effective placards at the controls.

MAINTENANCE: If you install movable shading devices, maintenance is critical. Schedule periodic checks of operation in your maintenance calendar. If you have an energy management control system, use it to monitor the operation of the movable shading devices.

MEASURE 8.1.2 Install internal shading devices.

RATINGS

New Facilities	Retrofit	O&M
D	C	

Internal shading comprises the category of shading techniques that architects call “window treatment.” This includes draperies, curtains, and blinds. For most applications involving windows, you can use techniques that are commercially available. However, if you want to exploit daylighting and passive heating, be ready to innovate. Also, skylights require custom shading techniques.

In comparison with external shading (Measure 8.1.1), the main advantage of internal shading is low cost. The equipment is light because it is not subject to wind loads or precipitation. Some types of internal shading adapt to all sun positions, so you may be able to use a particular method throughout the building.

Internal shading cannot be as efficient or as visually pleasing as external shading. All types of internal shading interfere with view, and some eliminate view completely. See Figure 1.

Internal shading is primarily a retrofit technique. If you are designing a new building, attempt to accomplish as much shading as possible with external methods.

Where to Use Internal Shading

Internal shading can be used with almost all windows and skylights. Consider it for all glazing that lacks an effective method of limiting solar gain. For example, corridor windows are often unshaded. Large skylights in areas such as atriums and lobbies often admit excessive sunlight, even though they may be tinted.

On the other hand, if a building already has glass that is heavily treated to reduce solar heat gain, internal shading may not provide much additional reduction of heat gain. If the glass uses absorption to reduce solar gain, it will absorb most of the sunlight that is reflected by internal shading, making the glass warmer. The increased heating of the glass increases the risk of glass breakage. See Measure 8.1.3 for details.

A majority of windows that receive direct sunlight already have internal shading of some kind. Examine the existing shading and decide whether it is worthwhile to replace it with a more effective type. Existing shading that is made of light-absorbing materials, such as dark draperies, does little to reduce the cooling load. Replace it with a more efficient type of shading, if it is economical to do so.

Energy Saving Potential

■ Heat Gain

Internal shading reduces heat gain from 20% to 70%. The best performance is obtained from highly

SUMMARY

The least effective method of reducing solar heat gain, but often the only one that is economical in existing buildings. In a new building, a need for internal shading testifies to careless design.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%		
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

reflective shading devices that are installed close to the glazing.

■ Cold Weather Heat Loss

Do not expect interior shading devices to reduce conductive heat loss during cold weather. Convection between the shade and glazing virtually eliminates any benefit from the thermal resistance of the shade. In the past, people have tried to seal shading devices at the edges to serve as a form of supplemental window insulation. Doing this causes heavy condensation and moisture damage. See Measure 8.1.3 for the right way to reduce heat loss through new glazing. See Measure 7.3.2 for the right way to reduce heat loss through existing glazing.

■ Daylighting

Some interior shading devices can be part of a daylighting system. However, ordinary inexpensive internal shading methods do not provide significant opportunity for daylighting by themselves. Don’t expect occupants to continually readjust their blinds to optimize daylighting. See Reference Note 46, Daylighting Design, for the main points to consider.

■ Passive Heating

Shading devices that reduce undesirable heat gain in summer also reduce desirable heat gain in winter. Most internal shading devices allow occupants to adjust the amount of sunlight admitted. However, don’t expect occupants to optimize the use of their shading devices to exploit passive heating. Control of passive heating requires more elaborate techniques that are explained in Reference Note 47, Passive Solar Heating Design.

Available Methods

There is no limit to the methods of internal shading that might be devised. Some types of interior shading devices worth considering are:

- **horizontal louver (venetian) blinds** have remained popular over the years because they are the only type that controls solar gain while preserving the view and avoiding glare. For vertical windows that are accessible to occupants, standard venetian blinds are the best choice for a majority of cases.
- **vertical louver blinds** apparently became popular because interior decorators became bored with horizontal blinds. They are useless for sun control on south faces, and they require much more adjustment on east and west faces than horizontal blinds. Occupants typically keep them closed and sacrifice the view. They may be satisfactory for controlling glare through glazing that faces north, eliminating direct sunlight into the space during early morning and late afternoon in summer.
- **roller shades** are available in wide range of materials. If they are highly reflective, they can reduce solar gain more than any other type of internal shading, but only if they are kept closed. Roller shades made of ordinary materials must be kept partially open to preserve view, so they admit heat gain and glare. Roller shades can be made with translucent material to provide diffuse daylighting. However, the transparency of the material must be very low to avoid glare problems. (See [Measure 8.3.1](#) for details.) Roller shades are also available with transparent material that has a reflective surface facing outward. The life of this material tends to be short.
- **draperies** have poor shading coefficients because the folds of the fabric trap sunlight. They cannot reconcile view with sunlight control, they have poor insulation properties, and they trap mechanical heating and cooling against the building envelope. Their merits are formal appearance and the ability to admit diffuse light.
- **miniature louver materials** (see [Measure 8.1.1](#)) could be used for internal shading. Their disadvantage when used indoors is that any sunlight they absorb adds to the cooling load. If they are used internally, their outward facing surfaces should be as reflective as possible.
- **diffusing materials** in general. These could include fabrics, mesh materials, milky plastics, or anything else that reflects most of the light while transmitting a part of it in a diffuse manner. Glare is a major issue with diffusing materials, as explained in [Measure 8.3.1](#). When installed as fixed panels, they limit or prevent the use of windows for ventilation. Skylights and other inaccessible glazing can be shaded with a large variety of custom devices or fabric hangings. These can be very decorative.
- **reflective materials** in general. Reflective film can be applied directly to the glazing, as recommended by [Measure 8.1.4](#). This is the most effective method of reducing cooling load that can be applied inside the building. This method cannot eliminate glare.

WESINC

Fig. 1 Typical interior window shading The first effect of most interior window shading is to abolish the window's original purpose, which is to provide a view and daylighting. Almost every occupied space on this side of the building has blocked out daylight completely. However, the windows still cause greatly increased heat loss and heat gain. The light color of the windows indicates that a considerable amount of sunlight is being reflected, but much is still trapped.

It has other disadvantages, such as increasing the possibility of glass breakage.

How to Select or Design Internal Shading

The following are the main points to consider when you select or design internal shading devices.

■ Shading Effectiveness

The term “shading coefficient” was defined to describe the effectiveness of various shading techniques for reducing cooling load. It is defined as the ratio of the heat gain that enters the space with the shading device installed, compared to the heat gain that would occur through a single pane of clear glass. The *Fundamentals* volume of the *ASHRAE Handbook* lists shading coefficients for common types of internal shading devices, such as venetian blinds and roller shades. Shading coefficients may also be provided by manufacturers of shading devices. These figures should not be treated as exact because the shading coefficient varies with factors such as the size of the window, the mounting position of the shading device, and the incoming angle of the sunlight.

For unconventional shading devices, base your estimates on the reflectance of the material and the geometry of the installation. It is easy to be too optimistic about the savings provided by custom shading. Unless the shading device is held snug to the glazing, a significant amount of sunlight will leak past it into the space. Also, any use of color on the outer surface of the material increases absorption.

■ View and Glare

All methods of internal shading, except for window films, significantly degrade the view through the windows. Some shading methods, such as draperies and roller shades, eliminate view entirely. Fixed or movable louver blinds may preserve most of the view while substantially reducing solar load. If a shading device allows glare, it harms the view.

Shading devices that allow direct sunlight to enter the space do not solve the problem of glare, even if they reduce the intensity of sunlight. (For an explanation of glare, see [Reference Note 51](#), Factors in Lighting Quality.) Window films do little to reduce glare. A shading device that diffuses direct sunlight may create a serious glare problem, because it appears as a bright light source. Louver materials must have dark undersides to keep from becoming a glare source.

■ Daylighting Potential

Early in your planning, read [Reference Note 46](#), Daylighting Design. On the positive side, achieving daylighting is compatible with control of solar heat gain. On the negative side, achieving good daylighting is more complicated than installing shading devices. In the realm

of simple daylighting, louver blinds may make daylighting possible near windows. If you have glazing that is located well above normal sight lines, such as skylights and clerestory windows, diffusing materials may allow it to provide effective daylighting.

■ Adaptability to Different Orientations

Most of the common internal shading methods do not need to be customized to the azimuth of the window. This simplifies the interior decorator’s task and reduces cost.

Expect to use one set of techniques for ordinary windows, and a different set of techniques for glazing that is located well above horizontal sight lines (e.g., skylights and clerestory windows).

■ External Appearance

In order to be reasonably effective, internal shading must have an outward facing surface that is highly reflective. This makes the shading devices quite visible from outside the building. Attempting to conceal internal shading devices by making them darker seriously reduces their effectiveness. If you want to maintain a uniform external appearance, consider fixed shading devices.

■ Longevity

The shading device needs a long service life to earn a good profit in energy savings. Select devices that are sturdy enough to survive normal handling and resist impact damage. (Recall how ugly venetian blinds become when their slats get bent.)

■ Installation

From an efficiency standpoint, the most important installation issue is mounting the shading device as close to the glazing as possible. If there is distance between the glazing and the shading device, sunlight will leak past the shading device, or it will be absorbed by the frame and adjacent wall structure.

Attaching internal shading is much less demanding than attaching external shading, which is subject to wind and weather. Still, expect to innovate and experiment to develop methods that are elegant and effective.

■ Control of Movable Shading

Flimsy or inaccessible controls undermine the effectiveness of movable shading, such as venetian blinds. Expect some difficulty in persuading the interior decorator that it is vital to have controls that are accessible and visible.

■ Fire Egress

Windows may be escape routes in the event of fire, or points of entry for firefighters. Do not install shading devices in a way that interferes with emergency use of windows.

Don't Forget the Placards

If a shading device needs occupant control, tell the occupants what to do. In most environments, you can do this best with placards. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: 20% to 50% of the cooling load caused by the shaded glazing.

COST: \$1 to \$5 per square foot of window area.

PAYBACK PERIOD: Several years. May be shorter if shading avoids the need to increase cooling capacity.

TRAPS & TRICKS

SELECTING THE METHOD: You can probably use a commercially available product. Shop around. The most popular product, horizontal venetian blinds, are the best compromise for most existing buildings. If you want to preserve the view, select blinds with reflective top surfaces and dark bottom surfaces. If you are selecting internal shading devices for a new building, you made a big mistake in the envelope design. Go back to [Measure 8.1.1](#) and start over.

EXPLAIN IT: In most cases where internal shading devices are needed, the occupants simply close them and sacrifice the view. If occupant control is to have any chance of working, you need to install placards that ask occupants to adjust the shading appropriately.

MEASURE 8.1.3 Install high-efficiency glazing.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
B	C	

In typical buildings, the glazing accounts for most of the solar heat gain. Glazing also accounts for a large fraction of heat loss during cold weather. For these reasons, your choice of glazing is a major factor in energy costs.

This Measure deals primarily with the efficiency properties of glazing materials. It covers all types of glazing, including windows, skylights, and glazed enclosures. It covers all types of glazing materials, including glass and the various plastic glazing materials. However, one specialized type of glazing, translucent structural panel materials, is covered primarily by [Measure 8.3.3](#).

This Measure does not deal with efficient layout of glazing. The layout aspects of glazing vary widely for windows, skylights, and glazed enclosures. These aspects are covered by other Measures throughout [Section 8](#) that deal with specific situations.

Selecting glazing involves many more factors than it did a few decades ago. The key is to understand the theory of each aspect of glazing performance, and to combine these aspects in an optimum combination. On the positive side, both raw glass and fabricated glazing units are available with a broad range of properties that allow tailoring energy characteristics and appearance to the application. On the negative side, mistakes in glazing design or selection sacrifice energy efficiency, and they may cause major problems, such as glass breakage, overheated spaces, and appearance problems.

In new construction, select glazing to minimize heat loss during cold weather, but rely primarily on external shading to limit solar heat gain (see [Measure 8.1.1](#)). Using glazing to control heat gain is less efficient than using shading.

In existing buildings, where it may not be economical to add external shading, you can still make substantial improvements in controlling heat loss and heat gain by replacing the present glazing. This Measure explains the choices that you have to make to achieve both of these objectives.

In both new construction and retrofit, consider glazing as one element in a system of features that control heat loss and heat gain. Combine it efficiently with the techniques that are recommended by the other Measures of this Subsection.

Where to Retrofit High-Efficiency Glazing

From an efficiency standpoint, this Measure applies to any building that has a large cooling load caused by glazing or a large heating load caused by glazing, or both.

SUMMARY

A powerful method of reducing both cooling load and heating load. There are many factors to consider.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	☺	☺	☺	☺

Retrofitting high-efficiency glazing is expensive. The payback period is long, so this Measure is economical for existing buildings only if they have a long remaining life. These situations favor glazing retrofits:

- climate and building orientation that cause a large total amount of heat gain and/or heat loss through glazing. Glazing replacement may be important on some faces of a building, but not on others.
- large numbers of windows, especially if they are similar
- windows that are individually large
- frame systems that allow easy glazing replacement
- the building is due to receive an exterior renovation
- the HVAC system is due to be renovated, and improved glazing can reduce the need for new cooling equipment.

Energy Effects of Glazing

Glazing affects energy consumption in a number of ways. Tally all the following effects when you estimate the potential savings.

■ **Solar Heat Gain**

The most efficient available glazing can reduce solar radiation heat gain as much as 85%, compared to clear glass. Achieving this degree of improvement requires the glazing to be as reflective as possible, or to selectively absorb the infrared component of sunlight. It also requires low-E coatings and insulating gas fills (explained below) to prevent the inward flow of heat that is absorbed in the outer glazing.

Glazing treatment that relies solely on maximizing reflection can reduce direct radiation heat gain reduction by about 50% to 70%. If a high degree of reflection is

not acceptable, and absorption is used instead, the reduction of heat gain may be limited to 40% to 60%.

These numbers are excessively optimistic because they use unshaded clear glass for comparison. When compared to a clear glass window with reflective interior curtains or blinds, the potential for reducing heat is perhaps half of the previous numbers.

■ Conductive Heat Loss During Cold Weather

In buildings with large amounts of glazing, heat loss through the glazing typically is responsible for about half the cost of heating.

The greatest relative improvement occurs when replacing single glazing with efficient triple glazing. This change reduces conductive heat loss by as much as 80%. On the other hand, replacing clear double glazing with “high-efficiency” double glazing reduces conductive heat loss by 10% to 50%.

■ Conductive Heat Gain During Warm Weather

Conductive heat gain during summer typically is less important than conductive heat loss in winter, because the temperature differentials are smaller. Still, conductive heat gain is important in a warm climate. It may account for 10% to 30% of the total heat gain through glazing.

The relative improvements that can be achieved are about the same as for conductive heat loss, just discussed.

■ Long-Wavelength Infrared Heat Loss During Cold Weather

Radiation heat loss from the interior of the building is much less important than conductive heat loss. Heat radiation from the interior of the building is absorbed in the glazing, where it warms the glazing. The heat moves by conduction and further radiation toward the outside of the building. Multiple glazing and low-emissivity coatings can reduce this component of heat loss by 50% to 80%.

■ Long-Wavelength Infrared Heat Gain During Warm Weather

This is radiation from the warm surfaces of the outside world (not including the sun) toward the building. The radiation is absorbed in the glazing, warming the glazing. This heat moves by conduction and further radiation toward the inside of the building. This is a minor component of heat gain. Wind and glazing treatment reduce it from 20% to 70%.

■ Passive Heating

All glazing that reduces solar heat gain also substantially reduces the potential for passive heating. This factor is unimportant in warm climates, but it may cancel much of the benefit of passive heating features in cold climates.

■ Daylighting

See [Subsection 8.3](#) about daylighting. All types of treated glazing reduce the amount of daylight available. Whether this matters depends on whether the building has more glazing than it needs for daylighting.

Get the Most From Your Glazing Decisions

Consider all the available opportunities for conserving energy when you select glazing. Use this approach to sort through the possibilities:

- **First, consider conductive heat loss, for both cold weather and warm weather.** This defines the number of panes of glass (the industry calls them “lights”) to be used. Make this decision before proceeding to the next step. If the conductive heat load is substantial, consider additional refinements, such as low-E coatings and low-conductivity fill gases.
- **Decide which types of glass and/or which coatings to use to reduce solar heat gain.** The number of possible combinations increases geometrically with the number of panes, but one combination usually stands out as the best. This decision has a major effect on the appearance of the building.
- **If you select openable windows, select a type of frame and weatherstripping that minimizes air leakage.** The configuration you select should keep out rain and minimize wind problems inside the space.
- **Consider whether to try to exploit daylighting or passive heating.** Either one commits you to a lot more brain work. Also, both usually require specialized equipment and/or building modifications in addition to the glazing replacement. Read [Reference Note 46](#), Daylighting Design, and [Reference Note 47](#), Passive Solar Heating Design, to help make this decision.
- **Consider the effect on the appearance of the building and the quality of the occupants’ view.** If there are problems with either, repeat the selection process to achieve an acceptable compromise.

Unfortunately, you may not be able to resolve all these factors by dealing with a single vendor. As the glazing industry is presently structured, two different parties are involved in making a finished window. The glass manufacturer controls the basic physical properties of the glass, such as its thickness and whether it is heat treated. The glass manufacturer also determines the optical properties of the bulk glass, which have a major effect on energy efficiency. The manufacturer adjusts the optical properties by adding dyes to the glass and by applying reflective coatings to the glass surface.

The glass manufacturer sells glass sheets to window fabricators, who may create a wide variety of glazing characteristics by combining different types of glass.

The window fabricator makes the frame, which may have important efficiency features. The window manufacturer may increase efficiency by using insulating fill gas between the panes, suspending plastic films between the glass panes, and installing integral shading devices.

To get the best combination of window characteristics, become familiar with the offerings of both glass manufacturers and window fabricators. Not all window fabricators offer all the available techniques, and new features continue to emerge. Shop around to find the manufacturers who are leaders in technology.

Another problem is that the architect may be oblivious to efficiency, and the person responsible for energy efficiency may lack esthetic sense. You may have to become a diplomat to reconcile the appearance and efficiency issues.

As with all efficiency improvements that involve sunlight, customize your glazing selection for each orientation of the building. This is a major departure from conventional architectural practice, and you may have trouble with designers and vendors in doing it. Everyone is accustomed to using glass with a single set of characteristics on all surfaces of a building.

Now, let's look at the main design and selection issues in greater detail.

How to Select and Design Glazing to Reduce Conductive Heat Loss

There are four main methods that contemporary glazing can use to reduce conductive heat loss:

- increase the number of surfaces
- improve the insulating properties of the frame
- use "low-emissivity" coatings on the surfaces
- use insulating fill gases.

Let's look at your options in each of these areas, along with some other selection factors.

■ Number of Surfaces

Glass itself has only minimal insulating ability. Most of the resistance to heat flow comes from a thin, stagnant layer of air that attaches itself to any surface. If the air layer is well protected, as between two panes of double-glazed window, it has an R-value of about 0.5. The exposed air layer on the outside of the building has a much lower R-value because it is dissipated by wind. The inside air layer typically has a higher R-value than the outside layer, but it may be dissipated by air discharged from conditioning equipment. The *ASHRAE Handbook* lists R-values of 0.9 for single glazing, 2.0 for double glazing, and 3.0 for triple glazing. These figures are based on a wind speed of 15 MPH and other standardized conditions.

In principle, you could improve the thermal resistance of glazing by adding many more surfaces. In

practice, three or four panes is presently the upper limit. Weight and cost increase with the number of panes, and clarity suffers.

In an attempt to reduce the weight and cost penalties of adding panes of glass, some manufacturers offer double-pane windows in which films of transparent plastic are suspended between the panes. These films can be coated in a manner similar to glass. However, using a plastic film inside glass does not seem to be a prudent approach, because the life of the film is only a fraction of the life of the rest of the window.

Under present conditions, these are typically appropriate numbers of panes:

- one, in climates where heating is minimal and air conditioning is not used
- two, in temperate climates
- three, in colder climates, such as the northern and mountain areas of the United States, and where energy costs are especially high
- four, in extremely cold climates, such as Alaska, Scandinavia, and northern Russia.

These recommendations may change if energy prices rise considerably, if multiple glazing becomes less expensive, if glazing with better thermal resistance becomes available, if movable insulation is used with the windows, etc.

■ Insulating Properties of Frames

Aluminum alloy is usually the best material for window and skylight frames. Don't bother with anything else unless you have a specialized application. Aluminum has much longer life than wood or plastic, and it does not change shape. It can be extruded into an unlimited number of shapes to ease installation, to accommodate effective thermal barriers, and to provide good sealing of movable panes. It can be anodized to hold any color, or to hold a smooth surface finish.

The main disadvantage of aluminum is high thermal conductivity. To prevent serious heat loss through the frame, window manufacturers include thermal barriers in the frame extrusions. Figure 1 shows how thermal barriers, or thermal breaks, are built into frames.

In effect, a frame with a thermal barrier consists of two frames, an outer unit and an inner unit. The two units are joined together by a plastic material that locks the two frame sections together. The plastic material has relatively low thermal conductivity, so it blocks heat flow between the inside and outside frame sections.

The plastic material is not a very good insulator, but it is much better than aluminum. The thermal barrier is fairly effective because it provides only a small cross section area for heat flow. All aluminum frames sweat somewhat during cold weather, especially the lower portion, unless the climate is dry. Deal with this by using trim materials around the window that are not harmed by occasional wetting.

Pay attention to the frame design. There are major differences in quality. Be sure that the thermal barrier does not weaken the frame excessively. If the thermal barrier is poorly designed, the frame could split apart eventually. A good frame design avoids this possibility completely by clever extrusion design, and by using a thermal barrier material that is reinforced with fibers of glass or other inorganic material.

You will not have trouble finding good frame design among the major window manufacturers. Unfortunately, skylights are a different story. Most large skylights are designed on a custom basis. You will have to work with the fabricator to develop a frame design that provides an adequate thermal barrier, as well as resisting leaking, allowing thermal expansion, etc.

Larger, undivided windows have less frame heat loss in relation to their size than smaller windows. This is because of the laws of geometry, not technology.

■ Low-Emissivity (“Low-E”) Coatings

A lesser amount of heat loss from glazing occurs by radiation. (Most glazing heat loss occurs by conduction.) All objects radiate electromagnetic radiation. The intensity and the wavelength of the radiation depends on the temperature of the material. Objects that are near room temperature radiate in the portion of the electromagnetic spectrum called the “far infrared.” (These wavelengths are much longer than the wavelengths of infrared light from the sun, which is called the “near infrared,” i.e., near the visible spectrum).

The environment outside the building radiates heat toward the building in the same way as the interior of the building radiates heat outward. The net heat loss is proportional to the temperature difference between the inside and outside, just as with conductive heat loss.

Ordinary glass absorbs almost all far-infrared radiation that falls on it. The absorbed radiation warms the glass, increasing radiation by the glass itself. If the outside is colder than the inside, the net energy flow is outward. For this reason, ordinary window glass is only partially effective in blocking radiation heat loss, although multiple glazing is much more effective than single glazing.

Low-emissivity glass (“low-E” glass, for short) blocks radiation heat loss in two ways, depending on which surface has the low-E coating. If the coating is applied to an exterior surface, it inhibits the radiation of heat from the window toward the outside. This causes the glazing to become warmer and radiate heat back into the space. (But, the coating does nothing to prevent loss of heat to the outside by conduction.)

If a low-E coating is applied to an inside glazing surface, it reflects the internally generated heat radiation back into the building. This is because a low-emissivity surface inherently has high reflectance. (Reflectance is high because the sum of the emittance, reflectance, and

absorptance of a surface must equal one. If the emittance and absorptance are low, the reflectance must be high.)

Low-E coatings are metal films that are microscopically thin. They operate on the principle that smooth conducting materials have low emittance. For example, the emissivity of a polished aluminum surface is about 0.08. By comparison, the emittance of ordinary glass is 0.84.

Major Industries, Inc.
Fig. 1 Thermal breaks in glazing frames The difference between these two skylights is the thermal breaks installed in the lower frame. The thermal breaks are strips of reinforced plastic that separate the inner parts of the aluminum frame from the outer parts.

Two categories of low-E coatings are used on glass. One category includes coatings that are deposited on the surface of the solid glass by a variety of physical, chemical, and electrical processes. For example, “sputtered” coatings are metals evaporated on to glazing in a vacuum. These surface coatings are very smooth, which allows them to have minimum emissivity, in the range of 0.10. On the negative side, surface coatings are exposed to both abrasion and corrosion.

The other category of low-E coating is “pyrolytic.” A chemical process implants the metal atoms under the surface of the glass while it is in a molten state. This process makes pyrolytic coatings much more durable than surface coatings, but it also makes them less efficient. The emissivities of commercial pyrolytic coatings are presently around 0.40, although emissivities as low as 0.20 are predicted.

Various metals are used for low-E coatings. For example, aluminum and silver are used for surface coatings, and tin oxide is used for pyrolytic coatings. One of the manufacturing tricks of low-E films is to deposit them in such a way that they reflect long-wavelength infrared, but not the shorter wavelengths of sunlight.

In practice, it makes little sense to use a low-E coating on single-pane glazing. It is cheaper and more efficient to install double-pane windows instead. Furthermore, the coating would be exposed, limiting the choice to the less fragile and less efficient pyrolytic type. Using two or more panes of glass solves these problems. The low-E coating is applied either to the outer side of the inner pane or the inner side of the outer pane.

Consider what happens when the low-E film is applied to the outer surface of the inner pane. The inner pane absorbs heat radiation from inside the building and is warmed. The low-E coating prevents the warm pane from radiating its heat outward.

Next, consider what happens when the low-E film is applied to the inside surface of the outer pane. The inner pane is warmed by absorbing radiation from inside the building. The warm inner pane radiates heat to the outer pane, but the low-E coating on the outer pane reflects that heat back to the inner pane, which absorbs it. Both approaches yield about the same heat retention.

This table shows the nominal effect of low-E coatings on the thermal resistance of glazing with different numbers of panes, assuming a temperature differential of 70°F across the window:

Coating	Approximate R-Value	
	Double Glazing	Triple Glazing
no coating	2.0	3.0
E = 0.40	2.5	4.0
E = 0.10	3.0	5.0

The double glazing uses a single low-E coating, which provides about the same performance if installed on either of the two interior surfaces. The triple glazing uses two low-E coatings, on the outward surfaces of the two inner panes. The figures include an allowance for edge losses.

These figures overstate the advantage of low-E coatings in most applications. They are based on ASHRAE data that assume a temperature differential of 70°F across the window. But, the average temperature differential is much smaller in most climates. (Other methods of improving window efficiency are not influenced strongly by the temperature differential.)

Solar reflective coatings that are used to reduce solar heat gain also act as low-E coatings, but not vice versa. Solar coatings reflect at all wavelengths, whereas low-E coatings reflect only at far-infrared wavelengths. Therefore, solar coatings can do double duty, reducing solar heat gain during warm weather as well as retaining building heat during cold weather. On the other hand, solar reflective coatings inhibit passive solar heating, whereas low-E coatings do not. Solar reflective coatings are discussed below.

■ Insulating Fill Gases

Many gases have better insulating properties than air. Some of these are used to fill the space between panes in high-efficiency windows. Gases used presently include carbon dioxide, argon, and krypton, all of which are relatively cheap because they are taken from the atmosphere. According to ASHRAE data, all three of these gases increase the R-value of clear double or triple glazing by about 7 percent. Chlorofluorocarbon gases offer better insulating properties, but these appear to be removed from consideration by concern about their effect on the ozone layer.

The benefit of insulating gases diminishes with age if the gas leak outs and is replaced by air. You might think that the gases would remain in the window because the pressure inside the window is the same as the pressure outside. However, the “partial pressure” of the insulating gas tries to drive it out of the window. (In a mixture of gases, each type of gas exerts its own pressure independently of the other gases. For example, the pressure of the atmosphere is the sum of the partial pressures of the oxygen and the nitrogen that make up air.)

The pure insulating gas has a partial pressure of one atmosphere inside the window, to balance atmospheric pressure. There is virtually no insulating gas in the atmosphere, so its partial pressure is almost zero outside the window. The difference in partial pressure tends to force the gas out of the window. Therefore, exploiting insulating gases requires reliable sealing, which we discuss next.

■ Seal Reliability

The Achilles heel of multiple-pane glazing has been the poor reliability of the seals between panes. If the seals leak, moisture enters the window and fogs it, leaving a permanent unsightly residue. If insulating gases are used in the window, failure of the seal allows the gases to escape. The best insurance against seal failure is to investigate the performance record of the types available, and to select a reliable window fabricator.

Ultimately, the best seal is provided by eliminating sealing compounds and fusing the panes of glass at the edges. This approach has been tried over the years, but glass breakage has been a problem. The search for better sealing methods continues.

One way of avoiding seal problems is to not use them. To avoid condensation and frosting in an unsealed window, the space between the panes must vent to the outside, i.e., the inner pane must seal more tightly than the outer pane. For this reason, old fashioned “storm windows” have small vent holes at the bottom of their frames.

Vented windows are less efficient than sealed units. Their primary market is retrofit applications. Adding a single pane of glass over existing windows may be much less expensive than replacing the existing windows with sealed units. This approach is antiquated, but it still merits consideration in rustic applications, such as country lodges, and in industrial applications. See [Measure 7.3.2](#) for this approach.

■ Gap Between Panes

Research indicates that the optimum separation between panes is about one half inch (between one and two centimeters). Thermal resistance declines rapidly with smaller gaps, but only slowly with larger gaps. In case of doubt, err on the side of a larger gap.

How to Select and Design Glazing to Reduce Summer Heat Gain

Heat gain through windows occurs in three significant ways: direct solar radiation through the glass, conductive heat gain from the outside air, and long-wavelength infrared radiation from the surroundings of the building. If glazing is exposed to direct sunlight, the direct radiation heat gain is much greater than conductive heat gain. Solar gain through directly illuminated glass may average as much as 100 BTU per hour per square foot during daylight hours. Glazing that is illuminated by indirect light from the sky may average about 20 BTU per hour per square foot.

In contrast, conductive heat gain through double-pane glass may average about 10 BTU per hour per square foot in a hot climate. The heat transfer process is the same as for winter heat loss. If the window is designed to minimize conductive heat loss in winter, it also minimizes conductive heat gain in summer.

Long-wavelength infrared radiation from the outside is absorbed in the outer glass and becomes part of the conductive heat load. A low-E coating installed on the inner surface of the glazing keeps the warmed glazing from radiating heat into the space.

■ Retain Sufficient Visible Light Transmission

In order to keep the view through windows from appearing too dark, the glazing should transmit at least 20% of the visible light, and 30% is probably a better figure. Glass that is more opaque may be acceptable if the glazing does not provide a view of anything but sky, and if it is installed above normal sight lines.

■ Minimize Infrared Transmission

To minimize cooling load, the glazing should transmit as little of the solar infrared radiation as possible. This radiation brings in heat without providing illumination. You can now buy glass that absorbs a much larger percentage of the sun’s infrared radiation than its visible light. The most effective glass of this type has a visible transmission greater than 60% and an infrared transmission less than 30%. This glass uses dyes to achieve its effect. The dyes absorb visible light more heavily at the red end of the spectrum, so the glass is green in color. This glass can be combined with low-E coating to minimize heat radiation from the absorptive glass to the interior of the building.

Because this glass blocks radiation by absorbing it, the energy of the radiation heats the glass. Therefore, the glass requires extra features to keep this heat from entering the space. At the present time, glass is not available that selectively blocks infrared radiation by reflection. This may change in the future.

■ Favor Reflection over Absorption, if Practical

Reflection is more effective than absorption in reducing solar input. This is because absorption increases the temperature of the glazing, causing the glazing itself to radiate heat into the building. The temperature increase is not trivial. For example, if a window has an absorption of 70%, it may absorb 150 BTU per hour on a bright day. This heat tends to be radiated toward the building interior, because the interior is cooler.

The high surface temperature of absorptive glass can create a serious comfort problem. The presence of a large warm surface on one side of a cooled space creates a strong heat flow gradient, like sitting around a camp fire on a cold night. The only comfort remedy available to occupants is to close the blinds to block the heat radiation. However, this eliminates the view and still allows the heat to enter the space by convection.

The heating of absorptive glass is strongly affected by wind. On a breezy day, wind may keep darkly tinted glazing near the outside air temperature. On a windless day, absorptive glass may become hot to the touch.

The inward radiation of heat from absorptive glass could be reduced by using a low-E film on the inner surface. However, this would increase the temperature of the glass, inviting glass breakage. For this reason, manufacturers advise against using low-E coatings with highly absorptive glass.

Reflective glass minimizes these problems. If you use reflective coatings without tints, the absorption of sunlight in the glass may be less than 20%. The actual absorption depends on the type of metal film used for the reflective coating. For example, aluminum and silver coatings have low absorption, while metals used to impart color to the glass have higher absorption.

There are two primary types of reflective coatings for glass, surface coatings and pyrolytic coatings, which are embedded under the surface. These two types are similar to the coatings used to create low-E glass, except that they are thicker. Pyrolytic coatings are tough enough to be used on the exposed outer surface of glazing, which minimizes absorption of light in the glass. Surface coatings are so fragile that they must be installed on an enclosed surface, which is the inside surface of the outer pane.

Reflective glazing has disadvantages, mostly related to its mirror-like appearance. The most acceptable compromise may be a combination of reflective and absorptive properties. We discuss this below, where we deal with the esthetic aspects of window design.

Note that this need to compromise between absorption and reflection arises *because designers use too much glazing area in the first place*. The most efficient solution is to limit the glazing area so that *clear* glazing admits no more sunlight than is appropriate, from the standpoints of cooling load, daylighting, view, etc. Even in existing buildings, consider reducing the glazing area. See [Measure 8.1.5](#) for more about this.

■ Be Wary of Integral Shading Devices

Some window manufacturers offer prefabricated units that include movable louvers between the panes of glass. In principle, this arrangement is more efficient than installing a shading device inside the space. However, the internal mechanisms of the window will fail long before the rest of the window fails, leaving either an inoperative device or a large repair bill. For this reason, keep shading devices independent of the glazing.

How to Select Openable Windows to Minimize Air Leakage

In many locations, making windows openable to allow natural ventilation is an important efficiency feature during warmer weather. However, openable windows allow a certain amount of air leakage during times when ventilation is not desired. Well designed openable windows are able to limit leakage to a small quantity throughout the life of the building. Openable

windows of poor quality develop serious leakage that cannot be corrected without major repairs.

Consider the effect of these factors on leakage when you select openable windows:

- **method of opening.** In the past, the worst leakage occurred with hinged windows, including casement (hinged on the side), hopper (hinged on the bottom), and awning (hinged on top) types, and with double-hung windows. Nowadays, hinged windows may be the most resistant to air leakage, because effective hinges and seals have been developed for them. Sliding windows have reasonably good sealing if they are well made. Double-hung windows continue to be vulnerable to leakage. (Vertical sliding windows, in which one element is fixed, have about the same leakage as horizontal sliding windows.) Louver windows have extremely high air leakage. Do not use them, except as wind barriers for unconditioned spaces, such as porches. Any window in which more than one element is moved by a single actuator cannot remain tight. This is another reason why louver windows are so bad.
- **sturdiness of construction.** Sturdiness equals longevity. Consider the sturdiness of frames, actuators, and locks individually.
- **weatherstripping type.** Examine the method of sealing. All parts of the weatherstripping should have positive contact in the closed position. The sealing system should be able to accommodate any looseness in the hinges and locks. The motion of opening and closing should not harm the weatherstripping. The weatherstripping should not be vulnerable to damage while the window is open.
- **ease of replacing weatherstripping.** All weatherstripping wears out, so select the weatherstripping system for ease of replacement. If the weatherstripping is specialized, bear in mind that you and your successors will need a source for replacement parts throughout the life of the building.

How to Design and Select Glazing for Passive Heating

Reducing light transmission blocks heat gain in winter as well as in summer. Therefore, the summer saving in cooling energy is partially cancelled by increased winter heating energy. The seriousness of the compromise between cooling load and heating load depends on the climate, the latitude, the operating schedule of the building, the amount of internal heat gain during daylight hours, and the relative costs of cooling and heating. Glazing is expensive, so make a detailed calculation to be sure of the net saving. Unless the situation is particularly simple, use an energy analysis capable computer program to make the calculation.

If passive heating capability is important, try to avoid treated glazing. Instead, use clear glazing and install separate external or internal shading devices that can be adjusted to meet shading and heating requirements. See [Measure 8.1.1](#) and [Subsection 8.4](#) about shading and passive solar heating, respectively.

Low-E coatings, which are used to reduce heat loss, are compatible with passive heating because they do not substantially reduce solar heat gain. In glazing with multiple panes, the location of the low-E coating is a compromise. Expert opinion says that low-E coatings provide the most heat gain if they are located on the outer surface of the inner pane.

In the future, glazing with variable characteristics may be able to reconcile passive heating with control of cooling load, but it does not appear likely that such glazing will become practical within the near future.

Daylighting Needs More than Special Glazing

Treated glazing can be used in combination with daylighting methods, which are covered in [Subsection 8.3](#). However, reducing the transmission of glazing reduces the amount of sunlight available for daylighting.

Treated glazing alone cannot reduce the intensity of direct sunlight enough to make it acceptable for lighting. The light level outside on a clear day is about 6,000 footcandles, in contrast with a typical office space light level of 60 footcandles. Glazing would have to be limited to a transmission of 1 or 3 percent to allow reading by direct sunlight. Glass with such a low transmission would make the view of the outside appear almost black.

To combine daylighting with reduction of cooling load, select glazing that selectively blocks transmission of the infrared portion of sunlight. This feature was discussed previously.

Minimize Air leakage Around Frames

Where prefabricated window units are installed in wall openings, air leakage between the window unit and the wall can be a source of energy waste, discomfort, and moisture damage. As a building contractor once said, the only way to put a window into a hole in the wall is to make the hole bigger than the window. Typically, wall openings are about an inch wider and an inch taller than the window. Installers typically make no attempt to fill this gap, but depend on the interior finish to hide it. The gap allows significant heat loss around the window frame. Even worse, the gap may serve as an entry point for outside air to leak throughout the adjacent wall.

The gap is too large for caulking. If the installer does anything to fill the gap, it usually consists of stuffing some fibrous insulation into the gap. This is better than nothing, but fiber insulation does not block air leakage effectively. You need to specify a method of closing the

gap that is tailored to the wall construction. If necessary, put detailed drawings in the glazing contract. Don't expect the glazing contractor to figure this out at the site.

The installation procedure should connect the vapor barrier in the wall to the window frame, so the gap cannot become a path for moisture in the building air to enter the wall structure. (For an explanation of vapor barriers, see [Reference Note 42](#).)

How to Avoid Thermal Breakage

If you increase the amount of heat that glazing absorbs, this increases the risk of breakage from uneven thermal expansion. The problem is that the portion of the glazing that is exposed to sunlight expands, while the shaded edges of the glass do not expand. This creates tensile (pulling) stress in the edges of the panes. Glass does not resist this well. Because of the laws of geometry, edge stress increases with the size of the pane.

Thermal stress is increased by massive framing systems, such as concrete, that tend to remain cool. Partial shading of the glass, for example, by overhangs and large mullions, also increases thermal stress. However, partial shading is less of a problem, because it does not cause differential expansion between the center and the edges of the glass.

You can reduce the risk of thermal breakage by using reflective glass rather than absorptive glass. But, be careful about combining reflective and absorptive properties. For example, using a reflective film on the inside of colored glass increases the temperature of the glass, because heat is absorbed both before and after reflection. Low-E films may increase glass temperature by keeping the glass from cooling by radiation.

Heat treatment, which is done when the glass is made, reduces the risk of thermal breakage, but this adds to the cost.

Other causes of glass breakage are the weight of the glass itself, wind forces, and vibration (earthquake, sonic booms, etc.). Control these hazards primarily by selecting glass thickness, heat treatment, and frame design. These are all major cost factors. Competent designers and glazing contractors are aware of these issues, but they may fail to provide an adequate margin of safety.

Select Components for Longevity

An inherent advantage of glass is that it lasts as long as the building. It is folly to surrender this advantage by installing windows or skylights that have built-in components of limited life. Using plastic window components is poor economy. Plastic frames, internal plastic films, and internal shading devices that require cords and actuators made of synthetic materials are eventually destroyed by sunlight and high temperatures. Even plastic that is hidden from direct sunlight, such as

thermal barrier strips, should not be used as a structural element, unless it is reinforced by strong inorganic materials, such as glass fiber. Gears and linkages made of aluminum and other soft metals also wear out prematurely.

Windows still rely on organic sealing and bedding materials. Recognize that these materials will eventually fail, and select the window design for easy repair. Keep an eye out for new windows coming on the market that seal by fusing the panes at the edges. This method avoids the need for organic sealants, but so far, it has been plagued by glass breakage.

All reflective and low-E coatings are vulnerable to damage, although some are much tougher than others. Coatings applied directly to the surface of the glass are fragile. They tolerate no mechanical abrasion, and even degrade from oxidation. Use them only on the interior surfaces of multiple-pane glazing units. The window assembly needs reliable seals to protect these films from oxidation and moisture corrosion.

Pyrolytic coatings are much tougher than surface coatings. Even so, these coatings are vulnerable to serious abrasion, for example, from contact with the metal parts of cleaning tools, scaffolds, etc. Also, pyrolytic coating gives glass a microscopically rough surface. As a result, materials that rub against the surface may create smudges that are difficult to remove. Oily substances create a visible change in surface appearance. Manufacturers who offer pyrolytic coatings claim that they can be used on exposed surfaces, but it seems prudent to restrict them to interior surfaces, as long as this does not reduce efficiency significantly or cause other problems.

Design for Good Appearance and View

Glazing is a dominant factor in the appearance of the building and the quality of the occupants' view. These factors demand careful consideration when selecting glazing. On the other hand, be careful not to let appearance considerations run away with the project. Architects tend to use glazing to make stylistic statements that are meaningful only to themselves, and they may be deficient in optical theory and practical experience. When you design glazing, make sure that technical and practical concerns (including appearance) take precedence over ethereal ones.

■ Color

Color can be created in a number of ways. One is by adding dyes to the glass that selectively absorb portions of the visible spectrum. The color imparted to the outside of the building is approximately the same as the color of light that is transmitted into the building. You have wide latitude in selecting color. However, dyes are absorptive, which increases heat gain.

A more efficient method of producing color is by using different metals for reflective coatings. For

example, copper and bronze produce a reddish color. Reflective coatings with a noticeable color are somewhat absorptive, but less so than dyes that permeate the glass. The range of colors available is limited by the availability of suitable metals for the reflective films.

Another technique is to use coatings that reflect the visible spectrum selectively, transmitting most of the rest. With this method, the reflected color seen on the outside is the complement of the transmitted color seen on the inside. For example, glass that selectively reflects the red end of the visible spectrum makes the building look reddish from the outside, but the view from inside the building has a bluish appearance. Such coatings are still evolving.

■ Reflective Appearance

Glazing with even a modest amount of reflectance has a mirror-like appearance from the outside. Some architects use reflectance deliberately to create a specific appearance, but reflective buildings have become trite as an architectural "statement."

Reflective glazing can have adverse effects on those outside the building. People facing the building may find themselves staring at the sun. The reflected heat may increase the cooling load of adjacent buildings. As a result of these annoyances, some local ordinances have prohibited reflective glass.

Glass manufacturers are developing coatings that reflect in a more diffuse manner. This approach lessens mirroring of the surroundings, but does not entirely solve the annoyance of reflected sunlight. Instead of reflecting an image of the sun, such glass reflects a brilliant halo.

A compromise between reflective and absorptive properties may produce the best results. A common practice is to put a reflective film on the inside surface of a mildly colored outer pane, which mutes the reflection. However, this combination also increases the temperature of the glass, so the glass may require heat treatment.

■ View

Glazing was used originally to provide light and view. In modern architecture, glazing is used primarily because it is a cheap way of covering the building, and the original purposes have largely been forgotten. However, if there is a good view outside, preserve it for those inside.

Visible light transmission should be at least 20% to 30% to keep scenery from looking dark and the sky gloomy.

Within wide limits, the color of the glazing does not have a significant effect on the view, because the human eye compensates when looking through a colored medium. As a rule, glass companies do not make glass that imparts a strange color to the view, but beware of bizarre architectural uses of glazing color.

■ Uniformity of External Appearance

Current architectural fashion considers it desirable for buildings to have a uniform, featureless external appearance. With clear glazing, people outside the building can see curtains and blinds that are positioned irregularly, and other distressing sights.

Reflective glazing blocks the view of the inside almost completely during the daytime. Reflection of the sky in reflective glazing yields a uniform appearance, although reflection of surrounding buildings and other features gives a somewhat quirky appearance.

Absorptive glass does not shield the inside from view as much as reflective glazing. This is especially true of interior window treatment and other objects close to the windows that may be illuminated by direct sunlight.

At night, both types of window treatment reveal the lighted inside of the building to the outside, but irregularity of window blinds and other features is less conspicuous.

■ Privacy

For the reasons given above, reflective and absorptive glazing provide privacy during the daytime, but not at night.

Extra Considerations for Skylights

Refer to [Measure 8.3.3](#) for special issues in the design of skylights.

United States Window Ratings

The National Fenestration Rating Council (NFRC), an organization funded by the United States Department of Energy, began to issue ratings of prefabricated windows in 1993. This work is evolving. By the time you read this, it may be worthwhile to refer to NFRC data when selecting windows. Some governmental units within the United States have already begun to use NFRC ratings as a basis for mandatory window standards in construction.

ECONOMICS

SAVINGS POTENTIAL: 40 to 80 percent of the solar cooling load related to glazing. 20 to 60 percent, if the building has interior curtains or shades.

30 to 75 percent of the heating load related to glazing, depending mainly on the thermal resistance of the original glazing.

The net saving may be reduced by the loss of passive heating during cold weather. The importance of this varies widely. In facilities where effective daylighting is used, lighting costs may be increased, but this is likely to be a minor factor.

COST: High-efficiency windows cost several hundred dollars apiece in typical sizes, in quantity. Costs in retrofit applications are typically 30% to 50% higher than in new construction.

PAYBACK PERIOD: In new construction, using high-efficiency glazing typically pays off within a few years. In retrofit, the payback period typically exceeds 10 years.

TRAPS & TRICKS

SPECIFYING THE EQUIPMENT: To select glazing systems properly, do your preparation in steps. First, study the glass characteristics that are offered by the glass manufacturers, including strength, color, types of coatings, etc. Second, decide how to combine the panes of glass to achieve the efficiency and the visual characteristics you want while protecting the coatings. Third, study the frame and support systems offered by window fabricators. Select a support system that minimizes the chance of breakage and fogging, and that minimizes leakage of insulating gases, if these are used. Effective seals are still evolving, so check on the latest developments. Make sure that metal window frames have a thermal barrier that is not vulnerable to long-term breakage. Make sure that the frame system is designed to make it easy to prevent air leakage around the window at the time of installation. Before signing the contract, check with sites where your proposed window system has been installed to see how well the installation worked out.

INSTALLATION: Window installers do not want to bother with sealing against air leakage when the windows are being installed, but that is the time to do it. Talk to the installer about this before the work commences. Have an enforcer at the site to make sure that sealing is done properly.

MEASURE 8.1.4 Install solar control films on existing glazing.

A common method of reducing solar heat gain in existing buildings is to apply a film to the inside surface of the glazing that reflects and/or absorbs sunlight. These materials are commonly called “window film,” but they can be used on any glazing, including skylights, greenhouses, etc. We will use the term “solar control films.” This name does not tell the full story, because glazing films are used to reduce heat loss, to reduce breakage, and for other purposes. However, from the standpoint of energy efficiency, reducing solar heat gain is by far their most potent capability.

Solar control films reduce solar gain by about 35% to 65%. They are offered in a wide range of reflectances, absorptions, and colors. By the same token, you need to select films carefully to achieve a good balance of efficiency, external appearance, and occupant view, and to avoid potential problems.

Installing solar control film is strictly a retrofit way of getting some of the desirable characteristics of high-efficiency glazing. Retrofit films are a less expensive and less effective alternative to replacing the glazing itself, the approach which is recommended by [Measure 8.1.3](#). Before going further with this Measure, review [Measure 8.1.3](#) for an explanation of these characteristics. You need to understand them to select films intelligently.

The economics of solar control films are not very favorable, primarily because the films have limited service life. Therefore, films are profitable primarily when they are installed on glazing that experience a large amount of heat gain.

Application Limitations

Unfortunately, solar control films face obstacles to providing a good payback, and they may cause serious problems. Be aware of these limitations at the outset, as they may disqualify films from your applications.

■ Limited Service Life

The major functional limitation of retrofit films is their short service life. Warranties range from five to ten years, depending on the manufacturing process used and the seller’s audacity. These warranties probably are not conservative, but may instead reflect a desire to make the life of the film appear as long as possible. The industry itself is reluctant to make definitive statements about film life. This undoubtedly reflects wide variations in film quality and operating conditions. The ultimate limitation is the nature of organic materials used for the films and the adhesives. All organic materials ultimately are destroyed by ultraviolet light and heat.

SUMMARY

A powerful retrofit method of reducing cooling load that is undermined by short life and other drawbacks.

SELECTION SCORECARD

Savings Potential	\$ \$ \$ \$
Rate of Return	% %
Reliability	✓ ✓
Ease of Retrofit	☺ ☺ ☺

■ Appearance Defects

Serious appearance defects may exist in the bulk material, or defective appearance may be caused by imperfect installation. Solar control films are made by a number of manufacturers. Some may not yet have mastered the ability to make films without appearance defects, such as stripes or blotches. These defects typically are not apparent until the film has been installed. The defense against this problem is purchasing the film from an experienced manufacturer who provides a reliable material warranty.

Another problem is peeling of the film, which is a failure of the adhesive. This may be the fault of the manufacturer, or may be due to poor installation. Any film will eventually peel. Once the film starts to peel, it must all be removed to keep the building from looking shabby. Selecting the best adhesive method and a good installer will delay peeling as long as possible.

Blotching of the film is usually caused by localized failure of the adhesive. This can occur early in the life of the film if the glass surface is not cleaned properly during installation.

Hazing of the film occurs over time as a result of cumulative scratching from cleaning and wiping. Hazing can be reduced by installing film with a scratch-resistant coating.

■ Are Shades or Curtains Installed?

For reasons explained in [Subsection 8.3](#), people tend to keep any curtains or blinds closed if they can admit direct sunlight. Although this eliminates the view, it reduces heat gain considerably. In this case, installing solar control film may not offer enough additional benefit to pay for itself within its service life.

Internal shading devices that are absorptive, such as dark colored venetian blinds, are not effective for reducing heat gain. (See [Measure 8.1.2](#) for details.) If

the interior decorator insists on dark shades or curtains, solar control films may still be cost effective.

■ Risk of Thermal Breakage

All solar control films absorb a significant amount of heat. The heat absorbed by the film warms the glass, causing it to expand, while the shaded edges of the glass remain cooler. This creates tensile stress in the edges of the panes, which glass does not resist well. Because of the laws of geometry, this tensile stress increases with the size of the pane.

Thermal stress is increased by massive framing systems, such as concrete, that tend to remain cool. Partial shading of the glass, for example, by overhangs and large mullions, increases thermal stress. The risk of thermal breakage is reduced by using reflective films instead of absorptive films. But, bear in mind that all types of films have a significant amount of heat absorption (except for clear films used for security purposes).

Before proceeding, inspect the glazing for conditions that are likely to cause thermal breakage. A trade association of window film manufacturers suggests “extreme caution” in using absorptive or reflective films with:

- single pane glass larger than 100 square feet
- double pane glass larger than 40 square feet
- any triple pane glass
- clear glass thicker than 3/8 inch
- tinted glass thicker than 1/4 inch
- reflective glass
- laminated, wired, or textured glass
- frame systems that hold the glass tightly
- frame systems of concrete or solid metal.

Heat treating reduces the risk of thermal breakage. In case of doubt, examine the building’s construction records to see whether heat treated glass is installed.

■ Whether to Install Film on Tinted or Reflective Glass

In principle, films can be used with glass that has already been treated to reduce solar gain. In practice, this is unfavorable for several reasons. From an energy saving standpoint, treated glazing already provides a large part of the potential benefit. Adding any type of film inside absorptive glass further increases the surface temperature of the glass, increasing discomfort and the chance of glass breakage. Film may undo the benefit of any low-E coatings on the original glass. And, further reducing light transmission may make the view dark and gloomy.

Energy Saving and Energy Penalties

■ Solar Heat Gain

When used with clear glazing, solar control films are typically selected to block 60% to 80% of visible

sunlight. Films are usually not selected to block a larger percentage of visible sunlight, because this would make the view through the glazing appear too dark.

The reduction in solar heat gain is usually less than the reduction in visible light. This is because films work partly by absorption, so a part of the sunlight that is blocked is converted to heat within the glazing. Retrofit films are installed on the innermost surface of the glazing, so the glazing traps the heat that is absorbed in the film. A portion of this heat enters the space by conduction and radiation.

With single glazing that is cooled by wind, highly reflective film may reduce solar heat gain by as much as 65%. Multiple glazing traps the heat absorbed by the film more seriously. Therefore, the maximum reduction in heat gain is about 50% with multiple glazing. Films that are less reflective and rely more on absorption reduce solar heat gain even less, from about 35% to about 50%. Again, the benefit is reduced with multiple glazing.

Unfortunately, present films are not able to reflect the infrared component of sunlight selectively, while passing the desired amount of visible light. Films may be able to offer this capability in the future.

If reflective interior curtains or blinds were used with the original glazing, the reduction in heat gain may be half of these percentages.

■ Long-Wavelength Infrared Heat Loss

Low-emissivity coatings used with some films can reduce radiation heat loss from the interior of the building by about 40%. However, in films intended primarily to reflect solar heat gain, low-E coatings involve performance conflicts, which are explained below.

■ Passive Heating

All films that reduce solar heat gain also substantially reduce the potential for passive heating. This factor is unimportant in warm climates, but it may cancel much of the benefit in cold climates.

■ Daylighting

In buildings where effective daylighting exists, all types of films reduce the amount of daylight available. However, most contemporary buildings do not have effective daylighting, even if it was intended. See [Reference Note 46](#), Daylighting Design, for the steps needed to make daylighting work.

Non-Energy Benefits

All films keep glass from fragmenting after breakage, and they may increase resistance to breakage. Some manufacturers of films for solar control also make clear films explicitly to provide shatter resistance against vandalism, storm damage, and other causes. Protective films are substantially thicker than solar control films,

typically about 0.002 to 0.004 inches. Solar control films enhanced for breakage resistance are available.

Solar control films can also be used to enhance or modernize the appearance of a building. Films can be dyed in almost any color or shade. If films are intended for decorative purposes as well as for efficiency, make sure that the colors are compatible with the desired solar control effect, and that the inside view does not become bizarre. Also, make sure that the film characteristics do not invite breakage of the glass from thermal stress.

How Solar Control Films Work

Solar control films reduce the fraction of sunlight that passes through glazing by reflecting or absorbing the sunlight, or both. All films are similar in construction. The following are their main features.

■ Materials

The active ingredients in solar control films are reflective metal films, dyes, and ultraviolet absorbers. The carrier material of the film is one or more layers of plastic. Polyester is the most common carrier material. A layer of acrylic plastic may be added for scratch resistance. A polypropylene layer may be added to protect low-E coatings.

The metal layer, if one is used, is deposited on the surface of one of the plastic layers. The metal layer is transparent because it is very thin. A variety of metals and alloys are used for the reflective films, including aluminum, copper, bronze, silver, gold, titanium, stainless steel, and others.

Dyes and ultraviolet absorbers are added to the plastic material. Ultraviolet absorbers are added to virtually all films. These protect the film itself and the inside of the building.

■ Optical Properties

The optical properties of solar control films stem from the properties of their components:

- **the plastic carrier materials**, such as polyester and polypropylene. These materials are similar to glass in the visible and solar infrared spectrums, except that plastics absorb somewhat more energy in the solar infrared. Plastics pass much more ultraviolet than glass. They pass a small amount of long-wavelength infrared, which is almost totally absorbed by glass.
- **dyes** added to the plastic material, primarily to absorb sunlight and to give color to the film. Dyes are absorptive, and by increasing the quantity of the dye, any amount of absorption can be achieved. Some dyes used in films absorb visible light and solar infrared about equally, whereas other dyes may absorb infrared more strongly.
- **ultraviolet absorbers** added to the plastic material, are dyes selected specifically to absorb ultraviolet

wavelengths. They may be almost completely transparent to other light, or they may impart color to the film.

- **metal reflecting coatings** mostly have high reflectances in the near and far infrared spectrum. The reflectance of metals typically declines toward the short wavelength end of the visible spectrum. For example, the reflectances of aluminum and silver drop abruptly at the blue end of the visible spectrum, but both have high reflectance across the rest of the visible spectrum, which makes them efficient for rejecting solar radiation. The reflectance of copper and gold starts to fall off gradually near the blue end of the visible spectrum, which accounts for their reddish color. Even the thin metal coatings used in films absorb a large part of the light that they do not reflect.

■ Adhesive Methods

The film is attached to the glass with an adhesive. Deterioration of the adhesive is usually the first cause of film failure. Therefore, consider the adhesive when you select the film. Specific adhesives may be covered by patents, making those types available only from individual manufacturers. Check the performance of the films that are candidates for your application. Your best bet is to call users who have installed the film a long time ago, and ask how well it has behaved.

There are two classes of adhesives for solar control films, water-activated and pressure-sensitive. Water-activated adhesives bond chemically to the glass surface, keeping the film tightly attached to the surface and minimizing optical problems. By the same token, these adhesives make the film difficult to remove at the end of its service life.

Films with pressure-sensitive adhesives are applied by removing a backing sheet from the film and pressing it into place. The pressure-sensitive adhesive is quick to apply because no wetting of the adhesive is required. The disadvantage is that the bond is relatively weak.

■ Low-Emissivity (“Low-E”) Coatings

The theory and composition of low-emissivity coatings are covered in [Measure 8.1.3](#). Low-E films can be included on retrofit films, but they suffer efficiency limitations when applied in this manner. The low-E coating is fragile, so it must be protected by a layer of plastic film. None of the available plastic films are highly transparent to long-wavelength infrared, so a significant fraction of the infrared is absorbed in the film.

To reduce this problem, plastics with lower absorption may be used to cover the metal film. For example, polypropylene may be used to cover the metal film instead of polyester. Plastics with lower absorption tend to be soft, so there is a compromise between efficiency and scratch resistance.

At the present time, retrofit films with low-emissivity coatings are covered by patents, so one manufacturer makes most films having this feature.

How much can low-E coatings in glazing films reduce cold weather heat loss? Probably not much, except in very cold climates. Almost any other method of reducing the heat loss through glazing (installing storm windows, curtains, etc.) should yield results that are as good or better. The available performance claims still appear to lack substantiation, and reading between the lines leads one to suspect that performance is unremarkable. Given the short life of films and their other problems, it does not appear that low-E films are the best approach to reducing heat loss in most applications.

Unlike high-efficiency glazing, where low-E coatings are applied between the panes, existing glazing must have films applied to the inside surface. As a result, solar films cannot block heat gain from long-wavelength infrared entering from outside the building.

How to Select Solar Control Films

Solar control films are offered in a wide range of reflectances, absorptions, and colors. Some also offer a limited range of emissivities for long-wavelength heat radiation. In addition to these optical characteristics, films are available with options in adhesive methods, scratch resistant coatings, shatter strength, and perhaps other features.

The hazard in this wealth of choice is making a selection that is less than optimum for the application. Here are the most important selection issues.

■ Manufacturers

At the time this is written, there are fewer than a dozen manufacturers of solar control films. Perhaps two of these could be considered major companies. The performance history of glazing films emphasizes the importance of dealing with manufacturers who have the capability of maintaining a high level of quality control, and who are likely to survive to honor any warranty claims. Check references. As a first filter, avoid any vendors who cannot provide serious technical product literature.

■ Visible Light Transmission

In order to keep the view through windows from appearing too dark, at least 20% of visible light should be transmitted, and 30% is probably a better figure. A lower visible transmission may be acceptable if the glazing does not provide a view of anything but sky, and the view is above normal sight lines.

■ Solar Infrared Transmission

The film's transmission in the solar infrared spectrum should be as low as possible, if the objective is reducing solar heat gain. Most films have somewhat lower transmission and higher absorption in the solar

infrared band than in the visible band. Films with substantially lower infrared transmission than visible transmission may become available in the future.

■ Reflection vs. Absorption

This issue is essentially the same for retrofit films as for treated glazing. See [Measure 8.1.3](#) about this issue.

■ Color

Color in glazing films is created in two ways. One is by adding dyes to the film that selectively absorb portions of the visible spectrum. The color imparted to the outside of the building is approximately the same as the color of light that is transmitted into the building. You can select from a wide range of colors. However, dyes are absorptive, which increases heat gain.

A more efficient method of producing color is by using different metals for reflective coatings. For example, copper and bronze produce a reddish color. Metals with a noticeable color are somewhat absorptive, but less so than dyes. The range of colors available is limited by the range of suitable metals.

■ Scratch Resistance

Some types of glazing films are much more resistant to scratching than others. A common scratch resistant coating consists of a thin outer layer of acrylic plastic applied over the main polyester film. All major manufacturers offer scratch resistant coatings as an option.

Unfortunately, the scratch resistant surfaces that are presently offered absorb long-wavelength infrared heat radiation. This makes them incompatible with low-E coatings.

■ Appearance and View

These issues are generally the same as for treated glass. See [Measure 8.1.3](#) for the details.

The choice between the reflective and absorptive properties has a major effect on the exterior appearance of the building. Reflective films make the glazing look like a mirror. Absorptive films make the glazing appear colored. You can balance these properties by a combination of reflective and absorptive properties.

How to Install Retrofit Films

Selecting the right installer is as important as selecting the right film manufacturer. Installation does not require genius, but it does require experience and discipline. For this reason, have the film installed by specialists. Also, film warranties may require professional installation.

Labor is the largest part of the cost of solar control films, so the installer is faced with a large temptation to cut corners. The important aspects of installation are protecting the film from damage in handling, cleaning the glazing surface, eliminating bubbles and wrinkles, activating the adhesive uniformly, and trimming the film

to fit the frame. If the glazing is wider than the film stock, the installer must know how to splice the film without making the seam too apparent.

Avoid Damage in Cleaning

Polyester film is relatively soft, and therefore develops hazing as a result of repeated cleaning. Scratch-resistant coatings resist hazing, and allow conventional window cleaning methods to be used. Some films have a silicone surface, which eases cleaning.

Relationship to Daylighting

Solar control films substantially reduce the amount of sunlight available for daylighting. However, sunlight is much brighter than is needed for daylighting, so films may be compatible with daylighting in some cases.

Films alone cannot produce acceptable daylighting. The light level outside on a clear day is about 6,000 footcandles, in contrast with a typical office space light level of 60 footcandles. Therefore, transmission would have to be limited to about 3 percent to allow reading by direct sunlight. Glass with such a low transmission would make the view of the outside appear almost black.

Relationship to Passive Heating

Solar control films block heat gain in winter as well as in summer. Therefore, the summer saving in cooling energy is partially lost as a result of increased winter heating cost. The compromise between cooling cost and heating cost depends on the climate, the latitude, the schedule of operation of the building, the amount of internal heat gain during daylight hours, and the relative costs of cooling and heating. If loss of passive heating may be an important issue, make a detailed calculation of the net saving.

If passive heating capability is important, solar control films are self-defeating. Instead of using films, install separate external or internal shading devices that can be adjusted to meet shading or heating requirements. See [Measure 8.1.1](#) and [Subsection 8.4](#) about shading and passive solar heating, respectively.

ECONOMICS

SAVINGS POTENTIAL: 35 to 60 percent of the solar cooling load, if there is no other window treatment. 20 to 45 percent of the solar cooling load, if the building has interior curtains or shades.

The net saving is reduced by loss of passive heating during cold weather. The importance of this varies widely. In facilities where daylighting is used, a part of the saving may be offset by higher lighting costs.

COST: \$2.50 to \$5.00 per square foot, installed. Installation labor is the largest part of this cost.

PAYBACK PERIOD: 5 to 10 years, typically. Payback period is a misleading economic criterion for glazing films because they may not last much longer than the time needed to pay them off. A more effective indicator is the ratio of total lifetime savings to initial cost. With present films, this ratio typically ranges from about 4:1 in the best cases, to about 1.5:1 in the worst cases.

TRAPS & TRICKS

CHOICE OF METHOD: Do you have alternatives that may be better, such as installing sun shades, or planting trees, or eliminating large areas of glazing? Would installing film create a risk of glass breakage? Expect the film to start looking shabby during the second half of its service life. This is a method with serious drawbacks, but it may be your only choice.

SELECTING MATERIALS: All films have limited service life, but some films are better than others. Make sure that the film has a good reputation and has all the features you want.

INSTALLATION: Make sure that the installer follows the manufacturer's installation procedures meticulously. Watch how the installer performs on somebody else's job before you sign the contract. Deal with an installer who is likely to remain in business long enough to honor the warranty. Ask for references, and check them.

CLEANING: You need to exercise vigilance for the life of the film to ensure that cleaning practices do not cause mechanical damage or hazing. One careless cleaning can ruin the film.

MEASURE 8.1.5 Reduce the area of glazing.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Glazing is responsible for two major energy costs, solar heat gain in summer and conductive heat loss in winter. You can reduce the heat gain and heat loss of glazing by replacing the glazing, or a portion of it, with insulating panels.

In new construction, this Measure is largely a matter of reversing the contemporary practice of using windows as walls. Deciding how much glazing to abolish is a judgement call. You may have to choose a different stylistic concept for the building. In fact, after you review all the Measures in this Section, your entire building envelope concept may change radically.

In existing buildings, reducing window area is a major change. However, it is more likely to be economical than you may expect. The challenge lies in taking the maximum advantage of the modification. Reducing glazing area may be a powerful opportunity to improve the appearance of the building. On the negative side, it may detract from the occupants' view. It also affects the potential for passive heating and daylighting. Reducing glazing area on a retrofit basis requires considerable thought, a sense of style, and attention to detail.

Where to Reduce Glazing Area

It pays to reduce glazing area in a wide variety of buildings. Obviously, the largest savings are achieved in buildings that have large areas of glazing. This Measure conserves both heating and cooling energy, so it is worth considering in most locations.

In the design of new buildings, reducing the glazing area requires rethinking the appearance concept of the building from the standpoint of energy efficiency. All building designs can benefit from such a review.

With existing buildings, retrofitting insulating panels tends to be less expensive if the contrast in appearance between an insulating panel and the adjacent wall and window is acceptable, or if the contrast can be used as an architectural accent. A requirement to match an existing decor can raise cost considerably. Figure 1 shows an example where the glazing area was reduced by a large amount without risk to the decor.

It might seem that glazing area cannot be reduced in "glass box" architecture because of the difficulty in maintaining uniform surface appearance. In fact, insulating panels can be made to match or complement virtually any style of glazing. Much of the "glazing" in many glass box buildings is actually the outer surface of an opaque curtain wall. However, using glass as the outer surface of an insulated panel requires careful

SUMMARY

A simple and effective way of reducing both heat gain and heat loss. Applies to a large variety of buildings.

technique to prevent glass breakage and irregular appearance.

Energy Saving Potential

For a given window or skylight, solar heat gain and conductive heat loss are proportional to the glazing area. In buildings with a large amount of glazing, the glazing is responsible for most of the cooling load in warm weather, and most of the conductive heat loss in cold weather. You may be able to eliminate a large fraction of the glazing, thereby reducing your cooling and heating costs substantially.

In colder climates, reducing glazing area may reduce the benefit of passive solar heating, or it may not. This is discussed below.

Reducing the glazing area may reduce the potential for daylighting, or it may not. This is discussed below.

General Approach

Plan to eliminate glazing in a manner that provides an optimum balance of these factors:

- solar and conductive heat gain during warm weather
- conductive heat loss during cold weather
- passive heating during cold weather
- daylighting
- occupants' view
- exterior and interior appearance
- security.

Don't be afraid to reduce glazing area radically, if you can do this without causing problems. Much of the glazing that has been installed in buildings serves no purpose except to allow the architect to pass off the work of envelope design to the glazing fabricator.

■ Reduce Solar Heat Gain

The potential for reducing solar heat gain depends on the exposure of the glazing. Estimate the amount of solar heat, per unit area, falling on each face of the building where you may reduce the window area. Take into account any shading of the building exterior.

The *ASHRAE Handbook* and other references have tables that help you do this quickly. Also, review [Reference Note 24](#), Characteristics of Sunlight, to see how the motion of the sun affects heat gain.

■ Reduce Conductive Heat Loss

The reduction of conductive heat loss is proportional to the reduction of glazing area. It does not matter much where the glazing is located in the building, assuming that it faces into a conditioned space.

Use materials with high insulation values to replace glazing. See [Reference Note 43](#), Insulation Selection, for materials and methods. If the building has curtain walls, coordinate this Measure with [Measure 7.2.4](#), which explains how to increase the insulation value of the opaque portions of curtain walls.

■ Optimize the Amount of Passive Solar Heating

Eliminating glazing sacrifices its ability to provide passive solar heating in cold weather. However, reducing

conductive heat loss may compensate for the loss of passive heating. You need a detailed calculation to estimate the net saving accurately.

In cold climates, you will usually achieve a net saving in winter heating if you replace single-pane glazing with well insulated panels. If the original windows have higher insulating value, passive heating may be providing a net benefit. However, if window treatments are installed that block sunlight, passive heating may not offset the conductive heat loss.

In milder climates, passive heating has a stronger effect than conductive heat loss. However, in mild climates, cooling load is likely to be a larger cost factor than heating load.

To exploit passive heating, retain more glazing on the building surfaces that are exposed to the sun for a large fraction of the day. Passive heating is tricky. To exploit it effectively, study [Subsection 8.4](#) and [Reference Note 47](#).

■ Exploit Daylighting

Whenever you do anything with windows, consider the possibility of exploiting daylighting. This takes some skill. See [Subsection 8.3](#) and [Reference Note 46](#).

Reducing glazing area reduces the amount of sunlight available for daylighting. This may not matter much, because the amount of sunlight falling on large windows is much greater than needed for perimeter lighting. Even reduced glazing area may leave plenty of daylighting potential, if the light is distributed effectively.

Keep in mind that daylighting is most effective when coming down from above. For example, in a building with tall windows, consider replacing the top portion of the glazing with light diffusing panels, and replacing the rest of the glazing with insulating panels.

■ Preserve Desirable Views

View is the only function that absolutely requires glazing. Examine the building skeptically to decide whether the existing windows are actually providing view. In a large fraction of buildings with extensive glazing, sunlight creates intolerable glare that causes occupants to block out all sunlight, along with the view. In such cases, decide whether to reduce glazing, to make changes to create acceptable view, or both.

With tall windows, you can eliminate glare by eliminating the upper portion of the windows, leaving the glazing at the bottom to provide view of surrounding landscape. If glare would still be a problem with the lower glazing, consider installing external or internal shading as part of the conversion. See [Measures 8.1.1](#) and [8.1.2](#) for shading methods.

■ Improve the Interior and Exterior Appearance

This Measure strongly affects the appearance of a building. In many buildings, this is a major economic and esthetic issue. If the change is designed by a person

Kalwall Corporation

Fig. 1 Reduction of window area Most of the bottom window has been replaced with translucent insulated panels.

with a good sense of style, it can enhance the appearance and value of the building. Conversely, a thoughtless job can make the building look derelict. Someone with good taste should have approval authority over the design.

You can achieve good insulating properties with any surface appearance. For example, you can use glass, polished metal, stone frieze, stucco, bronze bas relief, canvas awnings, etc. Let your imagination roam free.

■ Enhance Security

Unfortunately, the condition of our civilization makes it possible to claim increased security from burglary and vandalism as a benefit of eliminating glazing, especially for glazing near ground level. In locations where this factor is important, make the substitute material strong. The children of modern social policy are not easily denied.

Optimum R-Values and Economics

See [Reference Note 45](#), Insulation Economics. In most climates, the optimum insulation thickness is the largest amount that you can install in the panels without causing appearance problems or increasing fabrication cost.

ECONOMICS

SAVINGS POTENTIAL: *Up to 50% of total cooling costs, and up to 50% of total heating costs. The saving depends on the glazing area, the climate, internal heat gains, building geometry, and other factors.*

COST: *In new construction, reducing the glazing area may increase or decrease the cost of the building by a small percentage, depending on the other options being considered. In retrofit, replacing glazing with insulating panels costs from \$10 to \$50 per square foot, depending on the size of the job, the difficulty of replacement, and the nature of the replacement panels.*

PAYBACK PERIOD: *In new construction, the payback period can be immediate or very short. In retrofit, the payback period is several years or longer.*

TRAPS & TRICKS

DESIGN: *The simplicity of the concept hides the fact that a lot of brain work is needed to develop an optimized design. This modification is unusual as a retrofit. When used with a sense of style and a sense of humor, it can turn an old building into a showpiece. On the other hand, a thoughtless design may fail to achieve potential savings, disfigure the building, and ruin views.*

Reducing Cooling Load: Opaque Surfaces & Overall

Heat gain that enters through the opaque portions of a building's envelope is important. If the building has a large cooling load, consider steps to reduce this heat gain. The roofs of most buildings absorb enough heat to merit attention. Also, don't overlook the possibility of reducing heat gain through the walls.

The heat of sunlight passes through opaque surfaces in a sequence of steps. First, sunlight is absorbed in the outer skin, raising its temperature. Then, the absorbed heat is driven through the envelope by the temperature differential. Once inside the envelope, the heat is transferred to the cooled space by radiation, conduction, and perhaps by convection. You can reduce solar heat gain at each of these stages by using these methods:

- **prevent sunlight from reaching the outside surface**, by shading. [Measure 8.2.4](#) recommends tree shading. Various methods of attaching mechanical shading to the building could be used, but this approach is not economical for opaque surfaces, except in rare cases.
- **reflect the sunlight from the outside surface**. [Measure 8.2.2](#) recommends this approach.
- **cool the exterior surface**. Wind has an important cooling effect, but most locations do not have enough wind to keep the external surface near the air temperature. Evaporative cooling of exterior surfaces by keeping them wetted has been tried over the years, but this method no longer offers an advantage that makes it worth the bother.
- **minimize the conduction of heat through the envelope** by improving insulation. [Measure 8.2.1](#) recommends better insulation.
- **vent heat from the inside of the envelope** before it becomes a part of the cooling load. [Measure 8.2.3](#) recommends venting attics to reduce heat gain.

The Measures of this Subsection are presented in the approximate order of their importance in typical applications, considering energy saving potential and practical considerations. Try to combine the Measures where appropriate.

MEASURE 8.2.1 Improve the insulation of surfaces exposed to sunlight.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Insulation is a very effective way of stopping solar heat gain through opaque surfaces. The variety of available insulation methods makes it possible to add insulation to many buildings that lack insulation or have too little. Go to the Measures in Subsections 7.1 and 7.2 for the ways that you can improve insulation in different parts of the building envelope.

The value of envelope insulation for reducing heat gain in warmer climates tends to be underestimated. This occurs if a designer calculates heat gain based on the difference between outside air temperature and inside temperature. This is a mistake, because absorption of sunlight by exterior surfaces creates temperature differentials across the building shell that may be several times greater than the air temperature differential.

In retrofit applications, adding insulation is most cost effective when applied to large expanses, such as

roofs. Whenever a roof requires major maintenance, consider improving its insulation value. The economics are much less favorable when installation requires a large amount of fitting or finish work, such as insulating interior walls between windows.

Even if heating is not required, install insulation below or inside any vented areas, such as attics. This reduces the temperature differential across the insulation, increasing its effectiveness.

Combine Insulation with Other Methods

Insulation does not eliminate the high temperature differentials that sunlight creates across surfaces. Wherever it is economical to do so, combine insulation with other Measures of this Subsection that reduce solar gain. For example, if insulation is installed on top of a roof deck, cover it with a reflective surface.

MEASURE 8.2.2 Apply paint, coating, or sheathing that minimizes absorption of sunlight.

RATINGS

New Facilities	Retrofit	O&M
A	B	

The amount of solar heat that is absorbed by a building surface depends entirely on its finish. To minimize heat gain, the surface finish should do two things:

- **reflect sunlight** well. This includes both visible light and the sun’s infrared heat radiation.
- **emit heat radiation** well. Surfaces stay cool by radiating their heat back into space.

Many ordinary finishing materials satisfy both these requirements. For example, a clean coat of white paint minimizes heat gain. However, many construction materials do not reject heat well, even though they have a light color. You need to do some simple testing to find the best finish materials.

A carefully selected surface finish is a powerful tool to reduce heat gain at low cost. In new construction or in refurbishing an old building, it adds nothing to the cost. Otherwise, it may cost no more than a new paint job.

SUMMARY

An important way to reduce cooling load, especially in sunny climates. Often inexpensive.

Where to Use Non-Absorbing Surface Finishes

This Measure is effective with roof and wall surfaces that receive a substantial amount of direct sunlight, regardless of orientation. Consider it for all new construction and for exterior renovations, including repainting.

As a retrofit activity, it merits attention with any building that has a high solar cooling load, provided that you are able to change the surface finish. For example, this Measure would not apply to a building with a decorative masonry surface. Some finishes, such as asphalt shingles, cannot be coated, so they must be replaced. Changing the surface materials is usually too expensive for the purpose of reducing cooling load alone.

Energy Saving Potential

In a fairly clear climate, each square foot of surface area absorbs about 300,000 BTU per year (about 900 kilowatt-hours per square meter per year). A fraction of this energy reaches the conditioned space. The fraction depends on the absorption of the surface, the insulation value of the envelope, the amount of wind, the nature of the surface, the length of the cooling season, and other factors. In the case of roofs, venting is an important factor (see [Measure 8.2.3](#)).

The reduction of cooling load is greatest with large, poorly insulated surfaces. For example, you can greatly reduce the cooling load in a lightly insulated metal building just by selecting a more reflective surface color for the roof and walls, as in Figure 1. (In such cases, also consider improving the insulation. See [Subsections 7.1](#) and [7.2](#) for the Measures related to insulation.)

On the other hand, this Measure increases the heating load. If heating is a much larger cost than cooling, this activity may be self-defeating. However, the increase in heating load typically is much less than the reduction of cooling load. One reason is that the surface finish is important only when the sun is shining, and the sun shines longer in summer than in winter.

Another reason is that cooling temperature differentials are typically smaller than heating temperature differentials, so the effect of direct sunlight is more important for cooling.

The Tricky Part: Absorption and Emittance

You might think that reducing surface heat gain is simply a matter of selecting a surface finish that reflects light well. It is more complicated than that, for two reasons. First, visible light is only about 40% of solar radiation, and a surface that reflects visible light may not reflect the invisible portion. Second, the surface finish can stay cool only by radiating the heat that it absorbs back into space. The tendency of a surface to emit heat radiation is called “emittance.” The emittance of different surfaces varies over a wide range.

(Emittance is defined formally as the amount of energy that is radiated by a warm surface compared to the amount that would be radiated by an ideal radiating surface. Paradoxically, such an ideal radiating surface is called a “black body.” Surfaces at outdoor temperature radiate their heat at very long wavelengths, much longer than the wavelengths of the heat that reaches the earth from the sun.)

The visible color of a coating indicates the reflection, or absorption, of sunlight only at visible wavelengths. For example, bright white surfaces reflect about 90% of visible light. However, color is not a good indication of total heat absorption, because more than half of the heat in sunlight is at invisible infrared wavelengths. The surface may absorb infrared radiation much more strongly than it absorbs visible light. The energy of visible sunlight is concentrated in the narrow band of

WESINC

Fig. 1 Reflective paint provides most of the cooling of these buildings These buildings have metal roofs and walls, which makes it important to paint them with a fairly heavy coat of non-conducting paint. These buildings, located in a sunny climate, have good exhaust stacks, but they are too far apart. Continuous ridge vents would be better. The ventilation inlet louver on the end of the gable lacks sufficient open area.

wavelengths from 0.4 to 0.7 micrometers (microns), while the infrared energy of sunlight is spread out in the range of 0.7 to 2.5 micrometers. Thus, there is plenty of room for materials to have absorption bands within the infrared spectrum. For example, some white gravel used as ballast on flat roofs becomes hot in sunlight for this reason.

The emittance of a surface depends mostly on two factors: whether the surface is electrically conductive, and whether the surface is smooth. Almost all non-conductive construction materials have an emittance higher than 80%. This includes masonry, wood, gravel, glass, and non-metallic paint. However, as we noted earlier, some gravel appears to have low emittance, probably because it is made of crystals that have smooth surfaces.

Smooth metal surfaces have very low emittance, typically 0.1 or less. The emittance of metal increases if it becomes dirty or corroded, but it still remains down around 0.2. For this reason, you can observe that bare metal surfaces are usually warmer than other surfaces when exposed to sunlight.

Low emittance is a problem with metal surfaces even if they have high reflectance. For example, you can feel that the surface of a polished metal surface is much warmer in direct sunlight than a white painted surface, even though both reflect about 90% of the sunlight.

For this reason, metallic paint is not a good surface finish to protect against heat gain. For example, aluminum paint is sometimes used to reduce the heat gain of asphalt roofs, but you can observe that this does not work well. The high reflectance of the paint is offset by its low emittance.

If metal sheathing is used as a surface finish, it should have a thick coat of non-conducting paint. Emittance is a surface property, so the emittance of the sheathing is determined by the paint, rather than by the metal itself. (This is not true of anodized finishes, which are so thin that the emittance of the metal still matters.)

How to Select a Surface Finish

As a first step in selecting materials, apply the previous principles, i.e., start with light colors and avoid bare metals. Then, find out how well your candidate materials respond to actual sunlight.

The most reliable way to determine the heat rejection properties of surface finishes is to set up some test surfaces. This inexpensive test requires only a few hours in the sun, and it allows you to judge candidate materials before applying them on a large scale.

The procedure is simple. Use a portion of the existing surface to apply various candidate materials.

If possible, shield the test area and a portion of the original surface from wind. Measure the temperatures of the various surfaces under sunny conditions, and compare them to the air temperature.

You could try to get reflectance and emittance information from the manufacturer or from reference books, but this is usually not worth the bother. The manufacturer is unlikely to understand what you are asking. Testing the materials yourself is probably quicker.

Exploit Sheathing to Provide Shading

If you decide to install sheathing or siding over an exterior surface, try to use a method of attachment that allows ventilation between the sheathing and the envelope surface. In this way, the sheathing provides shading as well as reflection. For example, install sheetmetal siding over vertical furring strips. This is primarily a method for warm climates. If the weather spends much time being cold, a tight exterior surface is more valuable.

This method of installation makes the sheathing more vulnerable to wind and impact damage. Account for this by using more fasteners, and perhaps by installing battens over the surface material.

ECONOMICS

SAVINGS POTENTIAL: *Selecting the surface finish intelligently can reduce the cooling load through a sunlit surface from 30% to 70%, compared to using a finish with high heat gain. Savings in cooling are offset by increased heating costs, so the net saving depends on the climate profile.*

COST: *In new construction and in refurbishing existing buildings, selecting surface finish materials to reduce heat gain usually costs little or nothing. A good exterior paint job typically costs \$0.20 to \$0.60 per square foot. Fancy surface materials may cost several dollars per square foot, but that expense is for appearance, not energy conservation.*

PAYBACK PERIOD: *Immediate, to several years.*

TRAPS & TRICKS

SELECTING THE COATING MATERIALS: *You get to be a scientist in doing this Measure. Don't go out of your way to find exotic materials. Many ordinary surface finishes perform well. Select materials that are durable, economical, and easily cleaned. Test them for low temperature rise in bright sunlight.*

MAINTENANCE: *Dirt increases the sunlight absorption of a reflective surface. If the surfaces tend to get dirty, clean them during the warm season. Put this in your maintenance calendar.*

MEASURE 8.2.3 Provide effective ventilation of attics.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Many buildings have an attic space, which is a dead air space between the roof and the occupied space. When sun shines on the roof, the attic acts as an air heater. The heated air may spread to portions of the building that are cooled, or the heat may spread to occupied spaces by conduction. If the attic space contains cooling ductwork, the heating of the ducts increases cooling load.

To prevent these losses, make sure that the attic space is ventilated adequately. Warm air must be able to flow freely from every part of the attic to the outside. In some cases, air movement by convection is adequate. In others, you should install a ventilating fan. In some cases, you may be able to exploit wind to provide ventilation. Route the ventilation air to keep the roof surface as cool as possible. This reduces radiation of heat into the lower spaces.

Where to Improve Attic Ventilation

Most buildings that have an attic space can benefit from improved attic ventilation. There are some exceptions. If the attic space is used as an air return plenum, it cannot be ventilated, and the only practical way to reduce heat gain is to improve the roof insulation. If there is a partition between the attic and the

SUMMARY

Attics are often poorly vented. You may be able to substantially reduce the roof cooling load by improving attic ventilation.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

conditioned space, such as a suspended ceiling, attic ventilation is less important.

The economic benefit of this Measure increases with the size of the roof. All large attics deserve attention, but adding ventilation equipment to smaller attics may be uneconomical. Attic ventilation is most important when there is equipment within the attic space that is vulnerable to heat gain, such as air conditioning ductwork.

WESINC

Fig. 1 Attic that provides convective ventilation This roof illustrates the main feature needed to exploit convection, which is a significant height difference between the ventilation air inlet and discharge points. This roof shape can distribute ventilation air exceptionally well. The air can flow upward at all points, parallel to the rafters. To cool the entire surface of the roof, air inlets must be installed all around the eaves. In this example, the air discharge louvers should be larger.

WESINC

Fig. 2 Wind ventilators These are installed in pairs, as shown here. One unit has a vane that points it into the wind, and the other points downwind. They are placed at opposite ends of the attic. Dampers visible in the near unit blow shut in a high wind. They require a prevailing wind to be effective. In still air, they act as simple ventilation stacks, too far apart to be very effective.

Air conditioning and refrigeration condensers are sometimes installed in attics. This is a serious mistake that radically increases operating cost and reduces cooling capacity. You should correct this situation by moving the condensers to an external location. If that is not practical, ventilate the condensers aggressively with fans that draw air directly from the outside.

Energy Saving Potential

Improving attic ventilation rarely offers a dramatic saving. This is because an attic acts as a thermal buffer between the roof and the occupied space. Thermal isolation is increased by stratification, which creates a static air layer that has significant insulation value. Any partition between the roof and the occupied space enhances the isolating effect of the attic, and may have significant insulating value. For example, ordinary acoustical ceiling tile has an R-value of about 2.

If extensive cooling ductwork is installed in an attic, venting the attic may reduce heat losses through the ductwork by a factor of two or three. The importance of this depends on the amount of ductwork and how well it is insulated.

If you install fans for ventilation, their operating cost reduces the saving in cooling energy. However, if the ventilation layout is designed well, ventilation fans need relatively little power. Also, they should be equipped with controls that limit their operation to times when they provide a benefit.

How to Guide the Air Flow

You can observe that attic ventilation is typically a hit-or-miss proposition, with a few vents scattered around the perimeter of the attic, and maybe a couple of vents in the roof. You can do better than that. Follow these guidelines to provide the best possible ventilation.

(1) Create a defined path from inlet to outlet.

If the air does not know which way to go, it will just sit there in the attic and get hot. The air has to enter at one point and it has to leave at another. The layout depends on the geometry of the attic and the force (convection, wind, or fans) that moves the air.

If the roof is sloped, let air enter at the bottom and leave at the top. If the roof is flat, you may have the air move from one side of the roof to the other, or from the sides to center outlets.

(2) Circulate the entire air volume of the attic.

Don't leave any dead air space in the attic. If the roof is sloped, install outlets along the entire top of the ridge, and inlets along the entire eave or soffit.

If it is not practical to install an adequate number of inlets and outlets to guide the air flow, you can use lightweight ducts to route the air through the attic. Ducts can get ventilation air into all the nooks and crannies. Using ducts requires a fan or fans. Inexpensive ventilation ducts made of fabric or plastic film are widely available. They fit easily on inexpensive propeller fans designed for the purpose. You can get this equipment

WESINC

Fig. 3 Attic fan The fan is needed to cool ductwork and other equipment, as well as to minimize attic heat gain. Its location in the gable wall is not good, because it must blow against the wind part of the time. Operation of the fan should be controlled by a thermostatic switch in the attic. A tall attic like this one could be ventilated effectively with a continuous ridge vent and large gable louvers.

from companies that supply greenhouses and poultry buildings, and from other sources.

(3) Ventilate the entire underside of the roof surface.

Keep the underside of the roof as cool as possible. This minimizes the heating of air in the attic, and it minimizes radiation of heat to the bottom of the attic. To do this, route the ventilation air so that it sweeps across the underside of the roof. In most cases, a layout that works well for the previous step also works well for cooling the roof surface. For example, with a gable roof, feed air along the eave and vent it out at the ridge.

Arrange the air flow parallel to rafters, joists, or purlins. Otherwise, these will block the flow, creating a dead space of hot air under the roof.

If you use ducts to distribute ventilation air, have the ducts discharge upward, toward the roof surface.

(4) Provide large inlet and outlet area.

Like any fluid, air has a certain amount of mass and viscosity. That means, it doesn't want to flow. If you expect to rely on convection or wind to move the air, make it easy for the air to flow. The main restrictions are the inlets and outlets. Make them big. It is virtually impossible to overdo this. For example, if you want to use natural ventilation for a gable attic, consider installing ventilation louvers that cover the entire area of the gable end walls.

If you use a fan or fans for ventilation, big openings and big ducts minimize the fan energy that you have to pay for.

How to Move the Air

Attic ventilation should use as little energy as possible, preferably none. The possible sources of air

motion are convection, wind, and fans. The key to efficient ventilation with each of these is providing large inlet and outlet vents, so that a large volume of air can move easily at low velocity.

■ **Ventilation by Convection**

If possible, use convection to ventilate the attic. Convection is driven by the difference in temperature (and hence, density) between the air in the attic and the air outside. Convection does not depend on wind.

In order for convection to work, the warm air in the attic must flow upward toward the outside. The convection force is proportional to the temperature difference, and to the difference in height between the attic air outlet and the ventilation air inlet. The disadvantage of convection is that it is a weak force, except in very tall attics. Some styles of architecture enhance the height of the attic to increase attic ventilation by convection. Figure 1 is an example.

For effective ventilation coverage by convection, there must be outlet vents at all high points in the roof and there must inlet vents around the perimeter of the roof. On pitched roofs, full length ridge vents are effective outlets.

Ventilation stacks, such as those shown in Figure 1 of [Measure 8.2.2](#), do not provide much convection beyond that which is provided by any ridge vent. However, they are effective for allowing the attic air to rise to an elevated position from which it can be blown away by wind.

■ **Using Wind for Ventilation**

Wind is effective for attic ventilation only in locations where there is a steady wind during warm weather. If you want to rely on wind, provide an effective means of funneling the wind into the attic. One method is to install vents all around the attic.

Fig. 4 Turbine ventilators These are well placed. Static ventilators would probably be as effective. A continuous ridge vent would be even more effective, more attractive, and less expensive. The gable end louvers are large, and could be even larger.

If this is not practical, use large pivoting ventilators that point themselves using wind vanes. These were fairly common in the days before air conditioning, but they have since disappeared. They are arranged in pairs, with one unit facing into the wind and the other facing downwind. Figure 2 shows an example. You may have to get them made on a custom basis. Locate them at opposite end of the attic. Don't install these devices where they are shielded from wind, for example, below the level of parapets or behind decorative screens.

Using wind is tricky because its energy varies over an enormous range. Be prepared to deal with storm conditions that may occur only rarely during the life of the building. Wind inlets must prevent entry of precipitation during heavy winds. One solution is to use inlet dampers that blow closed above a certain wind speed. You can see this feature in Figure 2.

■ Ventilation Fans

If you use ventilation fans, install them so that they never discharge into the wind. For example, do not install fans in the vertical end walls of eaves, as is commonly done (see Figure 3). Fans that discharge vertically are not strongly affected by wind, unless there is a downdraft from an adjacent structure. Fans with hoods shield against wind, but even these should not be installed on vertical surfaces. In general, install the fans on the roof, at high points.

■ Turbine Ventilators

Turbine ventilators occasionally come into fashion among those who believe in perpetual motion machines. Figure 4 shows a typical installation. The idea is that convection causes the turbines to spin, and the spinning turbines draw air through the attic. In fact, turbine ventilators are usually spun by wind rather than by convection. They probably offer no significant advantage over static vents, as long as the vents are large enough. Turbine ventilators tend to squeak, annoying neighbors over a large distance.

How to Control Ventilation

■ Fan Control

If you use fans for attic ventilation, control them so that they do not operate unnecessarily. Simple, inexpensive thermostatic control is the way to do this. Install the sensing element of the thermostat in the stream of air that is being exhausted from the attic.

If there are days when the building is not cooled, such as weekends, consider time controls in addition to the thermostat. Control by the hour of the day, as well as the day of the week. For example, it may not be economical to run a ventilation fan at the end of the

day, because heat stored in the roof radiates away overnight. See [Reference Note 10](#), Clock Controls and Programmable Thermostats, for guidance in selecting time controls.

■ Adapting to Cold Weather

Excessive attic ventilation during cold weather wastes heating energy. This should not be a problem if the attic insulation is installed properly (see [Measure 7.1.1](#) for details). If you use an attic ventilation fan with a thermostat, the thermostat will prevent excessive ventilation.

Consider limiting air flow through the attic during cold weather if the attic contains heat distribution equipment. For example, steam heating systems typically feed downward, so the attic may be full of steam pipes. Excessive attic ventilation during cold weather may even create a freeze problem. In these specialized cases, it may be desirable to install dampers on the ventilation inlets and outlets. If so, the dampers need a reliable method of control. Again, thermostatic control is simple and relatively inexpensive. Manual operation is unreliable.

Do not seal the attic entirely during cold weather. A certain amount of venting is necessary to prevent condensation and ice formation in the insulation and in the attic. The appropriate amount of venting depends on weather conditions and on the effectiveness of the vapor barrier between the attic and the occupied space.

ECONOMICS

SAVINGS POTENTIAL: 30% to 70% of the cooling load entering through the attic. The amount of energy this represents varies widely depending on the roof and attic design.

COST: In new construction, inexpensive design changes may improve attic ventilation greatly. In existing facilities, the cost of improving ventilation varies widely. The cost per unit of roof area declines with roof size.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

DESIGN: The main point is to provide air flow throughout the attic. If you rely on vents alone, they must be large and numerous. If you use a ventilation fan, don't be shy about using lightweight duct to distribute the air.

MONITOR PERFORMANCE: Attic ventilation equipment is out of sight, and failure does not create alarms. Therefore, if the ventilation system relies on active devices, such as fans and motorized dampers, schedule periodic checks in your maintenance calendar.

MEASURE 8.2.4 Plant trees and other foliage to provide shading.

Tree shading is a technique as old as mankind, but it has not been used much in modern times to reduce mechanical cooling load. It deserves more attention for this purpose than it presently receives. Tree shading prevents direct entry of sunlight into the building through glazing, it reduces the surface temperature of the external opaque surfaces, and it lowers the temperature of the air surrounding the building. Figure 1 shows an application with a modern office building.

Trees may be the most economical and practical method of shading some buildings. Trees are inexpensive. They are fairly easy to plant. They do not have to be customized to the building. A special advantage is that they automatically adjust shading to the seasons. They may substantially improve the appearance of the property.

Tree shading has two major disadvantages. One is the long delay between the time the tree is planted and time it starts to produce savings. The other is a need for periodic maintenance.

Where to Consider Tree Shading

Consider tree shading for all types of buildings that receive a substantial amount of solar gain at an elevation below about 50 feet (15 meters). You can use trees to shade tall buildings, but they can shade only the lower portions of the buildings.

Trees also require soil, moisture, and sunlight conditions appropriate to the species planted. Trees can grow well even in areas that are heavily paved, provided that soil moisture is adequate.

Energy Saving Potential

Virtually no direct sunlight gets through the canopy of a healthy shade tree. A fully shaded surface has a solar gain of less than 20 BTU per hour per square foot. As a result, complete shading by trees eliminates over 90% of the solar energy falling on a surface. Shade trees are wide in relation to their height, so they continue to be effective when the sun is at low elevations.

Effect on Passive Heating

One of the major advantages of using deciduous trees for shading is that they do not seriously obstruct solar heat gain during cold weather. This makes tree shading compatible with passive solar heating.

Effect on Daylighting

Tree shading may help or hinder daylighting, depending on the geometry of the building and its

SUMMARY

Works well for shading low structures and the lower portions of tall structures. Improves appearance. You have to wait several years to get results. Requires surrounding land. Requires maintenance.

glazing. Tree shading may enhance daylighting if it encourages occupants to open internal blinds to admit the pleasant sunlight of the shaded environment. On the other hand, tree shading is incompatible with daylighting techniques, such as “light shelves” (see [Measure 8.3.2](#)), which are intended to distribute the full intensity of sunlight.

Non-Energy Benefits

Tree shading has strong esthetic potential. If accomplished with a good sense of style, it can greatly enhance the appearance of a property.

Tree shading can also increase the usable area of space outside the building during warm weather for uses such as patio restaurants, cart vending, etc.

Tree shading has been promoted as a means of purifying the atmosphere. This effect is minimal if trees are planted on a localized basis. Trees are more likely to succumb to air pollution than to correct it. Also, contrary to popular belief, trees do not reduce the amount of carbon dioxide in the atmosphere. Trees absorb a large amount of carbon dioxide as they grow, but they return carbon dioxide to the atmosphere as they decay.

Disadvantages

A serious disadvantage of tree shading is that it takes from three to eight years for trees to grow large enough to produce significant shading. This assumes that the trees are grown from small sizes. Trees that are purchased large enough to provide shading immediately are expensive. However, buying larger trees may be the most cost effective approach, especially if you need to shade large areas of glazing.

Trees require maintenance throughout their lives, although typically at long intervals. The life cycle cost of tree maintenance is not trivial, especially if you have to keep the trees manicured for decor.

How Tree Shading Works

Trees provide cooling in two principal ways:

- **blocking solar radiation.** Sunlight is either reflected from the tree, or it is absorbed by the foliage at a distance from the building. Heat absorbed by the tree is carried away by the surrounding air mass.
- **evaporative cooling through transpiration.** The surface of the foliage is cooled below ambient

temperature by evaporation. Water drawn through the root system is evaporated from the leaves, cooling them. This process is called “transpiration.” Its cooling effect does not appear to be well documented. Research by the Lawrence Berkeley Laboratory suggests that trees lower the air temperature by 3°F to 6°F (2°C to 4°C) in the vicinity. One could guess that the magnitude of the temperature drop is related to the evaporation rate (hence, to the species) and to the ambient wet-bulb temperature, as with any other form of evaporative cooling.

The beneficial effect of transpiration is limited if the climate is humid during warm weather.

WESINC

Fig. 1 Tree shading for an office building Above, two trees planted on the south side of this four-story building substantially reduce the cooling load through its large expanses of glass. Below, the trees shed their leaves in winter, allowing the building to benefit from passive solar heating. The trees form an effective visual divider between the office building and other buildings in this mixed-use neighborhood.

Evaporative cooling reduces sensible temperature by converting sensible heat in the air to latent heat, i.e., the heat in the air is used to evaporate water from the leaves. This increases humidity in the vicinity of the tree.

Some people have said that trees block “cooling breezes,” reducing their overall cooling benefit. This is wrong. In warm weather, breezes do not cool, instead they warm. Furthermore, air motion has a cooling effect only on damp surfaces, notably human skin. This “wind chill” effect does not apply to the dry surface of a building.

How to Select Tree Species

A good way to start with selecting tree species is to observe which types of trees flourish in the vicinity. Take into account the soil type, the sun exposure, and the drainage at the planting site. Try to avoid trees that you cannot find growing in the area. No matter what the nursery says, foreign trees may grow more slowly than expected, or they may not survive at all. Even if a tree species is known to grow in a similar climate, it may not flourish locally because of conditions such as air pollution, soil acidity, etc.

Select deciduous trees, rather than evergreens, except for sites that need cooling all year. Evergreen trees would substantially increase heating requirements in cold weather. Most evergreen trees have a less desirable shape for shading, and they cannot be pruned as well to create a desirable shape.

From the standpoint of shading, you want trees with these characteristics:

- **rapid growth.** A lot of cooling energy may be wasted during the 3 to 8 years that the tree grows to a useful height.
- **adequate life.** Tree life ranges from 30 years to 1,000 years. The more rapidly growing trees tend to have shorter lives, but the correlation varies. The tree should have a life span as long as the remaining life of the building.
- **good shape,** not only for shading, but also for view and for traffic under the canopy.
- **proper timing of leaf growth and shedding.** The tree should grow a well developed canopy by the beginning of the cooling season, if possible, and it should shed all its leaves by the beginning of the heating system. Not all deciduous trees shed well. For example, some species of oaks keep their dead leaves through the winter, and shed them only when new leaves push the dead ones loose in spring.

The fact that a particular tree can provide good shading does not alone make it desirable. Other important characteristics are:

- **ability to flourish at the site** without watering, fertilizing, or other frequent tending.

- **absence of damage from root growth.** Roots can damage adjacent foundations, lift sidewalks, and destroy pavement. Roots that grow on the surface can interfere with lawn mowing, and can make the space under the tree unusable.
- **wind resistance.** Some trees survive high winds by sacrificing branches, which is dangerous. Some trees topple in high winds. Resistance to toppling depends on soil conditions and local geology as well as the tree’s root pattern.
- **minimum shedding of annoying material,** such as twigs and seed pods that clog gutters, resin spattering that sticks to automobile finishes, etc.
- **compatibility with surrounding vegetation.** All trees have some effect on surrounding shrubbery, decorative plantings, and grass. Select both the trees and the surrounding vegetation to be compatible with each other.

Where to Plant

Consider these factors when deciding where to plant the trees:

- **the areas of greatest solar gain** in the building. Give top priority to shading large windows that are exposed to direct sunlight. Then, shade smaller windows. Then, shade dark roofs and walls.
- **how the sun moves** with respect to the areas to be shaded. Plant the trees so that they provide shade for the largest fraction of time, during the cooling season.
- **the tree’s shape and dimensions** during its useful life
- **avoiding interferences,** as with power and telephone wires. Utility companies perceive trees as a problem, and may cut them back drastically, without regard to the energy saving intentions of the building owner.
- **appearance** of the property, including arrangements with other plantings.

A common mistake is planting the tree too close to the building. The small sapling that you plant today will become a huge structure weighing many tons. Planting trees too close to the building, or too close to each other, may force them to be removed just as they become most effective for shading. Professional tree planters make this mistake as well as amateurs. If a tree is planted at a proper distance from the building, it will seem too far away from the building when it is still young.

Planting Foliage on Buildings

The concept of tree shading can be extended to the planting of shading foliage on the building itself. For example, a building with a large flat roof may have the roof covered with shading foliage.

Although this approach may have merit, it surrenders many of the advantages of planting trees in the ground. The building must be reinforced to support the weight of the foliage. Automatic watering systems are required. If the water is purchased, the annual cost is substantial, in contrast to trees planted in the ground, which find their own water. And, maintenance requirements are much greater.

Keep the Benefit Apparent

It is important to keep the building's owners and operators aware of the fact that the trees are intended to improve their summertime comfort and reduce cooling costs. This may be forgotten as the years pass, allowing some future decorator to remove the trees on a whim. As with other energy conservation measures, effective placards are a principal means of preserving the benefit. Install decorative, permanent (e.g., cast bronze, embossed stainless steel) plaques that describe the shading and comfort purposes of the trees, along with the usual botanical information. It is easy to get people interested in tree shading.

Possible Financial Assistance

Tree planting has become an ideological issue, which has prompted various levels of government to subsidize tree planting. Governments may provide funds directly or they may mandate subsidies by others, especially by utility companies. If you are going to plant only a few trees, government subsidies are probably not worth the paperwork. If you are going to plant many trees, cash in on any subsidies that are available.

For Additional Information ...

There does not appear to be much scientific research on tree shading to reduce cooling load. Research probably is less important than common sense, but it pays to begin by learning from the experience of others. For example, some electric utilities have tree shading programs.

Don't overlook the importance of checking local growth conditions, which you can learn from county agricultural agents and public arboretums. Take the advice of commercial landscape contractors with a grain of salt. They have a bias toward exotic and expensive species that require maintenance.

ECONOMICS

SAVINGS POTENTIAL: 70 to 90 percent of the cooling load of the shaded portions of the building, but only after the trees have grown sufficiently. The net saving is reduced by a small increase in heating load.

COST: \$50 to \$1,000 per tree, planted, depending mostly on the initial size of the tree.

PAYBACK PERIOD: Payback period does not apply to this Measure in the usual way, because there is a long delay before it starts to produce benefits. If you start the clock when the tree becomes large enough to provide substantial shading, the payback period would be one or two years.

TRAPS & TRICKS

CHOICE OF METHOD: If tree shading is a possibility, the big question is whether it makes sense to wait several years for results. Tree shading is especially attractive for existing facilities where other methods of reducing solar gain are not economical. Consider the other advantages and disadvantages of tree shading, which can be major issues.

SELECTING THE TREES: Have a strong bias in favor of trees that you observe to flourish in your locale. Find out all the bad habits of each species you are considering.

LAYOUT: Little trees become great big trees, which cannot be moved. Plant the trees in locations suitable for their final size. To get shading quickly without planting trees too close to the building, select species that have rapid vertical growth and that are tolerant of heavy pruning to limit their horizontal spread.

Subsection 8.3

Daylighting

Enough sunlight falls on most buildings to provide ample illumination for the entire building. Daylighting is an important method of saving energy in large, open buildings. It can also save lighting energy in the perimeter spaces of other types of buildings.

A serious obstacle to daylighting is a lack of effective methods for distributing sunlight throughout the building. At present, daylighting is limited to spaces that are adjacent to roofs and exterior walls. Floors, interior walls, and opaque partitions remain impenetrable barriers. In many buildings, only a small fraction of the space can be illuminated with daylight.

Daylighting is a complicated source of illumination. Achieving lighting of good quality requires a great deal of attention to match the glazing to the space. Furthermore, daylighting has major interactions with heating, cooling, electric lighting, and the building structure. See [Reference Note 46, Daylighting Design](#), for the issues that you need to consider.

The Measures of this Subsection provide daylighting to the extent that it is practical with current materials and equipment. Daylighting is much easier to accomplish well if it is designed into new buildings at the outset. These Measures show you how to exploit daylighting in new construction, how to retrofit it to existing buildings, and how to salvage defective daylighting installations in existing buildings.

MEASURE 8.3.1 Install skylights or light pipes.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Skylights can provide satisfactory lighting for activities that can tolerate large variations in illumination level. Getting good performance from skylights is not as simple as it may appear. You have to satisfy a number of requirements, some of which may not be easily compatible with each other.

When considering skylights, also consider “light pipes.” Light pipes perform the same function as skylights. They make it possible to transport daylight through thick roof structures and attics. They are easier to install in retrofit applications than skylights. For practical reasons, light pipes are limited to smaller light collection areas. They are still evolving.

In this Measure, we will use the term “skylights” to cover both skylights and light pipes, except when the distinction needs to be spelled out.

SUMMARY

Skylights are an old source of free lighting that needs to be improved in the way it is applied. Light pipes are a new way of achieving the same purpose with greater flexibility. Desirable for many large, open, non-office environments. Retrofit is usually difficult.

Fig. 1 Effective skylights in a shopping mall The percentage of ceiling area is about right for the type of illumination needed. Light distribution is good. The diffusing skylights are installed at the tops of tapered recesses, minimizing glare.

Where to Use Skylights and Light Pipes

Many types of activities can be illuminated well by skylights, but many others cannot be. In terms of illumination quality, the major advantage of skylights is the ideal color rendition of daylight. Their major disadvantage is large fluctuations in illumination intensity caused by movement of clouds across the sun. This annoyance varies with location.

Experience indicates that skylights can be effective for retailing, even in posh environments, because sunlight has excellent color rendition and brilliance. See Figures 1, 2, and 3.

Skylights are also effective for many manufacturing and maintenance operations. Warehousing can be a favorable application. Skylights can be used to provide a sense of natural ambience, which is valuable in applications such as restaurants (Figure 4), transportation centers, and other public areas.

Skylights are less likely to be satisfactory where paperwork occurs, as in offices, drafting areas, and reading rooms. The wide range and fluctuations of sunlight intensity are more noticeable in applications that require concentration on text. Also, daylighting makes it more difficult to avoid veiling reflections, which are a problem especially with paperwork. See Reference Note 51, Factors in Visual Quality, for more about veiling reflections.

With current technology, skylights and light pipes are limited to illuminating the area directly underneath them. The roof structure must allow penetrations to be made without undue expense. Therefore, skylights are most likely to be worthwhile in industrial-type buildings

and in large single-floor spaces, such as gymnasiums. Future types of light pipes may be able to transport sunlight far into the building interior.

Skylights must be located where the sun can shine on them directly. A skylight does not produce a useful amount of daylight if it is shaded by adjacent structures or foliage. Similarly, skylights are not worthwhile in areas that have heavy cloud cover for a large fraction of the time, unless the climate is mild and the structure can accommodate a large area of skylights. Clouds typically reduce solar illumination by a factor of five to ten.

When individual clouds pass in front of the sun, they cause abrupt changes in illumination level. The abruptness of the change is usually more objectionable than the reduction of light level. The large, quick variations of light level make skylights unacceptable for certain applications.

Retrofitting skylights in existing buildings is often impractical because of cost and structural interference. Even though skylights require only a relative small fraction of total roof area, installation usually requires structural changes, such as cutting through rafters and purlins.

If the building has an attic, installing skylights in the roof requires building a reflective enclosure to pass the light through the attic. Unless the attic is empty, this may be difficult. Light pipes are easier to pass through attics. In effect, a light pipe is a small skylight with an integral reflective enclosure.

Energy Saving Potential

In single-floor buildings, skylights may provide a large fraction of illumination requirements. Sunlight is so intense that skylights can provide virtually any illumination level that is required. Of course, artificial lighting is still needed at night.

Sunlight has a better ratio of light to heat than any type of electric lamp. Therefore, if the light from skylights is distributed efficiently and the skylights are not oversized, they may not substantially increase the cooling load. However, this ideal is difficult to achieve.

Skylights can provide significant passive heating during cold weather. This advantage is offset by conductive heat loss at night. In all but the coldest climates, there is a net heat gain if the skylights are located so that they collect the maximum amount of sunlight. On the other hand, skylights that face away from the sun may suffer a net heat loss even in relatively mild climates.

Surface Area Required for Daylighting

Outdoor sunlight from a clear sky produces an illumination of about 60,000 lux, most of which comes directly from the sun. Using this fact, you can easily calculate the fraction of the ceiling area that needs to be

converted to skylight. (For a quick introduction to “lux” and other measures of light intensity, see [Reference Note 50](#).)

For example, consider an application that needs an illumination level of 500 lux. To account for losses in reflection and diffusion within the skylight assembly, assume that 40% of the sunlight entering the skylight makes its way into the space. Thus, on a bright day, about 2% of the ceiling area needs to be skylights. To compensate for low sun angles, hazy conditions, dirty skylights, etc., double this to about 4%. To account for average cloudy conditions, increase this to 10% or 15%.

The installation in Figures 1 and 3 have skylights that are sized for approximately the latter percentages of ceiling area. The installation in Figure 2 has a much higher percentage, with the result that the glazing must be darkly tinted to avoid glare. The unusual installation in Figure 4 has a variable amount of skylight area.

These figures assume that the skylights are installed where they remain exposed to direct sun throughout most of the day. In some older industrial buildings, large skylights were installed facing north to avoid glare. This unnecessary practice is still followed in some new buildings, as shown in Figure 5. This greatly increases the glazing area required, which also increases heat loss in cold weather. To keep skylights as small as possible, install them so they face the sun as much as possible. Control glare with diffusion and careful space layout, as discussed below.

In predominantly warm climates, select the skylight area to give the best compromise between savings in lighting energy and extra cost for cooling energy. If the space is air conditioned, design the skylights for a clear sky. This means, keep them small.

In predominantly cold climates, the balance usually shifts toward larger skylights. This makes it more important to select the skylights for low conductive heat loss. If you want to exploit passive heating, the skylights must be much larger, and the whole arrangement

Super Sky Products, Inc.

Fig. 2 Large, attractive skylight This is a large amount of glazing area in relation to the illumination requirement.

becomes expensive and elaborate. For more about passive heating, see [Reference Note 47](#), Passive Solar Heating Design.

Use the minimum total skylight area that you need to provide good illumination, and if appropriate, passive heating. This is because surface area increases heat loss, cost, and structural problems. Therefore, make all skylights as transparent as possible, subject to the need for diffusion, multiple glazing, reinforcing fibers in

plastic material, etc. Do not use skylight materials with tints, and do not use skylight materials that reflect sunlight.

Efficient distribution of daylighting within the space is as important as the skylight area. Skylights should deliver their light where it is needed, and they should avoid creating visual problems. You achieve these characteristics by effective layout of the skylights, and by using diffusion. We will cover these two topics next.

WESINC

Fig. 3 Skylighting for a variety store The skylight consists of a small area of translucent panels surrounding the cupola. The lighting is effective for the colorful merchandise. The geometry of the skylight does not extend sufficient daylight into the ends of the space, so artificial lighting is needed there. Daylighting of this space was later abandoned, for unknown reasons.

Kalwall Corporation

Fig. 4 Adjustable skylight In this restaurant, insulated translucent panels with low light transmission can be retracted to provide a variable amount of skylighting. The layout must keep direct sunlight from entering the occupied area of the space, or diffusion must be used with the skylight glazing.

Skylight Layout

In general, it is better to use a larger number of smaller skylights, rather than one or a few large skylights. There are many examples of horrible daylighting in which someone attempted to illuminate a space with only one big skylight. Figure 6 shows a

good distribution of skylights for a space with a tall ceiling. Figure 1 in [Measure 8.3.2](#) shows the interior of this space. Using smaller skylights has several important advantages:

- ***you can tailor the light distribution within the space more accurately.*** The skylights do not have to be installed in a regular pattern. In general, the size of skylights, and the spacing between them, should be proportional to the ceiling height. Stated differently, skylights should not have to throw light far to the side.
- ***an array of smaller skylights provides illumination that is much more uniform*** than the light from a single large skylight. Installations with large skylights commonly suffer from excess brightness directly below the skylight, accompanied by gloomy dark areas surrounding the skylight.
- ***less modification of the roof structure is needed.*** Large skylights require special roof design to carry the roof loads around the skylight. In existing buildings, it is often possible to retrofit small skylights, but not large ones.
- ***it is easier to avoid leakage problems with small skylights,*** for the reasons discussed below.

It helps to think of skylights as a class of light fixtures. They must obey the same rules of physics and lighting quality as electric light fixtures.

Compare the skylight installation in Figure 1 of [Measure 8.3.2](#) with the skylight installation in Figure 7. The former provides better distribution of light throughout the space, with less glare. (However, it lacks proper diffusers, as we will discuss.)

Another useful guideline is that the dimensions of the skylight should be a small fraction of their height above the floor of the space. Thus, a large skylight over an atrium may be satisfactory, but not a large skylight over a dining room. The central skylight in Figure 3 is satisfactory because it is high above the floor. However,

WESINC

Fig. 5 Inefficient skylight orientation The skylights on this bus garage face north. This avoids glare problems and excessive solar heat gain, but it provides little light in relation to the heat loss from the glazing. Overhead equipment keeps much of the daylight from penetrating into the space.

WESINC

Fig. 6 Good skylight sizing and layout This shows the small fraction of roof area that is needed for typical illumination levels. These skylights are for a gymnasium, and the repetitive layout provides uniform illumination within the space. See Figure 1 of [Measure 8.3.2](#) for the inside.

Vistawall Architectural Products

Fig. 7 Gymnasium daylighting with a single large skylight Compare this to Figure 1 of [Measure 8.3.2](#). The barrel roof of this building makes it difficult to install distributed skylights.

the daylighting does not penetrate well to the perimeter of the space.

Skylights that are large with respect to the ceiling height may be decorative, but they are not optimum for daylighting, and they may be overwhelmingly bright. Figure 8 shows large clusters of skylights installed in a library. The brightness inside the space can be excessive. Figure 9 shows a huge skylight that covers an entire office.

Effective Diffusion is Essential

Skylights generally need diffusion. Direct sunlight through skylights is not suitable for illumination. It is

WESINC

Fig. 8 Large skylight arrays These illuminate areas of a public library with relatively low ceilings. The areas immediately beneath the skylights receive too much illumination and heat gain in bright daylight, while the light is unable to disperse to the rest of the space.

much too intense, it forms localized bright spots, and it shines on the wrong places. Diffusion corrects or reduces these problems by distributing sunlight in a fairly uniform pattern. It also minimizes changes in illumination caused the motion of the sun. Daylighting was abandoned in favor of electric lighting largely because of unsatisfactory illumination resulting from lack of diffusion.

For example, consider a space that has many small skylights. If the skylights are clear, they produce intense bright spots on the floor, surrounded by darkness. See Figure 1 in [Measure 8.3.2](#). As a result of this oversight, the skylights produce no useful illumination, and the electric lights must be turned on to compensate for the glare. On the other hand, if the skylights diffuse the light, it is spread throughout the space.

You can make any surface of the skylight glazing a diffuser by selecting the material for this purpose. Or, you can install separate diffusers either above or underneath clear glazing. It is easier and usually preferable to make the diffuser an integral part of the skylight, unless you are also trying to accomplish passive solar heating.

Diffusion introduces its own set of issues to consider. The main ones are limiting glare, dealing with solar heat gain, and limiting light loss.

■ Limit Glare

The term “glare,” as we use it here, means an area of intense brightness within the visual field. ([Reference Note 51](#), *Factors in Lighting Quality*, explains glare in greater detail.) Diffusion has the potential of creating serious glare because it makes skylights look like bright light sources. For example, small skylights are similar to flat-faced fluorescent ceiling fixtures in appearance and light distribution pattern, although they can be significantly brighter.

Glare is a problem only when the bright surface is within the field of vision. Fortunately, people tolerate bright light sources that are overhead. As with other light sources, the solution to glare is to locate skylights well above the line of sight. In spaces with very tall ceilings, such as gymnasiums and manufacturing plants, the height of the ceiling alone may be sufficient to keep glare within acceptable limits.

If the skylight is installed at the top of a shaft or recess in the ceiling, this keeps the skylight out of normal lines of sight. For this to minimize glare in a space with a low ceiling, the shaft or recess should be at least as tall as the maximum dimension of the skylight. In other words, the recess needs to be taller with bigger skylights.

■ Locate Diffusers to Minimize or Exploit Heat Gain

The solar heat gain into the space is strongly affected by how the diffuser is installed, and by the characteristics of the diffuser. Heat gain is lowest if diffusion is limited

to the outer surface of the glazing. In that case, a large fraction of the heat absorbed by the diffuser itself is carried away by the outside air. Heat gain is greatest if the innermost surface is used as the diffuser.

Heat gain is increased even more by locating the diffuser farther inside the space, so that less of the entering light is reflected back out. To capture solar heat for passive heating, install a separate diffuser inside the space that is made of absorptive material. [Measure 8.4.2](#) explains this arrangement in detail.

■ Where to Locate the Diffuser if the Skylight is Installed Above a Ceiling Recess

The location of the diffuser matters most when there is a recess or shaft between the skylight and the interior of the space, typically to create a path for the daylight through the roof structure.

The location of the diffuser in a shaft radically affects the light distribution pattern. Installing the diffuser at the bottom of the shaft produces a broad pattern. Installing the diffuser high in a tall shaft produces illumination similar to that of a downlight.

Installing a diffuser higher in the shaft keeps people from seeing it, except when it is more nearly overhead. This reduces the possibility that glare will be a problem.

The surface of the shaft absorbs light. A diffuser installed high in the shaft deflects more of the light toward the shaft surface, making it especially important for the shaft surface to be highly reflective. A specular surface saves more light than a diffuse surface, because it reflects all the light downward. However, a diffuse surface may give better light distribution. It depends on the relative geometry of the skylight, the shaft, and the space.

If you install a separate diffuser, make sure that no sunlight leaks around the diffuser directly into the space. Direct sunlight is an intense source of glare, and it is useless for illumination.

Avoid Nasty Surprises: Heat Loss and Condensation

The heat loss of skylights may be much higher than you expect. Hidden away in the technical literature is the fact that heat loss through glazing is two to three times higher when the glazing is installed in a horizontal or steeply slanted orientation than when it is installed vertically. Thus, the double glazed skylight that you expected to have an R-value of 2 actually has an R-value less than 1.

One of the unpleasant surprises that results from this low thermal resistance is a tendency for skylights to sweat profusely. The condensation can damage or disfigure the surrounding structure. Poorly insulated skylights may drip heavily on the space below.

In cold climates, it is worth going to great lengths to limit the heat loss of skylights. These are your possible solutions:

Super Sky Products, Inc.

Fig. 9 An illustrative example Analyze this skylight installation, which illustrates most of the issues of daylighting. How suitable is the skylight for the activities? How appropriate is the glazing area from the standpoints of glare, solar heat gain, and conductive heat loss? How effective are the controls for the electric lights? What should be the transparency of the glazing? Should diffusers be used? Internal shading? How would these issues be affected by the location of the building? Overall, is this effective daylighting or primarily an esthetic feature?

- **select multiple glazing.** Up to three or four sheets of glazing are practical. Light transmission is reduced somewhat, and weight and cost are increased.
- **use a glazing material that includes translucent insulation.** Translucent glazing systems are now available that offer R-values as high as 10. These systems combine a plastic or composite glazing material with a layer of translucent insulation, which may be glass fiber or foam. See [Measure 8.3.3](#) for the details. There is a strong compromise between R-value and light transmission, so skylights using this material must be larger than skylights that use conventional glazing.
- **install movable insulation,** which can greatly reduce heat loss without reducing light transmission. Movable insulation is challenging to design and to install. For an introduction to movable insulation, see [Reference Note 47](#), *Passive Solar Heating Design*.

All skylight frames should include gutters to catch condensation that flows off the interior surface of the glazing. This is important to keep the condensation from rotting or disfiguring the structure around the skylight. The gutters should be large enough to hold all the condensation until it can evaporate back into the space.

Skylight Materials

Skylights are commonly made from glass, glass composites, plastics, and plastic composites. All these materials can be treated to reduce light transmission and cooling load, either by adding dyes that absorb light or by adding a reflective surface. All glazing materials can be provided with diffusing properties. As discussed previously, the thermal insulation value of skylights can be increased by installing multiple sheets of glazing and by installing translucent insulation between the sheets.

All diffusing materials absorb a significant amount of the entering sunlight because there are multiple reflections within the material. Absorption is greatest with milky diffuser, and lowest with prismatic diffusers. Absorption is also increased by fibers, pigments, and other materials that are embedded in the material.

The advantages of glass include unlimited life, high light transmission, hardness, and rigidity. Glass can be treated to reduce cooling load by selectively absorbing the infrared portion of sunlight. At present, this capability is available only with glass, not with plastic. See [Measure 8.1.3](#) for details. The infrared absorbing surface should be outermost.

The main disadvantage of glass is its vulnerability to breakage, along with the safety hazard that falling glass creates. Glass can be made more resistant to breakage by increasing its thickness, by heat treating it, and by combining it with reinforcing materials. All

safety improvements for glass add cost, and they usually add weight.

Plastic materials are much lighter in weight, and they are resistant to shattering, so they pose only a minimal safety hazard. An entire skylight assembly can be molded from a single piece of non-reinforced plastic. Smaller plastic skylights can be molded so that they overlap a mounting curb, providing excellent resistance to water leakage and greatly reducing the cost of the frame. Plastic skylights can easily be fabricated with multiple layers of glazing to improve thermal resistance.

Plastics can be reinforced with fibers of various materials, including glass, to increase strength and service life. The fibers cause some light loss. They also diffuse light, which is useful in most applications. Reinforced plastic is more difficult to mold into compound shapes. It is normally made in flat sheets, which can be curved in one direction.

The plastics commonly used for glazing are acrylics and polycarbonates. Polycarbonates are stronger, but acrylics are more resistant to degradation by the ultraviolet component of sunlight. All plastics deteriorate in strength and light transmission over a number of years. The main causes of deterioration are ultraviolet light, heat, and oxidation, in that order.

The service life of plastic glazing can be extended greatly with additives. Unfortunately, you cannot judge the long-term performance of a plastic material except from manufacturers' claims, so purchase skylight material from a credible manufacturer. If you buy skylights as prefabricated assemblies, first examine the plastic manufacturer's data. If possible, investigate actual field experience with the particular products you are considering.

Flat plastic glazing material buckles as it ages. This can be quite noticeable when the material is observed from the outside, but not when looking at the skylight from the interior.

Glass and plastic can be combined in larger skylights to minimize their respective weaknesses. Glass is used for the outer sheet, where it can provide considerable protection to the plastic, while the inner plastic sheet protects against glass breakage. Ordinary window glass strongly absorbs the damaging ultraviolet portion of sunlight, so a plastic material will survive longer if it is installed inside glass. Design or select combination skylights so that the plastic elements can be replaced separately without a great deal of effort.

Skylight Configurations

Skylights are available in almost any configuration that you could want. Skylights made of glass and composite are usually built up from flat sections. Figure 10 shows a sampling. Plastic skylights can be molded into virtually any desired shape. Skylights made of reinforced plastic materials can easily be curved in

Major Industries, Inc.

one direction. Figure 11 shows a sampling of the latter two types.

How to Prevent Water Leakage

Water leakage is a common problem with skylights. Do not select a skylight design that depends primarily on sealants to prevent leakage. The most reliable method of avoiding leaks is to use one-piece molded skylights that overlap the curb. Unfortunately, molded skylights are limited in size.

If a skylight must have joints, design it so that the joints are steeply sloped to shed water. Ideally, no joint or sealant should face uphill, but this condition cannot be met everywhere in built-up skylights. Instead, the frame extrusion should be designed so that it conveys any water that leaks through seals to the outside of the skylight.

Pay attention to the curb on which the skylight is mounted. The curb should be sealed to the roof as effectively as curbs used for installing scuttles or rooftop air handling units. If a curb is installed on a sloping roof, install an eave on the uphill side of the curb to shed water to the sides of the curb.

Control the Electric Lights to Exploit Daylighting

A skylight or light pipe is useless unless it reduces the energy consumed by electric lights. This is not just a matter of turning off the electric lights in daylighted areas. You also have to avoid the tendency to increase the electric lighting levels in adjacent parts of the space that are not daylighted to compete with the brightness of the daylighted areas.

See [Measure 9.5.3](#) for methods of controlling electric lights in response to daylighting. Combine these

Fig. 11 Molded and curved skylights Molded units are limited in size, but they can be ganged together to create a skylight of any size. Individual units can be molded to overlap curbs, an excellent method of avoiding leaks. Large skylights can be made of sheets of reinforced plastic that are curved in one direction.

Major Industries, Inc.

with the other automatic lighting controls of [Subsection 9.5](#) that are appropriate for the activities that occur in the space.

Compatible Types of Electric Lighting

Fluorescent lighting is generally the best type to use in combination with skylights because its output can be adjusted efficiently to supplement reduced sunlight. Modulating dimmer systems are available for fluorescent lighting, and these work well with daylighting. Also, fluorescent lamps can be turned on and off repeatedly to respond to changes in daylight. However, frequent cycling reduces lamp life and annoys occupants.

It is common to use high-intensity discharge (HID) lighting in combination with skylights. (HID is the class of lamps that includes mercury vapor, high-pressure sodium, and metal halide.) This is because HID lamps have high output, so they can be installed at the height of the skylight in limited numbers, matching the light output of the skylight. Unfortunately, HID is usually a poor choice to combine with skylights. HID lamps take as long as ten minutes to reach full brightness, and they cannot restart for several minutes after being turned off. This makes them inappropriate for use with daylighting, where passage of clouds in front of the sun may require the output of the electric lights to change continually.

Huvco, LLC

Fig. 12 Rigid wall light pipe This unit has a reflector in the back of the dome to capture more daylight at low sun angles. A diffuser is installed at the ceiling.

A newer type of HID lighting is available that turns on instantly. These operate by keeping the lamps hot continuously, which sacrifices efficiency. HID dimming does exist, but it is limited by problems that are described in [Reference Note 56](#), HID and LPS Lighting.

There is a tendency to believe that fluorescent lighting cannot be used with tall ceilings. This is not true. However, individual fluorescent lamps are limited in light output. As a result, lighting a space with fluorescent lighting typically requires many more fixtures than with HID lighting. See [Measure 9.3.3](#) for a comparison of HID and fluorescent lighting.

It makes no economic sense to use incandescent lighting as a complement to skylights, even though this is done often. The saving in lighting cost by daylighting is eliminated by the higher cost of incandescent lighting during the periods of time that it operates.

Special Features of Light Pipes

The desire to gain the benefits of skylights without suffering their disadvantages created an interest in “light pipes.” As the name implies, light pipes convey light to locations within the building where it is needed. Many types of light pipes have been designed, but only a few are commercially available.

Some claims made for light pipes defy the laws of physics. A light pipe cannot deliver more light energy to the space than it collects on the outside of the building. At present, commercial light pipes do not concentrate sunlight from large exterior collectors into smaller pipes. Understand the principles of light pipes so that the installation will yield the results you expect.

Sun Tunnel Skylight

Fig. 13 Flexible wall light pipe This type is easier to install than rigid wall light pipes. However, light losses are greater because of the corrugated surface of the tube.

■ Light Loss from Reflection Inside the Pipe

The efficiency of fixed light pipes suffers from absorption that occurs when light is reflected from the walls of the pipe. Unless the sun is lined up with the axis of the pipe, the light is reflected repeatedly as it travels through the pipe. Even if the surfaces of the pipe have high reflectance, say 90%, a large fraction of entering light is lost with a few reflections. The light loss is proportional to the length-to-width ratio of the pipe. Therefore, efficiency is sacrificed if the pipe is long in relation to its width.

■ Simple Light Pipes

Most light pipes that are available commercially consist of an exterior transparent dome, a reflecting metal pipe, and a diffuser for installation at the ceiling level of the space. The pipe may be rigid or flexible. Flexible pipes are easier to install, but they suffer more light loss from increased reflection and scatter inside the pipe. Figure 12 shows a rigid light pipe, and Figure 13 shows a flexible light pipe.

■ Sun Trackers

A movable mirror or refracting system can be used to align the incoming sunlight with the axis of the light pipe, minimizing reflection losses. A light pipe with this feature is called a “sun tracker.”

Sun trackers have been built commercially. Figure 14 shows a number of installed units, and Figure 15 shows a cross section of the unit.

If mass produced, sun trackers could be relatively inexpensive. Their main limitation is that they lose effectiveness if the sky does not remain clear. The system is designed to collect light from the sun, which is a point source. The light reflecting apparatus gets in the way of the whole sky when the sun is obscured. Another disadvantage is the need for occasional maintenance.

■ Future Developments

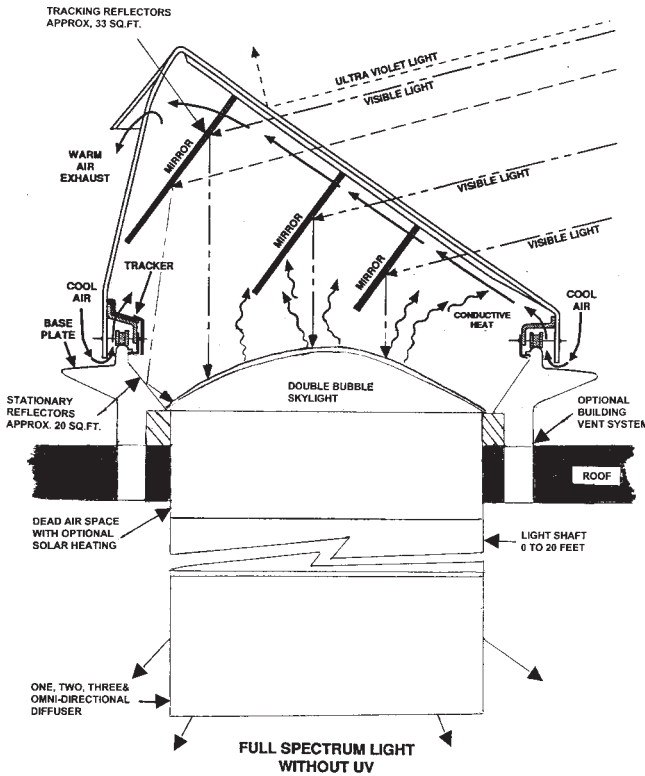

An ideal light pipe would have a large exterior collecting surface, it would funnel the light into a narrow conduit, and it would deliver the light wherever it is needed.

A small conduit is desirable to minimize heat loss and to make the light pipe easy to install. Funneling the light from a large collector into a small pipe requires a tracking mirror and a lens system. These do not have to be precision components. For example, light can be concentrated with flat fresnel lenses made of molded plastic. Both the tracking mirror and the lens system should be able to adapt to changes in sky conditions, from direct sunlight to a diffuse sky.

LightScience Corporation

Fig. 14 Sun tracking light pipes The rotating head contains mirrors that reflect direct sunlight straight down the pipe, minimizing losses. However, sun trackers may be less effective than simple light pipes for collecting sunlight from a diffuse sky.

LightScience Corporation

Fig. 15 Cross section of sun tracker The light shaft is sealed. The tracker head reflects sunlight through a double-glazed dome on top of the shaft.

Light pipes can avoid light loss by using the principle of fiber optics, which is an optical phenomenon called “total internal reflection.” This requires the light pipe to be made of a solid transparent material, such as glass or plastic. The light pipe can be long, and it can have any number of bends.

To make this economical, all the light has to be squeezed into a light pipe of small diameter. The small diameter is a major advantage in itself, but it involves complication at each end of the light pipe. This concept is presently used with high-intensity electric lamps as the light source, for special effects. Present light pipes of this type are too expensive for daylighting.

ECONOMICS

SAVINGS POTENTIAL: In the most favorable cases, skylights can provide a majority of lighting needed during the daytime. However, skylights increase heating cost. In mild climates, the heating cost penalty is not serious if the skylights are sized properly. Skylights may increase cooling cost, but this penalty should be minor if the skylights are sized and laid out properly.

COST: The major cost components are the skylights themselves, the roof penetrations, framing for the skylights, and electric lighting modifications. Molded plastic, double-glazed skylights cost \$15 to \$30 per square foot, depending on size. Large, self-supporting skylights with plastic composite glazing typically cost from \$30 to \$60 per square foot. Double-glazed glass skylights with safety glazing may cost up to \$100 per square foot. Small, simple light pipes can be installed for less than one thousand dollars, even in retrofit. See [Measure 9.5.3](#) for the cost of the electric lighting controls.

PAYBACK PERIOD: Up to several years, in new construction. Several years or longer, in retrofit.

TRAPS & TRICKS

MAKING THE COMMITMENT: Skylights do not disappear if you decide not to use them. They can create serious permanent problems, including glare, uncomfortable heat gain, heat loss, condensation, and water leakage. Do not use them unless you make a commitment to design and install them properly.

DESIGN: Skylight design is not something to do in a hurry. Consider the light distribution pattern, the effect on decor, the effect on cooling and heating, avoiding condensation problems, and avoiding water leakage. Provide effective controls to coordinate the electric lights with daylighting, or else the effort is wasted.

SELECTING THE EQUIPMENT: There are major differences between prefabricated units. Some have much better longevity and leakage resistance than others.

INSTALLATION: Even with the best design, avoiding water leakage requires good installation workmanship. See [Measure 9.5.3](#) about installing the daylight-sensing lighting controls.

MEASURE 8.3.2 Install diffusers for existing clear skylights.

RATINGS

New Facilities	Retrofit	O&M
		

Direct sunlight through skylights is not suitable for illumination. It is much too intense, it forms localized bright spots, and it shines on the wrong places. For example, consider a space with a tall ceiling that has many small skylights. If the skylights are clear, they produce intense bright spots on the floor, surrounded by darkness. The skylights produce no useful illumination in either the areas that are directly daylighted or the areas that are not. Occupants typically turn on all the available electric lights to compensate for the glare of the bright spots. Figure 1 shows an example.

You can correct these problems and create useful illumination by installing diffusers under the skylights or above them. Diffusers distribute the daylight uniformly in a broad area underneath each skylight. If the skylights themselves are reasonably well arranged, effective and pleasant illumination results.

In new construction, diffusion can be built into the skylight itself at little or no additional cost. Diffusion in new skylights is covered by [Measure 8.3.1](#). This Measure corrects the daylighting problems of clear skylights in existing buildings. This is often an easy and relatively inexpensive retrofit. It may also offer opportunities for decoration.

Fit the Solution to the Situation

Before you start making changes, figure out whether the skylights are oversized for daylighting, or not. If they are oversized, figure out what to do with the excess sunlight. In all cases, the location of the diffuser with respect to the skylight affects the light distribution pattern, the amount of light loss, the potential for glare problems, solar heat gain, and conductive heat loss. Here are guidelines for all the situations that can occur.

■ **If the Skylights are Not Oversized**

If the skylights are no larger than the optimum size for daylighting, as in Figure 1, you want to keep as much of the sunlight as possible, but distribute it better.

In this case, use diffuser materials that have high light transmission. You can use readily available diffuser materials made for fluorescent lighting fixtures. These have appropriate diffusing qualities, low light losses, and low cost. The most appropriate materials for most applications are clear prismatic diffusers and milky diffusers. The prismatic material has the highest light transmission, but a somewhat non-uniform light distribution pattern. It has a more intense, glittering appearance than milky diffusers, especially when viewed

SUMMARY

A fairly simple technique that converts useless skylights into effective sources of daylighting. May also reduce heat loss. Affects the appearance of the space.

from a short distance. Viewed from a distance, it is no brighter than any other type of diffuser that admits the same amount of light.

Locate the diffusers to avoid glare problems and to maximize or minimize heat gain. Glare is discussed later in this Measure. We will talk about heat gain next.

■ **If the Skylights are Oversized for Daylighting, and You Want to Minimize the Cooling Load**

In this case, you have to do two things. One is to admit enough of the sunlight to provide daylighting, and distribute it effectively. The other is to keep the unwanted fraction of sunlight outside the space. The solar heat gain into the space is strongly affected by the characteristics of the diffuser material and by the way it is installed.

To achieve the lowest possible heat gain in relation to the amount of daylighting, install the diffuser outside the skylight. In this way, almost none of the heat that is absorbed by the diffuser enters the building. The heat absorbed by the diffuser is carried away by the outside air. The disadvantage of this method is that the diffuser must be designed to have enough strength to withstand wind, snow loads, and hail. It is also exposed to the maximum solar ultraviolet radiation.

If you install the diffuser inside the skylight, try to reject the unwanted fraction of sunlight by reflecting it back out the skylight, rather than by absorbing it. Heat that is absorbed by the diffuser material becomes a cooling load inside the space. You may need two different materials to do this. For example, you may attach a reflective film to the glazing of the skylight (see [Measure 8.1.4](#) about this), and use a separate diffusing material underneath the skylight. Keep the reflecting surface as close to the skylight as possible, to keep any reflected light from being absorbed by parts

of the structure between the reflecting surface and the skylight.

All diffusing materials absorb a significant amount of the entering sunlight because there are multiple reflections within the material. For example, absorption is greater with milky diffusers than with prismatic diffusers. Absorption is also increased by fibers, pigments, and other materials that are embedded in the material.

■ **If the Skylights are Oversized for Daylighting, and You Want to Exploit the Excess Heat Gain**

If you want to absorb the excess daylight to warm the space, you can use any material for the diffuser that is both diffusing and absorbing. This case also offers opportunities for more decorative treatment. You can use many inexpensive translucent materials as diffusers, including fabrics, colored plastic sheets, and even paper. For example, you can create decorative effects by using patterned fabrics as diffusers.

For the most effective distribution of heat within the space, install the absorbing material as far inside the space as possible. This minimizes the amount of

sunlight that is reflected back out the skylight, and it improves the distribution of heat within the space. Adjust the absorption of the diffuser material to achieve the desired balance between daylighting and heating. See [Measure 8.4.2](#) for details of this arrangement.

In most geographic locations, you would like to exploit excess sunlight for heating during cold weather and reflect the excess sunlight during warm weather. In principle, you can design an arrangement that will do both. However, this requires the diffusers to be movable, and someone must control them. This involves a high degree of innovation, along with the risk that the installation will not be operated efficiently. See [Reference Note 47](#), *Passive Solar Heating Design*, for the many issues that you need to consider when using sunlight for heating.

Skylights Installed Above Shafts or Recesses

Skylights are often installed above shafts or recesses in the ceiling. A shaft may be needed to carry the daylight through the roof structure, or a recess may be created as a decorative effect. In these cases, the location of the diffuser with respect to the shaft or recess has a

WESINC

Fig. 1 Potentially good daylighting rendered useless by lack of diffusers The skylights for this gymnasium are clear. Therefore, direct sunlight creates bright spots on the polished floor which are blinding to players and spectators. Note their reflections on the walls and ceiling. Because this daylighting is useless, the electric lights are turned on. The fixtures here are HID. They require a long time to brighten, so they are left on, despite the fact that the gymnasium is usually vacant.

major effect on the light distribution pattern and the potential for glare.

The surface of the shaft absorbs light. To minimize the loss, cover the surface of the shaft with a highly reflective material. A specular surface is better than a diffuse surface for preserving the light, because it reflects all the light downward.

The location of the diffuser in a shaft determines the breadth of light distribution. Installing the diffuser at the bottom of the shaft produces a broad light distribution pattern. Installing the diffuser high in a narrow shaft produces illumination similar to that of a downlight. A diffuser installed high in the shaft deflects more of the light toward the shaft surface, making it especially important for the shaft surface to be highly reflective. Installing a diffuser higher in the shaft keeps people from seeing it, except when it is more nearly overhead. This reduces the possibility that glare will be a problem. Make sure that no sunlight leaks around the diffuser directly into the space.

No matter where you install a diffuser inside a shaft or recess, you will have to deal with the condensation issue discussed below. Try to exploit the increased insulation benefit of sealing the diffuser to the shaft.

Avoid Glare

Diffusion may create serious glare, which is not a condition that can be tolerated. Refer to [Measure 8.3.1](#) about avoiding glare with skylights.

Glare is a potential problem when the bright surface is within the field of vision. Fortunately, people tolerate bright light sources that are overhead, but the source cannot appear too bright. Diffusers are least likely to create a glare problem when they are far above the working level, or when they are installed in the top of shafts or ceiling recesses. Installing diffusers on skylights makes them similar to flat-faced fluorescent ceiling fixtures in appearance and light distribution pattern, although they may be much larger.

Select Materials for Longevity

Select diffuser materials for resistance to ultraviolet degradation. Solar ultraviolet light will darken or destroy all organic materials in time. Plastics, fabrics, and other materials are available with ultraviolet inhibitors to resist damage, but resistance to damage varies widely. Study the specifications of the materials you are considering. Ordinary window glass absorbs ultraviolet strongly, so organic materials will survive longer if the skylight is made of glass, rather than plastic.

Avoid Condensation and Exploit the Insulation Potential

In some cases, adding diffusers can create serious condensation problems. Or, adding diffusers may provide an opportunity to improve the insulation value of glazing.

If you add a diffuser inside an existing skylight, the diffuser will act as an insulating layer between the space and the skylight. The insulating effect lowers the inside surface temperature of the skylight. The lower temperature may radically increase condensation on the skylight glazing, its frame, and the surrounding structure. The problem is worst at night, when there is no sunlight to keep the glazing warm enough to prevent condensation.

There are several ways to avoid this problem. One is to install the diffuser far away from the glazing, allowing free convection around the diffuser so that it has minimal insulating effect. This solution is easy and cheap, but it wastes an important opportunity to reduce heat loss.

Another solution is to seal the edges of the diffuser tightly to the structure around the skylight, so that water vapor cannot migrate into the space between the diffuser and the glazing. The diffuser must be made of an impermeable material, such as plastic sheet. This method of installation makes the diffuser act as another pane of glazing, substantially reducing heat loss. For example, if the skylight has only single glazing, installing a diffuser may cut heat loss to less than half.

If you use this approach, the diffuser is acting as an interior storm window. See [Measure 7.3.2](#) for details about how to do this without causing condensation problems. The main point is that you have to vent the space between the diffuser and the glazing to the outside. If you don't do this right, serious moisture damage will occur in the space between the diffuser and the skylight.

Still another solution is to install the diffuser outside the skylight. This actually reduces the tendency to condense moisture. If an exterior diffuser can be fitted tightly to the skylight, like a storm window, it will add a significant amount of insulation value.

Control the Electric Lighting to Exploit Daylighting

Daylighting is useless unless electric lighting energy is reduced when daylighting is available. This is not just a matter of turning off the electric lights in daylighted areas. You also have to avoid the tendency to increase the electric lighting levels in adjacent parts of the space that are not daylighted to compete with the brightness of the daylighted areas.

See [Measure 9.5.3](#) for methods of controlling electric lights in response to daylighting. Combine these with the other automatic lighting controls of [Subsection 9.5](#) that are appropriate for the activities that occur in the space.

ECONOMICS

SAVINGS POTENTIAL: 30% to 80% of lighting costs in eligible areas. The amount of potential daylighted

area varies widely, depending mostly on the building and glazing configurations.

COST: Diffuser materials may cost from \$1 to \$10 per square foot, if you are not too fancy. Installation is often simple. The cost of the lighting controls is covered in [Subsection 9.5](#).

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

DESIGN: This is more complicated than it may seem. Consider light distribution pattern, decor, reducing heat loss, avoiding condensation problems, limiting heat gain, and avoiding potential glass breakage. Install effective controls for the electric lighting, or else the effort is wasted.

MEASURE 8.3.3 Install translucent roof and wall sections for daylighting.

Measure 8.3.1 recommended installing skylights or light pipes to provide daylighting. A newer method is to bring in daylight through translucent panels that are an integral part of the building structure. “Translucent” means that the material passes light, but that the material is not clear.

Figures 1, 2, and 3 show some dramatic applications of this technique.

There is not a clear boundary between using translucent panels as construction components for a roof and using these same materials, or similar materials, in skylights. For roof applications, the distinction is largely one of size. However, for wall applications, there are much greater distinctions between translucent panels and conventional glazing.

The use of translucent panels as structural elements for daylighting has these distinctive and important characteristics:

- Because the translucent panels are an integral part of the building structure, they substitute for other roof or wall components, and they do not require additional structural support. As a result, the overall cost of building with translucent panels may be less than the overall cost of using skylights of similar area. The entire surface of a building could be made of such materials, and this is done with greenhouses, for example.
- Translucent panels can be installed in walls as well as roofs. This allows them to provide daylighting at any level of perimeter spaces. This may be valuable in spaces with tall walls.
- Translucent material is available that has much better insulating properties than conventional skylights and windows. On the other hand, the large surface areas that are typically used make conductive heat loss a more important issue than with skylights that are sized for daylighting alone.
- Glare is an even more serious design issue than with skylights. This is because large panels are more exposed to view, especially when they are used in walls.
- The large surface areas and relatively low cost favor passive solar heating more strongly than when using skylights.
- Presently available materials are all inherently diffusing. This avoids the need for separate diffusers. However, views are not possible through the material.
- All presently available translucent structural panels are made of plastic, which has limited life. In many

SUMMARY

For generally the same applications as skylights, but very different to design. The material offers a wide range of compromise between optical and thermal properties. Requires particular attention to avoiding glare and minimizing electric lighting.

SELECTION SCORECARD

Ease of Retrofit	😊	😊		

buildings, the panels will not last as long as the building, so they will need to be replaced. (Do not be misled by the “economic life” of a building, which is a fiction that is meaningful only for accounting purposes.)

Where to Use Translucent Roof and Wall Panels

This method of daylighting applies to the same general categories of applications as skylights. To avoid duplication and to ease the comparison to skylights, refer to Measure 8.3.1 about applications. However, there are major differences between this method and using skylights. These differences may strongly favor one method over the other in particular applications.

Using translucent panels usually involves much larger surface areas than using skylights. None of the translucent materials can approach the thermal resistance of a well insulated roof or wall. This is a major negative factor in locations that have long, cold winters. On the other hand, the large surface areas can be effective for passive solar heating, which is valuable in locations that tend to have clear skies during cold weather.

This method is most widely applicable in new construction, where translucent panels offer the important economic advantage of substituting for other construction materials. Also, new construction can easily accommodate the installation requirements of the material. Retrofitting translucent panels in existing buildings is typically much more difficult than retrofitting small skylights. It may be practical to replace a lightweight roof in a building that does not have an attic. Retrofitting translucent wall panels may be

practical if the building presently has large, contiguous areas of windows, or if the building has a curtain wall that needs replacement, or with metal buildings.

Energy Saving Potential

Translucent roofs and walls can provide virtually any illumination level that is required during the daytime,

within the spaces that have the translucent surfaces. Of course, night operation still requires electric lighting.

Translucent panels may radically increase the cooling load if the panels are not designed carefully to avoid this problem, as discussed below. On the other hand, sunlight has a better ratio of light to heat than any type of electric lamp. Therefore, if the daylight is

Kabwall Corporation

Fig. 1 Extensive use of translucent panel construction in a manufacturing plant The translucent panels provide daylighting from overhead and from the sides. Small conventional windows provide view. The bottom photo hints at the degree of daylight penetration on a lower floor. Note the placement of the light fixtures.

distributed efficiently and the panels are selected properly, the increase in cooling load may not be serious.

By the same token, translucent panels can easily be designed to provide significant passive heating during cold weather. This advantage is offset by conductive heat loss at night. In all but the coldest climates, there is a net heat gain if the panels are located where they can collect the maximum amount of sunlight.

Characteristics of Fiber-Reinforced Composite Panel Materials

At the present time, two general types of translucent panels dominate the market. One is a composite material, which we will discuss first.

■ Construction Features and Structural Properties

This material is made of thin plastic sheets that are made by embedding glass fibers in polyester resin. This is similar to the construction of boat hulls and composite aircraft skins, except that less glass fiber is used in the

resin. The glass fibers give the material high tensile strength, even as the plastic material itself loses strength with age.

To provide additional strength and to keep the outer surface intact as the resin decays, the manufacturer may embed a thin, dense mat of glass fibers into the outer surface of the outer sheet. As an alternative, the manufacturer may laminate a more durable plastic surface to the outer surface, but this method itself is limited in life.

To create a rigid panel and increase thermal resistance, the flat sheets are bonded to spacers, resulting in a box structure. Figure 4 shows a cross section detail of a typical installed unit. The spacers may be aluminum extrusions or composite materials. The spacers can be curved in either the length or the width, allowing the panels to be curved in one direction. Spacers that include thermal breaks to reduce conductive heat loss are an important option.

Kalwall Corporation

Fig. 2 Translucent panel construction for a library Reading is a particularly challenging application for daylighting. The translucent roof section provides effective illumination for a relatively narrow central area that is limited by the tall joists that run underneath it. The translucent wall sections require careful selection to avoid glare problems. We hope that the lights are normally turned off with this much daylight.

The spacers act as beams that carry the loads that result from wind, snow, etc. The panels can be very large, each panel offering an unbroken surface that carries its own weight. The panels cannot carry loads from other parts of the building structure. Each panel is supported at its edges, so the frame is typically made of aluminum extrusions that include mounting flanges. A variety of mounting configurations are offered.

As with double-glazed windows, it is essential that the box structure be tightly sealed. Therefore, the manufacturer must install a frame that seals the edges reliably, even as the edge carries the weight on the panel and absorbs thermal expansion.

A radical improvement occurred with translucent glazing when manufacturers started to offer insulation inside the panels. At present, glass fiber batt insulation is the insulation used in composite panels.

Kalwall Corporation

Fig. 3 Translucent roof in airport waiting room The roof provides daylighting throughout the space, while conventional windows provide a view. The location is southern Florida, so roof heat loss is not a major issue. However, the translucent panels must be selected carefully to balance daylighting against solar heat gain.

■ **Available Dimensions**

Fiber-reinforced composite material is available in large, unbroken surfaces. For example, one major manufacturer offers widths up to 5 feet (1.5 meters) and lengths up to 20 feet (6 meters). The most common thickness (not including the frame) is somewhat less than 3 inches (about 70 millimeters).

■ **Service Life**

The glass fibers and the aluminum components of composite panels have virtually unlimited life. But, regardless of what the salesman says, plastic materials weaken, become brittle, and darken as they age. Also, the organic materials used for bonding and sealing plastic sheets to spacers and frames lose their effectiveness with time. The main cause of degradation is the ultraviolet component of sunlight. Oxidation, chemical instability of the material, and repeated flexing from thermal expansion are also factors.

The manufacturer of the glazing material can greatly extend the life of the resin by adding ultraviolet inhibitors and other agents to it, or less reliably, by adding protective surface coatings. However, in the long term, the glass fiber is what holds the material together as the plastic decays. Therefore, pay attention to the way that different manufacturers embed the glass fibers in the resin.

Vistawall Architectural Products

Fig. 4 Typical composite panel construction and installation This is for a roof installation. Notice the choice of insulation filler, the thermal breaks, and the condensation gutters.

Unfortunately, you cannot judge the long-term performance of the plastic material itself except from the manufacturers' claims, so purchase your panels from a manufacturer who can demonstrate that its material has long life in past installations.

■ Light Transmission vs. Insulation Value

In composite panels that use insulation inside the panels, the insulation interferes with light transmission. There is an inverse relationship between the maximum possible light transmission and the maximum possible insulation value.

For example, an uninsulated panel has a thermal resistance of approximately R-2 and a maximum light transmission of about 50%. Increasing the thermal resistance to R-4 reduces the maximum light transmission to about 30%. Panels that have the highest insulation value, presently about R-10, are limited to a maximum light transmission of about 10%. Increasing the strength of the material by adding additional glass fiber to the resin further reduces the light transmission that is possible for a given R-value. The overall average R-value of the panels is reduced by the high localized heat losses through the aluminum frames.

If desired, light transmission can be reduced by tinting the glazing material. However, it generally does not make sense to do this. Instead, use more insulation or glazing with more fibers to reduce the light transmission.

■ Diffusion and View

All composite panels diffuse light. All except the clearest versions appear white from the inside, which means that daylight enters the space in a broad, fairly uniform pattern. The clearest material, which has no insulation, has an opalescent or "crystal" appearance.

No translucent structural panel material is clear enough to provide a satisfactory view. To gain a view, you need to install regular windows. Windows are installed as with other types of wall construction, independently of the diffuser material.

■ Appearance

Composite panels have the appearance of a series of rectangles, created by the grid pattern of the internal spacers. From the inside, the material looks white when there is daylight, and neutral gray at night. From the outside, the material looks white to gray, depending primarily on the characteristics of the outer sheet.

The flat plastic glazing material buckles with thermal expansion and with age. This can be quite noticeable when the material is observed from the outside at a shallow angle, but it is usually not noticeable when looking at the panel from the interior.

The inner or outer sheets can be tinted, but this is rarely done, because it would waste light transmission or sacrifice insulation value.

■ Fire Characteristics

Plastic materials are made from petroleum, and they have considerable fuel value. All plastic materials will burn if they are exposed to temperatures that are hot enough. For this reason, manufacturers add fire retarding agents to the material. You have to decide whether installing plastic panels is acceptable in terms of fire safety.

Read the specifications carefully, including the temperatures at which the material is rated. A low rating temperature is meaningless in a hot fire. Bear in mind that buildings typically contain many types of combustible materials, and that the primary defense against fire is making it possible for all occupants to escape the building quickly.

Characteristics of Extruded Plastic Translucent Panels

The other common type of translucent glazing material consists of one-piece double-wall plastic extrusions. We will compare it to the composite material discussed previously. In summary, it has smaller maximum size and shorter life, but it may be less expensive to install, and it may be easier to retrofit.

■ Structural Properties

This type of glazing material is a continuous plastic extrusion. The plastic material is usually polycarbonate, which is preferred for its strength. The extrusion has two separate surfaces which are separated by ribs that run the length of the extrusion.

Extruded plastic is weaker than composite panels because the plastic is not reinforced, and because the ribs run only lengthwise. Therefore, the maximum panel dimensions are smaller. The ribs that join the inner and outer surfaces of the material act as beams to carry the loads of wind and snow. However, the ribs carry load only in the lengthwise dimension. The ability of the material to carry load and to resist deformation across the width of the panel depends primarily on the thickness of the inner and outer surfaces. Strength in both directions, and resistance to bending, depend strongly on the overall thickness of the extrusion.

The material is supported at its edges, typically by aluminum extrusions. The glazing extrusion is divided into lengthwise cells by the ribs, so in principle only the ends need to be sealed. However, it is common practice to leave the ends open inside the frame, and to seal the material by using gaskets on all four sides of the panels.

Leakage of water vapor into the cells of the plastic extrusion has the same effects as leakage of water vapor between the panes of multiple-glazed window, including permanent fogging of the material. (See [Measure 8.1.3](#) about this.) The problem of fogging is much less noticeable than with clear windows if the panels are designed to diffuse light.

■ Insulation Value and Light Transmission

Extruded plastic glazing typically has two separate surfaces, which are separated by closely spaced ribs. Two glazing surfaces, without additional features to reduce heat loss, yield an insulation value of about R-2. This value is substantially reduced by heat conduction through the ribs and the frame. In addition, the R-value is greatly reduced if the material is installed in a tilted orientation. Thus, extruded plastic glazing, by itself, has poor thermal resistance.

To increase the thermal resistance of plastic glazing, at least one manufacturer offers a layer of translucent plastic foam insulation that is bonded to one of the surfaces or is sandwiched between two sheets of the extruded glazing. Figure 5 shows a detail of the latter. The foam insulation reduces light transmission and it strongly diffuses the light. The manufacturer presently offers a foam insulation thickness of 6 millimeters, combined with one or two sheets of extruded glazing, each of which is 8 millimeters thick. The manufacturer claims an insulation value of about R-6 for the sandwich configuration.

There is a compromise between insulation value and light transmission. The polycarbonate glazing material is clear, unless the customer requests tinted material. The foam insulation material has surprising high light transmission. The sandwich combination described previously has a light transmission of about 45% for light striking the material perpendicular to the surface, and about 25% for light striking the surface at an angle of about 60 degrees from the plane of the ribs.

Duo-Gard Industries, Inc.

Fig. 5 Extruded plastic panel assembly with insulation
This is an end view of two extruded panels with a layer of translucent plastic foam insulation between them. The rigidity of the assembly depends mainly on the thickness of the individual extruded panels.

At present, the compromise between light transmission and insulation value does not extend far enough in favor of insulation. The light transmission may be much higher than needed when glazing large areas. Manufacturers of extruded plastic glazing offer tints to reduce light transmission. However, this is an inefficient solution, because it does not offer any advantage in improved insulation value. Unfortunately, efficient solutions are more complex. See [Reference Note 47](#), *Passive Solar Heating Design*, about dealing with more sunlight than you need.

All plastic materials darken as they age. The amount of darkening depends on the composition of the material and its exposure to ultraviolet light and other environmental factors. With the large surface areas being considered in this method of daylighting, it is usually easy to compensate for the darkening that can be expected during the life of the material.

■ Service Life

The life span of extruded plastic is shorter than the life of composite materials because the material lacks embedded inorganic fibers to hold the material together as it ages. Experience with polycarbonate plastics suggests that its maximum life in exterior applications is between ten and twenty years. This assumes that the manufacturer of the plastic material includes effective ultraviolet inhibitors and other agents to extend service life. In any event, the material weakens and becomes brittle as it ages, making it more vulnerable to damage from minor impacts.

Some manufacturers offer warranties as long as ten years. However, the duration of a warranty is a marketing decision as much as it is an indication of the reliability of the material. Again, purchase your panels from a manufacturer who can demonstrate that its material has long life in past installations.

■ Diffusion and View

Clear or tinted polycarbonate glazing is almost clear enough to provide a view, although the view is distorted by the molded ribs and by irregularities in the extrusion. However, in order to achieve diffusion for satisfactory daylighting, it is necessary to make the material diffusing, or to combine it with diffusing insulation. Tinting alone does not provide diffusion.

To provide a view, you need ordinary windows. Some manufacturers offer windows that are combined with diffusing panels in a single frame. However, this combination is usually limited to locations where the glazing is not in direct sunlight. Otherwise, direct sunlight entering the clear windows would cause excessive glare. In applications where the glazing is not in direct sunlight, the heat loss through the glazing during cold weather is not compensated by solar heating. Therefore, this combination should normally be limited to warmer climates.

■ Appearance

From the inside, the insulated material looks white when there is daylight, and neutral gray at night. If an inner sheet of extruded glazing is installed, the ribs add a striped pattern.

From the outside, the material looks white to gray, with a light striped pattern caused by the ribs of the extruded glazing. Tinting the glazing changes the grayness or color of the material.

Extruded glazing does not suffer from the surface buckling that occurs with the thin sheets of plastic used in composite panels. However, the exposed foam insulation has the esthetics of packaging material.

■ Fire Characteristics

The same cautions apply that were made previously with respect to composite panels.

Appropriate Surface Area

Translucent panels typically are used for all or a large fraction of the roof or wall area. In contrast, [Measure 8.3.1](#) explains that the appropriate area for skylights ranges from 4% to about 15% of ceiling surface area. However, small areas of panels cannot economically substitute for other construction materials because they would have to be fitted into the structure as a separate item. (Translucent panel materials are sometimes used in skylights, but they are as expensive as any other kind of skylight when used in this manner.)

As a result, there is an economic attraction to using much larger areas, perhaps covering an entire roof or wall. This violates the guideline for skylights given in [Measure 8.3.1](#), to keep the areas as small as possible. In order to avoid excess daylighting, the light transmission of the material must be reduced drastically. At the same time, this reduces the heat gain. Whether this is good or bad depends on the application.

A design based on large translucent areas suggests exploiting passive solar heating. In turn, this requires a separate set of techniques to maximize heat gain while controlling the illumination level. See [Reference Note 47](#), *Passive Solar Heating Design*, for an introduction to this complex subject.

Avoiding Glare Should be a Dominant Design Issue

With daylighting, avoiding glare is always a major issue. Using translucent panels of large area raises the glare issue to potentially disastrous proportions. If the design of the installation does not avoid occupant discomfort from glare, it is virtually certain that the translucent panels will be covered with opaque material at some later time, eliminating all of their benefits. To understand the problem of glare, see [Reference Note 51](#), *Factors in Lighting Quality*.

The problem of glare, and the methods of dealing with it, are closely related to the need for diffusion.

Daylighting requires diffusion, for the reasons explained in [Measure 8.3.1](#). On the other hand, diffusion creates glare.

There are two ways to avoid glare from large surfaces. One is to limit the surface brightness. This technique is essential in most wall installations, as illustrated by Figure 6. The other way to avoid glare is to keep the bright surface out of the visual field of the occupants. This may be your primary approach with roof systems, as illustrated by Figure 7.

■ How to Limit Glare in Wall Installations

Using translucent panels in walls involves the greatest potential for glare problems. To understand the problem, consider an occupant looking toward a clear, south-facing window that is exposed to direct sunlight. If the window is clean, the occupant sees only the scenery outside, and there is no glare. Although direct sunlight is coming through the window, it disappears into the carpet. The occupant does not experience any visual problem as long as the bright spot on the floor is hidden from view by furniture, partitions, etc.

Now, consider what happens if the window is replaced by a diffusing panel that has high light transmission. The panel scatters the strong sunlight into the space. The occupant sees the diffuser as a bright, uniformly illuminated surface. The effect is like looking directly at a large fluorescent fixture. Now, visualize the effect if the entire wall is that bright. It would be unbearable. With this in mind, look at the various figures in this Measure that illustrate translucent walls. Decide how you would avoid glare problems with them.

In general, the way to avoid objectionable glare with translucent walls is to select panel material with light transmission that is low enough to allow people to look at the walls directly without discomfort, at least for the length of time that the occupants will be facing the walls. For example, if a large space has cubicles where people work, and the cubicles keep the translucent walls out of the visual field of people who are working, the translucent panels can be much brighter. However, even in this case, remember that the space layout and usage may change during the life of the building.

As a crude guideline, if the glazing will be within the occupants' field of view for extended periods, the glazing should be no brighter than a typical well illuminated white painted wall. At this point in time, we can offer nothing better than crude guidelines on this issue. Experience is the only reliable teacher when it comes to visual quality, and there are still relatively few translucent wall installations that serve as good examples.

If sunlight can strike the exterior surface of the panels directly, avoiding glare requires you to select the light transmission of the panels for times when direct occurs. However, the panels will be illuminated by direct

sunlight at some times, and not at others. The amount of useful daylight that you will get when the sun is not shining directly on the panels depends on the range of illumination levels that is acceptable within the space. Again, the nature of the activities in the space and the space layout determine this range. Of course, additional illumination can be provided by electric lighting, but then the translucent wall is not paying for itself.

Diffused glazing with low transparency may look gloomy when the sun is not shining on it directly. If appearance is an important factor, make sure that you inspect similar installations before committing to translucent wall panels.

If you intend to exploit daylighting alone, and not passive solar heating, you will probably want to select panel material that has much lower light transmission than you commonly find in translucent panel installations. Fortunately, as we have seen, you can now get panel material that reduces its light transmission by increasing its insulation value.

If the building is located in a warm climate, or if the space has high internal heat gain, you can use panels of high light transmission on walls that face north. However, remember that even north-facing surfaces are illuminated by grazing sunlight during the early morning and late afternoon in summer.

More generally, each face of the building should have panels with different amounts of light transmission. For example, in southern latitudes, sunlight always strikes the south wall of a building at much more grazing angles than it strikes the east and west walls.

As a final note, you could deal with glare, at least in principle, by facing all activities in the space away from the windows. However, this would rarely be practical. For example, in a classroom, all the students could face away from the translucent wall, but the teacher would have to face the bright panels. Furthermore, this layout would cause people to cast their own shadows on their activities.

Kabwall Corporation

Fig. 6 A challenging translucent wall application In this computer classroom, the students are required to face the translucent walls for long periods. Avoiding glare must be a major design issue here. The potential for glare, as well as the potential for saving energy by daylighting, is determined by the transparency of the wall. The dominant factor in selecting panel transparency is whether the exterior of the panels is exposed to direct sunlight. The relative brightness of the walls and the computer screens must also be considered. The ceiling is full of light fixtures. If the walls are too bright, the lights will be kept in operation to compensate.

■ How to Limit Glare in Roof Installations

The problem of glare with translucent roofs is similar to the glare problem with skylights that is discussed in [Measure 8.3.1](#). However, there are significant differences. Skylights, if properly designed, are relatively small areas of high brightness. In contrast, translucent roofs have very large areas. However, if translucent roofs are selected for reasonable illumination levels, their surface brightness is much lower. As with skylights, exploit the fact that people tolerate areas of high brightness that are well above the line of sight.

To the extent that people must face toward translucent ceiling areas, follow the same guidelines given previously for walls. If necessary, consider making the lower portions of translucent ceilings less bright than the taller portions.

Select Panel Materials for the Solar Heat Gain Characteristics You Want

Solar heat gain through the panels is strongly affected by the optical characteristics of the sheets used to make the panels, and by their positions with respect to each other.

All diffusing materials absorb a significant amount of the entering sunlight because there are multiple reflections within the material. If the panels include a layer of insulation, most of the diffusion and absorption occur within the insulation. Absorption is also increased by fibers, pigments, and other materials that are embedded in the material. As with any glazing material, the manufacturer can reduce light transmission by adding dyes to make the material more absorptive. All light that is absorbed becomes heat within the panel. If you want to minimize heat gain, concentrate the absorbing and diffusing properties in the outer surface of the panel, to the extent that you have a choice. In this way, more of the absorbed heat is carried away by the outside air, rather than entering the space by radiation.

In principle, it is possible to reduce light transmission without absorbing so much heat in the glazing material by using a reflecting coating. This is a common technique with glass. However, reflecting surfaces are not yet offered as a feature of plastic panels by most manufacturers.

The best way to reduce heat gain is to use insulation as the method of reducing light transmission to the desired level, while minimizing other features that absorb light.

On the other hand, if you want to maximize heat gain to exploit passive solar heating, concentrate the absorbing and diffusing properties in the innermost surface, to the extent that you have a choice.

You can increase heat gain even more by making the panels as clear as possible, and by installing a separate diffuser inside the space that is made of absorptive material. [Measure 8.4.2](#) explains this

arrangement. It minimizes the amount of sunlight that is reflected back outdoors, and it makes it easier to distribute the captured solar heat within the space. If you install a separate diffuser, make sure that no sunlight leaks around the diffuser directly into the space. Direct sunlight is an intense source of glare, and it is useless for illumination.

However, this may not be the best arrangement, on balance. Minimizing conductive heat loss through the glazing is a major factor in passive solar heating. Exploit the fact that insulation is now available as an integral part of translucent panels. With large panel areas, it is probably better to sacrifice some heat gain during hours of daylight by increasing the amount of insulation to reduce heat loss during hours of darkness.

Deal with the Higher Conductive Heat Loss

Using translucent panels involves much larger surface areas than using skylights. Furthermore, all translucent structural panels have much lower thermal

Major Industries, Inc.

Fig. 7 Translucent roof with relatively low glare potential
The translucent roof provides daylighting for several levels. Glare is a major issue in this building because the occupants are elderly. The potential for trouble is minimized by the elevation of the translucent surface well above the line of sight and by the nature of the activities, which allow the occupants to choose their direction of gaze.

insulation value than a typical well insulated wall. As a result, the insulation value of the material is a major issue if the climate can be cold for extended periods. Don't sweep this issue under the rug, or you may lose more in additional heating costs than you save in lighting costs.

Again, exploit the fact that translucent panels are now being offered that have much better insulation value than ordinary glazing. By the same token, using translucent panels that have integral insulation also minimizes the severe problem of sweating that occurs with ordinary glazing. ([Measure 8.3.1](#) describes these problems.)

Another way to minimize heat loss is to use movable insulation, which provides high insulation value during hours of darkness. Movable insulation is challenging to design and to install. For an introduction to it, see [Reference Note 47](#), *Passive Solar Heating Design*.

How to Prevent Water Leakage

Translucent panels have large unbroken surfaces. Established manufacturers offer frame systems that are reasonably reliable for preventing water leakage between the panels and the frames. However, you need to make sure that the frame design provides a watertight seal between the frame and the building structure. The glazing supplier has seen all the problems before, so work with the factory on this.

Design to Protect and Replace the Material

All types of plastic glazing deteriorate within a fraction of the normal life of a building, for the reasons discussed previously. Therefore, make it easy to replace the glazing several times during the life of the building. Your successors will thank you. Even you may still be around to replace the glazing.

Recognize the weaknesses of the material, and design the installation so that the glazing survives as long as possible. Both plastic and aluminum expand and contract by large amounts with changes in temperature. The frame system should be designed to avoid motion of the glazing with respect to the frame, which will wear out the glazing seals. Design the panel installation to allow for the difference between the expansion of the panel and the expansion of the structure, while maintaining an airtight seal where the two meet. The frame design is part of this, but additional features may be needed, such as sliding seals and elongated bolt holes. Mounting the panels too rigidly will create large stresses in the frames and in the glazing, accelerating failure of the seals between the glazing and the frame, and between the frame and the structure.

In locations where severe hail is likely to occur, select roof-mounted panel material for high surface strength. Composite materials are available with a dense

layer of fibers embedded near the outer surface, and this may help resist impact damage. (Severe hail may not occur often in most locations, but only once is enough to destroy the glazing.)

Snow load is an issue with roof-mounted panels, as with any other roofing material. Fortunately, smooth glazing tends to shed snow. This is because heat that conducts through the glazing melts the snow adjacent to the panel surface, and slides it off. Of course, this effect is more dependable with steeper roof slopes.

Movable insulation can be employed to protect the glazing, if it is installed externally. However, movable insulation is a troublesome feature, and it does no good unless it closes reliably to provide protection when it is needed.

Control the Electric Lights to Exploit Daylighting

Daylighting is useless unless it reduces the amount of energy that is consumed by electric lights. The glare issue poses a particular problem with translucent glazing, especially when it is installed in walls. The reason is that occupants will tend to turn on all the interior lights in an attempt to match the electric lighting levels to the levels of lighting provided by the glazing. Thus, contrary to what you might expect, a high level of illumination by the translucent panels does not reduce the demand for electric lighting, but increases it. [Reference Note 46](#), *Daylighting Design*, covers this issue in greater detail. In summary, human beings try to keep illumination levels uniform inside buildings.

You need automatic lighting controls to adjust the electric lighting in response to the amount of daylighting. See [Measure 9.5.3](#) for the details. However, even automatic lighting control will not survive if glare makes occupants uncomfortable.

Compatible Types of Electric Lighting

Expect to use fluorescent lighting, rather than HID, in daylighted spaces. This is true even in the tall-ceilinged spaces where HID lighting is commonly used. See the discussion of this issue in [Measure 8.3.1](#).

ECONOMICS

SAVINGS POTENTIAL: *In the most favorable cases, translucent roofs and walls can provide a majority of lighting needed during the daytime. However, this method of daylighting may increase heating cost substantially, and it may also increase cooling cost.*

COST: *Plastic composite panels and plastic combination insulated glazing costs from \$10 to \$35 per square foot (\$100 to \$350 per square meter). Installation cost may be more or less than for the material that it replaces. See the Measures of [Subsection 9.5](#) for the costs of automatic lighting controls.*

PAYBACK PERIOD: *In new construction, several years or longer. In retrofit, the payback period is very long, unless the panels are a substitute for other materials that need to be replaced.*

TRAPS & TRICKS

MAKING THE COMMITMENT: *Do not use this feature unless you make a commitment to dealing with all the design and installation issues. Otherwise, you may create a big mess. Translucent roofs and walls are a major, permanent part of the building structure. They strongly affect lighting, heating, and cooling costs. They strongly affect the appearance of the building, both outside and inside. They have a major effect on occupant comfort. They may be incompatible with later uses of*

the building. The panels will probably require replacement during the normal life span of a building. To know what your building will look like twenty years from now, look at similar material that was installed twenty years ago.

SELECTING THE MANUFACTURER: *The manufacturer is as important as the material. Select a manufacturer who knows how to avoid potential problems related to installation, including water leakage and panel replacement. The manufacturer should offer detailed design literature, and he should have the patience to work with you. However, don't expect the manufacturer to be candid with you about the inherent difficulties of the material, such as glare and heat loss. You have to take the initiative to resolve those issues.*

MEASURE 8.3.4 Install diffusers to make windows more effective for daylighting.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Direct sunlight through windows is not suitable for illumination. The illumination where the sunlight falls is much too intense, blinding the viewer. At high sun angles, daylighting is limited to a region close to the window, where most of the light falls on the floor. As a result, windows exposed to direct sunlight are equipped with curtains or shades that exclude almost all of the sunlight, wasting the potential of daylighting.

You may be able to overcome this problem and create useful illumination by installing diffusers on windows. Diffusers can be any translucent material that redirects the sunlight into the space in a fairly uniform pattern. This substantially increases the penetration of daylight into the space, eliminates the intense contrast between lighted and unlighted surfaces, and projects the light on the illuminated surfaces from a higher angle.

Diffusers are fairly easy to install, and they may not cost much. You can use a variety of inexpensive materials for them. However, the range of applications is severely limited by the potential for serious glare from the diffuser itself.

Where to Consider Diffusers for Windows

Diffusion is useful only with windows that are directly illuminated by the sun for a large fraction of the day. Light from the empty sky is already diffused. Also, for diffusion to provide a benefit, the glazing must be located properly with respect to the activities in the space.

Even where these conditions are met, diffusers are satisfactory only if they can be installed in a manner that does not cause discomfort to the occupants from glare. The discussion below will help you decide whether you can install diffusers without excessive glare. As a first criterion, do not expect to use window diffusers if occupants must face toward the windows for extended periods.

Aside from the issue of glare, daylighting should strike the illuminated surfaces at an angle that is high enough to avoid forming shadows on the surface. Tall windows are most favorable for this technique. If the windows are low, most of the sunlight will strike horizontal work surfaces at a grazing angle, which is generally unsatisfactory.

If you are constructing a new building, do not use this technique. There are much less troublesome ways of providing daylighting. See the other Measures in this Subsection.

SUMMARY

An unconventional technique that increases the penetration of daylight from windows. Uses inexpensive materials. Avoiding glare problems is the major challenge.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, Retrofit	% % %
Reliability	✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

Energy Saving Potential

The amount of space that can be daylighted effectively by windows depends on their area and on their shape. The window height is important because daylight must shine downward to be useful. This factor limits the useful penetration of daylight to approximately two to three times the height of the windows above the illuminated surfaces. For example, if the windows are ten feet tall and the illuminated surfaces are three feet above the floor, useful daylighting may penetrate fifteen to twenty feet into the space.

If highly transparent diffusers are potentially too bright, you may be able to use diffusers of lower transparency. In this case, the need to limit brightness may become the limiting factor.

Electric lighting typically requires one to four watts per square foot (10 to 40 watts per square meter) of floor space. This amount of lighting power is saved during periods when daylighting can substitute for electric lighting.

Avoiding Glare is Your Main Challenge

Using diffusers with windows involves a potential glare problem that is so bad that you must take steps to avoid it. (The term “glare,” as we use it here, means an area of intense brightness within the visual field. [Reference Note 51](#), Factors in Lighting Quality, explains glare.) To understand the problem, consider an occupant looking toward a south-facing window. If the window is clean, the occupant sees only the scenery outside, and there is no glare. Although direct sunlight is coming through the window, it disappears into the carpet. The occupant does not experience any visual problem as long as the bright spot on the floor is hidden from view by furniture, partitions, etc.

Figure 1 shows what happens if a highly transparent diffuser is installed in that window. The direct sunlight is captured by the diffuser and scattered into the space. The occupant sees the diffuser as a bright, uniformly illuminated surface. The effect is like looking directly at a large fluorescent fixture. Whether you can effectively deal with this glare depends on the geometry of the space and the nature of the activities in the space.

In general, glare is less of a problem if the light source is located well above the line of sight. This favors tall windows. Indeed, you may want to install diffusers only on the upper parts of tall windows, and cover the lower portions of the windows with conventional shades or replace them with insulating panels (as recommended by [Measure 7.3.3](#)).

Glare from the diffusers is not a problem if all the occupants face away from them. See Figure 2. However, there are few activities where this layout can be assured for the life of the building. For one thing,

this orientation would cause people to cast their own shadows on their activities.

In most cases, expect to select diffuser material that has such low transmission that occupants can face the diffusers, at least for short periods, without discomfort. This reduces the amount of light entering the space, so the windows must be fairly large to provide a useful amount of illumination. (The extreme of this approach is installing translucent walls. See [Measure 8.3.3](#) about this.)

The window will be illuminated by direct sunlight at some times, and not at others. You will probably not get a useful amount of daylight through diffused glazing when sunlight does not shine on it directly. Furthermore, diffused glazing with low transparency may look gloomy when the sun is not shining on it directly.

Not matter which approach you take, test your ideas with a mockup at a typical window and activity area before you commit to permanent installations.

WESINC

Fig. 1 How window diffusers behave In this demonstration, sunlight is shining on two clear windows of an office. A milky white plastic diffuser is installed inside the window at right. The light fixtures are turned on for comparison. The diffuser causes a considerable amount of glare, the intensity of which cannot be conveyed by the photograph. In contrast, the scene outside the clear window is not bright enough to create glare. From this point of view, the surface of the diffuser appears considerably brighter than the surfaces of the fluorescent light fixtures. Notice the amount of light scattered by the diffuser on the ceiling. This aids daylight penetration. The ceiling should be highly reflective to exploit this.

How to Install Window Diffusers

In existing buildings where you will not be replacing the windows, your only option is to install a separate diffuser material inside the windows. Consider readily available diffuser materials made for fluorescent lighting fixtures. These have appropriate diffusing qualities, low light losses, and low cost. The most appropriate materials for most applications are clear prismatic diffusers and milky diffusers. The prismatic material has the highest light transmission, but a somewhat non-uniform light distribution pattern. It has a more intense, glittering appearance than milky diffusers, especially when viewed from a short distance. Viewed from a distance, it is no brighter than any other type of diffuser that admits the same amount of light.

For applications where you have much more sunlight than you need, you can use colored plastic sheet, fabrics, and even paper. For example, you can create decorative effects by using patterned fabrics as diffusers.

You can buy roller shades with various kinds of diffusing material.

If you plan to replace the windows in a building, decide whether or not to make the windows themselves diffusing, or to install separate diffusers. If you install diffusing windows, the decision to exploit diffusion will be irrevocable, so you need to be sure that diffusion will not cause glare problems.

If you decide to replace windows with translucent panels because of their higher insulating value, diffusion will be part of the package. See [Measure 8.3.3](#) if you decide to take this approach because it involves a number of choices and compromises, including the transparency and insulation value of the panels. Figures 3 and 4 show a typical window retrofit with diffusing panels.

Diffusing windows provide no view. If you want to retain some view, you must install regular windows along with the diffusing panels, as in Figure 3.

Select diffuser materials for resistance to ultraviolet degradation. Solar ultraviolet light will darken or destroy all organic materials in time. Plastics, fabrics, and other materials are available with ultraviolet inhibitors to resist damage, but resistance to damage varies widely. Study the specifications of the materials you are considering. Ordinary window glass absorbs ultraviolet strongly, but enough ultraviolet gets through glass to damage organic materials within a period of years.

Make the Ceiling Reflective

As we have seen, the ability of daylighting to penetrate into the space depends on the height of the windows. This is because light must shine downward to be useful. The window diffuser aims a large part of the incoming sunlight at the ceiling, as you can see in Figure 1. Don't waste this light. It is especially valuable

WESINC

Fig. 2 A lesson from the real world about window diffusion The orientation of activities with respect to the windows is a crucial factor in using window diffusers. In this office, the upper panes of the double-hung windows are made of diffusing glass. The diffuser to the side of the chair provides good illumination for the desk. However, the diffuser in front of the desk causes glare, so it has been covered with a venetian blind.

Kalwall Corporation

Fig. 3 Window retrofit with diffusing panels The top is the original configuration, with clear windows and roller shades. Notice that the outer row of light fixtures is turned on. The bottom shows the diffusing windows installed. These provide deeper daylight penetration and reduce heat loss. Some outside view is provided by clear hopper windows at the bottom, which can also be opened for ventilation. Notice that the children are all facing away from the diffusing windows, perhaps to avoid glare. However, the teacher must face the windows. See Figure 4 for the exterior appearance.

because it is shining downward from the highest angle. To exploit it, make sure that the ceiling is as reflective as possible. In fact, this is a good opportunity to use a specular (mirror-like) ceiling, if your decor can stand it. See [Measure 8.3.6](#) for more about interior surfaces.

Avoid Condensation and Exploit Insulation Properties

In some cases, using diffusers can create serious condensation problems. Or, adding diffusers may provide an opportunity to improve the insulation value of glazing.

When you install a diffuser inside an existing window, the diffuser acts as an insulating layer between the space and the window. The insulating effect lowers the inside surface temperature of the window. The lower temperature may radically increase condensation on the glazing, its frame, and the surrounding structure. The problem is worst at night, when there is no sunlight to keep the glazing warm enough to prevent condensation.

There are two ways to avoid this problem. One is to install the diffuser far away from the glazing, allowing free convection around the diffuser so that it has minimal insulating effect. This solution is easy and cheap, but it wastes an important opportunity to reduce heat loss.

The other solution is to seal the edges of the diffuser tightly to the surrounding structure, so that water vapor cannot migrate into the space between the diffuser and the glazing. The diffuser must be made of an impermeable material, such as plastic sheet. This method of installation makes the diffuser act as another pane of glazing, substantially reducing heat loss. For example, if the window or skylight has only a single pane, installing a diffuser may cut heat loss to less than half.

If you use this approach, the diffuser is acting as an interior storm window. See [Measure 7.3.2](#) for details about how to do this without causing condensation problems.

Minimize or Exploit Solar Heat Gain, as Appropriate

In many cases, the amount of sunlight falling on the window is much greater than you can use, even if the sunlight is diffused into the space. In such cases, you have to reduce the intensity of the sunlight as well as diffusing it. Even if you want to use all the daylight, all diffusing materials absorb a significant amount of the entering sunlight because there are multiple reflections within the material.

The sunlight that you do not use for illumination represents a considerable amount of heat energy. You may want to keep it outside the building to minimize the cooling load. Or, you may want to bring it inside the building to assist in warming the space. The characteristics of the diffusing material, and the way you install it, determine where this heat energy goes.

To minimize heat gain, minimize the amount of sunlight that gets into the space. For most effective results, consider installing diffusers outside the windows. In that way, almost none of the heat that is absorbed by the diffuser enters the building. This approach is highly visible from the outside, so the appearance of the diffusing material is important. Also, the diffusers must be installed so they resist wind, and the materials must resist exposure to the sun's ultraviolet radiation. Exterior diffusing screens made of glass fibers have been offered as a commercial product for reducing cooling load.

Kalwall Corporation

Fig. 4 The exterior of [Figure 3](#). The windows on the first and second floors have been retrofitted. The windows on the third floor remain. The appearance is changed from aged to slightly industrial.

To minimize heat gain while keeping the diffusers indoors, use a material that reflects the unwanted portion of the light back out through the window. For example, you might use a plastic diffuser sheet that has an aluminized surface. Or, you could install a reflective window film (see [Measure 8.1.4](#)) and install a separate diffuser. Be aware that any reflective method noticeably changes the exterior appearance of the building.

Reflecting the unwanted sunlight from the inside of the space is much less effective if the glazing is tinted, because heat is absorbed in the glass in both directions. On the other hand, tinted glazing typically absorbs 60 to 80 percent of the incoming sunlight, so you may not have to eliminate more sunlight before it reaches the diffuser..

On the other hand, if you want to capture the excess sunlight for warming the space, install a diffuser inside the space that is made of absorptive material. See [Measure 8.4.2](#) about this arrangement. [Measure 8.4.2](#) also suggests ways to install diffusers and absorbers so that you can reject unwanted heat at some times and capture the heat at other times.

Control the Electric Lighting to Exploit Daylighting

Daylighting is useless unless it reduces the energy consumed by electric lights. This is not just a matter of turning off the electric lights in daylighted areas. You also have to avoid the tendency to increase the electric lighting levels in adjacent parts of the space that are not daylighted to compete with the brightness of the daylighted areas.

See [Measure 9.5.3](#) for methods of controlling electric lights in response to daylighting. Combine these with the other automatic lighting controls of [Subsection 9.5](#) that are appropriate for the activities that occur in the space.

Effect on View

Diffusers eliminate any view through the glazing. With windows that face the sun, this is usually not a practical disadvantage, because the window would be blocked otherwise to avoid the glare of direct sunlight. Think of diffusers on windows as an alternative to closing off windows completely to avoid the glare of direct sunlight. If you want to exploit a desirable view, select a different Measure.

You could install a movable diffuser, such as a translucent roller shade, but manually operated devices are unreliable for conserving energy.

ECONOMICS

SAVINGS POTENTIAL: *30% to 80% of lighting costs in eligible areas. The amount of potential daylighted area varies widely, depending mostly on the building and glazing configurations. Typical lighting power that is displaced by daylighting is 1 to 4 watts per square foot (10 to 40 watts per square meter).*

COST: *Diffuser materials cost from \$1 to \$10 per square foot (\$10 to \$100 per square meter), if you are not too fancy. Installation cost varies widely, depending on the design. The cost of the lighting controls is covered by [Subsection 9.5](#).*

PAYBACK PERIOD: *Less than one year, to many years.*

TRAPS & TRICKS

CHOICE OF METHOD: *The potential for glare is a serious concern. Don't do this if it may create glare problems. Recognize that there is no view through a diffused window.*

DESIGN: *This is more complicated than it may seem. Consider the light distribution pattern, the decor, reducing heat loss, avoiding condensation problems, limiting heat gain, and avoiding potential glass breakage. Install effective controls for the electric lighting, or else the effort is wasted.*

MEASURE 8.3.5 Install a system of light shelves and shading.

You can make tall windows effective sources of daylighting by using “light shelves.” Figure 1 shows how they are installed.

Light shelves avoid the glare problem that limits the use of diffusers to exploit daylighting through windows (see Measure 8.3.1). Light shelves also provide the unique advantage of shifting the light from the window so that it comes from a more overhead direction, improving the quality of illumination.

The light shelf itself is a simple device that is installed inside the window. In most applications, it must be combined with other devices to avoid glare from sunlight entering the lower portion of the window. The light shelf itself is not difficult to install. Light shelf systems, including exterior shading devices, are now available from manufacturers as prefabricated units.

A serious disadvantage of light shelves is that only the portion of windows above head height is usable for daylighting. Light shelves require periodic cleaning, which is easy to neglect.

Where to Install Light Shelves

Light shelves require direct sunlight. The windows should face toward the sun for a large fraction of the time that the space is occupied.

Tinted or reflective glazing may greatly reduce the potential benefit of light shelves, or make them uneconomical. These types of glazing typically block about 70 to 80 percent of incoming sunlight.

Light shelves are useful primarily with windows that have a large amount of glazing area at a height greater than about 6.5 feet (2.2 meters). Applications include tall conventional windows and clerestory windows. (A “clerestory” is an elevated vertical section in a wall or roof that is intended to have windows for illuminating the interior portion of a space.)

Light shelves may be used with glazing at lower heights in some specialized cases where people cannot get close to the glazing.

As with any kind of daylighting, the electric lighting must be arranged and controlled so that it can be turned off to exploit the daylight provided by the light shelf system.

Energy Saving Potential

Light shelf systems provide useful daylighting of a zone that lies along the exterior wall. The width of this zone depends on the height of the top of the window, the orientation of the window, the latitude of the site, the time of day, and the clarity of the sky. The width of

SUMMARY

Used with tall windows and clerestory windows. In most cases, light shelves cannot exploit the portions of windows below head height.

Ease of Retrofit	😊	😊	

the zone varies with sunlight conditions. With typical clear windows, the zone may extend inward a distance of 10 feet to 20 feet (3 meters to 7 meters). The light penetration may be deeper if the window is very tall.

With typical interior lighting levels, this translates to a saving in electricity ranging from 10 to 40 watts per foot (30 to 120 watts per meter) along the wall. This assumes that no daylighting is available without the light shelves.

If the windows are tall, light shelves can provide deeper penetration than daylighting that is achieved by shading windows. This is because light shelves can throw all the energy of direct sunlight into the space. In contrast, using shading to tame sunlight for daylighting leaves most of the potential daylighting energy outside the building.

As with any kind of daylighting, the daylight entering the space becomes heat energy. This increases the cooling load in warm weather and reduces the heating load in cold weather. Light shelves disperse sunlight fairly efficiently, so the amount of heat energy added to the space is not much greater than would be added by an equivalent amount of electric lighting. (This is true of electric area lighting. Electric task light is much more efficient in terms of localizing lighting energy.)

What is a Light Shelf?

Windows that face the sun receive an enormous amount of energy that could be used for daylighting. In principle, if a window faces anywhere between southeast and southwest and if it receives direct sunlight, each unit of window area could illuminate 20 to 100 units of interior area. However, this is possible only if the sunlight can be distributed efficiently.

The challenges in distributing this free lighting energy are lighting geometry and glare. In order for illumination to be useful, it must come from overhead. Raw sunlight coming through a window falls on the floor, so some method is needed to redirect the sunlight so that it comes from overhead.

The problem of glare is explained in [Measure 8.3.1](#). In brief, if the light entering a window is simply deflected toward the interior of the space, occupants looking toward the window are blinded by glare.

Many concepts have arisen for taming the sunlight that enters through windows. A concept that appears promising at the present time is the “light shelf.” A light shelf is essentially a mirror that is installed inside a window, facing upward. The mirror reflects incoming sunlight toward the ceiling. The ceiling then distributes the light into the working areas of the space.

An effective light shelf system needs four components:

- **the light shelf itself.** The light shelf is simply a reflector. It could be as simple as aluminum foil taped to a piece of cardboard. Commercial light shelves include features that ease cleaning and enhance safety. See Figures 2 and 3.
- **the window.** The light shelf distributes daylighting only from the portion of the window that extends above the light shelf. The bottom portion of the window contributes daylight only to the narrow zone underneath the light shelf. The window must face toward the sun for a large fraction of the time, and it cannot be shaded by outside objects. If the window glazing is tinted or reflective, the daylighting potential is reduced substantially.
- **the ceiling.** The light shelf aims sunlight at the ceiling. The ceiling then distributes the light to the

Construction Specialties, Inc.

Fig. 1 Light shelves These are installed directly against the windows, just high enough to avoid being a hazard. The top of each shelf is a mirror, and it must be kept clean. Only windows exposed to direct sunlight are eligible. Glare must be avoided from the portion of the window below the shelf. The windows at left have internal shades. The windows at right are shaded by an external fixture, shown in Figure 4.

occupants. The ceiling plays the same role as the fixtures in electric lighting. In most cases, the ceiling should be highly reflective to conserve as much light as possible. The height and orientation of the ceiling, and the diffusion characteristics of the ceiling surface, determine how the ceiling distributes the daylight.

- **shading device(s) to prevent glare from the bottom portion of the window.** A window must be exposed to direct sunlight to be a candidate for a light shelf. The portion of the window below the light shelf needs separate treatment to prevent glare. For example, you may install a shade or diffuser inside the lower portion of the window, as recommended by [Measure 8.1.1](#). Or, you may install an external shade that increases the light collection of the upper part of the window, as we discuss below.

The rest of this Measure covers these components in greater detail. Think of light shelves as a system. Study [Measures 8.1.1](#) (exterior shading devices), [8.1.2](#) (interior shading devices), and [9.5.3](#) (automatic light switching) before attempting to install light shelves.

Effective daylighting by any method is still a rarity. It is impossible to convey the visual effect of daylighting by words or pictures. If you are interested in using light shelves, visit sites where they are installed, and judge their performance over a range of sunlight conditions.

The Lighting Pattern of a Light Shelf System

The pattern of illumination depends on the reflection characteristics of the light shelf, and it depends on the geometry and reflection characteristics of the ceiling

Fig. 2 Detail of typical light shelf The main feature is the reflective upper surface. A soft edge is valuable for safety. A sign is needed somewhere that the shelf is not for storage and that it should be cleaned at stated intervals.

Construction Specialties, Inc.

surface. If the reflection by the light shelf is specular (like a mirror), the reflection is controlled by the law of optics that says the angle of reflection equals the angle of incidence. If the sun is low in the sky, sunlight penetrates deeply into the space. If the sun is high, the ceiling is illuminated close to the wall.

Pure specular reflection creates a sharply defined rectangular bright spot on the ceiling. This may not be considered attractive, and it may be bright enough to annoy occupants. You can reduce this effect by making the reflecting surface of the light shelf more diffuse. This spreads out the light on the ceiling. However, it also concentrates the ceiling illumination close to the

Construction Specialties, Inc.

Fig. 3 Tilting light shelf Ability to tilt is most valuable for making the top surface easy to clean. A small amount of tilt may also improve performance. Tilting the shelf downward increases the penetration of light into the space, but it also introduces the possibility of reflecting sunlight into occupants' eyes at low sun angles. By the same token, tilting the shelf upward may avoid glare and increase daylighting at low sun angles.

light shelf. If the reflection is very diffuse, penetration into the space is sacrificed.

A taller ceiling provides deeper light penetration, and it also distributes the light more widely within the space.

It helps to think of a light shelf system as having two zones of daylighting. The interior zone is illuminated by light that is thrown on the ceiling by the light shelf. The exterior zone, adjacent to the window, is illuminated by the portion of the window below the light shelf. The exterior zone is partially shaded from the ceiling light by the light shelf itself. (A light shelf could be made of partially transparent material to allow the exterior zone to be illuminated through the light shelf.)

The boundaries of these two zones change as the sun moves and sky conditions change. Both zones move toward the interior when the sun is low in the sky, and they move toward the exterior when the sun is high in the sky. Both zones move in and out together. However,

diffuse reflection by the light shelf reduces the movement of the interior zone as the sun angles change.

When the sun is higher, less sunlight is able to enter the window. At the same time, the sunlight is concentrated in a smaller area, closer to the exterior. Therefore, the illumination level within the zones tends to remain constant.

On the other hand, if the sun is obscured, there is less total daylight, but it is distributed more deeply into the space. As a result, the illumination level within the zones falls dramatically, perhaps to the point that artificial light is needed.

Equipment Choices and Layouts

You have two main design issues with a light shelf system: (1) where to locate the light shelf, and (2) how to avoid glare and excessive heat gain adjacent to the portion of the window below the shelf. With typical windows, the window area above the shelf cannot provide as much light as you want, and the window area below the shelf provides too much. We will look at that

Construction Specialties, Inc.

Fig. 4 Exterior shades that work with light shelves These are unusual because they are installed below the tops of the windows, at the same height as the light shelves. Their purpose is to keep direct sunlight from entering the portions of the windows below the light shelves. The shadow pattern shows that the shades would be more effective if they were installed as a continuous unit. Exterior shades can increase daylighting by reflecting more light into the top portions of the windows. This design fails to exploit that opportunity.

problem first, and then look at several practical equipment layouts.

■ Shelves are Above Head Height, Usually

A fundamental problem with light shelves is the need to locate the shelf too high for efficient use of the daylight entering the window. As a practical matter, the light shelf usually has to be installed above the level of people's heads. In modern buildings, the ceiling height is typically eight to ten feet, and the windows may not reach all the way to the ceiling. Therefore, only a small fraction of the total window area is available for daylighting.

There are two reasons why the light shelf has to be installed so high. One reason is safety. The light shelf extends into the space. People could walk into the shelf if it were low enough. Therefore, the shelf must be installed above the height of a tall person.

The other reason is glare. The top of the shelf is a reflecting surface. If the shelf were located below eye level, sunlight could reflect into people's eyes.

Light shelves can be installed at a lower level if people are not able to get close to the windows. Such situations are rare, but they do exist.

■ The Shape of the Light Shelf

As the name implies, a light shelf looks like a shelf. It is as wide as the window, or somewhat wider. The depth of the shelf is proportional to the height of the window above the shelf, but the ratio is a compromise. The depth required to reflect all entering sunlight depends on the elevation of the sun. If the sun facing the window is low in the sky, it would take a very deep shelf to reflect most of the sunlight to the ceiling. A shelf this deep might be difficult to mount, or it might interfere with lighting the space under the shelf, or it might look too strange.

The sides of the light shelf should be designed to keep sunlight from shining down the sides of the shelf when sunlight is entering the window sidewise. You can do this by making the shelf wider than the window, or by installing a side piece that extends upward from the shelf.

The shelf does not have to be exactly horizontal, although a horizontal orientation is near optimum if the shelf is fixed. You could make the shelf adjustable, as in Figure 3. Tilting the shelf downward would improve daylight penetration at high sun elevations, and tilting it slightly upward would reflect more light at low sun angles. However, don't expect the occupants to do this. You could automate the tilt with a fairly simple optical sensor, and win a design award for innovation.

There is another light shelf configuration to consider. It consists of a stack of light shelves, each fairly narrow. It looks something like a venetian blind with the blades adjusted to a horizontal position. However, it behaves differently, because the tops of the blades reflect. If the

shelves are narrow enough to fit within the depth of the window frame, they would not pose much of a safety hazard. Also, being horizontal, they would not interfere much with the view. The main disadvantage of this arrangement is that it can reflect an image of the sun into the eyes of anyone standing nearby and looking out the window.

■ Relationship to Artificial Lighting

The spaces are illuminated with a combination of daylighting and artificial light. The light fixtures and their power circuits should be arranged so that they can dim or turn off when daylighting can provide sufficient illumination. The layout of the lighting should accommodate changes in sun position and cloud cover. This can be as simple as switching the fixtures in rows parallel to the exterior wall. Lighting switching and dimming should be automatic. See [Measure 9.5.3](#) about automatic lighting controls and [Measure 9.6.4](#) about the arrangement of the light fixtures and power circuits.

At night, the space must be illuminated with artificial lighting. The light shelves may interfere with illumination from ceiling-mounted fixtures. If necessary, modify the electric lighting to provide good nighttime illumination in the exterior zone.

■ Interior Shading for the Lower Window

In a typical light shelf installation, most of the window area is underneath the shelf. This provides an excess of sunlight to the exterior zone. You can use an interior shading device to block the excess sunlight. Refer to [Measure 8.1.2](#) to find your options.

An ordinary venetian blind is probably your best choice. If you want to reduce heat gain in the space, make the outer surfaces of the blades highly reflective. If you want to capture heat gain, make the outer surfaces of the blades moderately absorptive.

■ Exterior Shading

If the windows face toward the south, you can shade the lower portions of the windows with an exterior horizontal sunshade. See [Measure 8.1.1](#) for the issues to consider with exterior shading.

When exterior shading is used with a light shelf, it is installed in an unusual manner, as shown in Figure 4. It must be installed at exactly the same level as the light shelf. If it is higher, it will block the entry of useful sunlight to the space above the shelf. If it is lower, direct sunlight will enter the space through the gap between the light shelf and the shade. Both the shelf and the sunshade must butt against the glass closely to avoid leaving a gap through which sunlight can enter directly.

In this application, the exterior shade can serve double duty. If it has a reflective upper surface, it will reflect sunlight into the upper portion of the window. If the upper portion of the window is short, this will not help much, because the additional light will strike the ceiling close to the wall. However, if the window extends

well above the exterior shade, the additional light will penetrate farther into the space. The external shade shown in Figure 4 fails to exploit this opportunity.

■ Layout with Clerestory Windows

Clerestory windows offer a major advantage for light shelves. They are well above head level, so the entire window can be used to capture daylighting to illuminate the interior area of the space.

With this layout, there are no longer two separate lighting zones, as for windows at lower levels. A space with clerestory windows has a tall ceiling. Light reflected from the ceiling can distribute light to the area underneath the light shelf.

An exception occurs if the clerestory is part of the roof structure, well inside the wall. In this case, the area adjacent to the wall may be shadowed by the light shelf.

Keep the Top Surface Clean

The light shelf is horizontal, or nearly so. This makes it an effective dust collector. Within a period of weeks or months, enough dust can settle on the shelf to seriously degrade illumination. Therefore, light shelves need to be cleaned on a regular basis.

The best approach is simply to make this part of the activity of the cleaning crew. However, contract cleaning crews will overlook this unfamiliar requirement. Therefore, a responsible manager must keep educating the cleaning crews about the need to dust the light shelves.

Some commercial light shelf units are designed to pivot downward to allow cleaning, as in Figure 3. This allows cleaning without a ladder, which is an important feature for increasing the likelihood that the shelf will actually be kept clean.

Cleaning shelves that are located at great heights, as with clerestory windows, can be a major task. Consider this before deciding to install light shelves in such locations.

Cleaning is so important that each light shelf should be marked in a durable, highly visible manner to tell cleaning crews to clean the top surface with each room cleaning.

If you use exterior shades with reflecting top surfaces, you will probably have to depend on precipitation and wind to keep them clean, at least between long intervals of manual cleaning. Select a finish for the top surface that sheds dirt easily. Give the top surface enough slope so that rain flows off the surface freely.

Safety

The height of the shelf is a compromise between lighting effectiveness and safety. It is usually not practical to install the shelf so high that the tallest

basketball player cannot run into it. Therefore, the shelf should be designed so that the edge is as yielding as possible. Also, the edge should be made very visible, as with a bright colored stripe. Some commercial units offer a soft rubber bumper around the edge of the shelf, as shown in Figure 2.

Explain It

Install a placard at each light shelf to explain its purpose. Ask the occupants to exploit the daylighting and minimize artificial lighting. (In most cases, there should be automatic lighting controls to do this.) Spell out that the shelf is not supposed to be used for storage. You can use the same placard for the cleaning instructions.

ECONOMICS

SAVINGS POTENTIAL: *If light shelves make daylighting possible where it did not exist before, typical savings are 10 to 40 watts per foot (30 to 120 watts per meter) along the wall. Greater savings are possible with taller windows. This translates to a saving of about \$1 to \$10 per foot per year.*

If external shading is used, the greatest saving may occur from the reduction of cooling load, especially in warm climates. See [Measure 8.1.1](#) about this saving.

COST: *The light shelf unit itself may cost about \$100 per window, subject to wide variation. In addition, see [Measure 8.1.1](#) for the cost of external shading devices, and [Measure 8.1.2](#) for the cost of interior shading devices. See [Measure 9.5.3](#) for the cost of automatic lighting controls. In existing buildings, you may have the cost of rearranging the light fixtures and power circuits to exploit daylighting. See [Measure 9.6.4](#) about this.*

PAYBACK PERIOD: *Several years, in new construction. Ten years or longer, in retrofit.*

TRAPS & TRICKS

CHOICE OF METHOD: *Light shelves are still a novelty, so you are pioneering. Before you make any commitments, visit some sites where light shelves are installed, and judge their performance yourself. Remember that the efficiency objective is to minimize electric lighting and cooling load. See how well they do this.*

SYSTEM FEATURES: *The greatest design difficulties are not in the light shelf itself, but in the related shading. See [Measures 8.1.1](#) and [8.1.2](#) about this. Include features that enhance cleaning and safety. Consider effective placards to be an integral part of the installation.*

MONITOR PERFORMANCE: *Light shelves are easy to neglect. If you see people storing objects on top of the light shelf, you know the system has failed. Inspect the shelves periodically to make sure that they are being cleaned.*

MEASURE 8.3.6 Use light interior colors or mirrored surfaces.

RATINGS

New Facilities	Retrofit	O&M
A	B	

If a space has daylighting, and if it has appropriate controls for the electric lighting, you may be able to significantly improve the contribution of daylighting by using a highly reflective color scheme inside the space.

This Measure is similar to [Measure 9.6.1](#). Refer to there for details.

Passive Solar Heating

The Measures of this Subsection exploit passive solar heating for a limited number of applications. These Measures tap only a small fraction of the theoretical potential of passive heating, but they are practical to try without a great deal of pioneering. Exploiting passive solar heating to a greater extent involves a major commitment to unproven methods. For the perspective that you need to be successful in this fascinating and risky area, see [Reference Note 47, Passive Solar Heating Design](#).

MEASURE 8.4.1 Keep open the window shades of unoccupied spaces that need heating.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

If windows face the sun for at least part of the day, they receive enough sunlight to provide a significant amount of heating for the space. However, windows exposed to direct sunlight usually have shades or blinds to prevent glare. These shades may be left closed when the space is vacant, wasting the potential of passive heating.

If a space is vacant during long periods of daylight, open the shades during cold weather to admit solar heat. Accomplishing this requires people who can be assigned the task of opening the shades. For example, this responsibility can be assigned to maids for hotel rooms, to teachers for classrooms, to nursing staff in hospital rooms, and to the occupants of single-person spaces. Security patrols can be assigned this responsibility in many types of facilities.

Opening shades or curtains reduces their insulating value at night. This is not much of a penalty, because ordinary window shades and curtains provide little insulation. Convection bypasses them. The gain in solar heating during the daytime is much greater than the increase in heat loss overnight. This being said, try to close the curtains overnight, but only if you have a reliable procedure for opening them again before sunrise.

Energy Saving Potential

Throughout the middle latitudes, windows facing in any direction from southeast to southwest admit about 1,000 BTU per square foot of window area per day during winter, if the sky is clear. Conventional window treatments absorb 30% to 70% of this heat when they are closed. If they are kept open, all the heat gets into the space.

The total annual saving depends on the number of daylight hours during which the space is vacant, the size and orientation of the glazing, the clearness of the sky, the number of days requiring heating, and the heating requirements of the space.

This Measure may also save a significant amount of lighting energy, especially at the beginning of occupancy periods. For example, hotel guests arriving during the day typically rely on daylighting for most of their room lighting, provided that the windows provide satisfactory lighting.

SUMMARY
An easy way to save heating energy in spaces that are vacated for long periods.

Explain It to the Staff and Occupants

This sort of procedure tends to be neglected. Use whatever administrative methods work in your facility to keep the procedure in effect.

Ask occupants to control the shading to conserve energy. Placards are usually the best way to do this. See [Reference Note 12, Placards](#), for guidance in designing and installing placards.

ECONOMICS

SAVINGS POTENTIAL: 20% to 80% of heating costs in the sunlitged spaces, depending on the factors discussed above.

COST: Usually minimal. Customized placards typically cost about \$1 to \$5 apiece, in quantity.

PAYBACK PERIOD: Immediate.

TRAPS & TRICKS

ADMINISTRATION AND COMMUNICATION: This is primarily a matter of effective leadership and communication. Back up your request with a well written memorandum to the responsible managers. Show people what needs to be done. Say please and thank you.

MONITOR PERFORMANCE: This kind of procedure tends to fade away. Keep it refreshed by periodic contacts with the departments responsible. Put this in your tickler file.

MEASURE 8.4.2 Install combinations of sunlight absorbers and reflectors inside windows and skylights.

Measure 8.4.1 points out that most glazing exposed to sunlight is equipped with shading devices that block out the sun completely, wasting the sun’s heating potential. The inexpensive procedure recommended by Measure 8.4.1 is not effective for exploiting passive heating when spaces are occupied, because it does not correct glare problems that motivate people to close the shading.

A simple concept for exploiting solar heating while controlling glare is to install an absorbing surface inside the glazing that converts the sunlight to heat. There are two differences between the heat absorber and conventional window treatment:

- the absorber is intended to absorb heat, rather than reflecting it. It does this with an outward facing surface side that is dark.
- the absorber is installed far enough inside the space so that it acts as an efficient convector. The absorber does not have to intrude far into the space. However, you can install the absorber anywhere in the space where it will intercept direct sunlight and kill glare.

If absorbers are installed close to glazing, they can reduce the chill that occupants feel in cold weather when they are near glazing. When sun is shining through the glazing, the absorbing surfaces are warm, so they act as low-temperature radiators. When sun is not shining through the glazing, the surfaces limit radiation heat loss from the space to the windows.

You can make the heat absorbing surfaces from any opaque or translucent material, such as fabric. With a bit of creativity, you can use this Measure in most types of facilities, while adding a decorative touch.

In most cases, you still want to be able to minimize the cooling load during warm weather. You can do this by having a reflecting surface just inside the glazing when heating is not desired. In retrofit applications, you can keep the original window shading devices to serve this purpose.

An Example for Windows

You can put this concept into practice in many ways. For example, you can use two conventional venetian blinds. Install a highly reflective venetian blind as close to the window as possible, in the conventional manner. Install a second, highly absorptive venetian blind on a bracket that holds the blind about six or eight inches inside the wall. The inner blind can be a conventional blind that has a dark, fairly dull color. Suspending the dark blind inside the space keeps the convection from

SUMMARY

A simple but unconventional technique that can provide comfortable heating, and perhaps enhance daylighting. Uses conventional materials and equipment in a clever manner.

the dark blind from scrubbing the stagnant air layer off the window surface.

Only one blind is used at a time. When the weather is warm enough that passive heating is not useful, the reflective blind is lowered, and the dark blind is raised out of the way. Occupants adjust the reflective blind in the normal way to avoid glare and exploit the view as much as possible.

When passive solar heating is desired, the reflective blind is raised and the dark blind is lowered. Again, occupants adjust the dark blind in the normal way to avoid glare and exploit the view as much as possible.

Sunlight comes through the window at various angles. Therefore, the absorbing blind may have to be much larger than the window to keep sunlight from entering the space around the sides of the blind. Alternatively, you can install side fins, projecting from the wall, to keep sunlight from getting around the dark blind.

An important advantage of this technique is that the effectiveness of passive heating does not depend on occupants adjusting the blinds in any particular way. Most of the sunlight that enters the window is captured, no matter how the dark blind is set. The purpose of the dark blind is to capture most of the solar heat even when occupants close the blind to avoid glare.

Heat circulates through the space by convection, as with a conventional convector. The effectiveness of the circulation depends on the geometry of the space. In a space with a horizontal ceiling, the warm air circulates throughout the space. Cooler air remains near the floor. This cooler air is heated only if the warm part of the heat absorber is low enough to reach it.

Therefore, this method alone may leave an uncomfortable cold air layer near the floor. This is true even if there is ample solar energy. For this reason,

expect to use another method of heating the air near the floor. The most efficient solution is to let sunlight shine on a dark part of the floor near the window, if you can do this without creating glare.

Or, you might rely on your conventional heating equipment, such as a baseboard convector, but this uses purchased energy. (Any space needs a conventional heating system for periods when there is no solar energy available.)

Or, if the space has a forced-air heating system, keep the circulating fan running at low volume. The heating system must have a low-speed fan setting for this to be acceptable. Running a heating unit fan without heating the air will cause a wind chill effect on people. The air velocity must be kept low enough so that this effect is not objectionable.

An Example for Skylights

Skylights can produce oppressive heat and glare that motivates building owners to remove them or to paint over them. This wastes their potential for passive heating and daylighting.

A general approach that captures the heat of skylights while avoiding glare is to install a light absorbing screen under the skylight. The screen can be as simple as a hanging of dark fabric. This solution avoids the need for any additional structure, and the fabric is easy to attach.

In a space that uses skylights, the heat absorber will be visually prominent. Use it to create pleasant daylighting. At the same time, exploit its potential as a decorative item.

There is a fundamental problem when using heat absorbers with skylights, or with other glazing that is located high in the space, above the level of the occupants. The heat absorber releases virtually all of its heat by convection, so all the heated air rises to the space above the absorber. The absorber itself cannot project heat downward.

To solve this problem, try to feed the heat through the existing heating system, if it uses fan-forced circulation. This requires an air return located above the absorber, preferably near the top of the space. This is so important for the effectiveness of passive solar heating that you should consider adding an appropriate air return if none presently exists.

Even if the heat from the absorber cannot be distributed through existing heating equipment, installing the absorbers can still be a better alternative than abolishing the skylight. In a space with skylights, it is likely that most of the heat loss from the space occurs through the skylights themselves. The heat absorber allows the solar energy passing through the skylight to offset the heat loss from the skylights without creating visual problems inside the space. (During most daylight

hours, a skylight takes in much more energy than it loses by conduction.) The warm air bubble created at the ceiling level eliminates radiation cooling of the space below, improving comfort. And, the heat absorber can be designed to create effective daylighting.

Energy Saving Potential

Throughout the middle latitudes, windows facing from southeast to southwest admit about 1,000 BTU per square foot of window area per day (about three kilowatt-hours per square meter per day) during winter, if the sky is clear. Conventional shades typically absorb 30% to 70% of this heat. The heat collecting devices suggested here may capture 90% of the heat.

The total annual saving depends on the size and orientation of the glazing, the clearness of the sky, the number of days requiring heating, and the heating requirements of the space.

The potential saving depends on the transparency characteristics of the glazing. The devices recommended by this Measure capture only the solar heat energy that passes through the glazing. If the glazing is tinted or reflective, or if it has special features to block solar infrared radiation, the value of this Measure is greatly reduced.

Design Guidelines

This technique is unconventional, so you have to be an innovator. While you are being creative, follow these guidelines.

■ Select the glazing transparency for the application.

This Measure provides the greatest heating benefit if the glazing transmits a large fraction of the sunlight that falls on it, whether the glazing is clear or translucent. Glazing that is highly absorptive or highly reflective reduces the potential for passive heating so much that this Measure may not be worthwhile.

In new construction, you get to select the glazing. If you select clear glazing to maximize the benefit of this technique, the building will be married to it. This is a novel technique, so think hard about this decision.

■ Distribute the heat into the space effectively.

Provide enough clearance at the top and bottom of the absorber to allow free convective circulation. Install the absorber far enough from the wall so that the convective current from the screen does not scrub the surface of the wall. Leaving the wall's air layer intact reduces heat loss somewhat.

The absorbing device distributes its heat to the space mostly by convection. The absorber does not become warm enough to radiate strongly. The amount of heat that the absorber emits by radiation depends on the absorber's temperature and emissivity. Most non-metallic materials that you would use to make heat

absorbers have high emissivity, which increases the amount of heat they transfer to the space by radiation.

Too much heat radiation may be uncomfortable for occupants who are near the absorbing surfaces, but this is unlikely. If you want to decrease radiation and increase convection, use surfaces of low emissivity. This means smooth metal surfaces, or metallic coatings. Another method is to install a second screen inside the absorber. This innermost screen will block heat radiation regardless of its other characteristics (color, weight, etc.), as long as it is opaque.

If the heat absorbing surfaces are located high in the space, as with skylights, design them to radiate as much heat as possible downward to the occupied space. Heat that is transferred by convection rises. If this heat accumulates above the occupied space and does not circulate, it has limited value.

■ **Be able to reject excess solar heat.**

In most buildings, there are times when sunlight could overheat the space. To deal with this, provide reflective shades or other methods of reducing cooling load (See [Subsection 8.1](#)). In retrofits, the original shades may serve this purpose adequately.

Some large skylights have vents or openable panes to get rid of heat gain during warm weather. Make sure that any vents are airtight when closed, or they may waste large amounts of heating energy. (See [Measure 6.4.4](#) about this.)

■ **Exploit daylighting.**

This technique has potential for daylighting. The trick is not to absorb all the entering sunlight, but to distribute some of it within the space in a glare-free manner. See [Reference Note 46](#), Daylighting Design, for the full story on daylighting.

■ **Preserve the view, if there is one.**

If the glazing offers a good view, try to make it available. For example, using a pair of venetian blinds, as in the previous example, accomplishes this.

■ **Minimize waste of useful space.**

Space inside a building is valuable. Also, devices that stick out are more likely to be a nuisance and get damaged. Design the absorbing devices to use a minimum of space that is useful for other purposes.

■ **Have a sense of style.**

Make this an opportunity to enhance the appearance of the space. For example, using fabric heat absorbers offers endless possibilities for decor.

■ **Avoid condensation damage.**

Skylights are prone to serious condensation. The absorbers will make the glazing colder at night because they shield the glazing from the warmth of the space. This aggravates the condensation problem. The condensation may damage your absorbers and cause other problems. See [Reference Note 47](#), Passive Solar Heating Design, for ways of reducing condensation.

■ **Don't interfere with fire egress.**

Windows may be potential escape routes in the event of fire, or points of entry for firefighters. Do not install devices that conflict with safety.

■ **Select materials for longevity.**

Select materials that resist sun damage. If the absorbers can come in contact with people or moving equipment, design them to resist impact. Select movable components that resist wear. For example, pull cords should be designed so that they do not fray or jam. Select equipment that allows worn components to be replaced easily.

Explain It to the Occupants

The heat absorbing devices are vulnerable to being misused or abandoned because their purpose is not obvious, or because they appear to be a nuisance. Therefore, make people aware of their purpose. Also, if the shading devices require any human control, explain how to use them. Placards are an effective means of doing this. See [Reference Note 12](#), Placards, for guidance in designing and installing placards.

ECONOMICS

SAVINGS POTENTIAL: 10% to 100% of heating costs in the sunlit spaces, depending on the factors discussed above.

COST: Varies widely. You probably cannot invent anything that will cost less than \$100 per window. Heat absorbers for large skylights will cost much more.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

THE HAZARDS OF PIONEERING: This is an unusual concept. You have to develop it into a practical configuration. Don't try it unless you have the time and the discipline to work out all the details. Set up a test installation before extending your concept to many windows or skylights.

MEASURE 8.4.3 Install solar enclosures over areas that can benefit from heating.

RATINGS

New Facilities	Retrofit	O&M
C	C	

The ultimate in passive solar heating is creating a space that is heated entirely by sunlight. Many facilities have opportunities for using a glazed enclosure to cover an outdoor space, providing free heating for at least part of the year. The enclosure does not have to be made of glass. It can be made of any material that admits enough solar heat to offset the heat losses. Materials include glass, plastic glazing materials, translucent panels, thin plastic sheet, and more unusual materials.

Where to Consider Glazed Enclosures

Greenhouses are by far the most common type of glazed enclosures. Figure 1 illustrates the range of types. Experience with greenhouses provides valuable lessons for employing glazed structures for any purpose. For example, Figure 1 shows the major heat venting and ventilation requirements.

One purpose of glazed enclosures is to make an open space usable for a more valuable purpose. For example, the front of a restaurant may be turned into a sidewalk cafe.

Another purpose is to extend that length of time that a facility can be used. For example, Figure 2 shows a patio restaurant in a mid-latitude location that is usable for three or four months per year. Installing a glazed enclosure would approximately double the usable period. Furthermore, it would make the space usable in rain and wind.

Enclosing an outdoor swimming pool, as in Figure 3, typically extends its season of usage by several months.

Another purpose is to reduce heat loss from adjacent space, as when enclosing the common area of a shopping center.

Large glazed enclosures have the ability to collect enormous amounts of passive heating, and they are able to keep themselves warm even in cool climates. Figure 4 shows a huge courtyard in a Tennessee tourist hotel that is enclosed with glazing, making it comfortable under almost all weather conditions.

Beware of Unexpected Heating and Cooling Costs

There is a fly in this ointment. The glazed enclosure is able to heat itself only during the daytime, and heating is substantially reduced when the sky is overcast. The nature of the activity may require the space to operate when passive heating is not adequate. Or, the owners may discover that the increased value of the space makes it worthwhile to operate the space at night. In this case, heating equipment is needed. Unfortunately, a simple

SUMMARY

An opportunity to make space more useful without increased heating costs. Not as simple as it looks.

Ease of Retrofit	😊	😊	

glazed enclosure has only minimal insulation value. In the end, energy cost may be increased rather than decreased. If you examine glazed enclosures, you will see that many are heated in ways that require a large amount of energy.

Furthermore, a glazed enclosure may overheat badly during warm weather, and even during mildly cool weather. This sometimes prompts owners to install air conditioning. This can be very expensive, even in mild climates.

This leads us to an important point. Before installing a glazed enclosure, consider how the space is likely to be used afterward. If the space will be heated, design the enclosure to minimize heat loss. Also, try to prevent overheating without resorting to air conditioning.

Energy Saving and Comfort Benefits

Consider this Measure primarily as a way of improving comfort and/or space utilization. In some cases, you may reduce energy consumption at the same time. Or, you may achieve the improvement in comfort and/or space utilization at a relatively small additional energy cost.

If the newly enclosed space is not conditioned, there is no increase in energy cost. If it connects to conditioned spaces, it may substantially reduce energy cost. For example, enclosing the walkways of a shopping mall radically reduces heat loss from stores that are open to the walkway.

But, beware of using a glazed enclosure as a substitute for a properly designed building or building addition. Again, consider the ultimate mode of use.

Design Guidelines

A glazed enclosure is not as simple as it looks, if you want it to be comfortable and efficient. Concentrate

on the following points to achieve efficiency and comfort.

■ **Minimize the heating load.**

The insulating value of all transparent and semi-transparent glazing materials is poor. Furthermore, if the glazing is slanted away from the vertical, its insulating value declines radically, typically by a factor of two to three, compared to vertical glazing. The poor insulation value does not matter as long as the enclosed space remains unheated, because solar heat gain will

make the space much warmer during daylight than it would be if it were left open.

Some composite glazing materials, discussed in [Measure 8.3.3](#), offer fairly good insulation value. These materials are bulky and expensive. They offer no sense of the outdoors, and they have low light transmission. However, they can be used effectively in combination with transparent materials.

If the enclosed area will be used extensively during hours of darkness, use insulating panels for a

WESINC

Fig. 1 Plain and fancy greenhouses The upper one is made entirely of extruded double-wall plastic. The bottom one is made of glass. All glazed enclosures should apply the lessons that have been learned from a vast number of greenhouses. In both of these, notice the extensive vents that are located at high points. Venting is necessary for free temperature control in any application.

part of the enclosure surface area. Distribute the area of glazing and the area of insulated panels to save energy and create a pleasant environment. If practical, design the structure so that glazing and insulated panels can be swapped. This gives you a relatively inexpensive way of altering the daylighting and heat gain characteristics of the structure after it is built, if necessary. You may even be able to exchange glazing for insulated panels, or vice versa, on a seasonal basis.

■ **Deal with excess heat gain efficiently.**

A common mistake when adding glazed enclosures is overlooking the large cooling loads that they may create. If air conditioning is used to deal with the heat gain, the energy costs can be enormous in relation to the size of the space.

Deal with excess heat by venting it. Do this with a combination of vent dampers at high and low positions in the space. Locate the low vents where cold entering air will not cause discomfort. Provide dampers that seal tightly when venting is not required.

During warm weather, venting alone may not suffice. In such cases, consider using reflective glazing (see [Measure 8.1.3](#)) or opaque panels for part of the enclosure. If the weather can turn cold for significant periods, use insulating panels for as much of the enclosure as possible.

If the space will be air conditioned, avoid any vents at a low point in the structure, because these would waste cooled air. If you use vents at all when air conditioning,

limit them to locations at the highest points of the enclosure.

Even with adequate venting or with air conditioning, direct radiation of sunlight on occupants may be uncomfortable. This is most likely to be a problem if the occupants are stationary, e.g., at dining tables. In such cases, provide shade for the people.

■ **Control condensation adequately for the application.**

Glazing has low thermal resistance, so condensation forms if the outside temperature falls much below the dew point temperature of the inside air. This means that the glazing will sweat if there is any significant source of moisture inside the enclosed space. In many applications, sweating is transitory and causes no trouble, as long as the structure is made of materials that are not vulnerable to moisture.

Condensation is a major issue when enclosing moist environments, such as swimming pools and plant growing facilities. In such facilities, the glazing remains wet for long periods, and you need to use special techniques to prevent damage and unsightly conditions. Heavy condensation has a major effect on appearance and view. This may not matter with a swimming pool, but it is a problem for a restaurant that uses foliage for decor.

Swimming pools are a special challenge. The water temperature is typically around 80°F. Because of the large evaporating area of the water, the water temperature

WESINC

Fig. 2 Prime candidate for a glazed enclosure This is the roof garden of a busy pizza restaurant at an oceanside resort. Although more dining space is needed, customers avoid this area because it is too exposed to chilly winds and frequent rains. Also, the still air temperature is somewhat too chilly for outdoor dining during much of the active season.

becomes the dew-point temperature of the enclosed space. The glazing will sweat heavily whenever the outside temperature is much below the water temperature. Provide effective drainage to carry condensate away from any areas where it does not belong, including the floor and wooden structures.

Lingering condensation grows mold. Sunlight stops mold growth, but only on parts of the structure that are directly illuminated. Make shaded surfaces accessible for frequent cleaning.

■ Provide good daylighting.

Psychologically, people may be more sensitive to bright sunlight when a space is enclosed, even if the function remains the same. You may want to compensate for this effect by using various types of diffusing and opaque panels.

As a rule, transparent glazing provides a more pleasing visual environment than glazing that diffuses light. You can tint the glazing or use reflective glazing to reduce heat gain. (At the same time, remember this rule: if you need to treat glazing to reduce the cooling

load, there is too much glazing area. Few applications have a view that justifies excessive glazing.) To shade localized areas that cannot tolerate direct sunlight, provide localized shading inside the enclosure. For example, if you are enclosing an outdoor cafe, you could install sun umbrellas at the tables. Figure 5 shows an example.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely, depending on the application.*

COST: *Plain glazed enclosures start at about \$15 per square foot of horizontal space. With heating, motorized venting, and few other accessories, the price may be about \$30 per square foot in middle sizes. Very fancy enclosures can cost as much as several hundred dollars per square foot, but you are paying for glamor, not energy savings.*

PAYBACK PERIOD: *Many years, if you consider only energy cost. This is usually done to achieve purposes besides energy savings.*

Kalwall Corporation

Fig. 3 Swimming pool enclosure This swimming pool at an all-year campground uses an intelligent combination of translucent insulated panels, clear glazing, and venting. Notice that the upper portions of the roof can slide back to provide venting and daylight.

Vistawall Architectural Products

Fig. 4 A huge enclosed hotel courtyard This area the size of a village center is entirely under glass. Passive heating keeps it reasonably warm under most weather conditions, in a climate that can become fairly cold.

WESINC

Fig. 5 Localized shading This umbrella suspended inside a swimming pool enclosure shields people seated at the table from direct sunlight.

TRAPS & TRICKS

INVESTIGATE: Spend time inside enclosures similar to the one that you wish to create, under all weather conditions. There is no other way to appreciate what the end result will be like.

DETAILS, DETAILS: Work out effective methods of ventilation, preventing glare, avoiding overheating, and dealing with condensation. Talk to people who are in the business of installing glass enclosures. Anticipate changes in usage that will occur as a result of enclosing the space, and design the enclosure to accommodate those changes efficiently.

Section 9. ARTIFICIAL LIGHTING

INTRODUCTION

Lighting is an area of energy conservation that offers major savings in almost any facility. Lighting energy conservation offers a big payoff, but it is a big challenge for the lighting designer, the installer, and the facility operator. A typical facility has many lighting requirements. Each has its own set of opportunities for improving lighting efficiency. This makes it easy to overlook opportunities for savings. You must combine efficiency with good lighting quality. Doing this requires knowledge, imagination, and willingness to do things in a different way.

The Energy Saving Potential in Lighting

■ Lighting Energy Savings

In commercial buildings, lighting typically accounts for 20% to 50% of total energy consumption. In residential buildings, the figure typically is 10% or less. In energy-intensive industrial operations, lighting may account for no more than a few percent of total consumption, although representing a large amount of energy in absolute terms.

The percentage of lighting energy that can be saved typically is large, but impossible to define precisely. Centuries ago, a person might read by the light of a single candle. Today, a person in a typical office uses hundreds or even thousands of times more light. However, don't expect that you can reduce your lighting energy consumption by a factor of several hundred. Illumination standards have increased radically, modern activities require a larger illuminated area, and "background" lighting has come to be considered a necessity.

Experience suggests that aggressive lighting energy conservation can reduce average lighting energy consumption by a factor of three to ten compared to conventional practice, while providing good visual quality. In contrast, most contemporary lighting conservation programs reduce energy consumption by less than half. This says that there is plenty of room for improvement over present practice.

MARKING**

■ Contribution to Heating and Cooling Loads

In most non-industrial facilities, lighting is the largest source of internal heat gain, typically ranging from one watt to four watts per square foot. By comparison, the heat load from people in a typical office space is 0.3 to 1.0 watt per square foot. Even modern office equipment uses less energy than lighting, overall. For example, a desktop computer consumes only about as much energy as one or two typical fluorescent light fixtures.

Considered as heat sources, lighting fixtures are electric resistance heaters. Most of the energy consumed by lighting equipment remains inside the building. This energy input is beneficial if heating is required in the space. On the other hand, this heat adds to the cooling load if the space requires cooling. If electric cooling equipment is used, about one third watt of cooling energy is required for each watt of lighting energy.

Fixtures installed in a return air plenum ceiling typically deliver 30% to 50% of their heat into the return air stream. The amount of this heat that becomes a cooling load depends on the fraction of return air that is recirculated.

■ Daylighting

Lighting energy consumption can be reduced by using daylighting instead of artificial lighting. The energy saving potential varies widely. Many industrial facilities have a large potential for daylighting, while typical commercial buildings can displace only a small fraction of their lighting energy with daylighting. See [Subsection 8.3](#) and [Reference Note 46](#) for details.

The Cost of Lighting

Keep a sense of perspective when considering the cost of lighting and the cost of making changes. The major costs related to lighting, in approximate descending order, are:

- **human productivity.** The cost of labor may be hundreds of times higher than the cost of lighting for the worker. Hence, if a change in lighting causes even a small reduction in worker efficiency, any saving is lost. Properly executed lighting energy conservation does not degrade the quality of lighting, and may improve it. The key point is to invest the effort required to accomplish lighting conservation properly, and to avoid hasty, shotgun approaches.

- **energy** is by far the highest cost related to the lighting equipment itself, when tallied over the life of a facility. The most efficient lighting system is almost always the most economical overall.
- **lamps** typically cost an order of magnitude less than the energy they consume. The major classes of lamps — incandescent, fluorescent, and HID — all average about the same lamp cost per kilowatt-hour of service. However, there are large cost differences within each class.
- **lamp replacement labor** may cost more or less than the lamps themselves. Lamp life, lamp output (i.e., the number of lamps needed to illuminate the space), and accessibility of fixtures strongly influence the cost of lamp replacement. In the case of incandescent lighting, replacement labor usually costs much more than the lamps. Furthermore, incandescent lamps have short life, so the cost is repeated often. The labor cost for replacing fluorescent lamps is typically comparable to the cost of the lamps. The labor cost for replacing HID lamps is typically much less than the lamp cost, especially for lamps of larger size. However, the labor cost may be greatly inflated if the fixtures are difficult to reach. Make it as easy as possible to replace all types of lamps when they burn out. You can radically reduce the cost of lamp replacement by making fixtures accessible and by exploiting devices to aid lamp replacement, such as winches that allow fixtures installed in tall ceilings to be lowered to floor level.
- **fixtures** typically cost an order of magnitude less than the lamps inside them, when the lamps are totalled over the life of the facility. Lighting fixtures typically cost less than one percent of total construction cost. Fixture cost per lumen of light output does not differ much between lamp types, except for cheaper incandescent fixtures.

When you choose among different lighting options, include all these factors on your calculation pad or your computer spreadsheet. Compare lighting costs on a life-cycle basis.

How to Use Section 9

Ideal lighting provides the appropriate level of illumination at the activity with the minimum

input of energy, and with good visual quality. [Section 9](#) is organized to achieve ideal lighting as closely as current technology and your available budget will allow. The following “formula” breaks down the efficiency aspects of lighting into manageable parts:

Efficient Lighting = Efficient Lamps
+ Efficient Fixtures
+ Efficient Control
+ Efficient Light Path

The Subsections of [Section 9](#) parallel this “formula.” Each Subsection groups similar activities, including activities that are alternatives to each other. This grouping makes it easy for you to plan and execute your lighting improvements.

Most efficiency improvements involving lamps and their fixtures are done together. The methods of saving energy differ among the three major categories of lighting. Therefore [Subsections 9.1, 9.2, and 9.3](#) deal with lamp and fixture improvements for each of the three major types of light sources individually.

Efficient control of lighting is subdivided into manual control and automatic control, each requiring different equipment and techniques. The two areas are covered by [Subsections 9.4 and 9.5](#), respectively.

Establishing an efficient light path is essential to keep light from being lost on the way from the light source to the activity. The portion of the light path within the lamps and fixtures is covered implicitly by [Subsections 9.1 through 9.3](#). The light path from the fixture to the activity is covered explicitly in [Subsection 9.6](#).

The Measures in [Subsection 9.7](#) maintain the long-term efficiency of lighting.

Efficient lighting also exploits daylighting as a source. Daylighting involves activities that are fundamentally different from those involved in improving artificial lighting. For this reason, daylighting is covered separately in [Section 8](#).

The Measures in this Section are as specific as possible. However, the great diversity of lighting makes it impractical to define detailed improvements for each situation that may exist. To cover the range of possibilities most effectively, some Measures recommend specific actions that are related to clearly defined equipment or lighting situations, while other Measures are defined in a largely conceptual manner.

Use the Measures in this Section as components of an overall program of lighting efficiency. It is your job to knit the Measures together into an efficient lighting configuration for each application. You can achieve efficient and pleasing lighting in any environment. In retrofit applications, you will often find alternative ways to improve the lighting. You may have different Measures that you can apply to the same situation, or you may be able to combine Measures in different ways. Make your choices by analyzing the relative benefits and costs.

■ Deal with Each Activity Area and Each Fixture Individually

Each activity area has its own illumination requirements. Tailor the lighting to each activity. If a fixture is not providing illumination in the most efficient way possible, it does not belong.

In retrofit applications, start by inspecting each fixture individually. Ask yourself whether each fixture is located properly, whether it is oriented in the right direction, whether it is the right type for the job, whether it is using the appropriate type and number of lamps, and whether it is controlled properly. Lighting conservation tends to be time consuming and tedious, if you do it properly. There is no wholesale way to do it correctly.

■ Accommodate Future Changes in Activities and Space Layout

Try to make your lighting adaptable to future changes in the activities and space layout. Adaptable lighting equipment is still lacking, but the Measures in [Subsection 9.6](#) will give you useful ideas.

■ Stress Visual Quality

Remember that visual quality is the dominant cost factor in lighting because of its effect on human activity. Never compromise visual quality. If you stress it, you will waste less light.

Why We Don't Use Conventional Lighting Design Methods

Every profession involved in the design of buildings and plants has its own set of design procedures, which are formalized and promoted by the profession's leading organizations. In the case of lighting, the formal doctrine includes design calculations that are based on factors, like “room cavity ratio,” and idealized concepts, such as

"equivalent sphere illumination." This design doctrine is fairly new, compared to the design methods used by other branches of engineering. It is an honest attempt to provide guidance in dealing with a subject that is more complex and subtle than it initially appears to be.

Unfortunately, some of the assumptions of this doctrine have turned out to be dubious or irrelevant, while some important factors are overlooked. Overall, the official lighting design doctrine has grown in a direction that is fundamentally in conflict with energy efficiency. It wastes energy to an extent that ranges from moderate to extreme, depending on the application. The present doctrine provides fairly good lighting quality, but it does this by expending energy to make lighting uniform over areas that are typically much larger than the areas where the illuminated activities are occurring. Even so, it does not provide the best possible lighting quality. For example, it largely ignores veiling reflections, a significant cause of visual fatigue as well as a waste of lighting energy. The doctrine cannot become a guide to efficient lighting without changing its nature entirely, so it is not worth salvaging as a general approach to lighting design. To the extent that the doctrine is useful, it is primarily a guide for applications that require uniform large-area lighting.

In the real world of construction, all this is largely academic. Perhaps a majority of lighting designers do not use the official methods of lighting design. Many are not aware of them. You don't have to examine too many lighting plans before you recognize that the basic tool of contemporary lighting design is a rectangular grid, and that lighting layout is usually guided by non-lighting constraints, such as the spacing of ceiling tiles. There is a gap between theory and practice in all professions and trades, but in the case of lighting design, the gap is a chasm that has only a tenuous bridge across it.

For all these reasons, the *Energy Efficiency Manual* does not use the present methods of lighting design, nor does it refer to them. Instead, it bases

lighting selection, layout, and control on the principle of "task lighting" in its broadest conception. This principle is to design the lighting for each activity area as an individual entity, including the effects of lighting in adjacent areas, whether from artificial lighting or daylight.

This approach to lighting requires more care to design and to install than conventional lighting. Furthermore, it is hampered by the inability of presently available lighting fixtures to adapt easily to changes in the illuminated activities. Nonetheless, it is ultimately the path to best efficiency and best visual quality. We offer this approach to enable you to achieve the best available lighting efficiency. Also, we hope to reorient the lighting profession and lighting equipment manufacturers toward the full efficiency potential of lighting. Because this approach is still in its infancy, [Section 9](#) subdivides the different aspects of efficient lighting, as described previously. This allows you to exploit those aspects that are presently practical for your situation, while leaving the rest to future developments.

Before Getting Started ...

For a practical explanation of how lamp output, illumination, and brightness are expressed, see [Reference Note 50](#), Measuring Light Intensity.

Lighting quality is the most important aspect of lighting, so be familiar with the concepts in [Reference Note 51](#), Factors in Lighting Quality.

For a comprehensive comparison of the major types of light sources, see [Reference Note 52](#), Comparative Light Source Characteristics.

To help conform to standards of lighting efficiency, see [Reference Note 53](#), Lighting Efficiency Standards.

For details of the three major categories of light sources — incandescent, fluorescent, and HID — see [Reference Notes 54](#) through [56](#), respectively.

To understand the geometry of light distribution from fixtures, see [Reference Note 57](#), Light Distribution Patterns of Fixtures.

Lamps and Fixtures, Incandescent

The “energy crisis” of the 1970’s appeared to sound the death knell for incandescent lighting. It has long been recognized that incandescent lighting is much less efficient than fluorescent and HID lighting, and that it suffers from short service life. In recent years, further improvements in the efficiency and color characteristics of fluorescent and HID lighting have increased their advantage over incandescent lighting. All this makes it fair to say that eliminating incandescent lighting is a leading goal of energy conservation.

At the same time, recognize the advantages that have kept incandescent lighting popular. The color rendering of incandescent lamps is still the best available, although fluorescent and HID lamps have achieved radical color improvements in recent years. Incandescent lighting does not need ballasts, so it is free of the problems associated with them, including audible noise, electromagnetic interference, low power factor, and harmonic distortion of the power system. The small filaments of incandescent lamps allow tight focussing, which is important in some applications. Lamp and fixture costs are much lower than for other types. The lamps themselves are much less expensive, and they do not require the expensive auxiliary equipment of ballasts, capacitors, and ignitors that other light sources need.

The Measures of this Subsection improve the efficiency of incandescent lighting, in some cases by eliminating it. The Subsection starts with the Measures that are least expensive and most broadly applicable, and progresses to Measures that are more expensive or more narrowly applicable. Within this general sequence, similar Measures are grouped together.

Many of the Measures are defined broadly. The variety of possible lighting configurations is unlimited, so it is not practical for Measures to deal with each possible configuration. Combine the Measures in this Subsection and the following Subsections to create a lighting configuration that is optimum for each activity area.

INDEX OF MEASURES

- 9.1.1 Eliminate excessive lighting by reducing the total lamp wattage in each activity area.**
- 9.1.2 Substitute higher-efficiency lamps in existing fixtures.**
 - 9.1.2.1 Substitute screw-in fluorescent lamps for incandescent lamps.**
 - 9.1.2.2 Substitute tungsten halogen lamps for conventional incandescent lamps.**
- 9.1.3 Substitute lamps that minimize light trapping and/or improve light distribution.**
- 9.1.4 Modify existing fixtures to reduce light trapping and/or improve light distribution.**

RELATED MEASURES:

- Measures 9.6.2 ff, fixture layout and replacement in general
- Measure 9.6.3, combinations of fixtures that adapt to different lighting requirements

Before getting started, review [Reference Note 54](#), Incandescent Lighting. This explains how incandescent lighting works, the factors that affect efficiency and service life, and the ways that incandescent lamps are

named. See [Reference Note 52](#), Comparative Light Source Characteristics, for a comparison of incandescent lamps with other light sources.

MEASURE 9.1.1 Eliminate excessive lighting by reducing the total lamp wattage in each activity area.

The most common types of incandescent lamps all have the same type of socket, called a “medium” screw base. This allows a given incandescent fixture to accept lamps ranging from 10 watts to 1,000 watts in output. Similarly, most large incandescent lamps have “mogul” bases, and many sizes of smaller incandescent lamps have “miniature” bases. The fact that the common socket types accept many lamp sizes allows people to install incandescent lamps with excessive wattage.

You can save energy simply by substituting lamps that have the lowest wattage needed for the application. In facilities that use a lot of incandescent lighting, such as hotels and motels, this simple practice can yield large savings.

Of course, if the situation were really so simple, this opportunity for saving would not be so common. You have to expend the effort to determine the minimum acceptable wattage for each fixture. Then, you have to ensure that larger lamps are not substituted in the future. Incandescent lamps burn out often, so this is a continuing challenge.

Repeat with Later Improvements

Any time you make changes to incandescent fixtures, you have to repeat this Measure, even if the change is for the purpose of improving efficiency. For example, if you substitute screw-in fluorescent (Measure 9.1.2.1) or halogen lamps (Measure 9.1.2.2) in the existing fixtures, make sure that you use the lowest wattage of the new type that is satisfactory for the application.

First, Survey the Fixtures

Determine the appropriate wattage for each fixture individually. In a cafeteria, for example, the serving lines, cooking areas, cash registers, seating areas, etc., all have different illumination requirements.

Don’t expect the people who are replacing the lamps to select the proper sizes as they do the work. Even with exceptional personnel, this would waste time and create confusion. If you have to deal with many fixtures, make a planning survey first. The easiest way to do this is to mark the lamp wattages on a copy of the lighting plan from the building drawings.

Use a good light meter to measure existing lighting levels. With a little experience, you will get the knack of estimating the lighting levels that result from changing lamp wattages.

Appropriate lighting levels are suggested in Reference Note 51, Factors in Lighting Quality.

SUMMARY

Saves a significant amount of energy in each fixture where it applies. Costs little or nothing. Repeat this activity as you accomplish other Measures. Fixture labeling is critical to preserve the benefit.

Ease of Initiation	😊	😊	

Label Fixtures to Deter Backsliding

When a lamp burns out, it is easy to replace it with the wrong wattage or type. The most effective way to prevent this is to label the fixtures with the proper lamp type. Where a socket is to be left without a lamp, label it to say so. Measure 9.7.3 provides guidance for fixture labeling.

Wattage Choices

The common incandescent lamp types are available in a wide range of wattages. In response to the market created by energy conservation, the older sizes were supplemented with intermediate sizes. These “energy saving” sizes appear to be based on the assumption that lighting designers add a margin of 20 to 35 percent to their lighting capacities. For example, one major manufacturer offers 65-watt reflector lamps to replace the standard 75-watt size, and 120-watt lamps to replace the standard 150-watt size.

Understand that these new “energy saving” lamp sizes are no more efficient than other lamps of the same type and similar wattage. The energy saving simply results from lower wattage, along with lower light output. To get greater lumens-per-watt efficacy, you have to substitute more efficient types of lamps.

Account for Lumen Degradation

Ordinary incandescent lamps suffer a lumen loss of 10% to 30% toward the end of their service lives. Halogen lamps suffer a lumen loss that is typically less than 10%. If lumen loss is high, provide enough margin in lamp sizing to provide adequate illumination at the end of lamp life. See Reference Note 54, Incandescent Lighting, for details of the lumen loss of different types of incandescent lamps.

Efficiency, Service Life, and Wattage

[Reference Note 54](#) explains that incandescent lamps have an unavoidable conflict between efficiency and service life. All incandescent lamps have short lives, so the cost of lamp replacement labor may drive the compromise toward longer service life, at the expense of efficiency.

Common round (“A” style) bulbs larger than about 50 watts are mostly rated at 750 or 1,000 hours. Longer service lives are available in this wattage range, but at the expense of efficiency. Round bulbs of lower wattage have longer standard service lives, up to about 2,500 hours. Most reflector lamps are designed for a service life of 2,000 hours. These relationships are shown in Table 1 of [Reference Note 54](#), Incandescent Lighting.

Substitute Smaller Numbers of Higher-Wattage Lamps

The efficacy of incandescent lamps increases somewhat with wattage, for a given type and service life. For example, a 75-watt round bulb has an efficacy of 16 lumens per watt, whereas a 150-watt bulb has an efficacy of 19 lumens per watt (both having a life of 750 hours). If you are willing to accept shorter bulb life, you can get even greater efficiencies. For example, a conventional 100-watt bulb is approximately 80 percent more efficient than a conventional 25-watt bulb, while a 200-watt bulb is about twice as efficient as the 25-watt bulb.

You may be able to exploit this fact by using a smaller number of higher-wattage lamps to replace lower-wattage lamps. The opportunities are limited, because there are not many cases where you can abandon a fraction of the sockets or fixtures without affecting lighting quality or creating a shabby appearance.

If you use this technique, be sure to disconnect and label the unused sockets or fixtures.

Lamps Operated by Dimmers

Incandescent lamps are much more efficient when operated at full power than when operated at reduced power. For example, a 50-watt bulb operated at full brightness uses much less energy than a 150-watt bulb that is dimmed to produce the same lumen output.

Installing lamps with unnecessarily high wattage is commonplace in fixtures that have dimmers. Therefore, check all the lamps on dimmer circuits to ensure that the lamps have the lowest wattages that are appropriate for the application.

This problem occurs commonly in facilities such as restaurants and lounges. Low lighting levels are desired during service hours, but high lighting levels are needed for preparation and cleaning. The only efficient solution in this situation is to install separate fixtures for each function. See [Measure 9.6.3](#).

Light Distribution Patterns of Lamps

Incandescent lamps are available with a wide variety of light distribution patterns. Select the proper types for each application. See [Measure 9.1.3](#).

Avoid Tinted or Color-Corrected Lamps

Even mild tints absorb a large fraction of a lamp’s light output. For example, about one third of the light output of a “daylight” incandescent bulb is absorbed in a blue tint that is used to modify the color. Do not use such lamps unless the application demands them.

ECONOMICS

SAVINGS POTENTIAL: 20 to 40 percent of the energy used by incandescent fixtures, typically.

COST: Minimal, if the changes are made as lamps burn out.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

SURVEY: It is tedious to figure out the optimum wattage for each fixture and to label it accordingly. But, if you skip this preparation, you will miss energy savings, and the savings that you do achieve will disappear within a few lamp replacements.

EXPLAIN IT: Explain the importance of lamp selection to the staff. Make a list of the lamp types and wattages to be used in each location or type of fixture. Post the list in the lamp storage room.

REPEAT AS NECESSARY: Repeat this Measure any time light fixtures or lighting requirements change. Make this a long-term repetitive item in your maintenance calendar.

MEASURE 9.1.2 Substitute higher-efficiency lamps in existing fixtures.

The low efficacy of incandescent lamps has created a market for more efficient lamps that can be used in the same fixtures. The subsidiary Measures recommend two different types of higher-efficiency lamps:

- *screw-in fluorescent lamps* (Measure 9.1.2.1) provide major improvements in efficacy and service life
- *tungsten halogen lamps* (Measure 9.1.2.2) provide only modest improvements in efficacy and service life, but they are less expensive. They may be the only option in some applications.

Other Replacements for Incandescent Lamps

Two other types of direct replacements for conventional incandescent lamps are worth mentioning because they have been promoted under the banner of energy conservation. Both of these are probably dead ends in terms of energy conservation:

- *self-ballasted mercury vapor lamps* use an internal tungsten filament to serve as a ballast. This type of lamp is no more efficient than incandescent lamps

of comparable wattage, and it suffers serious lumen degradation. Its advantage is longer life, typically about 12,000 hours. It reduces labor cost for lamp replacement, but not energy cost.

- *krypton-filled conventional incandescent lamps* may improve energy efficacy by 5 to 15 percent, depending on wattage. The heavy krypton gas retards filament evaporation, allowing the filament to be operated at a somewhat higher temperature. The cost premium is high in relation to the small efficiency improvement. For applications where small lamps are needed, screw-in fluorescent lamps are a much better choice, from the standpoints of efficacy and service life. For applications where large lamps are needed, halogen or HID lamps are a much better choice.

(Krypton is also used in the small filament capsule of halogen lamps, where it serves an important purpose. It is more economical in halogen lamps because of the small amount used and the greater relative efficiency improvement.)

MEASURE 9.1.2.1 Substitute screw-in fluorescent lamps for incandescent lamps.

RATINGS

New Facilities	Retrofit	O&M
□	B	□

Screw-in fluorescent “lamps” are actually complete fixtures packaged on a standard lamp base. They include a fluorescent tube, a starter, and a ballast. The fluorescent tube itself may be permanently attached to the ballast or it may be separately replaceable. A large variety of configurations are available, including units with integral reflectors and various types of globes or diffusers. See Figure 1.

The best screw-in fluorescent lamps are somewhat less efficient than the best conventional fluorescent fixtures, but they are still three to four times more efficient than ordinary incandescent bulbs of similar light output. In applications such as the example shown in Figure 2, they can significantly reduce electricity cost. They last about 10 times longer, but they cost about 20 times more.

No special steps are needed to replace incandescent lamps with screw-in fluorescent units in most situations.

SUMMARY
 Radically improves lighting efficiency. Easy, quick, and fairly cheap, but not foolproof. Be careful to avoid junk brands.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

In some cases, a minor modification of the fixture is needed. However, there are many situations where screw-in fluorescent replacements cannot be used.

Some screw-in fluorescent lamps have magnetic ballasts and some have electronic ballasts. In units made

Osram Sylvania Inc.

Fig. 1 Three basic types You can select a bare lamp, or a lamp with a reflector, or a lamp with a diffuser.

by reputable manufacturers, electronic ballasts are more efficient. They add some problems, and they eliminate others. See [Reference Note 55](#), Fluorescent Lighting, for details about fluorescent lamps and ballasts.

The newest types of screw-in fluorescent fixtures use tubes of small diameter and high brightness. These were originally called “PL” fixtures (after Philips Lighting, who introduced them), and they are now called “compact fluorescent” fixtures. Older types of screw-in fluorescent fixtures, still being offered, use a conventional circular tube of large diameter that is mounted on a screw-in ballast.

Limitations

Screw-in compact fluorescent lamps were designed as replacements for incandescent lamps. However, they cannot be substituted in these common situations:

- **fixtures too small for the lamps.** The need for a ballast, which is mounted at the screw base, makes the units too fat for many existing fixtures. Also, screw-in units are too long for some fixtures. Some table lamps that use harps to hold the shades may be adapted to accommodate the lamps by using harp extenders.
- **need for high light output.** The largest compact fluorescent lamps cannot match the light output of the largest incandescent lamps.
- **need for dimming.** Compact fluorescent lamps should not be used with conventional lighting dimmers. Doing so shortens their life, reduces their efficiency, and may create a fire in the fixture.

- **frequent switching.** The filaments and starters of fluorescent lamps wear out with frequent on/off switching.
- **need for instant light.** Most compact fluorescent fixtures have preheat starters, which take a second or two to work. After starting, the lamps require a few seconds to reach full brightness. Lamps that use mercury amalgams (explained below) require almost a minute to reach full brightness.

There are some other, less common situations where you should not use compact fluorescent lamps. These include extremely low temperatures, a need for very good color rendering, sensitivity to acoustical noise, and sensitivity to electrical interference. See “How to Select Compact Fluorescent Lamps,” below, for more about these factors.

Energy Saving Potential

The following table compares the energy consumption of ordinary incandescent bulbs to the energy consumption of some typical compact fluorescent lamps that might be used to replace them. The figures indicate a typical saving of about 70%. Few other energy conservation measures offer this much potential for savings.

Incandescent		Fluorescent			Wattage
Watts	Lumens	Watts	Lumens	Type	Reduction (%)
25	230	9	400	bare lamp	64
40	460	11	600	bare lamp	72
60	890	15	900	bare lamp	75
60	890	17	950	with diffuser	72
75	1,200	20	1,200	bare lamp	73
75	1,200	23	1,550	bare lamp	69

However, this simple comparison does not tell the whole story. You need to make an energy savings analysis for each potential lamp substitution. For example, much incandescent lighting in commercial facilities is done with downlights and other shrouded fixtures. The lateral light distribution pattern of bare compact fluorescent lamps is inappropriate in such fixtures, so you may have to use fluorescent reflector lamps that are less efficient.

How to Select Compact Fluorescent Lamps

Replacing incandescent lamps with compact fluorescent lamps is a simple operation, but you need to be careful in selecting the substitute lamps. The following are the important criteria.

■ Lumen Output

Start by finding out whether the illumination levels provided by the present lighting match the requirements of the activities. Calculate any increases or reductions in the lumen output that are appropriate. Then, search the catalogs to find lamps that provide the output you need.

Screw-in fluorescent lamps are available in a range of sizes to replace the most common incandescent bulb sizes. See Figure 3. The output of the fluorescent units was somewhat limited at first, but output continues to be increased.

Experience indicates that manufacturers exaggerate the effective light output of compact fluorescent fixtures. For example, if a compact fluorescent lamp promises “as much light as a 75-watt bulb,” a person probably will not be able to see as well as with the original 75-watt bulb. This may be due to differences in color rendering, or to exaggerating the lumen output.

On the other hand, where fixtures are largely decorative, as with downlights in lobbies, compact fluorescent fixtures tend to produce an illusion of greater brightness than their lumen output suggests.

Light output deteriorates with age. Provide enough reserve capacity to provide adequate lighting at the end of the replacement cycle. The best compact fluorescent lamps lose about 20% of their light output at the end of normal service life.

■ Wattage Input and Efficacy

After you find the lamps that can provide the desired lumen levels, select among them for the lowest input wattage. In other words, select the highest efficacy.

Be skeptical of the efficacy figures published for compact fluorescent fixtures. Experience indicates that the actual efficacies of cheap compact fluorescent fixtures may be less than half that of better units. Reliable comparisons of the products of different

manufacturers are not available, so it is reckless to acquire units from any but the best manufacturers. (We said “best,” not “most popular.” One of the largest vendors of compact fluorescent fixtures produces cheap junk.)

These are efficacies for compact fluorescent fixtures derived from the published figures of one major manufacturer:

Watts	Lumens/Watt	Type
9	44	bare lamp
11	54	“
15	60	“
20	60	“
23	67	“
17	55	diffuser lamp
18	61	“
18	44	reflector lamp

Note that *these efficacy figures include the effects of the ballast, whereas this is not true of ratings for conventional fluorescent lamps.*

■ Reliability and Service Life

Some units presently on the market have poor reliability. Screw-in fluorescent lamps can be produced by marginal manufacturers, and units of poor quality can be made substantially cheaper than units of good quality. The market has not shaken out the poor

WESINC

Fig. 2 A good place to retrofit screw-in fluorescent lamps The ceiling of this lobby is a forest of downlights. Screw-in fluorescent lamps provide adequate illumination. Bare lamps provide the best efficiency in the existing reflector fixtures. Their appearance is satisfactory at this distance. Their longer service life greatly reduces the amount of labor required for maintenance.

products. On the contrary, because compact fluorescent lamps are perceived as expensive (compared to incandescent lamps), the lower cost of the poor quality units has allowed them to flood the market. The rated life of most compact fluorescent lamps is 10,000 hours. However, the rating does not guarantee quality. Some units of low quality last only a few hours or a few weeks.

Purchase compact fluorescent lamps only from manufacturers of good reputation. If you are going to install large numbers of lamps, make some calls to experienced users of compact fluorescent lamps to find which units are best.

If the unit allows the fluorescent tube to be replaced, the life of the ballast is rated separately. A life of 50,000 hours is commonly claimed for ballasts. Take such numbers with a grain of salt. Not enough time has gone by to allow such figures to be verified by field experience.

The life of a magnetic ballast declines with higher operating temperature. The operating temperature is increased if the unit is installed with the ballast above the lamp, and if the fixture is poorly ventilated. The life of an electronic ballast declines as the number of switching cycles increases.

■ Lamp Dimensions

You may have trouble finding models of compact fluorescent fixtures that fit many incandescent fixtures. Figures 1 and 3 show the problem. Compact fluorescent fixtures are all much wider at the base than incandescent lamps. Most are substantially longer, although shorter compact fluorescent tubes are entering the market. Manufacturers are achieving shorter lengths by bending the tubes into hairpin and corkscrew shapes.

■ Light Distribution Pattern

The light distribution pattern of the lamps affects the overall efficiency of lighting. For example, a bare compact fluorescent lamp radiates most of its energy in a direction perpendicular to the tube. If such a lamp is installed in a recessed downlight with an absorptive interior, most of the light is absorbed inside the fixture.

Compact fluorescent lamps are available with integral reflectors or diffusers to improve light distribution, as shown in Figures 1 and 4. For example, they are available with parabolic reflectors to minimize light loss when installed in downlights. The combination of greater light source efficiency and lower light losses can increase the overall efficiency of the fixture by a factor of 10 to 30 (that's not a misprint) when these lamps are installed in highly absorptive fixtures.

Osram Sylvania Inc.

Fig. 3 A range of light outputs The maximum size of screw-in units with bare lamps continues to grow. Units are available that substitute for the most common incandescent lamp sizes. However, beware of exaggerated claims about “equivalent” light output.

■ Ability to Replace Fluorescent Tube Separately

The ballasts in screw-in fluorescent lamps may last several times longer than the tubes. Some units allow the lamp to be replaced separately from the ballast. For example, see Figure 4. Units that allow the tube to be replaced separately may have better long-term economics. This is illustrated by the economic example given below.

■ Color Characteristics

The color rendering of fluorescent lamps is different from the color rendering of incandescent lamps, and this may be important in some applications. Fluorescent lamps emit light strongly in a few narrow bands of color that are created by the mercury vapor in the lamps. These color spikes are superimposed on a broader light spectrum produced by the phosphors.

The perceived white color of the fluorescent lamp is not the result of a continuous light distribution spectrum. Instead, it is the result of selecting the phosphors to produce the illusion of white light. This causes the lamp to distort the colors of illuminated objects. Human vision corrects for this, so people do not notice it, except in certain color-critical applications.

For more about lamp color in general, see “Color Rendering Index” and “Lamp Color” in [Reference Note 52](#), Comparative Light Source Characteristics. For more details of fluorescent lamp color, see [Reference Note 55](#), Fluorescent Lighting.

■ Starting and Operating Temperatures

All fluorescent lamps, including compact units, operate at peak efficiency only if the glass tube is near a particular temperature. The tube temperature is determined by the environment of the lamp and by the lamp’s heat output. The optimum temperature is about 105°F (40°C). The lamp usually starts at a lower temperature than this, and then warms up to a temperature that may be well below or well above the optimum temperature. If the space is kept at normal indoor temperature and the fixture is well ventilated, the lamp will stabilize near its optimum temperature. If the lamp is used outdoors, or if it is installed in a poorly vented ceiling fixture, its efficiency suffers seriously.

Fluorescent lamps require a minimum ambient temperature to start reliably. Compact fluorescent lamps have higher current densities, shorter arcs, preheat starting, and other features that allow them to operate at lower temperatures than conventional fluorescent lamps. Different models of compact fluorescent fixtures claim starting temperatures from -20°F to 32°F (-29°C to 0°C).

The product literature does not make it clear how much efficacy suffers at lower operating temperatures. Some manufacturers use an amalgam of mercury with another metal to stabilize the mercury vapor pressure inside the lamp. This keeps the lamp efficacy high over a wider range of temperature. A disadvantage of this

method is that the lamp may require as much as a minute to reach full brightness as the mercury separates from the amalgam.

Screw-in fluorescent fixtures that use conventional circular lamps should be used only at normal indoor temperatures.

■ Acoustical Noise

Units of good quality emit little noise. Cheaper units may be noticeably noisy. Refer to [Measure 9.2.4](#) for more about this.

■ Power Factor

Low power factor is a potential problem with magnetic ballasts, but generally not with electronic ballasts. [Measure 9.2.4](#) gives the details.

■ Radiated Electromagnetic Noise

This is a potential problem with units that have electronic ballasts. For example, problems have been noted with remote control units and security scanners. Refer to [Measure 9.2.4](#) for details.

Compact lamps are smaller and they draw less current than conventional fluorescent fixtures, so they have the potential of emitting less electromagnetic radiation. This does not mean that they actually make less noise. Cheaper units that lack adequate input filtering may cause the power wiring to act as an antenna, causing trouble at some distance from the lamps.

■ Harmonic Distortion

Harmonic distortion in compact fluorescent fixtures worries electric utilities, who have been using incentives and penalties to promote lower harmonic distortion. Units are commonly rated in terms of “total harmonic distortion” (THD). At present, a THD of 20% is considered acceptable. Some cheaper units may have a

WESINC

Fig. 4 Reflector fixture with separately replaceable lamp
The ballast may last several times longer than the lamp. A unit like this should be made of glass, rather than plastic, because the ultraviolet radiation from a fluorescent lamp will darken plastic.

THD much worse than this. See [Measure 9.2.4](#) for details.

Label Fixtures to Deter Backsliding

When a lamp burns out, it is easy to replace it with the wrong type. The most effective way to prevent this is to label the original fixtures with the lamp types to be used. [Measure 9.7.3](#) explains how to label fixtures to minimize these failure modes.

An Economic Example

Compact fluorescent fixtures are good devices in their own right, but they are also a fad, which causes people to use them uncritically. The economic benefit they provide may not be as great as widely assumed, so it is worthwhile to examine a typical case.

Assume that 23-watt compact fluorescent lamps are used to replace 75-watt incandescent lamps, resulting in a saving of 52 watts per lamp. Assuming a 10,000-hour life and an electricity cost of 8 cents per kilowatt-hour, each lamp replacement saves \$42 in electricity cost during its life.

During the unit's lifetime, it saves replacement of ten incandescent lamps costing \$0.50 apiece, for an additional saving of \$5.00. The compact fluorescent lamp costs \$18. Thus, the facility saves \$42 for a net investment of \$13.

This is a good ratio, but variations in the assumed factors could make the economics much worse or much better. There is great variation in electricity rates. The example did not include demand charges, which are a major factor in some locations, but not in others. The example did not include labor cost for lamp replacement, which is much lower for compact fluorescent fixtures.

The rate of return, as opposed to total savings, depends on the number of hours that the lamps operate each year.

If the fluorescent tube can be replaced separately, the typical replacement tube cost is about \$5. Therefore, lamps with replaceable tubes may have considerably better long-term economics.

It is worth stressing that cheap junk units, which infest the market, will not last long enough to pay off. Buy for quality, not for price.

ECONOMICS

SAVINGS POTENTIAL: 50 to 75 percent of lighting energy, depending on how closely the needed lumen levels can be matched by the fluorescent lamps.

COST: Good screw-in fluorescent lamp assemblies cost from \$15 to \$30, depending on wattage, features, and quantity purchased. Replacement tubes alone cost about \$5, for the more common types. The cost is reduced by the cost of all the incandescent lamps that would have burned out during the life of the fluorescent lamp. This is typically \$5 to \$10.

PAYBACK PERIOD: Less than one year, to many years. Refer to the economic example above.

TRAPS & TRICKS

SELECTING THE LAMPS: The continued popularity of junk units shows that buyers are not selecting wisely. Even the best equipment is too new to have a reliable performance record in real applications. Take care to select the proper lamp wattage and configuration for each application. Check with previous users about service life and problems.

MAINTAIN THE BENEFIT: Don't forget to label the fixtures.

MEASURE 9.1.2.2 Substitute tungsten halogen lamps for conventional incandescent lamps.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Tungsten halogen lamps are a variation of ordinary incandescent lamps that have a modest efficiency advantage. [Reference Note 54](#) explains how they work and shows a range of available types.

Remember that halogen lamps must compromise between improved efficacy and extended service life. Look at the performance figures to find out whether you are getting an advantage in efficiency, or an advantage in service life. You won't get a big improvement in both.

Halogen lamps are much less efficient than fluorescent or HID lamps. Select them only for applications where their advantages in color rendering, tighter focussing, and lower cost are more important than efficiency.

There is only a limited selection of halogen lamps designed to replace incandescent lamps directly, i.e., that have medium screw bases. At present, halogen lamps that replace ordinary bulbs are available in two configurations, bulbs and PAR-type reflectors. Wattages are limited to small and medium sizes.

Applications and Limitations

You can substitute halogen lamps for conventional incandescent lamps in most applications. Halogen lamps designed to fit conventional incandescent lamp screw sockets do not suffer the same restrictions on mounting position that apply to some other types of halogen lamps. Also, they do not emit amounts of ultraviolet light that require protective measures.

As a rule, do not use tungsten halogen lamps with dimmers. Some halogen lamps have diodes, and these lamps do not work with conventional dimmers. Most halogen lamps can be dimmed, but this is undesirable. Halogen lamps must operate at or near full power for the halogen cycle to work. Manufacturers state that operating the lamps at full power for a fraction of the time is sufficient to keep the glass clean, but forget about trying to do this on a scheduled basis.

Tungsten halogen lamps are much more dangerous than conventional incandescent lamps if they shatter. The inner quartz capsule operates at high temperature. It has enough mass to store considerable heat, unlike the naked filament of a conventional bulb. The fill gas inside the capsule operates at positive pressure. If the lamp shatters, the fragments may cause injury or fire. Halogen lamps that replace conventional incandescent lamps have heavy outer glass shells to contain failures of the filament capsule. However, keep the danger in mind, especially near combustible materials. Manufacturers caution against using halogen lamps in

SUMMARY

Offers either improved efficiency or extended service life, or a compromise between the two. Fairly foolproof. Unsatisfactory for some applications. The economic benefit is small, and payback is marginal.

wet locations because water droplets may shatter the hot outer envelope.

More Efficient Alternatives

Screw-in fluorescent lamps ([Measure 9.1.2.1](#)) are available in the same lumen output range as the halogen lamps that are designed to replace incandescent round bulbs. However, screw-in fluorescent reflector lamps cannot match the lumen outputs of larger halogen reflector lamps.

Compact HID lamps in reflector fixtures can substitute for larger incandescent lamps, but these require expensive fixture replacement. Refer to [Measure 9.1.5](#) for fluorescent and HID fixture retrofits.

How to Select Tungsten Halogen Lamps

Consider these factors in selecting halogen lamps to replace conventional incandescent lamps.

■ **Lumen Output**

Start by finding out whether the illumination levels provided by the present lighting match the requirements of the activities. Calculate any increases or reductions in the lumen output, and then scan the catalogs to find halogen lamps that provide this output.

Halogen lamps suffer less light loss with age than conventional incandescent lamps. Typically, this accounts for about 15% to 20% more light output at the time of lamp replacement. In marginal cases, this may allow you to reduce the initial lumens and wattage.

■ **Lamp Dimensions**

Check that the halogen lamp will fit the existing fixture. This is most likely to be a problem when replacing miniature styles of incandescent reflector lamps.

■ Light Distribution Pattern

Match the light distribution pattern of reflector lamps to the application. Check the catalog ratings for beam spread and for the candlepower at the center of the beam.

Halogen lamps that replace round bulbs distribute somewhat more of their light perpendicular to the lamp axis.

■ Wattage Input, Efficacy, and Service Life

[Reference Note 54](#) explains that there is an inherent trade-off between efficacy and service life in halogen lamps. By the same token, there is a compromise between energy cost and lamp replacement labor cost. Compare the lumens-per-watt efficacy of the candidate lamps with the efficacy of the lamps you are presently using, to ensure that the improvement is large enough to be cost effective.

At present, halogen lamps designed to replace conventional round bulbs put most of their advantage into service life, rather than efficacy. These lamps have a nominal life of 3,500 hours, which is three to four times longer than the lamps they replace. They offer little or no efficiency improvement.

Halogen reflector lamps offer a broader range of choice between efficacy and service life. Some units put all their advantage into service life, which can be as high as 6,000 hours, three times longer than with conventional lamps. These lamps offer no efficiency improvement.

A newer type of halogen reflector lamp, introduced commercially in 1990, uses special coatings to reflect infrared heat emission back to the filament, reducing the amount of electricity required to heat the filament. This type of lamp offers efficacy improvements up to 80%. Some older types of halogen reflector lamps offer efficacy improvements as high as 40%, while maintaining a service life of 2,000 hours.

■ Color Temperature

Where color is a factor, select the appropriate “color temperature” rating. For an explanation of this rating,

see [Reference Note 52](#), Comparative Light Source Characteristics.

Halogen lamps are often used because they offer light that is “whiter” and “brighter,” in the sense that its spectrum is closer to sunlight (has higher color temperature) than conventional incandescent lamps. This improvement results from higher filament temperature, which also provides higher efficacy. Be aware that halogen lamps optimized for long service life operate at lower filament temperature, and therefore they do not provide the “brighter,” bluer light.

Label Fixtures to Deter Backsliding

When a lamp burns out, it is easy to replace it with the wrong type. The most effective way to prevent this is to label the original fixtures with the lamp types to be used. [Measure 9.7.3](#) explains how to label fixtures.

ECONOMICS

SAVINGS POTENTIAL: *Halogen lamps that are optimized for efficiency (rather than extended life) save from 30 to 40 percent of the energy of the conventional incandescent lamps they replace.*

COST: *Halogen lamps typically cost several dollars more than their conventional counterparts. The higher cost is partially compensated by longer life.*

PAYBACK PERIOD: *One year, with typical operating schedules. However, this is misleading, because halogen lamps may burn out soon after paying off. The ratio of savings to investment may range from slightly more than 1 (not worth the effort) to 3 (a fairly good investment).*

TRAPS & TRICKS

SELECTING THE LAMPS: *Check the latest offerings of the reputable lamp manufacturers. The technology is still evolving. Decide whether you want higher efficiency or longer life.*

MAINTAIN THE BENEFIT: *Don't forget to label the fixtures.*

MEASURE 9.1.3 Substitute lamps that minimize light trapping and/or improve light distribution.

Many incandescent fixtures absorb a substantial fraction of the lamps' light output. These appear to be designed with a blatant disregard for the amount of energy they waste. You can reduce this energy waste, sometimes substantially, by exploiting the fact that incandescent lamps are available with many light distribution patterns. In addition to reducing light losses within the fixtures, you may also direct a larger fraction of the light in a useful direction.

Conversely, the variety of light distribution patterns makes it easy to install the wrong types of lamps in fixtures. Incandescent lamps burn out often, so it is a continuing challenge to keep the most efficient lamps in fixtures.

An Extreme Example: Downlights

An extreme example, but a common one, is recessed downlights with absorptive interior surfaces. The amount of light absorbed by this type of fixture varies enormously depending on the light distribution pattern of the lamp that is installed. For different types of lamps, these are typical percentages of the lamp's light output that manages to emerge from the fixture:

- 2%, with a bottom silvered bulb
- 5%, with a clear vertical-filament bulb
- 10%, with an ordinary frosted bulb
- 40%, with an R-series reflector lamp
- 60%, with an ellipsoidal reflector lamp
- 85%, with a screw-in fluorescent lamp having an integral reflector that extends to the rim of the fixture
- 70%, with a screw-in fluorescent diffuser lamp having an extender that allows surface mounting. (This lamp, unlike the others, greatly broadens the light distribution.)

These percentages show that you may be able to improve the efficiency of the fixture by a factor of 5 to 40 just by changing the type of lamp. This range of savings may seem too good to be true, but it is real. With many other types of existing fixtures, the potential savings are less dramatic, but well worth pursuing.

Better Ways of Improving Light Distribution

This Measure does not require fixture modifications, so it is relatively inexpensive in the short term. However, it may not be your best choice in the long term. The lamps are still incandescent, and hence inefficient. Furthermore, you still have to keep replacing them at short intervals. You can often achieve better long-term savings by replacing the fixtures entirely. So, review [Measure 9.1.5](#) before you get started.

SUMMARY

Sometimes provides major savings in lamp wattage. Lamp selection and fixture labeling are the important steps.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%

Ease of Initiation	😊	😊	😊

Even if you cannot afford major fixture changes at present, consider whether you can improve the existing fixtures inexpensively. See [Measures 9.1.4 ff](#) for ideas.

Your Lamp Choices

Incandescent lamps are available with a seemingly unlimited variety of characteristics. Consider these lamp choices for improving light distribution:

- **round bulbs with more efficient filament or lamp configurations.** Not all round bulbs ("A" shape) have the same distribution pattern. Select the right type for each application. A frosted round bulb emits light fairly uniformly in all directions, except toward the base. In clear incandescent bulbs, the filament configuration affects the light distribution pattern. The filament configuration also affects lumen degradation, as described in [Reference Note 54](#).

For example, a straight filament emits most of its light perpendicular to its axis. This makes it waste a lot of energy if the lamp is installed inside a downlight with an absorbing surface, or inside a shade. A circular filament is better in this case. (Ironically, straight-filament lamps have been favored for use in downlights, because this type of lamp darkens less when the base is upward.)

Screw-in fluorescent lamps behave in a similar way. They have little light emission along the axis of the tube(s). Install these with reflectors if you want the light to shine away from the base. Install them with diffusers if you want a broader distribution pattern.

- **R-series reflector lamps.** These have broad (floodlamp) light distribution. They are relatively fragile. Use them in fixtures that protect the lamps well.
- **PAR (parabolic reflector) lamps.** These are available in a variety of specified beam widths,

ranging from “spot” to “flood” patterns. They focus more sharply, with more abrupt cutoff at the edge of the beam. They are relatively rugged, so they are often used without an enclosure. Figure 1 shows a selection of rugged reflector lamps.

- **ellipsoidal reflector (ER) lamps.** These were developed specifically to overcome the trapping of light inside deeply recessed downlights. Figure 2 shows how they work. As the name implies, the glass bulb has an ellipsoidal shape. The inside of the bulb has a reflective coating, except for a flat end that allows the light to escape. The filament is at one focus of the ellipsoid. The other focal point is in front of the lamp, outside the fixture. From this point, the light can spread without being trapped.

(An ellipsoid is a three-dimensional shape created by rotating an ellipse around its long axis. An ellipse, or an ellipsoid, has two focal points. Light emitted from one focal point reflects from the surface of an ellipsoid in such a way that it focuses on the other focal point.)

- **screw-in fluorescent reflector lamps.** Some are designed specifically to aim light out of recessed fixtures. The reflector typically covers all or most of the absorptive inner surface of the fixtures in which they are used.
- **screw-in fluorescent extension lamps.** Another type of retrofit lamp intended for deep fixtures is mounted on an extension, so that the lamp is actually outside the original fixture. The extension lamp may have its own diffuser, creating the appearance of a surface mounted fixture. The extension fixture may have a much broader distribution pattern than the recessed fixture. Recessed fixtures typically are installed close together, and in large numbers, because of their

Osram Sylvania Inc.

Fig. 1 A selection of reflector lamps These may reduce light trapping greatly. However, the light still needs to go in the proper direction, and these lamps are still incandescent.

narrow light distribution patterns. Using screw-in extension fixtures may allow you to disconnect some of the original fixtures.

How to Select Replacement Lamps

Consider the following factors when you select retrofit lamps to improve light distribution.

■ Lumen Output and Wattage

Start by finding out whether the illumination levels provided by the present lighting match the requirements of the activities. Using a light meter, experiment by changing lamps to find the lowest wattage with any type of lamp that provides the desired illumination levels. If the fixtures are especially wasteful with the present types of lamps, you may be able to radically improve their light output.

■ Efficacy and Service Life

There is a big spread in efficacy and service life between the different types of lamps that can fit an incandescent fixture. Recognize that you have to compromise between efficacy and service life. See [Reference Note 54](#), Incandescent Lighting, for typical efficacy and service life ratings for incandescent lamps.

The lighting industry has effectively standardized on a service life of 750 or 1,000 hours for common bulbs of medium and large wattage, and a life of 2,000 hours for reflector lamps. See [Measure 9.1.2.2](#) for the service lives of tungsten halogen lamps. Manufacturers offer lamps with longer lives to reduce lamp replacement

Philips Lighting

Fig. 2 Ellipsoidal reflector lamp This is a special type of reflector lamp that focuses through a point well in front of the lamp. These are intended specifically to reduce light loss in deep fixtures.

labor, at the expense of efficacy. Manufacturers also offer lamps with shorter lives to achieve brighter color.

Screw-fluorescent lamps have radically different characteristics. Their efficacy is much higher, ranging from 40 to 60 lumens per watt, for good units. In comparison, incandescent lamps of similar light output have efficacies ranging from 10 to 20 lumens per watt. There is no conflict between efficacy and service life in screw-in fluorescent lamps. In fact, longer service life tends to go with higher efficacy, for reasons that are practical rather than theoretical. Most screw-in fluorescent lamps have a rated life around 10,000 hours, which is another major advantage they offer. The great efficacy and service life advantages of screw-in fluorescent lamps merit your attention. See [Measure 9.1.2.1](#) for more about them.

You may not be able to gain a reduction of energy input that is proportional to the greater efficiency of the substitute lamp. This is because of limitations in available wattages. For example, you might replace a 40-watt frosted bulb in a downlight with either a 17-watt R-20 incandescent reflector bulb or with an 18-watt screw-in fluorescent reflector fixture. These are the smallest sizes of each type. The fluorescent lamp produces more light than the incandescent reflector, but it cannot save more energy in this situation.

■ Light Distribution Pattern

Select the light distribution pattern of the lamp to serve two purposes. First, the light has to get out of the fixture with a minimum of loss. Second, the light has to go where it is needed within the space.

To satisfy the first requirement, match the light distribution pattern of the lamp to the characteristics of the fixture. For example, in a deeply recessed downlight, use an ellipsoidal reflector (ER) lamp to avoid light loss. On the other hand, if a downlight is relatively shallow, so that the rim of an R-lamp can rest at the rim of the downlight, the R-lamp provides a broader light distribution pattern, without light loss. To get an even broader distribution pattern, install extension lamps.

■ Cost

Try to avoid specialty types of incandescent lamps, such as bottom-silvered bulbs, tubular bulbs, and others. All types of specialty incandescent lamps are much more expensive than ordinary bulbs (“A” or “P” shapes). They do not last long enough to pay for themselves, unless they are replacing a type of lamp that is even more expensive.

Incandescent reflector lamps can provide a significant cost saving only if they provide a large wattage saving, or if electricity costs are high. You need to make some calculations to find the replacement that provides the best economics. The longer life of reflector lamps partially compensates for the higher cost. For example, long-life halogen reflector lamps merit special attention in cases where their improved light distribution allows wattage to be reduced significantly.

■ Color Characteristics

For a general explanation of lamp color, refer to “Color Rendering Index” and “Lamp Color” in [Reference Note 52](#), Comparative Light Source Characteristics. For specifics about the color characteristics of incandescent lamps, see [Reference Note 54](#), Incandescent Lighting.

■ Lamp Appearance

The appearance of the lamp itself may be a factor in the decor. For example, compact fluorescent lamps are not considered as beautiful as some incandescent lamps. Some designers make a fetish of keeping lamps completely out of sight, which invites extreme energy waste. Be prepared to negotiate with the decorator.

■ Additional Criteria for Compact Fluorescent Lamps

Refer to [Measure 9.1.2.1](#) for additional selection considerations that apply specifically to screw-in fluorescent lamps.

Label the Fixtures to Deter Backsliding

When a lamp burns out, it is easy to replace it with the wrong type. The most effective way to prevent this is to label the original fixtures with the lamp types to be used.

Be very specific in defining the lamp type. For example, an important feature of the filament may be buried in the lamp’s catalog number. See [Measure 9.7.3](#) about fixture labeling.

ECONOMICS

SAVINGS POTENTIAL: 20 to 90 percent of lamp energy.

COST: The price of incandescent lamps varies over a wide range among the different types. For example, common “A” lamps cost about \$0.25 apiece, in quantity. Reflector lamps cost \$3 to \$12. Screw-in fluorescent lamps with reflectors or extensions cost \$20 to \$30.

PAYBACK PERIOD: Less than one year, typically. However, this is misleading, because incandescent lamps burn out quickly and do not continue to generate savings. The ratio of savings to investment may range from slightly more than 1 (not worth the effort) to 5 (a good investment).

TRAPS & TRICKS

SELECTING THE LAMPS: Get into the details of the lamp manufacturers’ catalogs. Select the proper lamp type and wattage on a fixture-by-fixture basis. Make an economic calculation if the candidate lamp is more expensive than the original lamp.

LABEL THE FIXTURES: Don’t forget to label the fixtures with the correct lamp type. See [Measure 9.7.3](#).

MEASURE 9.1.4 Modify existing fixtures to reduce light trapping and/or improve light distribution.

Many incandescent fixtures trap a large fraction of the light produced by the lamps. Also, they may distribute light inefficiently, i.e., they do not put the light where it is needed. In some cases, you can improve the fixtures inexpensively. The subsidiary Measures deal with several specific opportunities. As part of the change, select the appropriate lamp type and wattage. See [Measure 9.1.3](#) about the lamps.

Alternative: Replace the Fixtures

It may be more economical to replace incandescent fixtures entirely than to modify them. Total replacement provides a clean slate for designing more efficient lighting. See [Measure 9.1.5](#) for this most general approach to improving lighting. Replacing fixtures provides the greatest benefit when switching to fluorescent or HID lighting.

MEASURE 9.1.4.1 In fixtures having shades that absorb light, modify or eliminate the shades.

RATINGS

New Facilities	Retrofit	O&M
	B	

Many incandescent fixtures use shades. Shades serve a useful purpose in preventing glare, but they often are chosen without regard to efficiency or light distribution pattern. For example, table lamps in hotel rooms may have shades that are virtually opaque. For example, see Figure 1. Making shades more translucent reduces light absorption, improves lighting throughout the room, and improves appearance.

WESINC

Fig. 1 Light shade, dark shade The fixture with the dark shade is located where it could be useful for reading in the chair, for writing at the desk, or for overall room light. However, the opaque shade makes it useless for all these purposes. This hotel knows where to find translucent shades, because one is installed at left.

SUMMARY
Simple and easy. Often inexpensive.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

This change is often simple and inexpensive, and it may reduce the need for lamp wattage by half. In other cases, it may take a certain amount of effort to improve a fixture. See Figure 2, for example. However, if a fixture has a large amount of incandescent lamp wattage, the effort is likely to pay off quickly.

With some fixtures and applications, such as a chandelier in a lobby, you may be able to remove shades completely and install decorative lamps.

Guidelines

There are innumerable styles of incandescent fixtures, so you have to figure out your own improvements. Here are some guidelines:

- **Make shades as transparent as possible.** It is virtually impossible to make shades too transparent. If a lot of wattage is at stake, it is worth buying some candidate types of shades and testing them with a light meter to find the most transparent models.

WESINC

Fig. 2 Quirky chandelier This unattractive chandelier has the energy waste of 18 downlights, and equally bad light distribution. Replacing the cylinders with globes or some other open type of lamp mounting would make it much more effective.

- ***If you eliminate shades, limit glare appropriately for the environment.*** The acceptable level of glare varies widely. For example, small bright bulbs may be a desirable accent in a lobby chandelier. On the other hand, keep lamp glare muted in locations where people linger for long periods, as in a dining room. Glare is less of a problem when the lamps are located well above the line of sight. Globe lamps and other types with large surface areas reduce glare. Read [Reference Note 51](#), Factors in Lighting Quality, to understand how people respond to glare.
- ***Match the lamps to the fixture.*** With shaded fixtures, the light distribution pattern from the fixture and the amount of light that is trapped are strongly affected by the light distribution pattern of the lamp. [Measure 9.1.3](#) deals with this aspect of lamp selection.
- ***Keep the fixtures and lighting attractive.*** Appearance is important with most shaded incandescent fixtures. More efficient shades are brighter, so they draw more attention to themselves. Better light distribution tends to provide lighting that is more pleasing.

ECONOMICS

SAVINGS POTENTIAL: Fixture wattages typically can be reduced from 30 to 60 percent.

COST: Varies widely, but usually modest.

PAYBACK PERIOD: Immediate, to several years.

TRAPS & TRICKS

DESIGN: Be creative. Find the most appropriate lamps. Use light measurements to find the minimum acceptable lamp wattage.

PRESERVE THE BENEFIT: Label each fixture to state the proper lamp type and wattage.

MEASURE 9.1.4.2 Install reflective inserts in fixtures that have absorptive internal baffles or surfaces.

RATINGS

New Facilities	Retrofit	O&M
	B	

Reflective inserts are a product designed specifically to correct the energy waste of downlights with light absorbing interiors. Most inserts have a shape that is approximately parabolic, so the light is projected outward through the fixture opening. These inserts can also be used anywhere else they fit, for example, in track lighting fixtures.

It may take some searching to find an insert that fits properly in the specific fixture. Exact fit is not essential to efficiency, but it may be important for appearance and ease of installation.

Some reflective inserts are offered with tints. Avoid them. The tints absorb a significant amount of light. If the decor needs a particular light source color, select the lamp appropriately.

ECONOMICS

SAVINGS POTENTIAL: 60 to 90 percent of lamp power.

COST: \$10 to \$20.

PAYBACK PERIOD: One year, typically.

SUMMARY

Simple. Foolproof. Fairly cheap.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Shop around. There are many manufacturers of this equipment. Select for efficient light distribution, ease of installation, safety, and low cost.

INSTALLATION: Use light measurements to determine the lowest lamp wattage you can use. Label each fixture to state the proper lamp type and wattage.

MEASURE 9.1.4.3 For task lighting, install focussing lamps on flexible extensions.

RATINGS

New Facilities	Retrofit	O&M
□	B	□

Flexible extension lamps are available that you can screw into existing fixtures, typically ceiling mounted downlights. You can use these to achieve task lighting, provided that the relative positions of the fixture and the activity are satisfactory. See [Reference Note 51](#), Factors in Lighting Quality, about glare and veiling reflections.

This is a specialized improvement that you may be able to use in a small number of locations. Extension lamps are not pretty, so this technique may be unacceptable where decor is a factor.

SUMMARY
 An easy way to achieve efficient task lighting. Applications are infrequent. Not elegant.

SELECTION SCORECARD

Savings Potential	\$			
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

ECONOMICS

SAVINGS POTENTIAL: 50 to 90 percent of the energy needed to illuminate the activity.

COST: Several dollars.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

CHOICE OF METHOD: Be sure that this method avoids glare and veiling reflections. If not, or if appearance is important, this is probably not the right approach. Instead, install a surface mounted aiming fixture.

MEASURE 9.1.5 Replace incandescent fixtures with fluorescent or HID fixtures.

RATINGS

New Facilities	Retrofit	O&M
A	B	C

Wherever incandescent lighting is installed or is part of the design of a new facility, consider whether you can replace it with fluorescent or HID lighting.

Design the lighting for each area from scratch. Consider all the factors that affect efficiency, visual quality, cost, decor, etc., for the particular activities and the space geometry. For overall lighting design issues, see [Reference Note 51](#), Factors in Lighting Quality. Refer to [Subsection 9.2](#) for Measures that optimize the efficiency of fluorescent lighting. Refer to [Subsection 9.3](#) for Measures about HID lighting.

Retrofit Alternative: Screw-In Fluorescent Lamps

You can replace many incandescent lamps with screw-in fluorescent lamps ([Measure 9.1.2.1](#)). This is by far the easiest and least expensive way to install fluorescent lighting. However, screw-in fluorescent lamps are not as efficient as the best fluorescent or HID lighting, they are limited in light output, and the existing fixture locations may not provide efficient light distribution.

Fluorescent or HID?

In the past, large differences in efficacy and color rendering created a natural division between applications for fluorescent lighting and applications for HID lighting. This division has largely disappeared. Fluorescent lighting now approaches the efficacy of the best HID lamps, and HID lighting has achieved color rendering almost as good as the best fluorescent lamps. As a result, many applications could use either type of lighting satisfactorily. See [Measure 9.3.3](#) for guidance in choosing between the two.

Don't Forget Efficient Control

Efficient control is a major part of lighting efficiency. Replacing incandescent lighting with another type will provide you with a number of opportunities to optimize control. Make this an integral part of your project. Refer to [Subsections 9.4](#), [9.5](#), and [9.6](#) for lighting control Measures.

SUMMARY

The most efficient and most expensive approach. Widely applicable. Requires a lot of thought to yield the most benefit.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	✓
Ease of Retrofit	☺	☺	☺	

ECONOMICS

SAVINGS POTENTIAL: 60 to 90 percent of lighting energy consumption in the affected areas.

COST: Fluorescent fixtures cost \$0.20 to \$1.00 per watt. The price depends largely on appearance and diffuser type. HID fixtures cost \$0.20 to \$3.00 per watt, the price depending largely on wattage. Installation costs are \$0.20 to \$2.00 per watt, depending on wattage, fixture accessibility, and labor rates. In new construction, substituting fluorescent or HID lighting for incandescent lighting adds only a fraction of these costs.

PAYBACK PERIOD: 1 to 5 years, in new construction. 3 to 10 years, in retrofit.

TRAPS & TRICKS

PLANNING AND EQUIPMENT SELECTION: This change gives you a chance to design lighting design from scratch. Start with a clean sheet of paper and consider all your options. See [Subsection 9.6](#) for general layout. See [Subsections 9.2](#) and [9.3](#) for fluorescent and HID lighting, respectively.

MEASURE 9.1.6 Modify or replace incandescent exit signs with fluorescent or LED light sources.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Commercial buildings are required by fire codes to have lighted exit signs. Until the 1980's, most units were illuminated with internal incandescent lamps, typically with two bulbs ranging in size from 15 to 40 watts each. The wattage of each fixture is small, but the units operate continuously, so it is usually worthwhile to replace the incandescent lamps with more efficient light sources.

Exit signs are visible everywhere and they are accessible, so upgrading them has become a popular energy conservation measure. In fact, this opportunity to save energy has fascinated some jurisdictions so much that they have passed laws requiring efficient exit signs.

Choices

You presently have these choices for improving exit sign efficiency:

- **retrofit existing fixtures with compact fluorescent lamps and ballasts.** Conversion kits are available with ballasts, lamps, and mounting brackets. The compact fluorescent lamps typically are from 5 to 9 watts. There may be one lamp and one ballast, two lamps and two ballasts, or two lamps and one ballast. Some of the ballasts are designed to operate with a pair of lamps, but they can operate only one lamp at a time. If one lamp burns out, the other lamp lights.

Compact fluorescent lamps of good quality are rated to last 10,000 hours, and the ballasts perhaps 50,000 hours. This greatly reduces lamp replacement labor.

WESINC

Fig. 1 Incandescent exit light The lamps in these are small, but they operate all the time. At your first convenient opportunity, replace incandescent units with one of the much more efficient models that are now available.

SUMMARY

A specialized activity that saves a modest amount of energy. Retrofit equipment is readily available.

SELECTION SCORECARD

Savings Potential	\$ \$
Rate of Return	% % %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

- **replace the fixtures with new fluorescent fixtures.** This approach achieves the same result as the previous. It is preferable if the existing fixture is difficult to convert or is unattractive. The equipment cost is higher, but the labor cost is usually lower.
- **retrofit existing fixtures with LED light strips.** Conversion kits are available that replace the incandescent bulbs with strips of light-emitting diode (LED) lamps. LED's use very little energy, typically 2 watts for each side of the exit sign. Also, LED's are claimed to have virtually unlimited life. LED retrofits are novel, so it is too early to believe these claims. The light strip is mounted at one side of the fixture, so the lighting may be uneven. At present, LED's are considerably more expensive than compact fluorescent lamps.
- **replace the fixtures with new LED fixtures.** This achieves the same result as the previous. In some fixtures, the LED's are used to backlight transparent letters. In others, the LED's themselves form the letters, which produces light that is stronger and more uniform.

Reliability

Reliability is a major requirement for exit signs. Compact fluorescent lamps of good quality have proven reliability. Cheap compact fluorescent lamps, which are common, have no reliability. See [Measure 9.1.2.1](#) for guidance in selecting compact fluorescent lamps.

If you select fluorescent lamps, consider installing double lamps and ballasts for adequate reliability. Check the codes in your jurisdiction for any specific requirements.

Fluorescent lamps do not function properly when the ambient temperature is too low. Compact fluorescent units typically start and operate reliably down to 32°F (0°C) and below. Check the unit's temperature

specifications if it will be located where it can get much colder than room temperature.

Fluorescent and LED exit signs are available with all the usual backup power arrangements. They draw little power, so they are well adapted to battery backup.

ECONOMICS

SAVINGS POTENTIAL: 70 to 90 percent of exit sign lighting energy. It isn't much energy overall, but everybody's doing it.

COST: Fluorescent retrofit kits cost \$8 to \$20. New fluorescent exit signs cost about \$15 for cheap plastic units, to much higher for decorative units. LED retrofit kits cost \$40 to \$60 at this time. New LED exit signs

presently cost \$80 to \$120, depending on features. Installation takes from a fraction of an hour to one hour per unit, depending largely on the number of units to be installed.

PAYBACK PERIOD: About one or two years, for fluorescent retrofits. Several years, for new fixtures or LED retrofits.

TRAPS & TRICKS

CHOICE OF EQUIPMENT: LED's are more expensive than compact fluorescent lamps, but they use somewhat less energy and they probably will last much longer. Considering that not much money is at stake, they probably are the best choice in most cases. Check with others who have experience with the equipment you are considering.

MEASURE 9.1.7 Install dimmers.

Dimmers are useful for saving energy with incandescent lighting in situations where the desired illumination requirement varies. Dimming may also be useful for decorative or esthetic purposes, with energy savings as a bonus. In retrofit applications, dimmers for incandescent lighting can be installed easily in place of the original switches.

If you want to exploit daylighting, don't use manual dimmers. Instead, use automatic dimming that senses the amount of daylight in the space. See [Measure 9.5.3](#) about daylighting controls.

Efficiency Limitations

Unfortunately, it is difficult to achieve the savings potential of manual dimmers. The response characteristics of the eye make it difficult for the person setting the dimmer to quickly judge an acceptable minimum position, even if he is willing to make the effort. In the real world, dimmers tend to be set willy-nilly.

Another limitation is that the efficiency of incandescent lamps declines rapidly as they are dimmed. Therefore, dimming is partially self-defeating.

Even more self-defeating, the availability of dimmers motivates people to install larger lamps, so that more power is consumed to achieve a given lighting level than before the dimmers were installed. This makes

SUMMARY

For applications where the desired illumination level changes. Dimmers are inexpensive and easy to install, but they are usually not the most efficient approach. It is difficult to get people to use dimmers efficiently.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability of Equipment	✓	✓	✓	
Reliability of Usage	✓	✓		
Ease of Retrofit	😊	😊	😊	

it essential to limit lamp wattage, as recommended by [Measure 9.1.1](#).

Types of Dimmers

Dimmers are available in a variety of styles, such as sliders, rotary knobs, and rotary knobs with push switches. Dimmers are available for 3-way operation.

Modern dimmers do not absorb much energy, but cheaper units may cause electrical interference.

Dimmers are easy to retrofit. Simply insert them in place of the original toggle switch. However, some dimmers are too wide or too deep to fit into some junction boxes. With deeper dimmer units, you may have to cut out excess wiring inside the box in order to install the dimmer. Check the dimensions of the dimmer before you buy.

Install Placards at the Dimmers and Fixtures

People tend to use dimmers inefficiently, so provide effective instructions. See [Measure 9.4.1](#) for the details.

Label fixtures that are controlled by dimmers, as recommended by [Measure 9.7.3](#). This tells the staff not to install lamps that are too large.

Electrical Interference

Modern incandescent dimmers operate by electronically interrupting (chopping) the line current at a frequency that is much higher than the line frequency. This higher frequency spreads through the power wiring. It can cause interference with radios, public address systems, computers, and other electronic equipment. Dimmers now have filters to minimize these problems, but the effectiveness of the filtering varies among models. In environments where electronic interference may be a problem, install a few dimmers on a test basis before proceeding with wholesale installation.

Audible Noise

Some dimmer models may make an audible buzzing noise at certain light levels. Modern units of good quality are generally free of this problem.

More Efficient Ways to Achieve Variable Lighting Levels

If the application requires incandescent light, consider multi-level switching of lamps or fixtures ([Measures 9.6.4 ff](#)). This may be satisfactory if fixtures have more than one lamp, or if a number of lamps are used to illuminate a particular area. Switching lamps,

rather than dimming them, keeps the lamps operating at maximum efficiency and provides positive control of the illumination level.

In new construction, you no longer have to install incandescent lighting to get dimming capability. Fluorescent dimming ([Measure 9.2.6](#)) is now an efficient and reasonably economical option, and most its previous weaknesses have been eliminated.

In retrofit applications, if a space has both incandescent and fluorescent lighting, consider installing dimmers for the fluorescent lighting and eliminating the incandescent lighting. Retrofitting fluorescent dimming costs much more than retrofitting incandescent dimmers, but dimming fluorescent lighting is much more efficient than dimming incandescent lighting.

HID lighting (i.e., mercury vapor, metal halide, and high-pressure sodium) does not yet have the dimming flexibility of fluorescent lighting. This may change in the future. See [Measure 9.3.2](#) about HID dimming.

ECONOMICS

SAVINGS POTENTIAL: 20 to 60 percent of the energy of controlled fixtures.

COST: Less than \$1 per ampere in common styles. Large dimming systems may be much more expensive.

PAYBACK PERIOD: Less than one year, typically, if it is properly applied.

TRAPS & TRICKS

CHOICE OF METHOD: This Measure will not save much energy unless the staff or occupants are motivated to use the dimmers efficiently. Even in the most favorable cases, dimming is usually less efficient than other techniques you might use, such as multi-level switching and automatic daylighting control. Consider all your options.

SELECTING THE EQUIPMENT: Avoid cheap junk models, which may fail quickly or make electrical noise. Test units in a sensitive location before buying in quantity.

INSTRUCTIONS: Don't forget to install effective instruction placards, which are just as important as the dimmers themselves.

Lamps and Fixtures, Fluorescent

Fluorescent lighting provides the best combination of efficiency, good lighting qualities, and other characteristics for most applications. Fluorescent lighting is by far the most common type used in commercial and industrial applications, the main exceptions being outdoor lighting, lighting for spaces with very tall ceilings, and decorative applications. Fluorescent lighting is even spreading rapidly in residential applications, largely in the form of compact screw-in lamps.

It appears likely that fluorescent lighting will continue to dominate. The technology is presently undergoing major changes, oriented primarily toward improved efficiency and color rendering, but also driven by style and marketing. A dark cloud on the horizon is concern about the mercury content of fluorescent lamps, which probably will lead to major changes in design, and perhaps to compromises with performance and economy.

The Measures of this Subsection reduce the energy consumption of fluorescent lighting. The Subsection starts with the least expensive and most broadly applicable Measures, and progresses to Measures that are more expensive and more narrowly applicable. Within this general sequence, similar Measures are kept next to each other.

Use the Measures in this and other Subsections as building blocks to create a lighting configuration that is optimum for each area. Tailor the lighting to each activity area individually. In retrofit applications, start by examining the environment of each fixture, and then select the appropriate Measures that apply to that fixture. For example, delamping ([Measure 9.2.1](#)) is appropriate if the environment is grossly overlighted, but replacement with high-efficiency tubes ([Measure 9.2.3](#)) is appropriate if the present lighting level is about right.

Before getting started, review [Reference Note 55](#), Fluorescent Lighting, for an overview of the way that fluorescent lighting works. This will give you a basis for selecting from among the many types and models of fluorescent equipment. For a comprehensive comparison of fluorescent lamps with other lamp types, see [Reference Note 52](#), Comparative Light Source Characteristics.

INDEX OF MEASURES

9.2.1 Eliminate excessive lighting by removing lamps and disconnecting or removing their ballasts.

9.2.1.1 To remove single tubes from 2-tube ballasts, substitute dummy lamps.

9.2.1.2 To remove single tubes where 2-tube ballasts are installed, substitute single-tube ballasts.

9.2.1.3 To remove single tubes from groups of fixtures, rewire the ballasts between fixtures.

9.2.2 Where fixtures have been delamped, disconnect or remove the ballasts.

9.2.3 Replace fluorescent lamps with high-efficiency or reduced-wattage types.

9.2.4 Replace ballasts with high-efficiency or reduced-wattage types, or upgrade ballasts and lamps together.

9.2.5 Install current limiters.

9.2.6 Install fluorescent dimming equipment.

9.2.7 Consider retrofit “reflectors” for fluorescent fixtures.

RELATED MEASURES:

- [Measures 9.6.2 ff](#), fixture layout and replacement in general
- [Measure 9.6.3](#), combinations of fixtures
- [Measure 9.6.5.1](#), installation of pullcord switches on fluorescent fixtures

MEASURE 9.2.1 Eliminate excessive lighting by removing lamps and disconnecting or removing their ballasts.

The two most common causes of lighting energy waste are excessive illumination levels overall and failure to locate fixtures in relation to the activity areas. Typically, the entire space is illuminated at a uniform level that is sufficient for the most demanding work, with an additional margin thrown in. This pattern is especially common with fluorescent lighting.

Where this kind of lighting exists, you can save a large amount of energy quickly and cheaply by removing lamps from fixtures that are producing more light than needed. To maintain the savings in the long term, disconnect or remove the ballasts serving the lamps that are removed.

Removing lamps is often called “delamping”, and disconnecting or removing ballasts is often called “deballasting.” We will use these terms because they are handy.

Benefits of Delamping

Energy saving is the main benefit of delamping. Delamping eliminates a major fraction of the energy consumption of each fixture that is delamped. In many facilities, delamping can eliminate a major fraction of overall lighting cost.

Delamping can also improve the quality of illumination, primarily by eliminating lamps that cause veiling reflections and glare. In facilities that have uncomfortably high illumination levels, delamping eliminates discomfort from this cause.

Delamping saves the cost of the lamps and ballasts that do not have to be replaced. It may also save some replacement labor cost, but this saving may be less than expected, because a fixture with half its lamps operating still requires lamp replacement at the same intervals as if all the lamps were operating. (See “The Cost of Lighting”, in the [Section 9](#) Introduction.)

Drawbacks of Delamping

Delamping produces an irregular pattern of fixture brightness and the appearance of having a lot of burned-out lamps. Whether this is important depends on the nature of the space.

Immediately after delamping, occupants may complain about reduced lighting levels, for the reasons explained below. Good public relations eases this transition. Complaints should cease after an initial period, provided that the delamping is accomplished properly.

SUMMARY

Widely applicable, saves lots of energy, cheap to accomplish. Needs a detailed survey before making the changes. Needs public relations and fixture labeling to survive.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	%
Reliability	✓	✓		
Ease of Retrofit	😊	😊		

Where to Delamp

Consider delamping where a large reduction in the light output of an individual fixture is acceptable. Such cases are common. For example, offices with multiple fixtures usually do not require full output from all the fixtures. Storage and transit areas do not need illumination at the same levels as office work.

Once you get started, don’t be surprised if you find some fixtures that you can delamp completely. For example, a kitchen fixture that illuminates only the top of a hood or upright freezer is useless. Refer to [Measure 9.6.2.1](#) if it makes sense to remove these fixtures.

Ballast Connection Limitations

Most fluorescent ballasts are designed to operate two tubes. Ballasts are also available to operate a single tube. In fixtures having more than one tube, the usual practice is to use 2-tube ballasts, except for odd tubes (e.g., in 3-tube fixtures). Some electronic ballasts can drive a variable number of tubes.

With most 2-tube ballasts, the lamp current flows in series through the two tubes. This makes it easy to tell which tubes are connected to a common ballast, because removing one of the tubes extinguishes the other. An exception occurs with some electronic ballasts that power the tubes in parallel. These ballasts may operate efficiently with one tube disconnected, or they may not.

The minimum reduction of light output that is possible by removing lamps depends on the number of ballasts in the fixture. If a fixture has only one ballast, delamping disables the fixture completely. In a 4-tube fixture with 2-tube ballasts, the choices are to reduce the light level to one half or to disable the fixture completely. In a 6-tube fixture with 2-tube ballasts, the choices are two thirds of full output, one third, or none. And so forth.

The subsidiary Measures provide ways to work around these limitations, but they require lamp or fixture modifications.

Survey Before You Delamp

Delamping is not dummy work. You need to make a detailed survey to determine the number of lamps that need to be operated in each fixture. Delamping without adequate planning creates vision problems, misses opportunities for savings, and gives energy conservation a bad reputation. Figure 1 shows an example.

Do not expect to get satisfactory results just by giving general guidelines to the people who remove the lamps, unless they are exceptionally well trained. Even with exceptional personnel, it probably wastes time and creates confusion to plan the delamping at the same time as the lamps and ballasts are being removed.

Instead, make a detailed, fixture-by-fixture plan that shows the number and location of the tubes to be removed from each fixture. An easy way to do this is to mark the delamping instructions on a copy of the lighting plan from the building's architectural drawings.

Assign one individual on each work team exclusively to call out the modifications for each fixture and to check the work.

■ Select the Appropriate Illumination Levels

Use a good light meter to measure lighting levels at the activity areas. You will quickly become adept at estimating the lighting levels that will result from delamping by measuring the existing lighting levels.

Appropriate lighting levels are suggested in [Reference Note 51](#), Factors in Lighting Quality. Illumination levels are controversial, and widely varying standards have been established in the United States and other countries. Lighting efficiency standards are covered in [Reference Note 53](#).

As an example of the need to tailor delamping within a space, consider a typical office area illuminated by fixtures using tubes of 32 to 40 watts. If fixtures and ceiling heights are typical, you might use these guidelines for the numbers of tubes at each activity area:

- for routine paperwork, two tubes
- for detail work, four tubes
- for work at computer terminals with bright displays, and no other detail work, two tubes per 150 square feet
- for filing and storage areas, two tubes per 100-200 square feet, depending on the level of illumination required to find objects in storage
- for transit areas, one or two tubes for each 15 to 20 feet of length, but separate lighting is needed only if sufficient illumination is not available reliably from adjacent areas.

For other types of activities, refer to standard tables of illumination levels, such as those in the IESNA

Lighting Handbook. Temper these guidelines with good judgement. The lighting trade is still governed by the "more is better" philosophy of lighting.

On the other hand, youthful, sharp-eyed lighting planners should leave a margin of lighting intensity because:

- ***elderly persons need more light than young persons.*** The illumination levels that people need to see well start to increase noticeably at age 40, and escalate rapidly thereafter.

WESINC

Fig. 1 Stupid delamping Some of these hospital corridors are much brighter than necessary, while others have long unlighted areas. Nobody planned this work, and nobody checked it.

- *all types of lamps lose light output as they age and get dirty.* Fluorescent lamps may lose 10 to 40 percent of their light output as they age, depending on the type.

■ Delamp to Improve Visual Quality

A task area within a space may be illuminated by several fixtures, presenting several different ways of delamping to satisfy the illumination level at the task area. Whenever possible, delamp fixtures in a way that improves visual quality. Try to minimize:

- *veiling reflections*, which occur when the fixture is in front of the viewer
- *source glare*, which can occur with a bright fixture located anywhere in the viewer's visual field
- *shadows on the task*, which occur when the fixture is behind the viewer or behind a shadowing object
- *excessively uneven illumination*, which results from the fixture being too far off to the side.

Veiling reflections is the most common problem with fluorescent lighting. This is because paperwork and other common activities that are vulnerable to veiling reflections commonly use fluorescent lighting. Source glare may sometimes be a problem, but delamping is less effective as a cure for glare.

Your ability to solve visual problems by delamping is limited by the present locations of the fixtures and the tasks. In open spaces with a number of occupants, fixtures may contribute collectively to the lighting of several task areas. This requires you to work out delamping patterns that provide satisfactory lighting at all the task areas. In many cases, delamping alone cannot correct poor lighting geometry. You may have to move fixtures ([Measure 9.6.2.2](#)) or use other methods.

As part of your planning, review [Reference Note 51](#), Factors in Lighting Quality. Remember that the best position for a light source usually is to the side of the task area, and slightly behind the viewer.

If the space has daylighting, it is even more difficult to eliminate visual problems. Try to arrange the tasks so that both daylighting and artificial lighting come from the same or opposite sides. See [Reference Note 46](#), Daylighting Design, for the special steps needed to make daylighting satisfactory.

■ Which Tubes to Remove?

Removing tubes changes the light distribution pattern of the fixture as well as reducing its total light output. For example, in most 4-tube fixtures, the outer tubes are connected to one ballast, and the inner tubes to another. Delamping the outer tubes may narrow the light distribution pattern much more than delamping the inner tubes. The difference in light distribution pattern is probably important. Use your light meter to study how your fixtures will behave when they are delamped.

Socket adapters are available that relocate the remaining tubes to a position halfway between the

original sockets. These adapters simply plug into the existing sockets. You probably will not need these, but keep them in mind. They would be useful if they provide the only way to achieve a satisfactory light distribution pattern.

Another possibility is changing the connections of the ballasts to the sockets. For example, in a 6-lamp fixture with 2-tube ballasts, you could rewire the ballasts to deactivate any two sockets in the fixture, leaving the rest in operation.

Public Relations is Essential

Objections by the occupants can be a major obstacle to delamping. To avoid this problem, explain the purpose of the activity ahead of time, and assure occupants that lighting will be maintained at a level that is appropriate for each area. Stress that the changes will maintain or even improve lighting quality.

An odd phenomenon makes people averse to reasonably reduced lighting levels in the short term. It has been observed that some people complain of insufficient lighting when they work in an inside environment where the lighting level is maintained higher (yes, higher) than approximately 70 footcandles. The reason for this has not been discovered, but one could guess that this behavior is related to visual fatigue.

Similarly, people tend to assume that visual problems are due to insufficient light, rather than too much. Thus, occupants get the wrong impression that delamping will make any discomfort worse. (Among older persons, this may be a residue of an intense public relations campaign waged by electric utilities before the 1970's that tried to convince the public to increase lighting levels.)

Veiling reflections appear to be a factor in this phenomenon, but they do not explain all of it. Daylighting worsens the problem by making the non-daylighted portions of the space appear darker. This is one of the main factors that make daylighting tricky. See [Reference Note 46](#), Daylighting Design, for methods of avoiding visual problems.

People will eventually accommodate to reasonably reduced lighting levels, but there appears to be a delay of one or more weeks before individuals become comfortable with it.

How to Delamp and Deballast

■ Remove the Lamps

Remove the lamps entirely and place them in storage for use elsewhere. Do not leave them to dangle in the lampholders. This is insecure, and invites putting the lamps back into operation.

Remove all the tubes connected to a ballast. Don't leave one tube connected to a 2-tube ballast, as this may damage the tube or ballast. In tubes that have filaments,

the filaments will continue to operate until they burn out. These problems will not occur if you disconnect the ballast, but there is no sense in leaving tubes connected to a dead ballast.

■ Disable the Ballasts

After you remove the tubes and verify that the remaining light level is adequate, disconnect the ballast or ballasts. Disabling the ballast is important because:

- ballasts that are left connected continue to draw a significant amount of power even though the tubes are removed
- if the ballasts are not disconnected or removed, the removed tubes will be replaced sooner or later. The absence of a ballast is an effective signal that the tubes are supposed to be absent. (Delamped fixtures should be labeled, but people may ignore the labels.)

Ballasts are almost always installed inside the fixtures. When you are delamping, the ballast is easy to reach because the diffuser and the lamps in front of the ballast have already been removed. The ballast is usually installed behind a cover plate that usually comes off quickly. To disconnect the ballast, simply remove the power wiring from the primary. Wire nuts are commonly used for ballast installation, and they can be removed in a few seconds.

Occasionally, ballasts may be installed remotely from fixtures. This is done to isolate the noise emitted by ballasts. The ballasts are usually accessible inside an electrical panel.

Of course, there is an electrical shock hazard in doing this work, so the people doing the electrical work should be properly qualified.

Removing the ballast takes only a few more seconds. Remove the wire nuts that connect the secondary side of the ballast to the lamp sockets. The ballast is typically held in place by two easily accessible nuts. Remove these, and the ballast drops out of the fixture.

■ Disconnect or Remove Ballasts?

You can leave the disconnected ballasts in the fixtures or remove them. Removing the ballasts is better. This makes it much less likely that excess lamps will be put back into service. Use the removed ballasts as spare parts, or sell them.

■ How to Deactivate a Single Tube

Sometimes, you want to eliminate only one tube in a fixture. There are ways to do this, even if the fixture has multi-tube ballasts. However, it takes more effort and expense. The subsidiary Measures tell you how.

■ Delamping Screw-In Fluorescent Lamps

Screw-in fluorescent lamps usually include an integral ballast, so disconnecting ballasts is not a separate requirement with these lamps. You still need to electrically disconnect the fixture that held the lamp.

Label the Delamped Fixtures

Label each fixture that has been delamped. Otherwise, people will assume that the fixtures are defective, and the lamps will be replaced. This step is as important as the rest of the work. See [Measure 9.7.3](#) for the details of labeling fixtures.

Repeat the Process When Changing Space Layout

If delamping is tailored to individual areas, future changes in the location or orientation of the activities will require corresponding modifications of the delamping pattern. Neglecting to keep up with changes will result in unsatisfactory lighting.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of lighting energy in the delamped spaces. Delamping one pair of 40-watt tubes saves about 300 KWH per year, on a typical workday schedule. In addition, this saves several dollars per year in lamp replacement cost.

COST: \$1 to \$10 per fixture, depending on labor rates, the number of fixtures, and accessibility.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

PREPARATION: The big risk is the temptation to start delamping without doing a thorough planning survey first. Don't expect people to select lamps for delamping on the fly. Even if they could, it would be an inefficient use of labor. Don't neglect an effective public relations program immediately before you start delamping.

FIXTURE LABELING: Train the supervisor of the delamping crew to label the delamped fixtures as the work is accomplished.

MEASURE 9.2.1.1 To remove single tubes from 2-tube ballasts, substitute dummy lamps.

RATINGS

New Facilities	Retrofit	O&M
□	B	□

A dummy lamp is simply a wire that runs from one socket of a fluorescent fixture to the opposite one, in place of a real tube. The wire has minimal electrical resistance. It mimics the ionized gas of an operating fluorescent tube, which also has minimal resistance. The wire dissipates no power, and there is no filament. Some models enclose the wire in a glass envelope that looks like a lamp, but the glass plays no role except to protect the wire and look official. A capacitor may be included with the dummy lamp to improve power factor.

All magnetic 2-tube ballasts operate the lamps in series. Fluorescent lamps are essentially short circuits while they are operating, so they do not affect each other's operation. Therefore, substituting a wire for one of the lamps makes no difference to the other lamp or to the ballast, at least during operation.

Potential Problems

Dummy lamps have been used successfully, but they never became popular, probably because people suspect that they may damage the ballast or the remaining lamp. In fact, some technical representatives of ballast manufacturers have stated that dummy lamps are harmless to conventional ballasts. Even so, using them may void ballast warranties.

There is at least one real problem. With rapid-start tubes, which have filaments, using dummy lamps may shorten the life of the lamp by increasing the voltage across the tube when starting. The problem occurs because the tubes are connected to the ballast in series. When starting, the initial high resistance of both tubes is additive. However, a dummy lamp has zero resistance even when the fixture is starting, so the entire starting voltage is applied to the real tube.

This suggests that you should use dummy lamps only if the fixtures are not turned on and off frequently. For example, corridor lighting is a good application. In appropriate applications, dummy lamps probably have little effect on lamp replacement cost. On one hand, there is only one lamp to wear out, instead of the original two. On the other hand, the lamps may have reduced lamp life.

SUMMARY

Efficient, easy, and cheap. Check for possible lamp or ballast problems.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

There is always the possibility that a dummy lamp can cause trouble with some ballast models. For example, some electronic ballasts may not be able to cope with the absence of starting resistance. So, check with the engineering departments of both the lamp and ballast manufacturers before using dummy lamps.

How to Install Dummy Lamps

Installing dummy lamps is simplicity itself. Just remove one of the fluorescent tubes and insert the dummy lamp in its place. Nothing needs to be done with the ballast.

Most of the work is in the supporting steps needed to make any delamping program successful, which are spelled out in [Measure 9.2.1](#), above. Label the fixtures and do your public relations.

ECONOMICS

SAVINGS POTENTIAL: All the energy of the removed tubes. For example, eliminating one 40-watt tube save about 150 KWH per year on a typical workday schedule.

COST: Dummy lamps cost \$2 to \$10 apiece, depending on style. Labor for installation and supporting activities may cost from \$0.30 to \$3 per fixture, depending on the environment.

PAYBACK PERIOD: One year, typically.

TRAPS & TRICKS

See [Measure 9.2.1](#). In addition, be sure to check that the dummy tubes do not have significant adverse effects on the ballasts or the remaining tubes.

MEASURE 9.2.1.2 To remove single tubes where 2-tube ballasts are installed, substitute single-tube ballasts.

RATINGS		
New Facilities	Retrofit	O&M
□	C	□

In fluorescent fixtures that have even numbers of tubes, the tubes are usually powered in pairs by 2-tube ballasts. Magnetic 2-tube ballasts cannot operate a single tube, and the same is true of some electronic 2-tube ballasts. You can get around this limitation by replacing the 2-tube ballasts with single-tube ballasts.

How to Select the Ballasts

Refer to [Measure 9.2.4](#) for the factors to consider in selecting ballasts.

First, Survey and Plan

To be successful, this activity needs the kind of planning that is spelled out in [Measure 9.2.1](#), above.

Opportunity to Add Switching Flexibility

Installing a single-tube ballast for one of the lamps in a fixture allows light output to be adjusted with great flexibility, provided that the appropriate switching circuits are installed (see [Measure 9.6.4](#)). This is valuable in spaces that have widely varying lighting requirements.

For example, in a function room that has 4-tube fixtures, one of the pairs of tubes in each fixture can be replaced by a single tube. This gives occupants the option of turning on one, two, or three tubes in each fixture.

If you provide manual switching options, be sure to label the switches effectively. See [Measure 9.4.1](#) for tips.

SUMMARY
Efficient and foolproof. Moderately expensive.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

ECONOMICS

SAVINGS POTENTIAL: All the energy of the removed tubes. For example, eliminating one 40-watt tube saves about 150 KWH per year, on a typical workday schedule.

COST: Efficient single-tube ballasts cost \$10 to \$40, depending on wattage and type. Labor for installation and supporting activities adds \$2 to \$10 per fixture, depending on the environment. The removed ballasts have salvage value, at least as spare parts.

PAYBACK PERIOD: One to five years.

TRAPS & TRICKS

See [Measure 9.2.1](#). In addition, select the replacement ballasts for efficiency and reliability.

MEASURE 9.2.1.3 To remove single tubes from groups of fixtures, rewire the ballasts between fixtures.

RATINGS

New Facilities	Retrofit	O&M
<div style="border: 1px solid black; width: 60px; height: 60px; margin: 0 auto;"></div>	<div style="border: 1px solid black; width: 60px; height: 60px; margin: 0 auto; display: flex; align-items: center; justify-content: center;">C</div>	<div style="border: 1px solid black; width: 60px; height: 60px; margin: 0 auto;"></div>

If adjacent fixtures have 2-tube ballasts, you can rewire the ballast connections to operate a single tube in that fixture and a single tube in another fixture. This technique can be applied in a variety of ways. It applies to fixtures with any number of ballasts.

For example, consider a row of 2-tube fixtures connected end-to-end. A single tube is left in each fixture, and the ballast in every other fixture is used to power the lamps.

Or, in this same situation, you can create two levels of lighting. To do this, retain both tubes in each fixture, rewire the ballasts, and install two light switches. The two switches control alternate ballasts, so that one switch controls one tube in each fixture, and the other switch controls the other tube in each fixture. In this way, a single continuous row of tubes can be turned on, or two continuous rows.

The wiring modifications are awkward, especially with rapid-start lamps. Rapid-start ballasts provide filament heating for each socket, so you have to feed several socket wires from one fixture to the next.

Limitations on Wiring Length

If the present ballasts are an electronic type that operates at high frequency, there may be problems if the ballast wiring is extended to great lengths. The ballast may not be able to drive long connections, or there may be noise propagation problems. Check with the ballast manufacturer to find out about wiring length limitations.

SUMMARY
Efficient. Labor intensive. Limited to closely spaced groups of fixtures.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	😊 😊 😊

Supporting Activities

As with any method of delamping, the planning and public relations steps recommended in [Measure 9.2.1](#) are needed to make the activity successful.

ECONOMICS

SAVINGS POTENTIAL: All the energy of the removed tubes. For example, eliminating one 40-watt tube in typical daytime service saves about 150 KWH per year.

COST: \$5 to \$40 per fixture. The cost is mostly for labor, and depends on labor rates and the ease of wiring between fixtures. Leftover ballasts may have substantial salvage value.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

See [Measure 9.2.1](#). In addition, the awkwardness of the wiring work invites mistakes.

MEASURE 9.2.2 Where fixtures have been delamped, disconnect or remove the ballasts.

RATINGS

New Facilities	Retrofit	O&M
□	B	□

Delamping fluorescent fixtures (see [Measure 9.2.1](#)) is a quick and easy method of saving energy. However, in facilities where delamping was accomplished in the past, it is common to find that disconnecting the ballasts was neglected. If you have this situation, correct it.

Disconnecting the ballasts is important for two reasons. One is that a ballast continues to dissipate a certain amount of energy even with no lamps connected to it. The other reason is that disconnecting the ballast is needed to prevent lamps from being replaced and put back into operation.

Amount of Energy Waste

Energy waste by the ballast itself is primarily a problem with magnetic ballasts. These are similar to transformers in construction. The primary winding continues to draw a certain amount of power even when the secondary is disconnected. This power is dissipated as heat. The energy waste typically is a few watts per lamp.

Electronic ballasts may not draw much current when the lamps are removed, but it is still important to disconnect them to prevent lamps from being reinstalled.

How to Disconnect Ballasts

Disconnecting ballasts is simple. See [Measure 9.2.1](#) for the details.

Label the Fixtures

Label the fixture when you disconnect the ballast. See [Measure 9.2.1](#) for the details.

SUMMARY
An essential step in delamping that is often neglected.

SELECTION SCORECARD

Savings Potential	\$ \$
Rate of Return	% % %
Reliability	✓ ✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

ECONOMICS

SAVINGS POTENTIAL: *The power consumption of a magnetic ballast with no lamps is typically several watts per lamp connection. Disconnecting ballasts may save much more energy by preventing lamps from being re-installed in delamped fixtures.*

COST: *\$0.50 to \$5 per fixture, depending on labor rates, the number of fixtures, and fixture accessibility.*

PAYBACK PERIOD: *Less than one year, to several years.*

TRAPS & TRICKS

CONSIDER STARTING OVER: *If the ballasts were not disconnected when delamping was first accomplished, the delamping was probably not planned properly. Start all over again with a thorough delamping survey. Go back to [Measure 9.2.1](#).*

MEASURE 9.2.3 Replace fluorescent lamps with high-efficiency or reduced-wattage types.

The efficiency of fluorescent lamps improved considerably between the 1970’s and the 1990’s. In new construction, where you can design the lighting with a clean sheet of paper, it is virtually always desirable to use lamps of the highest efficiency available. Efficient lamps cost more, but the saving in energy cost is usually greater than the cost premium for the lamps.

In retrofit applications, one of the more popular energy conservation measures is replacing older types of fluorescent tubes with newer types that operate at lower wattage. Reduced-wattage and high-efficiency lamps are now available in all the common sizes and shapes. For example, the venerable 4-foot 40-watt tubes are widely being replaced with 32-watt and 34-watt tubes.

Some lower-wattage substitute lamps are more efficient than older types, and some are not. We will use the term “reduced-wattage lamps” to refer to both types collectively. When referring specifically to lamps with improved efficacy, we will use the term “high-efficiency lamps.”

Replacing one type of lamp with another requires no physical effort. However, you have to be careful to select the replacement lamps properly. This Measure explains the factors that you should consider.

Applications and Alternatives

In retrofit applications, reduced-wattage lamps are most likely to be the best technique in cases where illumination is slightly excessive and lighting requirements are uniform. This situation is found in public spaces, such as corridors and cafeterias, and in large, open spaces with tall ceilings, such as auditoriums.

Reduced-wattage fluorescent lamps typically reduce power consumption by 15 to 20 percent. They may also reduce lighting levels up to 20 percent. More efficient models may retain original lighting levels while reducing power consumption by a lesser amount.

If the spaces have a substantial excess of illumination, reduced-wattage lamps are not the appropriate way to reduce lighting levels. You can easily achieve bigger reductions in energy consumption by delamping (Measures 9.2.1 ff), while improving lighting patterns. Other Measures, such as dimming (Measure 9.2.6) and overall layout changes (Subsection 9.6), may provide even larger reductions in lighting energy.

The next stage in improving efficiency is operating high-efficiency lamps with high-efficiency ballasts. This may require different lamps than the higher-efficiency lamps used with older ballasts. See Measure 9.2.4 about upgrading ballasts. You should decide at the outset

SUMMARY

Reduces lamp wattage up to 20 percent, and may improve efficiency. There are many selection issues, and some pitfalls. Backsliding is a challenge.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

whether to upgrade the lamps alone, or to replace the lamps and ballasts as a matched system.

Higher Efficiency or Just Lower Wattage?

Some replacement lamps are more efficient, so they can maintain the original light output at the lower wattage. Other replacement lamps have about the same efficacy as the older types, or less, so they reduce light output in proportion to the power reduction.

High-efficiency types are considerably more expensive than other reduced-wattage lamps. In retrofit applications, you need true “high-efficiency” lamps only in the relatively uncommon cases where present light levels are just barely adequate. Or, you may want them in some specialized applications for their superior color characteristics.

All or Nothing

Try to make an all-or-nothing decision about using reduced-wattage lamps. Reduced-wattage lamps have the same appearance as conventional lamps, so keeping both types in stock invites putting the wrong lamps in fixtures. It also increases the bother of ordering and storage.

Furthermore, reduced-wattage lamps are offered in different colors than conventional lamps. Occupants will notice the difference in lamp color if fixtures with different lamp types are within sight of each other.

How to Select Replacement Lamps

See Reference Note 52, Comparative Light Source Characteristics, for the criteria that may be important in selecting lamps for a given application. Also, review Reference Note 55, Fluorescent Lighting, which explains

the factors that determine fluorescent lamp efficiency. Then, for each type of lamp that you need, study the catalogs for the following selection factors.

■ Ballast Compatibility

Check the ballast's specifications for the types of lamps that it is designed to drive. This information is found in lighting supply catalogs. If a ballast is fairly new, the types of lamps it drives may be printed on the ballast.

There are many types of lamps and ballasts, and the number is increasing rapidly. If a lamp is connected to the wrong ballast, efficiency always suffers. Lamp life and light output may also be reduced. If your existing ballasts are not appropriate for the kind of lamps you want to install, you may be able to find another type of lamp that achieves your purpose. Alternatively, you could change the ballasts, which gives you an unlimited choice of lamps. This is an expensive step, but it is often profitable. See [Measure 9.2.4](#) if you take that path.

Make sure that the lamps you select are compatible with these characteristics of the ballasts:

- **current rating**
- **number of tubes**
- **filament connections.** This is usually determined by the socket type, so it is usually not expressed.
- **starting method.** This may be expressed by the terms "instant-start," "rapid-start," "preheat," or "trigger-start."
- **starting voltage.** This may be higher than the operating voltage. For example, a lamp may need a higher starting voltage if it is located in a cold location. The higher starting voltage may be expressed as a temperature rating, or in other ways.

If the ballasts are electronic or a hybrid type, you need to check additional compatibility issues, including:

- **the frequency of power supplied by the ballast.** Electronic ballasts operate the tube at a frequency that is much higher than line frequency. Most tubes can tolerate the higher frequency, even though this is not stated.
- **dimming provisions,** if the ballast has dimming capability. Not all fluorescent tubes operate properly with all dimming ballasts.
- **filament switching.** Electronic and hybrid ballasts usually turn off the filament after the lamp has started.

For example, most high-efficiency tubes require a specialized ballast to operate properly. Also, the new T8 series of lamps are not suited to any ballasts for T12 lamps, even though they fit in the original sockets.

If the ballasts were installed before 1979, it is not prudent to install any kind of reduced-wattage lamp with them. Experience has shown that reduced-wattage lamps hasten the failure of older ballasts, and that they use an increased amount of power while doing so.

Unless the ballasts have a high power factor, reduced-wattage lamps may be difficult to start, or they may operate in an unstable manner.

■ Wattage

For each lamp configuration, there may be a range of wattages. For example, 4-foot tubes typically are available in 40-watt, 34-watt, and 32-watt families.

■ Lumen Output

Lumen output can vary widely for a given wattage. For example, one manufacturer offers 34-watt, 4-foot rapid-start lamps with lumen outputs ranging from 1,900 lumens to 2,900 lumens. With a range this wide, the wrong lamp selection will make a space too dark if the original light level is marginal.

Take into account the normal degradation of light output as the lamp ages. Select the lamps to provide satisfactory illumination at the end of the service life. Fluorescent lamps may lose from 10 to 40 percent of their light output with age. High-efficiency lamps with the newer types of phosphors have substantially less lumen loss than older types.

■ Combined Lamp-and-Ballast Efficiency

The efficiency and light output of lamps are affected by the ballasts that drive them, so try to look up the efficiencies of the particular lamp and ballast combinations you are considering. If this information is not readily available, it is worth making a call to the lamp and ballast manufacturers to see if they have the figures. For any given ballast, the "lumens per watt" rating of the lamp provides an approximate indication of relative performance. If only the lumen rating of the lamp is given, you can estimate its efficacy by dividing the lumen output rating by the wattage rating.

■ Filament Operation

Some rapid-start lamps save energy with internal switches that turn off the filaments after the lamp starts. The switch is a simple bimetal contact that is kept open by the warmth of lamp operation. A disadvantage of this feature is that the bimetal contact may take up to a minute to cool after the lamp is turned off, preventing restarting for that period of time.

Turning off the filaments of rapid-start lamps can be done externally by hybrid ballasts and by some electronic ballasts. If you are going to upgrade ballasts (see [Measure 9.2.4](#)), it is generally better to let the new ballasts perform this function.

■ Color Characteristics

In fluorescent lamps, efficacy and cost increase along with color rendering because all three are related to the composition of the phosphors.

The color of older fluorescent lamps was commonly described by colloquial terms, such as "cool white," "warm white," and "daylight." Newer models of fluorescent lamps for general lighting designate lamp

color by “color temperature.” The current versions of older types still carry the old color descriptions, and any lamp may have a promotional name that implies a color.

For an explanation of lamp color in general, refer to “Color Rendering Index” and “Lamp Color” in [Reference Note 52](#), Comparative Light Source Characteristics. For specifics about fluorescent lamp color, see [Reference Note 55](#).

■ Lamp Life

Lamp life is not a factor in efficiency, but it is a major factor in labor and lamp cost.

Catalog specifications typically show little or no difference between the lives of different lamps within a family. For example, one major manufacturer rates virtually all of its 4-foot rapid-start lamps at 20,000 hours. However, experience has shown that some reduced-wattage lamps fail well short of their rated service lives. This fact makes it worthwhile to ask major lamp users about their experience with the types of lamps you are considering.

■ Voltage Sensitivity

Fluorescent lamps turn on and off with each cycle of the alternating current. Reduced-wattage lamps contain less of the gases needed to aid starting, so they require higher voltage to start. This means that the lamp turns on close to the voltage peak of each cycle of alternating current. If the supply voltage is reduced, the lamp may flicker or fail to operate. Therefore, avoid reduced-wattage lamps in areas where brownouts or voltage fluctuations are common.

There is an exception. Some electronic ballasts compensate for voltage fluctuations. However, if you are upgrading older types of lamps, it is unlikely that these ballasts are installed. By the same token, this would be an argument for upgrading the ballasts.

■ Starting and Operating Temperatures

Conventional indoor fluorescent lamps usually are rated with a minimum temperature of 50°F, but high-efficiency types usually are rated at 60°F. Again, this is related to the lower gas density inside the lamps. Temperature ratings are not sharp cutoff limits, but stability, light output, and efficacy diminish rapidly below the rated temperatures. You are asking for trouble if you install reduced-wattage lamps in spaces that operate below normal room temperature.

■ Cost

There is a large range of prices among fluorescent lamps of a given shape, and some of the newer high-efficiency lamps are quite expensive. It is pointless to pay high prices for high light output or outstanding color rendering if you do not need these characteristics.

Factors other than performance affect lamp cost. For example, curved tubes are more expensive than comparable straight tubes. As a rule, the most common lamp sizes are the least expensive, usually by a wide margin.

Label Your Fixtures to Prevent Backsliding

When a reduced-wattage tube burns out, it may be replaced incorrectly with any lamp that fits the same socket, unless you use effective measures to prevent this. The most effective method is to label each fixture with the correct tube type. See [Measure 9.7.3](#) for guidance in fixture labeling.

It helps if you can standardize on a particular type of tube for the entire facility. This lets you establish a purchasing policy that restricts tube purchases to the proper type. However, a fluorescent lamp may last ten years, and administrative policies rarely survive so long.

ECONOMICS

SAVINGS POTENTIAL: 10 to 20 percent of lamp energy.

COST: Reduced-wattage lamps have a cost premium of \$1 to \$5 apiece, depending on efficacy and color quality. In retrofit installations, planning and installation costs \$0.50 to \$5.00 per fixture, depending on labor rates and accessibility.

PAYBACK PERIOD: One year, to several years, for typical workday operating schedules.

TRAPS & TRICKS

CHOICE OF METHOD: Use this approach only if it is appropriate for the environment, namely, if lighting levels are uniformly and only moderately excessive. This Measure is not a substitute for careful delamping, or for careful fixture selection and placement.

SELECTING THE LAMPS: Take the trouble to find the proper types of lamps for the existing ballasts. A mismatch will save little or no energy, while reducing light output excessively and possibly shortening equipment life. Check the ballasts in all the fixtures where you plan to change lamp types. After you have identified your candidate lamp type, check with other users who have operated the lamps with your type of ballasts for at least one life cycle.

FIXTURE LABELING: As sure as the sun rises, if you fail to label the fixtures with the types of lamps to be installed, the wrong type will be installed within a few years.

MEASURE 9.2.4 Replace ballasts with high-efficiency or reduced-wattage types, or upgrade ballasts and lamps together.

The efficiency of fluorescent ballasts improved considerably between the 1970's and the 1990's. In new construction, it usually pays to install high-efficiency ballasts. Ballast efficiency has a large price premium, but the energy consumed by the ballasts and the lamps costs much more than the ballast itself. You need high-efficiency ballasts to get the most efficiency from lamps, and to be able to use the most efficient types of lamps. Also, high-efficiency ballasts offer a variety of other advantages.

Ballasts have several functions in fluorescent lighting. They regulate lamp current, which is necessary because an operating fluorescent lamp has minimal electrical resistance. They increase the supplied voltage for starting. And, some types of electronic ballasts provide dimming capability.

Electronic ballasts are the most efficient type. They have only about 25% of the internal losses of older magnetic ballasts. In addition, electronic ballasts improve the efficiency of the lamps themselves by about 10%. An optimum combination of ballast and lamp types may improve lighting efficiency by as much as 30%, compared to older fluorescent lighting.

Some reduced-wattage ballasts do not have particularly high efficiency. They save energy by reducing the power input to the lamps. Such ballasts reduce light output roughly in proportion to the reduction in power. These ballasts are limited to retrofit applications as a means of reducing excess lighting.

Upgrade Ballasts, Lamps, or Both?

If you are upgrading existing fluorescent lighting, you have to make a big decision at the outset. The ballast type you select will limit your ability to make further improvements in the future. The limitation is compatibility between ballasts and lamps. You have to decide whether to install high-efficiency ballasts that are compatible with your existing types of lamps, or to install a matched combination of new ballasts and lamps.

As a matter of comparison, upgrading ballasts alone provides roughly the same magnitude of savings as upgrading lamps alone, as recommended by [Measure 9.2.3](#). As with lamp replacement, ballast replacement can provide a simple reduction of wattage, or an improvement in lumens-per-watt efficiency, or both. However, upgrading ballasts is much more expensive than upgrading lamps.

Then, why would you want to install upgraded ballasts, while continuing to use an old type of lamp? Two major reasons are reliability and long-term lamp cost. The older lamps are less sensitive to voltage

SUMMARY

A major equipment change involving many selection issues. Select ballasts and lamps for compatibility. Beware of ballast and lamp reliability problems.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

fluctuations and to low temperature, and they seem to last longer in typical usage. Also, the older lamps are much less expensive, primarily because the old phosphors are less expensive than the tri-phosphors of high-efficiency lamps. The cost difference is a significant factor over the life of the facility. Thus, using high-efficiency ballasts with older lamps may be a rational choice.

This approach lets you phase in high-efficiency ballasts as replacements for older ballasts that fail. However, ballast life is so long that this approach produces savings at a snail's pace.

If you decide to take this course, you may not be able to upgrade later to lamps of higher efficiency. This is because high-efficiency ballasts that are optimized for older tubes are not optimized for newer high-efficiency tubes. For example, ballasts designed to drive T12 tubes will not drive T8 tubes at all. Even if the ballast works with a high-efficiency T12 tube, there may be a serious loss of performance.

If you want to upgrade both ballasts and tubes, the proper course is to select high-efficiency ballasts and high-efficiency tubes that are specifically matched to each other. Until recently, ensuring compatibility between high-efficiency lamps and ballasts was an uncertain matter because the development of lamps and ballasts proceeded almost independently of each other.

At the present time, the new T8 lamp system appears to be the only system rationally designed for maximum overall efficiency in fluorescent fixtures of conventional type. You can get T8 lamps in a variety of lamp sizes that correspond to the most common types of T12 lamps. T8 lamps fit conventional T12 lampholders, so you can retrofit lamps and ballasts in existing fixtures without too much trouble. See Figure 1.

It also appears that T8 lamps, when operated with ballasts designed for them, are less prone to the temperamental performance that afflicts other high-efficiency lamps. However, it is still too early to judge the long-term performance of this system.

If you consider replacing both lamps and ballasts, do not limit your choices to the old fashioned lamp shapes. Consider the new possibilities that compact fluorescent lamps provide. These lamps are available in smaller wattages that allow you to tailor lighting energy to small task areas. Also, the small physical size of the lamps may allow you to provide more efficient light distribution. See Figure 2.

Compact fluorescent lamps have major potential for task lighting, which cannot be done well with large fluorescent lamps. See [Measure 9.6.2](#) about this.

However, compact fluorescent lamps are not as efficient, in terms of lumens per watt, as the larger conventional lamps. We do not know how good they really are. Manufacturers remain coy about their actual efficiency, resorting to the word “nominal” in the specifications.

They are an evolving type. They have not been in the field long enough to establish a reliable record of actual service life. Too many new shapes and base types

are coming on the market for all of them to remain in service over the long term.

Retrofit Applications and Alternatives

High-efficiency ballasts, or combinations of high-efficiency ballasts and lamps, provide approximately the same lighting levels as older equipment, but use less energy. Therefore, this Measure is appropriate for retrofit if present lighting levels are about right.

If the spaces have a substantial excess of illumination, consider other Measures, perhaps in combination with this one. For reductions in wattage and light output, but without improved efficiency, consider current limiters ([Measure 9.2.5](#), next). Note that current limiters are compatible only with magnetic ballasts. Bigger reductions in energy consumption can be made at lower cost by delamping ([Measures 9.2.1 ff](#)), while providing an opportunity to optimize lighting patterns. Other Measures, such as dimming ([Measure 9.2.6](#)) and overall layout changes ([Subsection 9.6](#)) also provide large reductions in lighting energy.

Types of Reduced-Wattage Ballasts

Reduced-wattage ballasts and “high-efficiency” ballasts are available both in the original magnetic type

Osram Sylvania Inc.

Fig. 1 T8 lamps These lamps have high efficiency and very good color rendering. They fit in the same fixture dimensions as the most common older lamps, but they are not interchangeable with the older lamps. Consider these along with high-efficiency ballasts.

and in the newer electronic types. In addition, a hybrid type has been developed that combines features of the two. The following are the main features of reduced-wattage and high-efficiency ballasts.

■ Reduced-Wattage Magnetic Ballasts

The energy consumption of a conventional magnetic ballast can be reduced simply by designing it to deliver less current to the lamp. This does not by itself change the efficiency of the ballast. In fact, this approach is less efficient overall because the ballast and lamp losses do not decline with lamp current. In the U.S., reduced-wattage ballasts that do not offer an efficiency improvement are being forced off the market by recently enacted efficiency standards.

The efficiency of magnetic ballasts has been increased by a number of improvements that are explained in [Reference Note 55](#), Fluorescent Lighting. High-efficiency versions of conventional ballasts eliminate about 40-50 percent of the losses of older magnetic ballasts. In a typical ballast for two 40-watt tubes, this amounts to a saving of about 8 watts.

The description “high efficiency” does not have a quantitative meaning as it applies to ballasts. The efficiency advantage of improved conventional ballasts may differ substantially from one manufacturer to another, or from one model to another.

High-efficiency magnetic ballasts generate less internal heat, so they operate at a lower temperature and they promise longer life. It remains to be seen whether they will deliver on this promise.

■ Electronic Ballasts

The efficiency of electronic components gives electronic ballasts inherently higher efficiencies than magnetic ballasts. There are significant differences in efficiency among electronic ballasts, but the less efficient units have already demonstrated low reliability and have largely died out.

(The ballasts in compact fluorescent fixtures are an exception, with junk units surviving on the basis of cheapness, largely in residential sales. Subsidies by electric utility companies keep this junk on the market because the homeowner whose unit fails after a few hours of operation has little incentive to take it back to the store. This is a lesson in why centrally planned, third-party programs of any kind tend to fail.)

The best electronic ballasts consume about one fourth as much energy as older magnetic ballasts. For example, an electronic ballast driving two 40-watt tubes dissipates about 5 watts, in contrast with losses of about 20 watts for the older ballast.

Virtually all electronic ballasts create alternating current at high frequency (over 20 KHz) to drive the

Osram Sylvania Inc.

Fig. 2 Compact fluorescent lamps These are available in smaller wattages than common conventional lamps. Their small physical size allows them to concentrate light on small task areas, and they can be mounted in aiming fixtures. For these reasons, they hold the key to using fluorescent lighting in task lighting. However, they are less efficient, per watt, than the larger lamp styles. The emerging multitude of lamp wattages and base types is creating a future standardization problem that will probably cause many of the present types to become obsolete.

lamps. This improves the efficiency of the lamps themselves by about 10 percent, for reasons explained in [Reference Note 55](#).

Electronic ballasts usually are designed to reduce their input power to maintain approximately the same light output as with a conventional magnetic ballast. Thus, for example, retrofitting electronic ballasts to an older fixture with two 40-watt tubes may save about 23 watts, while retaining the same light level.

■ Hybrid Ballasts

“Hybrid” ballasts are magnetic ballasts that include an automatic switch to turn off the filaments of rapid-start lamps after the lamp starts. The switching feature saves about 2 watts per lamp.

Major ballast manufacturers base their hybrid units on magnetic ballasts whose efficiency has been substantially improved over earlier models. Therefore, hybrid ballasts typically reduce overall energy consumption by about 10 percent compared to older magnetic ballasts.

Like standard magnetic ballasts, hybrid ballasts can operate reduced-wattage lamps as well as standard lamps. Thus, hybrid ballasts combined with reduced-wattage lamps may lower energy input to almost the same levels as some electronic ballasts operating with standard lamps. However, the lumen-per-watt efficacy is not as high.

How to Select Ballasts

Once you decide whether to seek high efficiency, reduced wattage, or both, you need to select the specific equipment. There is a fairly large number of factors to consider, although some of them may not be important to a particular application. You can get information about the factors that matter in most applications from the ballast catalogs.

■ Compatible Lamp Types

As we discussed before, the need for compatibility forces you to decide what kind of lamps you plan to use in the future. Some of the more sophisticated electronic ballasts adjust themselves to drive a broad range of lamps, including conventional, high-efficiency, and reduced-wattage types. Such ballasts allow you to keep using your original type of lamps with the option of possibly upgrading lamp efficiency in the future. However, the range of lamp options is still limited. For example, do not expect to find a ballast that will drive both T12 and T8 lamps.

■ Wattage Input

The wattage input of the ballast and lamp combination is the bottom line in terms of energy consumption, but it does not indicate efficiency. A ballast may have different wattage input when driving different types of lamps.

Reduced-wattage ballasts may reduce input power by as much as 20%. In principle, ballasts could be designed for much larger reductions in input power, by reducing light output also. However, the major manufacturers do not produce such ballasts. They would make no sense in new construction, and would be too expensive as retrofit devices. If you want larger reductions in wattage and light output than reduced-wattage ballasts provide, you can add current limiters to the present ballasts (see [Measure 9.2.5](#)).

In the past, the wattage input was the criterion that you would select to tailor the light output of the lamp and ballast combination to the application. Now, a better approach is to use “ballast factor,” which we discuss next.

■ Ballast Factor

“Ballast factor” is a measure of light output. Ballast factor is a comparison of the light output of a particular ballast when it is driving a standard lamp, compared to the light output of the same lamp when driven by an ANSI standard ballast. The ballast factor is expressed as a ratio. When a ballast drives a lamp to the “standard” output, the ballast factor is 1.0.

Ballast factor is now routinely specified in ballast catalogs. Use it as your starting point in “fine tuning” the light output to the application, after you have selected the proper number and size of lamps. If you don’t pay attention to ballast factor, you may get a nasty surprise when you check light levels. You may get much more light than you expect, or much less.

Most ballasts have a ballast factor less than 1.0. “Normal” ballasts have ballast factors in the range of 0.85 to 1.0. In new construction, the ballast factor should fall within this range if the lighting has been designed properly.

Some ballasts are available with exceptionally low ballast factors, as low as 0.7. These are used specifically to reduce power consumption. Ballasts that have an exceptionally low ballast factor may be labeled as “energy saving.” However, note that the ballast factor does not indicate efficiency, only light output. To know relative efficiency, you have to divide the light output (measured in lumens) by the energy input (measured in watts).

For an efficient installation, you need to do two things together. Select the ballast factor and the lamp to provide the proper light output for the application. At the same time, look for a combination of lamp and ballast that gives you the lowest energy input for the light output you desire.

You can also find ballasts that have ballast factors higher than 1.0, even as high as 1.3. These are intended to increase light output. Exceptionally low and exceptionally high ballast factors are likely to reduce overall efficiency. They are used primarily in retrofit applications, where changing the ballast factor is the

most efficient and economical way to adjust the illumination level of existing fixtures.

If you are upgrading both lamp and ballast efficiency in an existing facility where the illumination level is correct for the application, you will want a ballast with a lower ballast factor. This is to take advantage of the higher efficiency of the new lamps. For example, if you are upgrading from old T12 lamps to the newer T8 lamps, the new ballasts will have a lower ballast factor to take advantage of the higher efficiency of the T8 lamps. Calculate the new ballast factor that you need from the relative efficiency of the old lamps and the new lamps.

■ Efficiency

Strictly speaking, the efficiency of a ballast alone cannot be stated, because the characteristics of a ballast depend on the lamp to which it is connected, and vice versa. Therefore, look for the efficiencies of the lamp-and-ballast combinations that you are considering. This information may be easy to find for common combinations. If you cannot find the information in the catalogs, contact the ballast manufacturer's engineering department.

Lamps and ballasts are not made by the same companies. It is usually better to call the ballast manufacturer than the lamp manufacturer, because the ballast is subject to more variations in efficiency, compatibility, and other features than the lamp.

"Ballast efficiency factor" (BEF) is a rating that was developed to provide a standard baseline for ballast efficiency. It is defined as the ballast factor divided by the ballast input wattage. Ballast efficiency factor is specified in some laws that require minimum ballast efficiency. It is intended primarily for ballast manufacturers. Unfortunately, it is awkward for ballast purchasers to use as a criterion because the rating numbers indicate relative performance only within individual lamp families corresponding to the ANSI standard ballasts. You would have to do some arithmetic to compare BEF's between lamp families. Furthermore, it does not tell you the efficiency of an existing ballast when retrofitted with newer types of lamps.

■ How the Lamps are Connected to the Ballast

Magnetic ballasts are available to drive either one or two lamps. At present, electronic ballasts are available to drive from one to four lamps. In fixtures with more than two lamps, using a single electronic ballast to drive all the lamps partially compensates for the higher cost of electronic ballasts.

If a magnetic ballast is designed to drive two lamps, it drives the lamps in series. Therefore, if one lamp fails, the other lamp cannot operate properly, either. In contrast, electronic ballasts may (or may not) drive lamps in parallel. With parallel ballasts, if one lamp fails, the other lamp or lamps continue to operate normally.

■ Lamp Current Frequency

This is basically a choice between magnetic and electronic ballasts. Magnetic and hybrid ballasts drive lamps at line frequency. Electronic ballasts drive lamps at high frequencies, above 20 KHz. High frequency improves lamp efficacy about 10%, but it may cause electronic noise problems, as explained below.

■ Filament Operation

The filaments of rapid-start and preheat lamps may be operated in different ways by different ballasts, affecting efficiency, lamp life, and starting characteristics. The three basic modes of operation are:

- *leaving the filaments heated continuously*, which is the conventional mode of operation for "rapid-start" lamps
- *providing no heating power for the filaments*, and starting the lamps solely by using higher voltage. This is the normal mode of operation for "instant-start" lamps. Some magnetic and electronic ballasts operate "rapid-start" and "preheat" lamps in this manner. This saves filament operating energy. Ironically, this mode of operation reduces filament life, sometimes drastically. The reason is that most loss of filament material is caused by the high electric field that exists during starting. According to industry figures, about 25% of service life is lost with 3-hour starting cycles. The loss in lamp life is proportional to the number of starting cycles. Ballasts that operate this way are most suitable for applications where the fixtures operate for long durations, as in corridor lighting.
- *operating the filaments only for starting*. This mode of operation eliminates most filament energy consumption and preserves lamp life. It is available with hybrid ballasts and some electronic ballasts.

The bare catalog data may not be clear about the specific mode of filament operation. In case of doubt, call the manufacturer.

■ Dimming Capability

Some types of electronic ballasts are capable of dimming the lamps by varying the lamp current. They have input connections that allow them to be controlled by a variety of lighting level controllers. Refer to [Measure 9.2.6](#) about fluorescent dimming.

Various types of add-on controls provide limited dimming capability with non-dimming magnetic and electronic ballasts by varying the primary voltage to the ballast. Most such arrangements create unsatisfactory lighting, and all are now outdated.

■ Crest Factor

"Crest factor" is the ratio of the peak lamp current produced by the ballast to the average lamp current. High crest factor implies high peak current, which hastens the loss of the emissive material on the lamp electrodes. This loss reduces lamp efficiency and service

life. Crest factor is not a commonly published rating for fluorescent ballasts, but if you find it, give preference to low numbers.

■ Lamp Starting Temperature

All fluorescent lamps suffer serious loss of light output and efficacy when they operate much below rated temperature (about 100°F at the lamp surface), although they may continue to operate weakly at much lower temperatures. If lamps in cold environments are well enclosed, they may operate adequately. However, getting them started may require special low-temperature ballasts.

The nominal starting temperature is 50°F for most conventional lamps, and 60°F for reduced-wattage lamps. The newest types of compact fluorescent lamps are designed to start at lower temperatures, some as low as 32°F (0°C).

■ Acoustical Noise

The cores of magnetic ballasts are made of thin metal laminations to minimize eddy currents. These laminations want to respond to the 60 Hz magnetic field like the voice coil of a loudspeaker. Magnetic ballasts all have a certain amount of hum, and it is easy for them to become abnormally noisy.

Some electronic ballasts have large filtering inductors that generate noise in the same way. Furthermore, any device driven by alternating current may find ways to vibrate.

Good ballasts typically have an “A” noise rating. Sound covers a broad frequency spectrum, and human hearing response varies widely with frequency, so it is not possible to characterize noise output with a single rating. Therefore, noise ratings are defined in several ways. If ballast noise could be important in your facility, check the manufacturers’ technical literature for details.

■ Power Factor

See [Reference Note 21](#) for an explanation of power factor. Many electric utilities impose a penalty for low power factor. Therefore, power factor may be an issue if lighting comprises a large part of the facility’s electrical load. Low power factor can also cause overloading of circuits.

Low power factor is a problem primarily with magnetic ballasts, since they are essentially big inductors. The power factor in magnetic ballasts can be improved by adding a large capacitor in series with the coil. Power factor is generally not a problem with electronic ballasts, because they do not use the inductive principle to control current. Both types of ballasts are available with power factors better than 90%.

■ Radiated Electromagnetic Noise

Electronic ballasts radiate electromagnetic noise that may interfere with communications equipment and other electronic apparatus. The reason why they have this bad habit is that electromagnetic radiation is emitted

more easily at the high frequencies at which electronic ballasts operate. Another reason is that electronic equipment is more susceptible to interference at these frequencies.

Both the fixture wiring and the lamps themselves act as transmitting antennas. If the metal case of the fixture is properly designed, not much radiation escapes from it. However, the arc in the lamp acts as an antenna, so the lamp can radiate through the plastic diffuser. In applications where electrical noise radiation is a potential problem, the radiation can be blocked by using lamps that have a transparent conductive coating, or by using fixtures that have a conductive, grounded coating on the diffusers. These solutions are expensive.

Even the best electronic ballasts may interfere with some electronic equipment. One problem is interference with some theft detection equipment made before 1992. The problem occurs in the vicinity of the checkout locations where scanners that operate on the same frequency as electronic ballasts search for tags on stolen merchandise. Electronic ballasts may also interfere with consumer electronics, such as audio and video equipment that has circuitry operating at similar frequencies. There may also be interference with power line carrier signals.

The problem of electromagnetic noise radiation from the wiring usually makes it impractical to install electronic ballasts remotely from the fixtures.

In the United States, electromagnetic interference from the ballast itself is governed by Federal Communications Commission Regulations, Part 18, Subpart J. “Class A” criteria apply to equipment intended for use in commercial environments. “Class B” criteria, which are more restrictive, apply to equipment intended for use in residential environments. In other words, Class B is better.

■ Harmonic Distortion

Ballasts do not absorb power evenly during each part of the input cycle of alternating current. As a result, they distort the waveform in the power wiring. This distortion is expressed as “harmonic distortion” because it can be described as multiples, or harmonics, of the input power frequency. Harmonic distortion can be viewed as low-frequency electrical noise that enters the power distribution system from the input end of the ballast.

Like power factor, harmonic distortion is a problem that concerns electric utilities. Third-harmonic distortion is especially troublesome in 3-phase electrical power distribution because it creates large return currents in the neutral leg, which normally carries little current and is smaller in capacity than the main phase wires.

Harmonic distortion also affects the internal wiring of the building. It causes inefficiency and overheating in motors, it interferes with power line carrier

communication, and it may interfere with electronic equipment that is connected to the same power system.

Electronic ballasts can cause the worst harmonic distortion. For this reason, electronic ballasts have input filters. However, low-frequency filtering is expensive and bulky, so lower-frequency distortion of the supply waveform still occurs.

Ballasts are now rated in terms of total harmonic distortion (THD). THD of 10% to 20% is presently typical. Some units have THD higher or lower than these figures. Magnetic ballasts typically have high THD, while electronic ballasts cover the range. The type of distortion differs between magnetic and electronic ballasts, and this difference is not revealed by the THD figure.

■ Reliability and Service Life

A magnetic ballast consists of little more than a coil of wire wrapped around a steel core and embedded in tar. If reasonably well made, a magnetic ballast can last forever. On the other hand, an electronic ballast is an active semiconductor device. While semiconductors may last a long time, they have a finite service life. Thermal cycling, when the lamp turns on and off, causes failures. Also, semiconductors are vulnerable to voltage spikes in the electrical power system that may occur for a variety of reasons.

High-efficiency ballasts have not enjoyed a good reliability history overall. The design of electronic power handling equipment is a compromise between reliability and cost, and many models err on the side of cheapness. Therefore, check with other users who have experience with a particular model before selecting it. In any event, expect to replace electronic ballasts on a continual but unpredictable basis.

Ballast Standards and Certification

In the United States, standards for ballasts are set by the American National Standards Institute (ANSI), but ballasts can be sold without meeting their standards. The Certified Ballast Manufacturers Association (CBM), an association of ballast manufacturers, has a program of certifying individual ballast models for compliance with ANSI standards. ANSI ballast standards specify various performance factors, including lamp output, reliable starting, ballast life, and preservation of lamp life.

An inherent problem in ballast certification is that the performance of a ballast depends on the lamp which it drives. For this reason, ANSI ballast testing is based on standard lamp types. ANSI or CBM certification may not provide useful guidance about performance with newer lamp types.

In the United States, a 1988 federal law established minimum ballast efficiencies for the most common types of ballasts, namely, those that drive:

- one or two F40/T12 lamps
- two F96/T12 lamps
- two F96/T12/HO lamps.

The efficiency requirements are expressed in terms of ballast efficacy factor (BEF), which is defined above.

Manufacturers may choose to certify other characteristics, such as electronic and acoustical noise output. Or, they may do so if requested by a potential purchaser.

Label the Fixtures

Label the fixtures with the lamp type, as explained in [Measure 9.7.3](#). This is especially important if the new ballasts are intended to be used with new types of lamps.

ECONOMICS

SAVINGS POTENTIAL: *Improved efficiency can save up to 4 watts per lamp with magnetic ballasts, up to 6 watts per lamp with hybrid ballasts, and up to 8 watts per lamp with electronic ballasts. Electronic ballasts also improve the efficacy of lamps by about 10%, usually reducing lamp power to maintain the same light output.*

Ballasts may be designed to reduce wattage input by reducing lamp current, without efficiency improvement, but major U.S. ballast manufacturers do not use this approach.

COST: *High-efficiency magnetic ballasts average about \$10 apiece, for two F40 tubes. Hybrid ballasts cost about \$15 apiece, for two F40 tubes. Good electronic ballasts cost from \$25 to \$45 apiece, for F40 tubes, depending on features. Installation labor costs \$3 to \$15 per fixture, depending on labor rates and accessibility. Refer to [Measure 9.2.3](#) for lamp replacement cost.*

PAYBACK PERIOD: *Several years, or longer.*

TRAPS & TRICKS

CHOOSING THIS APPROACH: *This is one of the most expensive lighting modifications you can make. Don't do it until you have planned your lighting configuration to eliminate excess fixtures and lamps.*

SELECTING THE EQUIPMENT: *At the present time, you need to decide whether to use T8 lamps, because these require ballasts that are designed especially for them. If you want to continue using the less expensive T12 lamps, you can protect your options by selecting an electronic ballast that adapts to different lamp types. However, you will pay a premium for this flexibility. Check the performance of any type of ballast or lamp that you are considering. Reliability is still evolving, even among the major manufacturers, and there is a lot of cheap junk on the market.*

FIXTURE LABELING: *Be sure to label each fixture with the type of lamps that should be installed in it.*

MEASURE 9.2.5 Install current limiters.

A fluorescent current limiter is a coil that is installed in the secondary circuit of an existing magnetic ballast to reduce the lamp current. In effect, it is an extension of the coil in the ballast. Current limiters are smaller than ballasts, and there is usually plenty of room for them inside the fixture, but not always.

Current limiters reduce lamp wattage and light output by approximately equal amounts. Ballast losses are not affected significantly, so the overall efficiency of the lighting system is somewhat reduced. The current limiter itself incurs a small loss.

In principle, a current reducer can be designed to limit lamp current to any value up to the limit of stable lamp operation, which is about a 50% reduction for conventional lamps.

Applications and Alternatives

Current limiters fit into a narrow range of retrofit applications between delamping and reduced-wattage lamps. Current limiters have the field almost to themselves for providing power and light reductions in the range of 30% to 50%. Most units provide reductions in this range.

Delamping (Measure 9.2.1) may be an alternative to current limiters, depending on the number of tubes in each fixture, and the excess in the number of fixtures. Delamping is more efficient, much less expensive, and much simpler. For example, delamping a fixture with two ballasts provides a 50% power reduction, with a corresponding reduction of light output. This is about the same as the most aggressive current limiters. In fixtures that have more than four tubes, delamping can provide smaller percentage reductions in light output, e.g., by removing two tubes in a 6-tube fixture.

At the other extreme are reduced-wattage lamps (Measure 9.2.3) and reduced-wattage ballasts (Measure 9.2.4). These provide power reductions up to 20 percent, and some models improve lighting efficiency up to 20 percent. Reduced-wattage lamps are much cheaper and much easier to install than current limiters. Current limiters operate with lamps that are less expensive, but the break-even point is not reached until several sets of lamps have lived out their lives.

Reduced-wattage ballasts are more expensive, but the better models offer a significant improvement in efficiency, which current limiters do not. The labor cost for replacing ballasts is about the same as for installing current limiters, or somewhat less.

SUMMARY

Reduces wattage and light output 20 to 50 percent. Labor intensive. Use only with magnetic ballasts. Becoming an obsolete method.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

Ballast and Lamp Compatibility

Current limiters can be used only with magnetic ballasts, including high-efficiency models.

Current limiters should not be used with reduced-wattage lamps, which are too sensitive to reduced current.

Different models of current limiters are required for different families of lamps, depending on their lamp current and whether they have filaments to heat the electrodes.

Effect on Lamp and Ballast Life

Manufacturers of current limiters claim that the devices increase lamp and ballast life, and reduce lumen degradation. These claims seem credible. It is true that lumen degradation is proportional to lamp current. Also, ballast temperature is reduced by reducing the lamp current, and ballast temperature is the primary factor in ballast life.

On the other hand, there is concern that some current limiters may reduce filament life in rapid-start and preheat lamps. The current limiter is installed in a branch of the ballast wiring that powers one of the lamp filaments in addition to carrying the lamp current. The current limiter must include a feature, typically a transformer, to maintain full filament voltage in this circuit while reducing the lamp current. If this feature is not properly designed, the filament may burn out early.

How to Install Current Limiters

The current limiter is screwed to the sheetmetal of the light fixture, near the ballast. Then, the current limiter is wired into the secondary circuit of the ballast as explained in the instructions.

A potential problem is finding enough space to install the device inside the fixture. This is most likely in a fixture that has several ballasts. Install a unit on a trial basis before purchasing the units in quantity.

Performance Claims

No certification standards presently apply to current limiters, so be skeptical about manufacturers' performance claims. The devices are simple and legitimate, but not foolproof. Purchase them from a company that can refer you to customers who have had a long history of satisfactory experience.

ECONOMICS

SAVINGS POTENTIAL: Typically 30 percent of lamp energy.

COST: Current reducers cost about \$10 each. Installation costs \$3 to \$15 per fixture, depending on labor rates and accessibility.

PAYBACK PERIOD: One to five years.

TRAPS & TRICKS

CHOICE OF METHOD: Make sure that this Measure is the best approach for your situation. Remember that current limiters do not improve efficiency, but only reduce energy consumption at the expense of light output. They work only with magnetic ballasts. You may want to combine this Measure with delamping for tailoring light output in big increments.

PLANNING: Approach this Measure with the same thorough planning described in [Measure 9.2.1](#).

SELECTING THE EQUIPMENT: Current limiters are not a mainstream product, so you will have trouble getting credible information about how they perform. First, ask vendors for references, and talk with purchasers who have used the units for several years. Before buying quantity, test a few units in typical fixtures. Use a light meter to measure the effect on light output, and use a wattmeter to measure the reduction of input power.

EXPLAIN THEM: The purpose of the current limiters will not be obvious to maintenance personnel who have to work on the fixtures later. Therefore, label the fixtures where current limiters are installed, explaining their purpose.

MEASURE 9.2.6 Install fluorescent dimming equipment.

Dimming of fluorescent lighting without serious performance penalties became a practical reality during the 1990's. The price of satisfactory dimming equipment is still high, but it continues to fall as the equipment becomes more common and competition increases.

The market is still evolving. Many types have been put on the market. Manufacturers have failed to survive, leaving owners with orphaned equipment. Fluorescent dimming remains a pioneering activity that demands study to develop an optimum system and to minimize the chance of failure.

Where to Consider Fluorescent Dimming

There are several broad categories of applications where fluorescent dimming offers important capability:

- **exploiting daylighting.** Dimming is a major breakthrough for daylighting because it adjusts the fluorescent lighting level smoothly and continuously to complement daylighting. A less expensive alternative is using ordinary photoelectric switching to control the number of lighted tubes in response to daylight (see [Measure 9.5.3](#)). However, switching lamps creates abrupt changes in lighting that may annoy occupants.
- **other applications that benefit from a gradual change of lighting level.** In lavish environments, smooth transitions in lighting level are considered more elegant than stepped switching. In dark environments, such as movie theaters, dimming the lights gradually avoids the sensation of being plunged into darkness. In the past, such environments would have installed incandescent lighting and older, less efficient types of dimmers.
- **applications that benefit from fine adjustment of lighting level.** An example is changing the lighting level in restaurants and bars from day to night. Alternatives are stepped switching and installing separate fixtures for each lighting level.
- **where a high turndown ratio is needed.** The best fluorescent dimming equipment can reduce lighting levels to a few percent of maximum levels. Dimming is the only way to achieve such a large range without installing separate types of fixtures for low-level lighting. However, installing separate fixtures to handle low lighting levels is usually the best approach.
- **where dimming is needed with color stability.** In contrast with dimming incandescent lamps, dimming fluorescent lamps produces little color change. This is because the color of fluorescent

SUMMARY

Adjusts wattage and lighting levels over a wide range. Makes daylighting practical, but is expensive overkill in many other applications. Does not eliminate the need to customize control for each space. The best equipment is fairly efficient. Reliability is still in doubt.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

light is determined primarily by the composition of the lamp's phosphors and gases, which are constant factors. Color stability is most likely to be important in technical applications involving photography or video recording.

Other Ways of Changing Lighting Level

In principle, you could use dimming equipment for most applications that need variable lighting level. However, dimming is not always the best approach. Fluorescent dimming is expensive. It also reduces lamp efficiency, especially at low settings. The least expensive method of changing fluorescent lighting level is switching individual lamps. Measures in [Subsections 9.4 through 9.6](#) recommend various ways of accomplishing this.

Turndown Ratio and Efficiency

The turndown ratio of a dimming system is the ratio of the maximum lighting level to the minimum lighting level. A high turndown ratio is essential to economic success, because the high initial cost of the dimming equipment can be justified only in applications where the average lighting power is much lower than the maximum.

Typical electronic fluorescent dimmers provide turndown to about 20% of full light output with good stability. Some dimmers claim to turn down as low as 1% of full light output. However, the fine print for these units states outlandish requirements to achieve this extreme turndown, such as aging new lamps for 100 hours at full output.

Manufacturers claim that electronic ballasts maintain full lumens-per-watt efficiency down to about 50% of full output, and that efficiency suffers only modestly below that point. However, the technology is new, standards are not established, and there is little independent testing to deter manufacturers from fudging their claims.

How Fluorescent Dimming Works

Fluorescent dimming works by varying the lamp current. Doing this while maintaining stable lamp operation and good energy efficiency is the technical challenge that obstructed fluorescent dimming until electronic ballasts appeared.

To understand the problem, recognize that fluorescent lamps turn on and off with each half cycle of the alternating supply current. At the beginning of each half cycle, the ballast must provide sufficient voltage to restart the lamp.

With magnetic ballasts, the voltage supplied to the lamp has a fixed relationship to the current limiting characteristics of the ballast. The ballast voltage is designed for cold starting, so it has a certain amount of excess voltage for restarting the lamp each half cycle when it is warm. The first types of magnetic ballast dimmers exploited this voltage margin by reducing the ballast voltage once the lamp started. However, larger reductions of voltage and current pushed beyond the stability range of the lamps, making them operate inefficiently and giving the lamp a wavering, defective appearance.

The development of electronic ballasts was a breakthrough for fluorescent dimming because electronic ballasts can be designed to adjust voltage and current separately. The ballast feeds current to the lamps in controlled pulses. The circuitry of electronic ballasts can be designed so that the appropriate starting voltage is applied with each cycle, or pulse, of lamp current.

Electronic ballasts also keep the mercury arc stable because they provide power to the lamps at high frequencies, above 20 KHz. The mercury vapor in the lamps remains partially ionized during the much shorter off cycles, so the arc does not wander and the flow of current resumes easily.

Modern Dimming Equipment

The first fully satisfactory types of fluorescent dimming equipment started to appear on the market in the early 1990's. Earlier types of fluorescent dimming equipment, based on either magnetic or electronic ballasts, are now outmoded.

Good dimming requires control of the lamp current from within the ballast. Some early types of dimming

systems attempted to minimize cost and simplify installation by controlling the primary power to existing ballasts, both magnetic and electronic, but this method did not yield a good turndown ratio.

A modern fluorescent dimming system has two basic elements. The heart of the system is an electronic ballast that is designed specifically for dimming control. The other element is control of the light level by one or more control devices that are located outside the fixture where the need for lighting can be sensed or adjusted.

■ Light Level Controllers

Dimming systems that are based on controlled electronic ballasts have essentially unlimited control flexibility. Any device that generates a compatible control signal (e.g., a standard 4-to-20 milliamp analog signal) can be used to control the ballast output. Standard lighting control devices for use with controllable ballasts are becoming increasingly available.

A variety of specialized lighting control devices are presently available from established manufacturers of lighting equipment. These include manual dimmers (that you can get to coordinate in appearance with other light switches), light level sensors, motion sensors, time controls for programming lighting levels, etc.

Equipment Selection Factors

The dimming electronic ballast is the critical element in a fluorescent dimming system. The selection factors for dimming ballasts are the same as for other electronic ballasts. Refer to [Measure 9.2.4](#) for these factors. In addition, turndown ratio is an important characteristic. The ballast should produce its minimum light output without discernible flickering, sensitivity to voltage fluctuations, or other instability.

Install Effective Light Level Controls

A dimming system will not provide its potential energy savings unless it is controlled to keep lamp output at the minimum needed under all circumstances. Without effective control, a dimming system is just an expensive frill. For example, if the light level is set with manual slider switches in a space where people have no reason to minimize lighting levels, the sliders may be left in any position, and most likely will tend to stay near maximum output.

As with other aspects of lighting, lay out the dimming control on a fixture-by-fixture basis. For example, control fixtures near windows with daylight sensors, control fixtures in spaces with sporadic occupancy with personnel sensors, and so forth. Refer to [Subsections 9.4](#) and [9.5](#) for manual and automatic lighting control techniques, respectively.

Lamp Compatibility

Lamp compatibility varies widely among dimming systems. The more sophisticated and expensive dimming ballasts adjust themselves to drive a broad range of lamp types. Other dimming systems are specific as to lamp type. In particular, some dimming ballasts are not compatible with reduced-wattage lamps.

Compact fluorescent fixtures that have integral preheat starters cannot be dimmed. Compact fluorescent lamps without integral ballasts can be dimmed effectively with compatible dimming equipment.

Reliability

Electronic lighting equipment has had protracted teething problems. Electronic ballasts needed about ten years to become reasonably reliable after they entered that market, and that was for major manufacturers. Fluorescent dimming equipment is an outgrowth of electronic ballasts, and is newer. Check the performance record of the specific equipment being considered.

Don't Expect Daylighting to be Easy

If you want to use fluorescent dimming to exploit daylighting, understand that installing the dimming equipment is only part of the job. Daylighting is still a pioneering activity that is characterized by more failure than success. Study [Subsection 8.3](#) before venturing into this challenging area.

ECONOMICS

SAVINGS POTENTIAL: *In applications that are appropriate for dimming, savings should average 30 to 60 percent of maximum wattage.*

COST: *Good dimming ballasts cost \$50 to \$100 apiece, and may control up to four lamps. The cost of control devices varies widely. Installation labor costs \$10 to \$200 per fixture, depending on labor rates, accessibility, and the number fixtures per control device.*

PAYBACK PERIOD: *Several years, or longer.*

TRAPS & TRICKS

CHOICE OF METHOD: *Fluorescent dimming is legitimate technology with limited application. Daylighting and theater dimming comprise a large fraction of the appropriate applications. At present, fluorescent dimming is largely a fad, giving bored lighting designers a chance to make a splash with something expensive and technical. It is irresponsible to use dimming where cheaper, more reliable methods will serve as well.*

PLANNING: *Daylighting control is tricky. Study [Subsection 8.3](#) and [Measure 9.5.3](#). For manual dimming applications, you have the challenge of getting people to use the controls efficiently. Make a complete installation plan. Optimize the controls separately for each location.*

SELECTING THE EQUIPMENT: *Fluorescent dimming equipment may still be evolving, and the most efficient types have not been in service long enough to demonstrate long-term reliability. Check with others who have used the equipment you are considering. Avoid any equipment that has been in service for less than a few years.*

EXPLAIN IT: *All lighting controls require placards, even if the controls are automatic. See [Measure 9.4.1](#).*

MEASURE 9.2.7 Consider retrofit “reflectors” for fluorescent fixtures.

“Reflector” retrofits for straight-tube fluorescent fixtures are thin reflective overlays inserted into fixtures behind the tubes. The common feature of these overlays is that they have mirror-like (“specular”) surfaces instead of the diffuse white surfaces that are commonly used in fluorescent fixtures. The overlays may also have curvatures to concentrate light downward more narrowly than the fixture does.

The most common claim for specular reflectors is that installing them in 4-tube fluorescent fixtures allows two of the tubes to be removed with minimal loss of light. This claim is not credible. Although the devices do indeed reflect light from the fixture, they do not provide the improvement promised. When promoted with such claims, reflectors fall into the category of snake oil.

Bogus Claims

The explanations usually given for this miracle of free light are that the specular reflectors have better reflectivity than the original fixture, and that the light distribution pattern is improved. Both of these claims are false.

With respect to the issue of reflectivity, the original surface of the fixture typically is a glossy white enamel having a reflectivity in excess of 90%. The retrofit reflector typically has an aluminum or silver surface with about the same reflectivity. The significant difference is that the specular retrofit reflector yields the glinty brilliance of sharply reflected light. This glinting effect leads the naive purchaser to believe that the light output is higher.

Still, tests have been conducted that seem to demonstrate major increases in light output with specular reflectors! Why? In some of the tests, dirty fixtures with old tubes were used as a basis of comparison. The new reflectors are clean, and two new tubes are installed to replace the four old ones.

Bogus “tests” of specular reflectors also exploit the fact that they may concentrate light more narrowly, so they show a higher footcandle level in the brightest part of the distribution pattern. Of course, this robs light from the rest of the distribution pattern.

Presumably, the light distribution pattern of the original fluorescent fixture was selected by the building designer to suit the illumination requirements. Therefore, changing the pattern is likely to do more harm than good. In addition, the light distribution pattern of the modified fixture is likely to be irregular, in contrast with the carefully shaped light distribution pattern of the fixture originally. “Reflector” retrofits are like

SUMMARY

Widely promoted with false claims, “reflectors” for straight-tube fixtures typically provide little real benefit, and may cause unsatisfactory light distribution. They may be useful in fixtures with inefficient diffusers.

Ease of Retrofit	😊 😊 😊

converting a van to a pickup truck when the original van is the proper vehicle for the job. As P. T. Barnum once said, . . .

Actual Efficiency Improvement

The only way that reflectors can provide a real benefit is to reduce trapping of light within the fixture. Some common types of fluorescent fixtures do trap a significant amount of light. To judge whether specular reflectors may provide a benefit, consider the three ways that light may be trapped in a fluorescent fixture:

- **shadowing by the fluorescent tubes.** In fixtures where tubes are close together, as in most fixtures with four or more tubes, each tube blocks light output from its neighbors. Tubes are fairly reflective, but they do absorb some light. Also, they reflect some light back into the fixture. Removing alternate tubes from a fixture eliminates most of this loss. Installing a specular reflector does not contribute to this improvement
- **internal reflections.** For a given reflector shape, a diffuse reflector surface may direct more light back into the fixture than specular reflectors, but this is not necessarily true. Internal reflection increases light absorption by the reflector itself and by the tubes. However, most fluorescent fixtures have shallow reflectors, so there is little reflection from one part of the fixture to another.
- **absorption in the diffuser.** Diffusers are responsible for most of the light loss in fluorescent fixtures that have them. Clear prismatic diffusers, which are the most efficient common type, absorb about 30% of lamp output. Colored egg crate diffusers may absorb as much as 75% of lamp output, but these are a rarity. Installing a specular

reflector would probably have little effect on absorption by the diffuser. There is one possible exception. A retrofit reflector that is shaped to concentrate light in a downward direction may increase the light output from fixtures with absorptive diffusers, especially diffusers having some depth, such as egg crate styles and deep parabolic louvers.

In summary, reflectors that concentrate light downward may increase light output somewhat in rare cases involving wasteful diffusers. Even in these cases, the narrower light distribution patterns of the fixtures are likely to produce spotty coverage. Where fixtures are designed to provide lighting on an area basis, the combination of specular reflectors and delamping is likely to deprive some task areas of adequate lighting.

Energy Saving Potential

Specular reflectors do not save energy unless they are necessary to make some other modification to the fixture that reduces energy input. The small increase in light output that reflectors may provide even in unusual cases usually does not allow such modifications.

A Better Alternative: Improve the Diffusers

In grasping for a legitimate application for reflectors, we suggested that specular reflectors might be useful in fixtures with diffusers that absorb a large amount of light. However, a more direct approach is to improve the diffusers. See [Measure 9.7.2](#) about this.

Types of Specular Reflectors

Retrofit reflectors are formed from thin sheets of aluminum. Differences relate to the type of reflective surface and to the shape.

The cheapest reflectors simply have a polished surface, with a coat of varnish to delay corrosion. More expensive reflectors improve reflectivity by using sputtered (vacuum deposited) coatings. These coatings need to be protected, and a tough polyester film is added for this purpose. Silver is sometimes used as a reflective material because its reflectivity is a few percent higher than that of aluminum. However, silver is even more vulnerable to oxidation, so the protective coating is even more important with silver.

Reflector shapes are usually generic, rather than being customized to particular fixture models. Some reflectors are shaped to follow the general contours of the fixture. Others have pseudo-parabolic shapes to concentrate light downward. Some reflectors cover the entire inside surface of the fixture, and some cover just the ballast housing. Some surround individual tubes.

Degradation of Reflectivity

The original enamel diffuser of the fixture suffers little loss of reflectivity over the life of the fixture, but

retrofit reflectors suffer some degradation of reflectivity and specular quality as the aluminum or silver oxidizes. Plastic coatings can be effective for blocking oxidation, but the film itself is subject to long-term degradation, primarily from the ultraviolet light emitted by the lamps. Therefore, over the life of the fixture, the average reflectivity of the retrofit reflector is likely to be lower than the reflectivity of the original surface that it covers.

Socket Modifications

Reflectors are installed with the assumption that pairs of tubes will be removed. Removing the tubes alters the light distribution pattern of the fixture. To compensate for this, some reflector kits include socket adapters that relocate the remaining tubes to a position halfway between the original sockets. This is done to keep the light distribution pattern from becoming too lopsided, and it may also reduce light trapping within the fixture.

Socket adapters are available separately. You can use them when delamping fixtures even if you do not use reflectors.

Reflectors for Screw-in Fluorescent Fixtures

Many fixtures that use screw-in fluorescent fixtures, especially downlights, can benefit from reflective inserts to reduce absorption inside the fixtures. These inserts are covered in [Measure 9.1.4.2](#).

ECONOMICS

SAVINGS POTENTIAL: *There are probably no mainstream applications where reflectors can save money. It is possible to imagine some oddball applications where they might, but these cases are too speculative to estimate.*

COST: *Reflectors cost \$5 to \$30 per fixture, depending on size, shape, and other features. Installation costs \$5 to \$30 per fixture, depending on labor rates, accessibility, and whether other modifications and cleaning are performed at the same time.*

PAYBACK PERIOD: *Reflector retrofits usually do not pay back.*

TRAPS & TRICKS

CHOICE OF METHOD: *Treat reflectors as snake oil. They rarely provide significant benefit, so they almost never pay off. There is a common misconception that you need reflectors in order to delamp fixtures. You don't.*

SELECTING THE EQUIPMENT: *In those rare cases where reflectors may be useful, select the reflector shape to give you the light distribution pattern you want. Select reflector materials to resist oxidation, ultraviolet degradation, and abrasion from cleaning.*

Lamps and Fixtures, H.I.D. and L.P.S.

High-intensity discharge (“HID”) lighting has long been the dominant type for industrial facilities and outdoor lighting. Major improvements in color rendering have allowed HID lighting to move into the commercial sector, where it competes with incandescent and fluorescent lighting for many applications.

The first type of HID lighting was mercury vapor (which is abbreviated “MV” in this book). In recent decades, mercury vapor lighting was joined by metal halide (“MH”) and high-pressure sodium (“HPS”) lighting. These two newer types offer much better color rendering and higher efficiency, leaving lower cost as the only remaining advantage of mercury vapor.

This Subsection also covers low-pressure sodium (“LPS”) lighting. LPS lighting does not fit within the strict definition of HID lighting, but it is similar in operation and installation. It has exceptionally high electrical efficiency. Unfortunately, it is limited in application by poor color rendering, mainly to outdoor lighting.

At present, there are fewer opportunities for improving HID lighting than for fluorescent and incandescent lighting. Unlike the other two types of electric lighting, HID lighting forces you to compromise between efficiency and color rendering. HID provides fewer ways to make small reductions in wattage. Delamping opportunities are limited because the high intensity and focussed light distribution of HID lamps make each lamp essential. Dimming options are presently limited, and not well proven. Opportunities for improving control are limited by long starting and restarting times.

Even so, you may be able to make major improvements in the efficiency of your HID lighting. At present, your main opportunities are selecting the best available equipment and improving lighting layout. For the latter, combine the Measures of this Subsection with the Measures of [Subsection 9.6](#).

HID lamps with much better efficiency have become available in recent years. Unfortunately, the efficiency of HID ballasts continues to be poor. Electronic ballasts may create the same opportunities for conservation in HID lighting that they did in fluorescent lighting, and they may lessen or overcome the starting and restarting problems of HID. Watch for developments, but beware of the kinds of troubles that first beset fluorescent electronic ballasts.

Before getting started, review [Reference Note 56](#), HID and LPS Lighting. It tells you how HID lighting works, and gives details of the main types of HID lamps. Armed with this knowledge, you can select the best types and models of HID equipment. [Reference Note 56](#) also provides an overview of the present status of HID lamp and ballast efficiency. For a comprehensive comparison of HID lighting with other light sources, see [Reference Note 52](#), Comparative Light Source Characteristics.

INDEX OF MEASURES**9.3.1 Install the most efficient HID lamps, ballasts, and fixtures.**

MEASURE 9.3.1 Install the most efficient HID lamps, ballasts, and fixtures.

RATINGS

New Facilities	Retrofit	O&M
A	B	

A flurry of new HID lamp models have appeared over the past several decades. These provide a broad selection of characteristics among all three types of HID lamps. You can now get a combination of energy efficiency and good color rendering in HID lighting. However, you still have to select a compromise between these two fundamentally important characteristics.

It is relatively easy to upgrade many existing HID fixtures. In most cases, this requires changing the ballasts, along with capacitors and ignitors, if they are needed. Ballast conversion kits are available for most modern types of HID lamps. For example, see Figure 1.

However, even in retrofit applications, consider replacing the entire fixture. HID fixtures, including ballasts, may not be much more expensive than installing a ballast conversion kit. This approach becomes more desirable if a new fixture would provide better light distribution.

Energy Saving Potential

See Table 1 of [Reference Note 56](#), HID and LPS Lighting. It shows that there are large differences among different types of HID lighting. Careful selection can reduce lamp energy consumption from 40 to 65 percent in typical applications.

Where to Upgrade Existing HID Lighting

You can improve most HID lighting, except for the most efficient modern types. Upgrading is fairly expensive because you have to change both the lamps and ballasts.

Retrofitting HID lighting for greater efficiency is most likely to be economical where you can replace existing mercury vapor lighting with metal halide or sodium vapor lighting. Some metal halide and high-pressure sodium lamps have been designed as direct replacements for mercury vapor lamps, without the need to change ballasts. This upgrade is covered by [Measure 9.3.1.1](#). Unfortunately, it improves color more than it saves energy. Replacing HID lamps without replacing ballasts is not yet possible without paying a high price in efficiency.

Upgrading becomes more valuable in applications where the color characteristics of the lighting are important. The greatest improvements to HID lighting in recent years have been in color rendering. The muddy color seen under older mercury vapor lamps is no longer a penalty that must be paid. Some models of metal halide and sodium vapor lamps approach the color rendering of the best fluorescent lamps.

SUMMARY

A reliable source of energy savings. Fairly easy to retrofit. The biggest improvement is replacing mercury vapor lighting with metal halide or high-pressure sodium. Select carefully for efficiency and color rendering.

Ease of Retrofit	☺	☺	☺	☺

Low-pressure sodium lighting is rarely a suitable replacement for other lamp types, despite its exceptionally high lumens-per-watt output. It may be the best choice in uncommon applications where color is unimportant and people are exposed to the light only for short durations.

■ **Ballast Conversion Kits**

Conversion kits are available for modifying existing mercury vapor fixtures to use other types of HID lamps. These typically consist of a new ballast, capacitor, ignitor (if needed), and mounting hardware.

Before committing to conversion on a large scale, try a conversion kit in one lamp to make sure that it does not require too much troublesome fitting.

Advance Transformer Co.

Fig. 1 HID conversion kit This kit converts a fixture to use a high-pressure sodium lamp. From left to right are the ballast, ignitor, and capacitor, along with some universal mounting hardware.

■ Consider Improving the Entire Fixture

Replacing fixtures entirely may be a better alternative than retrofitting new ballasts in the old fixtures, especially if new fixtures can provide more efficient light distribution and more efficient lamp layout. All other factors being equal, efficacy increases sharply with lamp size. Where you have a choice, it is usually better to use a smaller number of larger lamps. Refer to [Measures 9.6.2 ff](#) for guidance on fixture layout.

In some applications, replacing the present HID lighting with fluorescent lighting provides better efficacy than replacing it with improved HID lighting. See [Measure 9.3.3](#) for this approach.

■ Do Not Substitute Smaller Lamps on the Same Ballasts

HID lamps are not incandescent lamps. You can't just install a lower-wattage lamp without changing the ballast, unless the lamp is explicitly designed for such service. Using a smaller lamp will not reduce wattage much. This is because the lamp current is controlled by the ballast, not by the lamp itself. The smaller lamp is driven at greater power than it was designed to handle, and it burns out quickly.

Consolidate Lamp Types

Try to make an all-or-nothing decision about the types of HID lamps and ballasts that you plan to use, for these reasons:

- having several types of lamps and ballasts makes it easy to install the wrong type of lamp in a fixture
- keeping similar-looking lamps in stock invites ordering and warehousing mistakes
- occupants will notice differences in lamp color if fixtures with different lamp types are within sight of each other.

There is an interesting exception to this guideline. You can mix lamp types to improve color. This is a way of getting around the fact that HID lamps with better color characteristics have lower efficacy and cost more. This method works only if there is a lot of overlap in the light from different fixtures. For example, in a tall ceiling with closely spaced fixtures, you could alternate metal halide lamps with high-pressure sodium lamps in a checkerboard pattern. The bluish light of efficient metal halide lamps blends well with the reddish light of efficient high-pressure sodium lamps. But, be careful. This combination provides light that is attractive for many applications, but the color rendering is irregular. Furthermore, with recent advances in HID lamp design, it is no longer necessary to go to this bother to get a combination of good color rendering and good efficiency.

How to Select HID Lamps

[Reference Notes 52](#) and [56](#) give you the general background you need to select HID lamps. When you get ready to buy, select for the following specific characteristics in the lamp catalogs.

■ Initial Lumen Output

In retrofit applications, start by finding out whether the illumination levels provided by the present lighting match the requirements of the activities. Calculate any increases or reductions in the lumen output, and then scan the catalogs to find lamps that provide this output.

Take into account the effect of color rendering on lumen requirements. Poorer color rendering may require higher lumen output, but only if the work involves colors. Color rendering does not strongly affect lumen levels with activities that do not rely on colors, such as routine paperwork, reading stencils on crates, and work at computer terminals (which are their own light sources).

■ Degradation of Lumen Output

HID lamps suffer serious loss of light output as they age. Ensure that enough light is provided at the end of the lamp replacement cycle (which is not necessarily at the end of rated service life). The lamp specifications usually do not provide this information. Instead, they state the initial lumen output, and perhaps some sort of average figure. The lumen output at the end of the lamp's rated life typically is 60 to 75 percent of its initial lumens.

High-pressure sodium lamps have somewhat lower lumen loss than mercury vapor and metal halide. Also, the most lumen loss in high-pressure sodium lamps occurs toward the end of lamp life, whereas the other two types have their highest rate of lumen loss at the beginning.

■ Color Characteristics

All three types of HID lamps have improved their color rendering in recent years. Both metal halide and high-pressure sodium models are available with "color rendering index" (CRI) ratings that are almost as good as the best fluorescent lamps. Older types with low CRI still remain, leaving a wide range of color rendering and efficacy for each type of HID lamp.

Unlike fluorescent lighting, HID lamps have a conflict between color rendering and lumen-per-watt efficacy, so do not select a higher CRI than you need. Also, lamps with higher CRI usually are more expensive.

Low-pressure sodium lamps stand apart from the other types because they have almost no ability to bring out colors. This serious deficiency is covered below.

■ Mounting Position

Some HID lamps need specific mounting positions to keep the arc from touching the wall of the arc tube, or to protect the lamp from overheating. These lamps

are specified for mounting “base up,” “base down,” and “horizontal.” Lamps that can be operated in any position are listed as “universal.”

If a lamp is specified for vertical mounting (base-up or base-down), it is usually limited to a variation of about 15 degrees from the vertical. If a lamp is specified for horizontal mounting, it is usually limited to within 45 degrees of horizontal.

■ Starting and Operating Temperatures

All mainstream HID lamps operate well down to a temperature of about -20°F (about -30°C), and they may operate at lower temperatures if enclosed. The minimum starting temperature is determined by the ballast, as explained below.

■ Wattage and Efficacy

Select lamps that satisfy the previous requirements with the best efficiency. Lamp efficacy may not be stated outright in the catalogs. It is easy to calculate. Simply divide the lumen rating by the lamp wattage. Table 1 of [Reference Note 56](#), HID and LPS Lighting, illustrates the range of efficacies you can expect to find.

■ Service Life

Lamp life does not relate directly to efficacy, but it is a major factor in labor and lamp cost. These are the ranges of lamp life for mainstream lamps of each type:

mercury vapor	24,000 hours
metal halide	10,000 - 20,000 hours
high-pressure sodium	15,000 - 24,000 hours
low-pressure sodium	18,000 hours

Specialized lamps designed for exceptional color rendering, compact size, or other needs may have much shorter life.

How to Select HID Ballasts

Select the ballast to match the lamp. Get the following information from the ballast catalogs.

■ Dimming Capability

Decide first whether you want dimming capability. If so, your choice of ballasts will be limited, perhaps to relatively unknown equipment. Refer to [Measure 9.3.2](#) for the details of HID dimming.

■ Lamp Compatibility

The lamp and the ballast must be matched. Otherwise, efficiency and service life suffer, if the unit operates at all.

The ANSI ballast code system simplifies ballast selection by assigning a standard ballast code to each lamp model. The ANSI lamp code consists of a single letter that indicates the type of lamp, followed by a number that indicates the ballast type. The lamp type codes are:

H mercury vapor

M metal halide

S high-pressure sodium

L low-pressure sodium

A particular ballast may have more than one ANSI code. For example, a particular 400-watt ballast may have ANSI codes of H-33 and M-59. This means that it can operate some types of mercury vapor lamps and some times of metal halide lamps.

The ANSI code is not a rating system for either the lamp or the ballast. It tells you only the electrical power characteristics that the lamp requires from the ballast. Different ballast models for a given lamp may have major differences in efficiency, power factor, etc. You still have to select the specific ballast model.

Some lamps may not have ANSI ballast codes. For these, the manufacturer provides a list of specific ballasts that can be used.

■ Number of Lamps

HID ballasts are available to drive either one or two lamps. Using a single ballast to drive two lamps saves money in purchasing the ballast, but it eliminates the possibility of operating one of the lamps alone.

■ Sensitivity to Voltage Fluctuations

“Reactor” ballasts allow large changes in lamp wattage if the line voltage varies. To avoid this problem, use “constant wattage” (CW) or “constant wattage autotransformer” (CWA) ballasts.

■ Number of Fixtures per Circuit

The low power factor of “reactor” ballasts is improved by installing a capacitor in parallel with the ballast coil. Unfortunately, this simple technique has the disadvantage that it limits the number of fixtures that can be installed on a circuit. If the lamp stops drawing current, because it fails or is cooling down to restart, the current drawn by the ballast actually increases because the capacitor becomes a short circuit for the alternating current. For this reason, the number of power circuits required may be more than doubled by using high-power-factor reactor ballasts.

One way around this problem is to use reactor ballasts that are designed to disconnect the capacitor when the lamp circuit opens. Another solution is to use a different type of ballast, such as the common CWA type.

■ Crest Factor

“Crest factor” is the ratio of the peak lamp current to the average lamp current. High crest factors cause more rapid loss of the emissive material on the lamp electrodes, reducing lamp efficacy and service life. Crest factor varies widely among different types of HID ballasts. Look for the lowest numbers.

■ Acoustical Noise

This issue is the same as for fluorescent ballasts. Refer to [Measure 9.2.4](#).

■ Power Factor

Power factor measures the phase relationship between the current and voltage of an electrical device. A lower power factor increases the current required to deliver a given amount of power. This increases the size of wiring, transformers, and switching in the power system. Many electric utilities impose a penalty for low power factor. Therefore, power factor may be a major issue if lighting comprises a large part of the facility's electrical load. Low power factor can also cause overloading of circuits.

Reactor ballasts without capacitors have very low power factors. Aside from this case, all types of HID ballasts are available in models that provide a power factor of 90% or better.

■ Starting Temperature

HID ballasts start lamps down to their normal minimum operating temperature, which is about -20°F (about -30°C). Lamps can operate at lower ambient temperatures if they are enclosed in suitable fixtures. However, to start the lamps in extremely cold weather, you may need special low-temperature ballasts.

■ Lamp-to-Ballast Distance

Ballasts for large lamps may be mounted far from the lamps, for example, on the side of a light pole. Special ballasts and ignitors may be needed to cope with separations greater than about 30 feet (10 meters).

■ Reliability and Service Life

The main areas of failure in conventional magnetic HID ballasts are the coil insulation, the capacitor, and the ignitor (if used).

Ballast insulation failure is usually caused by long exposure to high temperature. Ballasts that are designed for improved efficiency offer the potential for extended coil life because they operate at lower temperatures.

“Dry” capacitors are preferable to electrolytic capacitors, which fail by drying out. Also, dry capacitors do not require attention to grounding.

■ Integral or Separate Ignitors and Capacitors

Capacitors and ignitors may be separate or they may be an integral part of the ballast assembly. The choice is usually dictated by the fixture. If there is an option, installing separate components makes it less expensive to replace failed components in the future, but initial installation takes more time.

In HID lighting, the term “core-and-coil” ballast usually means the bare ballast without the capacitor or ignitor.

■ Wattage Input and Efficiency

Once all these mandatory features have been defined, select among the candidate models for the

lowest input wattage. This is important because contemporary HID ballast losses are high, especially for small sizes.

■ Wiring Convenience Features

Some models of HID ballasts offer features that simplify installation. Take advantage of these features, if they are useful in your installations:

- **power leads for external control.** HID is commonly used for exterior lighting, so ballasts may include leads intended for easy connection of photocell control. The same leads could be used for any other mode of on-off control.
- **multiple line voltages.** This feature simplifies spare parts inventory if a particular type of lamp is installed in fixtures that are supplied with different voltages.
- **power leads for emergency lighting.** If there is momentary loss of power, all the HID lighting may be lost for several minutes while the lamps cool down to restart. For this reason, incandescent lamps may be installed as emergency lighting. Some ballasts include leads for powering emergency lamps.

If a ballast has taps for multiple input voltages, you may be able to use one of the taps to power emergency lighting. For example, you could use the 120-volt tap for emergency lighting if the ballast is operated at higher voltage. This avoids the need to run a separate 120-volt circuit to the emergency lamp. However, the emergency lamp current is limited by the current capacity of the ballast coil. Therefore, the amount of light available from the emergency lamp is substantially less than the light from the HID lamp, because incandescent lighting is less efficient than HID.

■ Additional Concerns for Electronic Ballasts

It seems inevitable that electronic ballasts will soon be widely available for HID lighting. When this occurs, they will bring the same additional selections concerns that presently apply to fluorescent electronic ballasts. These include harmonic distortion, radiated electromagnetic noise, power line noise, and initially low reliability. For a preview of these problems, refer to [Measure 9.2.4](#).

How to Select New Fixtures

In selecting new fixtures, use the same ballast criteria given previously. A new fixture will not provide efficiency or good color rendering unless you shop for these characteristics.

Be sure that you know the light distribution patterns of fixtures you select. If half of the fixture's light goes where you don't need it, overall lighting efficiency has been cut in half, regardless of what else you do.

Select fixtures for low light loss. Fixture specifications generally do not state the light loss, so estimate this by examining the fixture design. Most light loss in HID fixtures occurs in diffusers. Therefore, fixtures without diffusers are likely to be most efficient. Diffusers that create a great deal of diffusion are likely to be least efficient. Plastic diffusers absorb more light than glass, and they darken with age.

Don't Misuse Low-Pressure Sodium Lamps

Low-pressure sodium (LPS) lamps have exceptionally high lumens-per-watt ratings. This seduces people into using them where they do not belong. Remember that LPS lamps produce very poor visual quality. (Indeed, low-pressure sodium lighting provides an extreme example of the weakness of the lumens-per-watt method of judging lighting efficiency.)

What really matters to vision is the amount of light reflected from the scene, not the amount of light that falls on the scene. If an object does not contain the exact color emitted by the LPS lamp, the object appears black, i.e., it is not illuminated. This is why scenes lighted solely by LPS lamps appear black-and-white, and dim.

Another defect of the lumens/watt rating of efficiency is that vision is largely a matter of discriminating colors. LPS lighting fails completely in this regard because all its light is emitted at (essentially) one color. Even a colorblind person sees less well in LPS light. This is because reflection of light from an object is only at the wavelength of the sodium light, so there is no gradation of intensity provided by other colors.

Low-pressure sodium lighting is so poor in color rendering that it has virtually no applications as a replacement for other types of lamps. (The CRI of LPS lamps is typically listed as zero!) There are certain black-and-white applications, such as reading labels on cartons, where the superior lumens-per-watt efficiency of LPS can reduce lighting power. However, the monochromatic light is distressing to people.

In terms of overall lighting effectiveness, there are probably more cases where it is desirable to get rid of LPS lighting than to install it. This is even true for road and parking lot lighting, the most common applications for LPS lamps. The most likely replacement for LPS lamps is high-pressure sodium lamps of moderate CRI

rating. With the improved vision that results, it probably would not be necessary to increase the wattage of the lamps.

Label Your Fixtures to Deter Backsliding

When a lamp burns out, it is easy to replace it with the wrong type. The most effective way to prevent this is to label the fixtures with the lamp type. See [Measure 9.7.3](#) for guidance in fixture labeling.

ECONOMICS

SAVINGS POTENTIAL: 40 to 65 percent of lamp power in typical applications.

COST: Metal halide and high-pressure sodium lamps cost 20% to 80% more per watt than mercury vapor lamps. The cost per lumen may be higher or lower than for mercury vapor. Metal halide lamps must be replaced more often than mercury vapor, increasing the lifetime lamp cost.

Ballast conversion kits for metal halide and high-pressure sodium lamps cost \$100 to \$300, depending on wattage. Entirely new fixtures are more expensive in retrofit, but perhaps not much more. Labor costs depends on local rates and the accessibility of the fixtures.

PAYBACK PERIOD: On or two years, in new construction. Several years, or longer, in retrofit. The payback period may be very long for smaller lamps. On the other hand, the value of improved color rendering may be important.

TRAPS & TRICKS

PLANNING: Make a thorough planning survey to determine the appropriate light levels for each area. Decide on the CRI that you really need, which may differ from one area to another.

SELECTING THE EQUIPMENT: Fortunately, you have many choices. Search the catalogs. Different manufacturers offer different features. Buy from major manufacturers, and check with other users before buying. There are wide variations in lamp and ballast quality. Be wary of new lamp types.

SPELL IT OUT: Label each fixture with the type of lamp that should be installed. Put a list of ballast and lamp types for each fixture or group of fixtures in the lamp stock room.

MEASURE 9.3.1.1 For lowest retrofit cost, replace mercury vapor lamps with metal halide or high-pressure sodium lamps that do not require ballast replacement.

Normally, each type and size of HID lamp needs a different ballast. This makes it expensive to replace mercury vapor lighting with metal halide or high-pressure sodium. To avoid this cost barrier, some models of metal halide and high-pressure sodium lamps have been developed specifically to replace mercury vapor lamps without the need to replace the ballasts.

These lamps are intended primarily to improve color rendering and light output. They are substantially more efficient than mercury vapor lamps, but not as efficient as mainstream metal halide and high-pressure sodium lamp models. As a price for ease of replacement, they compromise some other characteristics, including service life.

Energy Saving Potential

Generally, this substitution is not economical on the basis of energy savings alone. Although the replacement lamps have higher efficacy, most of this advantage appears as higher light output rather than lower input energy. Depending on the wattage of the original lamp, the maximum energy saving ranges from 5 to 20 percent.

The energy saving may be greater in uncommon cases where the improved light output of the replacement lamps allows less lighting wattage to be used elsewhere.

Where to Consider this Method

Consider this approach where you need greater light output and better color rendering. These lamps provide 40% to 75% more light output than the original mercury vapor lamps. Their color rendering is considerably better than that of mercury vapor lamps, but not as good as the color rendering that is provided by HID lamps that are designed for high color rendering.

Not many lamps of this type are presently on the market, so you may not be able to find the right wattage for upgrading your existing lamps.

How to Select the Lamps

The selection factors for this type of lamp are generally the same as for other HID lamps, as listed in [Measure 9.3.1](#). The lamp manufacturer usually provides a list of the specific ballast models with which the lamps operate. The manufacturer may also provide a list of ballasts to avoid. However, manufacturers do not claim that these lists are complete, so you may have to call either the ballast manufacturer or the lamp manufacturer for further information.

SUMMARY

Provides more light output and better color rendering than the original lamp, but does not reduce energy consumption as much as lamps using metal halide or high-pressure sodium ballasts.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

The ANSI lamp designation system (described in [Measure 9.3.1](#)) does not help in selecting this type of lamp. The ANSI system defines compatibility narrowly for optimum efficiency and performance, whereas direct-replacement lamps involve serious performance compromises.

Label Fixtures to Prevent Backsliding

When a lamp burns out, someone may replace it with any type of lamp that fits the socket. To ensure that the right kind of lamp is used, label the fixture with the exact lamp model to be used. [Measure 9.7.3](#) provides details about this important step.

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of the original lamp wattage. The increased lumen output and improved color rendering add substantial value in some applications.

COST: The replacement lamps cost 20 to 50 percent more than the original mercury vapor lamps. In addition, they have shorter service lives, which increases the lifetime cost of lamps.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

CHOICE OF METHOD: There are few applications for using this type of lamp purely as an energy conservation measure. Other Measures produce higher efficiency. Consider this approach primarily where you need more light, and light of better quality, at modest cost.

SELECTING THE EQUIPMENT: This type of lamp is specialized. Search for the best models. Buy from major manufacturers.

SPELL IT OUT: Label each fixture with the type of lamp that should be installed. Put a list of ballast and lamp types for each fixture or group of fixtures in the lamp stock room.

MEASURE 9.3.2 Install HID dimming equipment.

RATINGS

New Facilities	Retrofit	O&M
D	D	

Dimming works by reducing the lamp current. The only HID dimming equipment with much application history is single-stage dimming. The first generation of this equipment has become notorious for failing after a relatively short period of service. This equipment still needs to mature. Electronic dimming, which promises a large turndown ratio while maintaining stable lamp operation and good energy efficiency, is not yet a proven technology for HID lighting.

Step Dimming

Step dimming works by inserting a capacitor in series with the lamp. The reactance of the capacitor reduces the lamp current by a fixed amount. Retrofit equipment is available that consists of the capacitor plus switching equipment to switch the capacitor into and out of the lamp circuit as dimming is needed.

Step dimming works only with transformer or autotransformer ballasts, especially CWA types. If the ballast is incompatible, one option is to replace the ballast to allow dimming. Ballasts with built-in switching are available for some lamp models. A more expensive option is to buy fixtures with built-in dimming capability.

Electronic Dimming

Electronic dimming of HID lamps is similar in concept to electronic fluorescent dimming. Electronic ballasts power the lamps with high-frequency pulses. This allows the lamp current and voltage to be controlled independently of each other, so that the ratio of voltage to current can be optimized for all operating conditions.

As of the mid-1990's, major U.S. ballast manufacturers were not offering electronic dimming, but some smaller companies were introducing units. The present situation is reminiscent of the early years of fluorescent electronic dimming, which had a long and troubled period of introduction to the market. While that history of troubles may not repeat itself, it seems

SUMMARY

Useful mainly for responding to occupancy, rather than exploiting daylighting. Lack of long-term reliability remains a problem.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % %
Rate of Return, Retrofit	% % %
Reliability	✓
Ease of Retrofit	☺ ☺ ☺

prudent to wait until the technology of HID dimming has become more mature.

Applications and Alternatives

The most common application for step dimming is reducing lighting power when a space is unoccupied. Dimmers are available with matching occupancy sensors for this purpose.

Dimming is also a necessary part of daylighting. However, step dimmers cause abrupt changes in lighting, which annoys occupants. If and when electronic dimmers become proven, refer to [Measure 9.2.6](#) for the selection factors. (They will probably be the same as for fluorescent dimmers.)

If the application offers the potential of major savings by exploiting dimming, consider replacing the HID lighting with fluorescent lighting ([Measure 9.3.3](#)). This change also allows the lights to be turned on and off at short intervals. It is especially worth considering if the existing HID lighting is inefficient.

Turndown Ratio

The maximum turndown ratio depends on the type of lamp and the type of dimming equipment. Simple

step dimming, using a capacitor to limit lamp current, is claimed to provide a maximum turndown ratio of 70% with high-pressure sodium lamps, and a maximum turndown of 50% with metal halide lamps. Electronic dimming may allow higher turndown ratios, but it is too early to tell what the ultimate limits will be.

Efficiency

Dimming is a fairly efficient process in HID lamps, within limits. Reliable numbers are not available, but it appears that an efficacy loss of 10 to 20 percent can be expected near maximum turndown. This does not include any losses in the dimming equipment itself. Capacitor dimmers do not have much loss in themselves. Electronic dimmers may add about 10% loss, judging from experience with fluorescent dimmers.

Adverse Effects on Lamp Operation

Dimming is possible with all three types of HID lamps, but it imposes some constraints on lamp operation, including:

- **change in color and color rendering.** Metal halide lamps contain a variety of light emitting metals that differ in their response to changing lamp current. Therefore, metal halide lamps change color as they are dimmed. The severity of the change varies with lamp model and wattage.

High-pressure sodium lamps lose their broad color spectrum at low current because more of the lamp energy goes to generating the characteristic monochromatic color of low-pressure sodium lamps. The lamp color changes from white to yellow, and color rendering suffers.

Mercury vapor lamps do not experience much color change with dimming. However, their color rendering is poor in any event.

- **operating temperature.** Reducing the lamp current slows the processes that create and maintain the arc. These processes are also proportional to temperature, so lowering the current requires a higher minimum operating temperature. Electronic dimming may be able to avoid this problem by using higher voltage to compensate for lower temperature.
- **mounting position.** Reduced lamp current may allow the arc to wander closer to the lamp envelope, which quenches the arc. Therefore, there may be stricter limitations in lamp position.

Dimming Controllers

HID lamps must be started at full output so that the light-emitting metals will vaporize. Therefore, any controls used with dimmers should include a feature that starts them at full output.

HID lamps normally must cool down for an extended period before restarting. Therefore, the controller should have a feature that resets the lamp to full output after a shutdown, including shutdowns from brief power interruptions.

In the future, electronic modulating dimmers may be able to start lamps at any level of output. However, starting at low output extends the warm-up time, during which the lamp is operating inefficiently.

Dimmers can be controlled by signals from any appropriate source, such as manual controls, light level sensors, motion sensors, time controls, etc. Controllers for electronic dimmers usually provide an analog input signal to the ballast.

Daylighting is a Complex Application

If you really want to install HID dimming equipment to exploit daylighting, study [Subsection 8.3](#) before venturing into this complex area. Dimming is only one part of daylighting.

ECONOMICS

SAVINGS POTENTIAL: *The maximum wattage reduction is 50 to 70 percent, depending on lamp type. The average reduction depends on the application.*

COST: *Step dimmers and appropriate controllers cost about \$100 per lamp, typically. Installation may cost about the same amount. The cost of electronic dimming systems remains to be seen.*

PAYBACK PERIOD: *Several years, typically.*

TRAPS & TRICKS

CHOICE OF METHOD: *It's probably too soon for this. Try something else, or wait a while. If you want to gamble, try step controllers for the time being.*

MEASURE 9.3.3 In appropriate applications, substitute fluorescent lighting for HID lighting.

In the past, HID lighting tended to be limited to applications that were clearly inappropriate for fluorescent lighting. However, there are now large areas of overlap in applications for fluorescent and HID lighting. This has led to one type being used in applications where the other type would serve more efficiently. Examine all your HID lighting to see whether you can save energy and cost by shifting to fluorescent lighting.

Reasons to Substitute Fluorescent Lighting

The following situations usually favor fluorescent lighting enough to provide a significant saving in energy consumption.

- **The space, or areas within the space, are occupied irregularly.** HID lamps take a long time to warm up from a cold state, and they may take even longer to restart if they are turned off when hot. This makes it impossible to save energy by turning off HID lighting to follow unscheduled or irregular occupancy. In contrast, fluorescent lighting can respond instantly. Applications where this is important include gymnasiums, loading docks, parking garages, localized areas within warehouses, maintenance shops, etc. One way to improve the efficiency of HID lighting in these situations is to install dimming equipment, as recommended by Measure 9.3.2. However, the energy saving is limited to about half of full power.
- **The application would benefit from dimming or variable lighting levels.** Fluorescent lighting offers two efficient method of adjusting light output, switching individual lamps in fixtures and electronic dimming. In comparison, present HID dimming technology has limited range, it causes color changes in metal halide and sodium vapor lamps, and it still has a poor reliability record.
- **Color rendering is important.** HID lamps can now provide CRI's that are almost as high as those of the best fluorescent lamps. However, HID lighting pays a large efficiency penalty to get good color rendering. In contrast, the fluorescent lamps with the best color rendering also have the highest efficiency. Color rendering is important in a large fraction of all lighting applications, including applications that traditionally use HID lighting.
- **HID lamps have too much light output for efficient light distribution.** HID lamps must be large to be efficient. This means that they illuminate large areas. An individual HID lamp with enough

SUMMARY

Don't install HID lighting by rote. Some "typical" HID lighting applications can be served better with fluorescent lighting.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	✓
Ease of Retrofit	☺	☺	☺	

wattage to be efficient typically illuminates an area of 200 square feet (20 square meters) or more. In contrast, an individual fluorescent lamp may efficiently illuminate an area of 10 square feet (one square meter).

If the layout of spaces is irregular, or if illumination requirements vary between areas, efficient light distribution requires a larger number of smaller lamps. However, smaller HID lamps and ballasts are substantially less efficient than good fluorescent lighting. Also, if the fixture must be close to the viewer, fluorescent lighting is more pleasant.

- **The installed HID lamps are inefficient.** In retrofit applications, consider fluorescent lighting as a replacement for inefficient HID lighting. Of course, you can also replace inefficient HID with more efficient HID lighting, as recommended by Measure 9.3.1.

Reasons to Keep HID Lighting

It is not always feasible to substitute fluorescent lighting for HID, even in cases where it might provide a large energy saving. The following situations make it difficult or impractical to substitute fluorescent lighting.

- **The space operates at low temperature,** either continuously or occasionally. The optimum lamp temperature for fluorescent lamps is about 100°F (38°C). Efficacy and light output decline rapidly below this temperature. Fluorescent lamps can be kept warm by using tight enclosures, but this creates temperatures that are too high when the ambient temperature rises. Also, special ballasts are required to start fluorescent lamps in cold conditions. In contrast, HID lighting is tolerant of wide temperature variations.

- **The fixture environment is dirty.** Incandescent lamps and fixtures have large surface areas in relation to the amount of light they produce. If the environment is dirty, the cost of cleaning the lamps and fixtures to maintain efficiency may be prohibitive.
- **Fixture installation cost is high.** It takes a number of fluorescent fixtures to provide as much light as a single large HID fixture. If installation costs are high, retrofitting fluorescent lighting is unlikely to be economical.
- **Lamp maintenance is difficult.** The labor cost for lamp replacement may be prohibitive if fixtures are hard to reach. Consider whether you can install fluorescent fixtures at lower heights, making lamp replacement easier. This possibility is explored further, below.
- **It is difficult to locate the fixtures to provide efficient light distribution.** HID fixtures are typically installed in tall ceilings. Their ability to focus sharply makes them well adapted to this geometry. In contrast, conventional fluorescent fixtures have broad light distribution patterns. As a result, they cannot exploit their ability to illuminate small areas efficiently if they are installed high above the task areas. Fluorescent lighting in tall ceilings can be efficient only for illuminating large areas, such as gymnasiums. See Figure 1, for example. In spaces with tall ceilings, consider whether you can install the fluorescent fixtures closer to the task areas, as discussed below.

Comparative Lamp and Ballast Efficiencies

If none of the previous factors tilt your decision strongly toward either fluorescent or HID lighting, make your decision largely on the basis of comparative lamp and ballast efficiencies. The efficiency of HID lamps is inversely related to their CRI, and higher CRI increases the cost of both HID and fluorescent lamps. Bearing this in mind, shorten your analysis at the outset by deciding the lowest CRI that is acceptable for the application.

It is widely believed that HID lighting is more efficient than fluorescent lighting. Table 1 of [Reference Note 56](#), HID and LPS Lighting, shows that this is not true in general. The table shows that HID lamps with good color rendering may be much less efficient than the best fluorescent lamps. Only a few HID models combine efficiency and color rendering as well as the best fluorescent lamps. Only certain models of high-pressure sodium lamps have efficacies that are much higher than the best fluorescent efficacies, and they achieve this at the expense of color rendering.

The common, inexpensive 40-watt cool white fluorescent lamp, which has a CRI of 62, has an efficacy of 78 lumens/watt when driven by a magnetic ballast, and about 85 lumens/watt when driven by an electronic ballast. Comparable “high-efficiency” fluorescent lamps achieve efficacies near 100 lumens/watt with electronic ballasts, and they have CRI’s as high as 85.

Consider the effects of ballasts when making your efficiency comparison. (See Table 2 of [Reference Note 56](#), HID and LPS Lighting.) HID ballasts consume a

WESINC

Fig. 1 Fluorescent lighting in a gymnasium It is possible, and it produces good illumination on short notice. The activity here is wrestling, which poses no hazard to the fixtures.

much larger fraction of the input energy than the best fluorescent ballasts, except with very large HID lamps. In the middle range of HID lamp wattages, ballast losses largely negate the efficiency advantage that some HID lamps have over fluorescent lamps.

Fluorescent lighting still has another important efficiency advantage related to ballasts. The efficacy ratings of both fluorescent and HID lamps assume that they are operated from magnetic ballasts. However, the electronic ballasts that are available for fluorescent lighting improve fluorescent lamp efficacy by about 10% over their published lumens-per-watt figures. In fact, some high-efficiency electronic ballasts may save more energy in the lamp than they consume themselves.

A Special Case: Compact Fluorescent Lighting

Compact fluorescent fixtures are still evolving in efficiency and variety. At present, there are not many applications where you would consider compact fluorescent lamps as a replacement for HID lighting. One reason is that their efficiency is lower than the efficiency of conventional fluorescent lighting. Another is that they produce less light output per fixture, so it would take many compact fluorescent fixtures to substitute for one large HID fixture.

On the positive side, compact fluorescent fixtures are not as sensitive to space temperature, and they can be focussed more tightly. Because they are smaller, they allow even more localized control of lighting.

How to Select Fluorescent Lighting

The main selection factors for fluorescent lighting equipment are:

- **ballast efficiency.** See [Measure 9.2.4](#) for the full story on fluorescent ballasts.
- **ballast dimming capability.** Decide whether you want dimming capability. If so, the only satisfactory method is using electronic ballasts that are specialized for this purpose. Refer to [Measure 9.2.6](#) about fluorescent dimming.
- **lamp efficiency.** Coordinate lamp selection with ballast selection. Refer to [Measure 9.2.3](#) for lamp characteristics. Unlike HID lamps, fluorescent lamps do not sacrifice other performance characteristics to achieve efficiency (except for needing slightly higher minimum operating temperature).
- **diffuser efficiency.** Fluorescent fixtures typically have larger diffuser losses than HID fixtures. If appropriate, select fluorescent fixtures that do not have diffusers. Otherwise, refer to [Measure 9.7.2](#) about diffuser selection.
- **light distribution pattern.** The light distribution geometry of fluorescent lighting is radically different from the geometry used with HID lighting. Design your layout from scratch, rather than trying

to mimic the light distribution pattern of the HID lighting. The localized light of fluorescent lamps provides an important opportunity for task lighting. Refer to [Subsection 9.6](#) for guidance in lighting layout.

Make it Easy to Clean and Replace Lamps

Design your fluorescent lighting to ease lamp maintenance. Try to compensate for the larger number of fluorescent fixtures by installing them at a height that is convenient for maintenance. The fact that HID fixtures are installed at great heights does not necessarily mean that fluorescent fixtures must be installed at the same height. In fact, one of the advantages of fluorescent fixtures is that they can be installed close to people.

In many facilities, you can suspend fluorescent fixtures from the ceiling at any desired height. If you install a suspended ceiling to save heating energy, you can lay fluorescent fixtures into the suspended ceiling.

If fork lift trucks, traveling cranes, or other interferences make it impractical to suspend the fixtures from overhead, consider mounting them on equipment, on wall brackets, or even on floor stands. This is an opportunity to innovate.

Aiming Fluorescent Fixtures

Fluorescent fixtures do not have to aim straight down. If you tilt a fixture that uses long tubes, try to keep the tubes nearly horizontal. Too much tilt in long tubes may cause the mercury to accumulate at the lower end under some circumstances, making it difficult to start.

Be aware that non-vertical orientation can cause serious glare for people facing the fixture. See [Measures 9.6.2 ff](#), which cover task lighting, for guidance in dealing with this problem.

Lighting Controls

Installing controls to minimize lighting operation is an integral part of this Measure. Refer to [Subsections 9.4, 9.5, and 9.6](#) for control techniques.

ECONOMICS

SAVINGS POTENTIAL: 30 to 60 percent of lighting energy consumption, in appropriate applications.

COST: Fluorescent fixtures typically cost \$0.20 to \$1.00 per watt of capacity. Installation costs are similar. Lamp replacement cost, per lumen, is much lower than for HID lamps, except for the largest HID lamps. An important difference is the larger numbers of fluorescent fixtures that are required. This increases the costs of fixtures, fixture mounting, and wiring.

PAYBACK PERIOD: One year to several years, in new construction. Several years or longer, in retrofit.

TRAPS & TRICKS

CHOICE OF METHOD: *This Measure is mostly a matter of avoiding or correcting inappropriate HID installations. These are most likely to occur where HID lighting cannot respond efficiently to irregular schedules or to variable illumination requirements.*

SELECTING THE EQUIPMENT: *Take full advantage of the opportunity to maximize efficiency, reliability, color rendering, and other features. Review [Reference Note 55, Fluorescent Lighting](#). Plan to exploit the Measures in [Subsection 9.2](#).*

Lighting Controls, Manual

The Measures in this Subsection recommend manual lighting controls that enable people to use lighting efficiently, and encourage them to do so. These Measures can be accomplished easily, with little or no change to the connections between the controls and the fixtures. However, in existing facilities, you may need to relocate or rewire lighting controls to make it possible for people to use them effectively. See [Measures 9.6.4 ff](#) and [Measure 9.6.5](#) for these aspects of your improvements.

Understand that manual control is unreliable for saving energy, especially in commercial and industrial environments. Advances in technology and lower equipment prices have greatly expanded the opportunities for automatic lighting control, which is covered in [Subsection 9.5](#). Examine all your manual lighting controls to see whether you can replace or supplement them with automatic controls.

A NOTE ON TERMINOLOGY

To avoid confusion, be aware that lighting specialists use the word “control” to mean shaping the light distribution pattern. In this context, a parabolic reflector is a “control” device. However, “control” is used in this Subsection in the same way that it is used for other equipment, namely, turning things on and off, changing levels of output, etc.

INDEX OF MEASURES

[9.4.1](#) Install effective placards at lighting controls.

[9.4.2](#) Use security forces, watch engineers, or other regularly assigned personnel to keep unnecessary lights turned off.

[9.4.3](#) Install all single-pole toggle switches so that the toggle is down when the switch is off.

[9.4.4](#) Replace rheostat dimmers with efficient electronic dimmers.

[9.4.5](#) Where fixtures are not easily visible from the switch locations, install telltale lights.

[9.4.6](#) Draw attention to switches that should be used in preference to others.

[9.4.7](#) In applications where fixtures may be operated improperly by unauthorized personnel, use key switches.

MEASURE 9.4.1 Install effective placards at lighting controls.

RATINGS

New Facilities	Retrofit	O&M
A	A	

People need information to control lighting efficiently. Placards are an effective and inexpensive method of providing this information. Using placards is a powerful conservation measure that remains to be exploited in most facilities. However, even where placards have been used, they have not yet enjoyed great success. They require more effort to design and install than you probably expect. To be effective, placards must attract attention, they must provide enough information, and they must be easy to comprehend. This Measure tells you how to get the most benefit from lighting control placards.

The effectiveness of placards varies considerably in different environments. You get the best results in facilities where there a high level of personal responsibility, where occupant turnover is low, and where the space layout allows a person at the switch locations to see the other people in the space.

In most environments, placards can be effective in keeping excess lights from being turned on. Placards are less successful in getting people to turn lights off, especially in spaces with multiple occupants.

The only effective alternative to installing placards for manual controls is installing automatic controls, which is covered in [Subsection 9.5](#). However, even automatic lighting controls may require placards.

WESINC

Fig. 1 An effective placard for the environment
 This placard works because it is big and because it is located in the right place. The light switches are next to the door handle, where they belong, so the user has all the needed information. In contrast, see Figure 3, where the amount of information given by this placard is inadequate.

SUMMARY

A fundamental part of lighting energy conservation. It takes effort to earn results.

Where to Install Placards

Install instruction placards at virtually all manual switches and dimmers.

Why Placards Are Important

Lighting control placards serve two distinct functions: (1) when a person enters the space, they provide information about how to get the desired lighting without turning on unnecessary lamps, and (2) when a person leaves the space, they motivate and grant permission to turn off the lights.

When a person enters a space, he needs to know which switches and dimmers control the lighting in the part of the space that he will be occupying. If this information is not immediately apparent, the person is likely to turn on more lighting equipment than he needs.

The second function is primarily a matter of overcoming inhibition. Most people realize that leaving lights turned on in a vacant space wastes energy, and they would like to save energy. However, people may not be certain which parts of the space are controlled by which switches. They may fear criticism for changing the lighting. And, people wish to avoid causing inconvenience to others. Except in their own homes or in personal spaces, people feel that they lack permission to turn off unnecessary lighting. Placards provide both the needed information and the permission to act.

How to Design Placards

Expect to spend money and effort to create effective lighting control placards. The key to success is customizing each placard to the particular space and lighting equipment. Generic “turn off the lights” signs are of little value, except in single-person spaces.

■ **Make Placards Easy to Use**

Make placards conspicuous. Make them easy to understand. Locate each placard where it has an obvious

relationship to the location of the controls. Figure 1 shows a crude but effective placard that illustrates these principles.

(By the same token, the controls themselves must be accessible. See [Measures 9.6.5 ff](#) about this.)

Words are cheap, so don't be cryptic. For example, instead of labeling the light switch for a kitchen hood as "hood," say "This switch controls the lights inside the hood." Just saying "Hood" might mean that the switch starts a fan in the hood, or that it starts the stove, or that it activates a hood fire alarm, etc.

■ Tell Users What They Need to Know

Be complete and specific. The placard should:

- **identify the controls**, if this is not readily apparent ("This switch controls the lights in the men's restroom.") Do not assume any prior knowledge. For example, a person cannot tell that an unmarked toggle switch is even a light switch (it might start a fan, trigger an alarm, etc.).
- **identify the fixtures that are controlled** (for example, "chandeliers," "fluorescent fixtures," "perimeter wall light dimmers," "the row of downlights in front of the projection screen," etc.) Figure 2 illustrates this aspect of placards. Without this, a person cannot guess which light fixtures are controlled by each switch.
- **tell what to do** ("Please turn off the lights ...") However, saying this alone is usually useless. See Figure 3 as an example.
- **say when to do it** ("... when leaving the room," "... when the blinds are open," etc.)
- **alert occupants to automatic lighting controls** ("The row of fixtures adjacent to the windows is controlled by an automatic dimmer that responds to daylight. This switch allows the fixtures to be turned off when the room is vacant.")
- **tell occupants whom to contact if the controls fail**. ("Call Extension 329 if ...") Otherwise, an inefficient condition may continue indefinitely.

Specific Situations

The following are guidelines for some common lighting control situations. Combine them as appropriate.

■ All Lighting is Controlled by a Single Switch

This is the easiest case. Install a placard asking the last person leaving the space to turn off the lights.

■ Lights are Controlled from Multiple Locations

If lighting is controlled from more than one switch location, install the appropriate placards at each switch.

■ There is a Group of Switches

When a person encounters an unmarked group of light switches, the common response is to turn them all on. Users also are inhibited from turning off lights

selectively because of the effort or embarrassment that is involved in experimenting to determine which switches to use.

The solution is to label each switch to indicate the fixtures that it controls. Label the switches in a clear, permanent manner. Make the lettering big enough for people to see without their reading glasses. The placard should also request occupants to turn on a minimum number of fixtures ("Use only as much light as you need.>").

WESINC

Fig. 2 Lighting control panel for a large ballroom This marking performs the basic function of identifying each control. It is fairly permanent. Pieces of tape are used on the top three dimmers to suggest brightness settings, but this is not explained. The lower left master dimmer controls a lot of electricity, but it is not marked. There is no guidance about how to set the lighting so that it is most pleasing and efficient for all the functions that may occur in the space.

■ The Space has Daylighted Areas

Many spaces have windows that provide effective daylighting for a portion of the space. Often, switches are installed in such spaces to provide separate control of fixtures near the windows. In addition to labeling each switch, ask occupants not to turn on the lights in daylighted areas when daylight is available.

■ Light Switches are Not Located Near Exits

The common and expected location for light switches is on the wall adjacent to the knob side of the door. If the light switch is not located there, users will not search for it. In such cases, install an appropriate placard at the switch and also at the exit, to direct the user to the light control. (“Please turn off the bathroom lights when you leave. The switch is located outside on the right.”)

■ Fixtures are Not Visible from the Switches

It is poor practice to install switches and dimmers where users cannot see the fixtures they control. In such cases, the preferred solution is to relocate the controls (see [Measure 9.6.5](#)).

If this is not practical, label the switches to indicate which fixtures they control. (“This switch controls the parking lot lights.”)

In this situation, it is also valuable to install telltale lights at the switches (see [Measure 9.4.5](#)).

■ The Spaces have Emergency Lighting

People are inhibited from turning off lights in large spaces because they are concerned that others may be trapped in the dark. If spaces have continuous emergency lighting, the placard should say so. (“Please

WESINC

Fig. 3 Useless placard This sticker tells us to turn off the lights. So, now what? These switches are in an obscure location. Which spaces do they control? Which fixtures does each switch control? How do we know if there are other people still in the space?

turn off all the light switches when you leave. The emergency lights will remain lighted.”)

■ Some Lighting has Automatic Controls

If some of the lighting has automatic controls (e.g., timeclocks, photocontrols, motion detectors, interval timers), describe the operation of the automatic controls at the location of the manual switches. The purpose is to keep the automatic controls from confusing people, as this discourages them from taking initiative to use manual switches.

For example, in a room where daylighting is available, you might install a photoelectric switch to override the manual switch for the fixtures adjacent to the windows. However, this has the effect of making the manual controls incomprehensible. To correct this problem, explain what the photocontrol is doing. On the placard for the switch group, highlight the switches for the daylighted area and say that they alone have automatic control.

■ The Lighting has Multi-Level Control

Where separate switches are used to control different numbers of lamps within fixtures, this capability is often ignored by the occupants. The solution is to label each switch to state the brightness level (“normal brightness”, “extra bright”, etc.) The placard should also request occupants to turn on the minimum number of lamps in each fixture (“Use only as much light as you need.”).

■ Programmable Lighting Controllers are Installed

Refer to [Measure 9.6.4.1](#) about programmable lighting controllers. These are used with low-voltage relay control systems. The controller should have clear instructions stating, as a minimum:

- what the available lighting patterns are, using diagrams if necessary
- when each lighting pattern should be used
- how to press the buttons or turn the dials to select the desired pattern. This is important because some programmable controls are user-hostile.

■ Dimmers are Installed

People habitually turn up dimmers to about two thirds of full power, regardless of the actual illumination requirement. This may result from the insensitivity of human vision to relative differences in lighting levels, and from the long time required for humans to adapt to lower light levels. It may also reflect a desire by people to make use of available lighting capacity. In any event, install dimmer placards that say something like, “To save energy, set the dimmer to the lowest level you need.”

People tend to be careless in turning off dimmers. The lights may seem to be turned off, but they continue to operate at low power during unoccupied hours. Manufacturers contribute to this problem by using click stops in the off position of many dimmers. Users tend not to move the dimmers forcefully enough to overcome

these stops unless they are told to do so. This makes it important to customize the placard to the particular dimmer configuration (slider, rotary knob, etc.). For example, “To turn off the lights, push the knob down past the click.”

Wherever it is practical to do so, label the faceplates of the dimmers to tell occupants the recommended settings for each type of activity. For example, in a hotel ballroom, label different levels as “banquet”, “dance”, “slide projector”, etc.

How to Make Effective Placards

See [Reference Note 12](#), Placards, for the details of effective placard design, materials, and installation.

Make placards from materials appropriate for each application, considering factors such as durability, visibility, and cost. For example, inexpensive adhesive labels applied over switch plates are effective and economical in applications where the only function of the placard is to remind occupants to turn off the lights. At the other extreme, instructing people how to use complex lighting controls usually requires custom placards and special materials, such as photographically printed metal. In all cases, make placards durable enough to survive the environments where they are installed.

Appearance is Important

Facility managers may resist installing placards in visible locations because of their previous experience with unattractive energy conservation stickers, such as the ones given away by utility companies and government agencies. The solution is to design the placards to fit the decor.

For example, in designing placards for the guest rooms of a luxury hotel, use a complementary color scheme and attractive lettering. Invite the hotel’s interior decorator to participate in the design.

Coordinate with Other Energy Conservation Placards

Energy consuming equipment throughout the facility should have instruction placards to motivate efficient operation. Placards for different types of

equipment are covered in the Measures dealing with those types of equipment. Placard design is an intensive activity, so try to do it throughout the facility at one time. This saves effort and gives you an opportunity to combine information. For example, use a single placard to ask occupants to turn off both the lights and the air conditioning when departing.

Introduce the Placards with Fanfare

Placards are effective for providing information. However, passive objects such as placards are not very effective in getting people to change their behavior. Personal contact is the best way to do this. When you install placards, ask managers to explain them to occupants and to ask everyone to take the indicated actions to save energy.

To keep placards effective, make them part of a continuing energy conservation motivational program that includes posters, newsletters, talks by managers, etc.

ECONOMICS

SAVINGS POTENTIAL: 10 to 60 percent of the lighting energy under manual control. Lamp cost and replacement labor may be reduced by a similar amount.

COST: \$0.10 to \$50 per placard, depending on quantity, materials, and complexity. Expect high placard design costs for special situations.

PAYBACK PERIOD: Less than one year, usually.

TRAPS & TRICKS

DESIGN: Designing effective placards takes a lot of time and effort. Don’t take shortcuts. Read [Reference Note 12](#).

MATERIALS: Your choice of placard material matters. See [Reference Note 12](#).

INSTALLATION: Your choice of installation methods matters. See [Reference Note 12](#).

KEEP IT UP: Placards are part of a system of communication. Keep the whole system alive, in a manner appropriate to your environment.

MEASURE 9.4.2 Use security forces, watch engineers, or other regularly assigned personnel to keep unnecessary lights turned off.

A powerful way of reducing energy costs is to use the facility staff to turn off excess lighting, as well as to perform other energy management functions. Eligible personnel may include security police, watch engineers, or anyone else who is assigned to the facility on a regular basis.

If the facility has security police, these may be the best people to carry out this responsibility. They usually are present for the largest number of hours per day, and they have access to most spaces. In fact, making police responsible for monitoring lighting makes them more alert to security conditions.

Also, consider assigning engineering personnel to control lighting. Engineers typically have access to most of the facility. However, they are less inclined toward patrolling.

Alternatively, if spaces are under the administrative control of a particular group, those groups may have individuals who can be assigned to turn off unnecessary lighting. For example, ask the executive chef to be responsible for turning off lights in the kitchen and dining areas.

In some facilities, the savings potential may be large enough to justify paying overtime, or hiring an additional person, to monitor the after-hours operation of lighting and other energy consuming equipment.

Where to Use This Method

This method of turning off lights is desirable in facilities that have some degree of irregular occupancy. Examples are office buildings, laboratories, recreational facilities, etc.

Where suitable personnel are available for lighting patrols, this Measure may cost little or nothing, making it the most economical method of lighting control. In some environments, it may also be the most efficient method. For example, in large spaces occupied by many people, both occupant control and automatic control may be impractical.

Using facility personnel to control lighting may be valuable in combination with other control methods. It also serves as a check on other methods. No manual method of lighting control is completely effective, and automatic control methods should be checked periodically for proper operation.

Provide Effective Instructions

Achieving success with this Measure is largely a matter of effective personnel management. This starts

SUMMARY

A powerful way to save energy where space usage is irregular. Requires effective, continuing management.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return	%	%	%	%
Reliability	✓	✓		
Ease of Initiation	😊	😊	😊	

with effective instruction at the outset, and continues with effective supervision. To provide motivation, explain the high cost of lighting.

Monitor all spaces with manual lighting control, except where special circumstances exist. There is rarely a reason to keep lights turned on in a vacant space.

Look for unnecessary operation of lighting both during and outside of normal hours of occupancy. After hours, lights are turned on by late workers and by cleaning crews. During normal working hours, lights may be left on by people who leave for activities elsewhere.

The placards recommended by Measure 9.4.1 are a valuable way of instructing lighting patrols as well as the regular occupants. Design them accordingly.

Combine with Other Energy Conservation Activities

Don't limit this activity to lighting. The same people who monitor lighting can also be assigned to other energy conservation functions, such as turning off air handling units (Measure 4.1.1.5) and room conditioning units (Measure 5.1.2), closing windows and doors, etc.

ECONOMICS

SAVINGS POTENTIAL: A significant fraction of all facility lighting energy. Lamp cost and replacement labor may be reduced by a similar amount.

COST: Minimal, if regularly assigned personnel are used.

BENEFIT-COST RATIO: Usually high.

TRAPS & TRICKS

See Measure 4.1.1.5, which uses the same technique for control of air conditioning equipment.

MEASURE 9.4.3 Install all single-pole toggle switches so that the toggle is down when the switch is off.

RATINGS

New Facilities	Retrofit	O&M
	B	

People in the United States expect lights to turn off when the switch is pushed down. In some other countries, it is customary for the up position to be off. If a switch is installed the wrong way, people tend to leave those lights turned on. Furthermore, reversed switches interfere with the habit of turning lights off.

If a switch is installed upside down, simply remove it from the junction box and turn it over. This takes only a few minutes.

This Measure applies only to single-pole switches, i.e., switches that control lights from one location only. Switches that are designed to control fixtures from multiple locations do not have defined on and off positions. These switches are either “3-way” or “4-way” switches. To preserve energy conserving habits, install 3-way and 4-way switches separately from single-pole switches, and mark them with distinctive placards.

SUMMARY

An easy fix for a common flaw that promotes energy waste.

Rate of Return	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	😊

ECONOMICS

SAVINGS POTENTIAL: *Small and unpredictable.*

COST: *Minor.*

PAYBACK PERIOD: *Short.*

MEASURE 9.4.4 Replace rheostat dimmers with efficient electronic dimmers.

RATINGS

New Facilities	Retrofit	O&M
	B	

Rheostat dimmers are found with incandescent lighting in older facilities. Rheostats are large variable resistors in series with the lamps. The rheostats absorb power in the same way as the lamps themselves.

You can eliminate most of this energy waste by replacing the rheostats with modern electronic dimmers. These absorb little energy. See [Measure 9.1.7](#) for details about electronic dimmers. They do have some limitations.

Energy Saving Potential

The greatest amount of energy is wasted by rheostats when they reduce the lamp power to half, at which point they absorb as much energy as the lamps themselves. This is an amount equal to one fourth of the rated lamp capacity. At lower light output, rheostats absorb an even larger fraction of the total energy consumed, although they consume less energy in absolute terms.

Where to Upgrade Dimmers

It is almost always economical to get rid of rheostats if the lights are dimmed for long periods of time. On

SUMMARY

Usually a simple and inexpensive change. However, there are some applications that still require rheostats.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	😊

the other hand, rheostats waste little energy in applications where they quickly change the lighting from full on to full off, or vice versa. For example, if rheostats are used in a theater to dim out the house lights, they waste energy for only a few minutes per year. In such cases, keep them.

Electronic dimmers can replace rheostats in most cases. However, they create some electrical interference

and faint audible noise. Therefore, you may have to retain rheostats in sensitive applications, such as laboratories with sensitive electronic equipment.

Alternative: Fluorescent Dimming

If incandescent lighting is still being used because the application requires dimming, consider substituting fluorescent lighting that has dimming capability. See [Measure 9.2.6](#) for this option.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. Don't expect to save much money in applications where dimmers are used only for brief periods.*

COST: *Less than \$1 per ampere in common styles. Large dimming systems may be much more expensive.*

PAYBACK PERIOD: *Varies widely, depending mainly on the length of time that lights operate in a dimmed state.*

TRAPS & TRICKS

SELECTING THE EQUIPMENT: *Be wary of cheap dimmers. Make sure that the dimmers you buy do not cause radio interference or audible noise. Good dimmers have become inexpensive, if you know how to shop.*

MEASURE 9.4.5 Where fixtures are not easily visible from the switch locations, install telltale lights.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Lighting is likely to operate unnecessarily if it is not visible from the switch location. For example, this is a common problem with outside lighting.

To reduce this energy waste, install a telltale light at a location that is visible at the switch. The telltale light is simply a small light that is wired in parallel with the fixtures being controlled.

The easiest way to install a telltale light is to install a switch that is combined with a telltale light. These are available in different styles. A common type consists of a toggle switch and a separate neon light. It is installed in a standard double receptacle box. Figure 1 shows this type of telltale light.

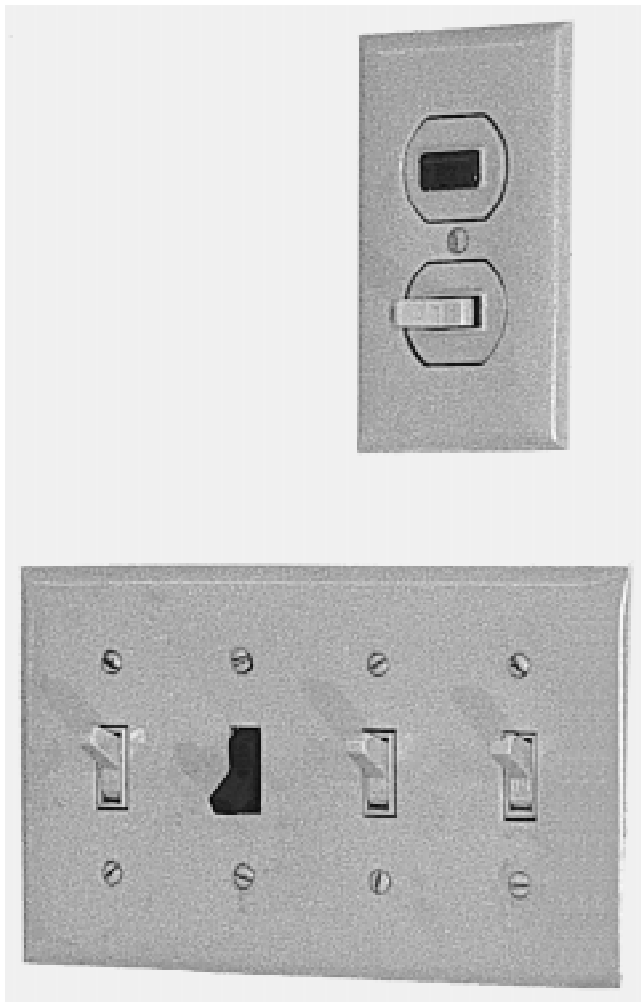

Fig. 1 Telltale light The 3-way switch on top controls an outdoor light from several locations. The light is not visible from this location. The telltale reveals whether the light is on. In the bottom group of switches, the dark toggle is for one 3-way switch among a group of single-pole switches. All these switches need to be identified individually.

SUMMARY

An important switch feature for fixtures that are out of sight. Cheap with single-location switches, more expensive with multiple locations.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

An even more compact arrangement is a switch that has a lighted toggle. This type fits in a single-switch connection box.

Installation is simple and cheap if the lights are controlled from a single location. No change in wiring is needed, outside the connection box.

You can install any number of telltale lights for a given fixture. If lighting is controlled from multiple locations, you need a telltale light at each switch. This is especially important because the position of 3-way and 4-way switches (up or down) does not indicate whether the fixture is on or off. Installing telltale lights at multiple locations involves a significant wiring cost, because each telltale light needs its own wiring run.

If the switch itself is installed out of sight, install an extra telltale light where it can attract attention to the switch. In such cases, install an appropriate placard at the remote telltale (see [Measure 9.4.1](#)).

ECONOMICS

SAVINGS POTENTIAL: A substantial fraction of the energy used by the affected fixtures. Lamp cost and replacement labor may be reduced by a similar amount.

COST: \$10 to \$30, if no additional wiring is required. With fixtures controlled from multiple locations, the additional wiring for the telltale lights may be expensive.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

ANALYZE THE PROBLEM: Is the main problem that the switch is inaccessible or out of sight? In such cases, relocate the switch, but still use a telltale light if appropriate.

MEASURE 9.4.6 Draw attention to switches that should be used in preference to others.

Groups of switches are a problem for efficient lighting control because they make it difficult for occupants to associate an individual switch with the lights that the switch controls. The primary method of getting people to use groups of switches properly is installing an effective placard that points to each switch and identifies it. See [Measure 9.4.1](#) for this step.

An additional step is important if one switch should be used in a manner different from the rest. For example, draw attention to a switch that controls night transit lighting, to keep people from turning on the other lights in the space.

Here are some ways of drawing attention to a particular switch in a group:

- **use a contrasting toggle color.** For example, install a dark brown toggle in a group of ivory-colored switches. Figure 1 in [Measure 9.4.5](#) shows an example.
- **use a lighted toggle.** Switches with lighted toggles are a direct replacement for conventional toggle switches. You can also get lighted toggles on some models of personnel sensor switches ([Measure 9.5.4](#)) and rundown timer switches ([Measure 9.5.5](#)).
- **install a decal around the toggle.** Design a sticker to attach to the switch plate, with a hole for the toggle. You can print a message on the sticker. Be aware that a sticker will eventually come off when the adhesive dries out, and that rubbing from using the switch will wear through the sticker.
- **install the switch alone or in a separate group.** This is more expensive, especially to retrofit. However, it is a powerful way of setting a switch apart. See Figure 1 in [Measure 9.4.5](#) for a typical example. This method is particularly valuable for separating 3-way and 4-way switches from single-pole toggle switches. This is because the position of a single-pole switch tells whether it is on or off,

RATINGS		
New Facilities	Retrofit	O&M
A	A	

SUMMARY

An important ergonomic feature that works in combination with an effective placard. Inexpensive and reliable.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	😊

but the same is not true for 3-way and 4-way switches. (See [Measure 9.4.3](#) about this.)

You may be able to think of other effective methods. Use your imagination.

ECONOMICS

SAVINGS POTENTIAL: A significant fraction of the energy controlled by switches other than the lighted switch. This also reduces the cost of lamps and replacement labor.

COST: Lighted toggle switches cost several dollars apiece. In retrofit, replacement labor adds \$10 to \$30 per switch.

PAYBACK PERIOD: Less than one year, typically.

TRAPS & TRICKS

BE BOLD: Installing the lighted toggle switch is easy. The part that takes effort is designing an effective placard for the whole group of switches. Don't be inhibited. For example, maybe install a big, bold arrow pointing to the lighted toggle, with a sign that says, "Use only the lighted switch when passing through the space."

MEASURE 9.4.7 In applications where fixtures may be operated improperly by unauthorized personnel, use key switches.

RATINGS		
New Facilities	Retrofit	O&M
C	C	

Using key switches is an absolute method of controlling lighting. Its major advantage is that it avoids the need to depend on occupants to control lighting. Low cost is another advantage, compared to other control methods. Figure 1 shows a typical installation.

A serious limitation is that an individual with the proper key always needs to be available to turn the lights on and off. Key switches make it awkward to use spaces outside normal hours of occupancy. As a result of the difficulty that they cause, key switches tend to be abandoned. Use them only where you cannot find a better method.

In most applications where the purpose of lighting controls is to keep unauthorized persons from turning on lights, consider automatic control (see Subsection 9.5). You can combine these with key switches. For

WESINC

Fig. 1 Key switches The “keys” are inexpensive, non-custom items. However, anyone who has a need to turn the lights on or off must have one. As a result, the lights tend to be left on, and key switches tend to be abandoned.

SUMMARY
 Avoids the uncertainty of occupant behavior. Inexpensive. Easy to retrofit. But, too inflexible for most applications.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	
Ease of Retrofit	😊	😊	😊

example, use key switches to turn off the overall lighting in a large space, and use motions sensors to provide localized lighting within the space.

ECONOMICS

SAVINGS POTENTIAL: All the lighting energy controlled by the switches during off periods. Lamp cost and replacement labor may be reduced by a similar amount.

COST: Key switches typically cost several dollars apiece. In retrofit, labor for replacing existing switches typically costs \$10 to \$30 per switch.

PAYBACK PERIOD: Less than one year, typically.

TRAPS & TRICKS

CHOICE OF METHOD: This method is not as simple as it looks. Key switches that are used alone tend to be abandoned, because some light must always be made available. Either limit key switches to a fraction of the lighting, or combine them with other methods of control.

Lighting Controls, Automatic

In many existing facilities, installing automatic lighting control can save more energy than any other lighting improvements. The Measures in this Subsection automatically turn off lighting when it is not needed. Many of these Measures can be accomplished easily, with little or no rewiring of the connections between the controls and the fixtures. In other cases, optimum performance requires changes to the lighting circuits, which are covered by the Measures in [Subsection 9.6](#).

Safety is a Major Issue

Any automatic method of lighting control involves some possibility of turning off the controlled lights unexpectedly while people are still in the lighted area. Therefore, with any automatic lighting control, ensure safe egress from the space if the controls turn off the lights. Generally, you can do this by providing a minimum amount of light that is not under automatic control.

Tailor Lighting Control to Each Space

Don't install automatic lighting controls in a shotgun fashion. This will waste money and conservation potential, and create user problems. Review all the Measures in this Subsection to find the most appropriate automatic lighting control methods for each space. Expect to use a combination of control methods to achieve optimum performance.

A NOTE ON TERMINOLOGY

To avoid confusion, be aware that lighting specialists use the word "control" to mean shaping the light distribution pattern. In this context, a parabolic reflector is a "control" device. However, "control" is used in this Subsection in the same way that it is used for other equipment, namely, turning things on and off, changing levels of output, etc.

INDEX OF MEASURES

9.5.1 Where lighting is needed on a repetitive schedule, use timeclock control.

9.5.1.1 To combine time switching with daylighting, use astronomical timeclocks.

9.5.2 Control exterior lighting with photocontrols.

9.5.3 Install interior photocontrols to exploit daylighting.

9.5.4 Where the need for lighting is determined by the presence of people, use personnel sensor switching.

9.5.5 Where lighting can be turned off after a fixed interval, install timed-turnoff switches.

9.5.6 If a door remains open when lighting is needed, use door switches.

RELATED MEASURES:

- [Subsection 9.4](#), for manual controls to be used in combination with automatic controls
- [Measure 9.2.6](#), daylight sensing dimmers for fluorescent fixtures
- [Measure 9.3.2](#), daylight sensing dimmers for HID fixtures

- [Measure 9.6.4](#), for circuit changes needed to maximize the effectiveness of some control improvements

MEASURE 9.5.1 Where lighting is needed on a repetitive schedule, use timeclock control.

RATINGS

New Facilities	Retrofit	O&M
A	B	C

There are many lighting applications where occupancy occurs on a repetitive schedule. Safety is the main factor that determines whether you should use timeclocks to control the lighting in such applications. The controls should not trap people in unexpectedly darkened spaces.

Where to Use Time Control for Lighting

You can use time control by itself for these types of applications:

- **lighting that is not related to safety.** Examples include advertising sign lighting and decorative lighting.
- **lighting that exceeds levels needed for safety.** For example, the lighting in the dining area of a cafeteria may be turned off on a time schedule if the space has continuous emergency lighting. (Motion sensors would not be effective in this application because people walking through the space would keep turning on the lights unnecessarily.)

Time controls can be used more broadly in combination with other types of automatic or manual control. For example, in a large, open office area, use time controls to turn off all but the emergency lighting outside normal working hours. For late workers, use personnel sensors (Measure 9.5.4) to control lighting of smaller areas within the larger space.

SUMMARY

May save lots of energy at relatively low cost. Usually needs to be combined with other types of control.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓		
Ease of Retrofit	😊	😊	😊	

Time control is often useful in combination with daylight sensing control. For example, photocontrols are used to turn on parking lot lights at sunset. If there is no need to continue lighting the parking lot after midnight, install a time control to turn off the lights after midnight. For example, see Figure 1.

Another way to achieve the same effect is to use a time control called an “astronomical” timeclock, which is recommended by the subsidiary Measure 9.5.1.1.

You can use a timeclock to change the patterns of a programmable lighting controller (Measure 9.6.4.1) at different times of day. For example, in a restaurant, a programmable controller can change from incandescent

WESINC

Fig. 1 Subway station parking lot After the subway stops running, why is it necessary to keep all these lights on? A timeclock is the appropriate method of turning these lights off. A photocontrol is the appropriate method of turning them on.

mood lighting during meal hours to more efficient incandescent lighting during set-up and cleaning hours.

How to Select and Install Time Controls

A great variety of timeclocks are available, with virtually any degree of scheduling flexibility that you could want. This includes separate schedules for weekends and holidays, automatic changeover to daylight saving time, etc.

See [Reference Note 10](#), Clock Controls and Programmable Thermostats, for the equipment features, installation practices, operating procedures, and overrides that you need to achieve satisfactory performance with time controls.

If the facility has an energy management computer system, you can use it for time control instead of installing individual timeclocks, but this approach is usually much more expensive. For more about this, see [Reference Note 13](#), Energy Management Control Systems.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of the energy used by controlled fixtures. Lamp cost and replacement labor may be reduced by a similar percentage.

COST: Appropriate modern electronic time controls cost from \$80 to \$500, depending on schedule options, number of circuits, power backup features, etc. Installation labor varies widely.

PAYBACK PERIOD: Less than one year, to several years. Depends on the lighting wattage, occupancy patterns, labor costs, etc.

TRAPS & TRICKS

CHOICE OF METHODS: In many applications, this is the best method to turn lights on, or to turn them off, but not both. Think in terms of combining time control with other methods.

SELECTING THE EQUIPMENT: Time controls are inexpensive and readily available, but don't grab the first unit you find. Shop to find the features that your application needs. Use [Reference Note 10](#) as your guide.

INSTALLATION: Be careful to avoid safety problems. Install the timeclock itself so that it is obvious and accessible only to those who should set it. Install a placard at the timeclock that says which lighting it controls and the schedules that should be set.

MONITOR PERFORMANCE: Sooner or later, all time controls fail or get out of time. Schedule periodic checks of all time controls to verify proper operation and settings. Keep a list of all timeclocks and the functions they control in your plant maintenance manual. (You do have one, right?)

MEASURE 9.5.1.1 To combine time switching with daylighting, use astronomical timeclocks.

RATINGS

New Facilities	Retrofit	O&M
C	B	

Most outdoor lighting, such as security, parking lot, decorative, and advertising lighting, is turned on at sunset. The same is true of heavily daylighted interior spaces, such as atriums and greenhouses. However, most of these applications do not need lighting all night. For such applications, an “astronomical” timeclock is a single piece of equipment that can turn the lights on and off at the proper times.

Paragon Electric Company, Inc.

Fig. 1 Old fashioned astronomical timeclock This type adjusts for seasonal changes in the length of daylight. The latitude of the location has a major effect on seasonal daylight variation, so make sure that it is set properly. In most cases, you would prefer to use an electronic version, primarily for benefits such as battery backup, flexible scheduling, etc.

SUMMARY

An easy way to combine control by time and by daylight.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓		
Ease of Retrofit	😊	😊	😊	

The time of sunrise and sunset varies considerably with the seasons. An astronomical timeclock calculates the times of sunset and sunrise, based on the date and the facility’s geographic location. You can install an astronomical timeclock anywhere that is convenient, minimizing wiring cost.

How to Select and Install Time Controls

Select and install an astronomical timeclock like any other timeclock, except for the additional “astronomical” feature. See [Measure 9.5.1](#) for guidelines. Earlier astronomical timeclocks were mechanical units, but these are now obsolete. Buy an electronic unit made by an established manufacturer.

Alternative: Photocontrol

An alternative is using a photosensitive control ([Measures 9.5.2](#) and [9.5.3](#)) in combination with a conventional timeclock. Photocontrols provide a direct indication of available daylight, so they never get out of time. Also, they can account for overcasts, eclipses, etc. On the other hand, you have to install them where they can “see” daylight. The wiring may cost much more than the controls themselves.

ECONOMICS

SAVINGS POTENTIAL: 40 to 70 percent of the energy used by controlled fixtures, compared to operating all night. Lamp cost and replacement labor may be reduced by a similar percentage.

COST: A typical single-circuit electronic astronomical time control with battery backup and other features costs about \$200. Installation typically costs no more than one or two hundred dollars, because the unit can be installed anywhere that is convenient.

PAYBACK PERIOD: Less than one year, to several years. Depends on the lighting wattage, operating schedule, wiring costs, etc.

TRAPS & TRICKS

CHOICE OF METHOD: An astronomical timeclock can get off schedule, and it cannot respond to unexpected periods of darkness, which makes it less reliable than photocontrol. In new construction, photocontrol is usually

preferable. In retrofit applications, the lower wiring cost of an astronomical timeclock may be the deciding factor.

SELECTING THE EQUIPMENT: An astronomical timeclock is basically a timeclock. Get all the timeclock features that would benefit the application. Use Reference Note 10 as a guide.

INSTALLATION: See Measure 9.5.1.

MONITOR PERFORMANCE: See Measure 9.5.1.

MEASURE 9.5.2 Control exterior lighting with photocontrols.

Leaving exterior lights turned on during daylight, as in Figure 1, is a useless waste of energy. On the other hand, exterior lighting applications are often critical, so they need to be turned on as soon as it becomes dark. The most precise way to tailor exterior lighting to the availability of daylight is to control the lighting with a daylight sensor. Such devices are called by a variety of names, including “photoelectric,” “photocontrol,” and “photocell.”

This is also the most reliable method of controlling exterior lighting. The equipment is highly reliable, and it is much less vulnerable to tinkering than other methods, such as timeclocks.

A photocontrol is essentially an on-off switch that is activated by a light sensor. Most photocontrols are small units that typically weigh a few ounces. Photocontrol is so popular for exterior lighting that inexpensive units are available in many configurations, with standardized features. Figures 2 and 3 show two common types.

You can control any type of lighting with photocontrols. However, if you are controlling HID lamps (mercury vapor, metal halide, or sodium vapor) or low-pressure sodium lamps, it is important to select a photocontrol that avoids turning off the lamps for brief periods.

How to Select Photocontrols

Consider these features in selecting a photocontrol for exterior lighting:

- **mounting method.** Photocontrols are available for convenient installation using all common electrical mounting methods. Many types are available that fit standard knockout holes in electrical boxes and lamp posts. Units are available that screw into

SUMMARY

Simple and reliable. Often inexpensive. Usually combined with time control.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	😊	😊	😊

medium lamp bases, and require no wiring. Figure 3 shows a common type that is installed on a bayonet base.

- **orientation flexibility.** Some units have a swivel base that provides extra flexibility in pointing the unit. This may be necessary to keep the sensor out of direct sunlight or to receive daylight from the right direction for proper sensing.
- **ruggedness.** Select units that can withstand abuse. This is primarily a matter of selecting metal over plastic. Plastic units are generally flimsy, and they deteriorate from sunlight and lamp heat.
- **light level adjustment.** Some photocontrols have an adjustable shutter over the sensor window that lets you adjust the light levels at which the lights turn on and off. Figure 2 shows an example. With these, the ratio of on and off light levels is fixed at about 1:3. Newer, more expensive photocontrols may provide more flexibility.
- **response delay.** To keep photocontrols from responding to light flashes from vehicle headlights,

lighting, and other sources, most photocontrols have a built-in delay. The delay is usually not adjustable.

- **amperage.** For cost reasons, photocontrols typically do not have enough current capacity to control all the amperage of a single power circuit. This is easy to handle. Either buy a photocontrol that has enough capacity for the lighting load, or use the photocontrol to provide power to the lighting through a relay of sufficient capacity.

How to Install Photocontrols

Installing photocontrols for exterior lighting is usually simple. The unit can be inserted anywhere in the lighting power circuit. If the wiring is accessible, installation may take only a few minutes. Some exterior fixtures have standardized receptacles for photocontrols.

Keep the photocontrol out of precipitation and direct sunlight, unless it is designed specifically for exposed locations. If necessary, make a small hood for the unit.

WESINC

Fig. 1 Lights turned on in the middle of the day These lights are turned on because the switch is installed at some remote location where the lamps cannot be seen. Photocontrol is the most reliable and least expensive control method for this situation.

A unit that is properly selected and installed may last for the life of the facility.

Keep the sensor from seeing direct sunlight, as this shortens sensor life. At the same time, install the sensor so that it sees enough daylight to keep the lights turned off during cloudy days. Typical units can be set to remain off until the light level falls to about one footcandle (about ten lux). The setting may drift from the effects of aging and from dirt on the sensor window.

Combine Photocontrol with Other Methods

Unless the application needs continuous lighting all night, combine photocontrols with other controls that turn off the lights during selected hours of darkness. To turn the lights on or off at specific times, combine with time controls, as recommended by [Measure 9.5.1](#).

If you provide any manual control, be sure to install effective control placards. See [Measure 9.4.1](#) for guidance. Also, telltales lights ([Measure 9.4.5](#)) are valuable with manually controlled exterior lighting.

Paragon Electric Company, Inc.

Fig. 2 Exterior photocontrol This unit, shown approximately actual size, is inexpensive and rugged. The sliding metal strip on the cover acts as a mask to reduce the sensitivity of the cell behind the window. The on-off light level ratio is fixed.

Paragon Electric Company, Inc.

Fig. 3 Bayonet mounted photocontrol This style allows quick replacement, which is useful in awkward locations, such as the tops of light poles. Some outdoor light fixtures have an integral socket to accept sensors of this type.

Alternative: Astronomical Timeclock

An astronomical timeclock ([Measure 9.5.1.1](#)) calculates the times of sunset and sunrise, and can turn lighting on and off accordingly, as well as providing other timeclock functions. They are more expensive than photocontrols, and they are more vulnerable to tampering and setting errors. The main advantage of astronomical timeclocks is that they do not have to be installed where there is daylight.

ECONOMICS

SAVINGS POTENTIAL: 10 to 70 percent of exterior lighting energy. Lamp cost and replacement labor may be reduced by a similar percentage.

COST: Typical photocontrols for exterior applications cost less than \$10. New fixtures can be selected with integral daylight sensors. In retrofit, sensors can be mounted at the fixtures, minimizing wiring cost.

PAYBACK PERIOD: Usually less than one year.

TRAPS & TRICKS

CHOICE OF METHODS: Unless the lights are needed during all hours of darkness, combine this method with timeclocks or other appropriate methods of control.

MEASURE 9.5.3 Install interior photocontrols to exploit daylighting.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Turning interior lighting on and off with photocontrols is a possibility that deserves more attention because it may save substantial amounts of energy in spaces that have glazing. Photocontrol of interior lighting is more difficult to accomplish in a satisfactory manner than photocontrol of exterior lighting, which was recommended by the previous Measure. Here, we cover the additional complications of indoor photocontrol.

Where to Consider Photocontrol for Inside Lighting

Consider photocontrols for any space that has lighting from windows or skylights, provided that the space has fluorescent or incandescent lighting. Figures 1 through 4 show favorable examples.

Don't overlook opportunities in spaces that are only partially daylighted. A common example is using photocontrol for the row of fixtures adjacent to the windows of a room, as in Figure 2. Figure 4 shows where photocontrols should be installed in the area adjacent to a daylighted atrium.

To find out whether there is enough daylight to make photocontrol worthwhile, survey candidate areas using a light meter. There should be a many hours during

SUMMARY

A technique with great untapped potential. Don't overlook any lighting that would benefit, such as emergency lighting. May be tricky to design and install. Expect to combine photocontrol with other types of control.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% % %
Reliability	✓ ✓
Ease of Retrofit	☺ ☺

which the daylight level is about three times higher than the minimum lighting level required for the activities. The reason for this ratio is explained below.

If there is adequate daylight, consider whether the abrupt changes in lighting level that occur as fixtures turn on and off will be an annoyance. The worst problem is created by thick, localized clouds of the kind shown in Figure 5. However, don't assume that clouds are an insurmountable obstacle. When light fixtures are turned on and off in a brightly daylighted space, the change is much less noticeable than turning lights on and off in a dark space. Furthermore, if the photocontrols are installed properly, the lights will not switch often.

Interior photocontrol is most acceptable in transient areas, such as daylighted corridors (Figure 1), common

Fig. 1 Daylighted corridor This is an ideal application for photocontrol of lighting. Daylight provides ample illumination under most daytime conditions. The light fixtures are fluorescent, with multiple lamps, so they can even be switched in stages for a more gradual response.

Fig. 2 Daylighted reading area in a library The row of light fixtures adjacent to the windows is a prime candidate for photocontrol.

areas in shopping malls that are illuminated by skylights, and daylighted atriums (Figure 3). Photocontrols are less likely to be acceptable in offices and classrooms. However, a greater awareness of the need for energy conservation may make photocontrol acceptable even in such locations.

Security lighting is an especially fruitful application for photocontrol. Only low levels of light are needed for emergency egress, so daylighting may serve as emergency lighting for a much larger portion of the building than for conventional lighting. For example, photocontrol may eliminate the need for most emergency lighting on weekend days, when no people are present to require high lighting levels. Also, photocontrol of emergency lighting may not require the complexity of other applications. Check that local codes allow turning off electric emergency lighting when daylight is available. This is an unusual way of dealing with emergency lighting, so you may have to request a variance.

Limitations with HID Lighting

All types of HID lamps (mercury vapor, metal halide, and high-pressure sodium) require a time of several minutes to start, and most require an even longer time to restart from a hot condition. Therefore, do not use photocontrols with HID lamps in applications where fluctuations in daylight during the day, typically caused

by clouds, might require starting or restarting during occupied periods.

Combine with Other Types of Lighting Controls

Expect to combine photocontrol of interior lighting with other methods of control. Photocontrols alone would keep the lights turned on during all hours of darkness. Provide additional controls to turn the lights on and off in response to the presence of people. Photocontrol alone is useful only for lighting that is required throughout hours of darkness, such as security lighting.

A common pitfall is using manual switches in combination with photocontrols. In such cases, the manual switch may inadvertently be left in the on position even though the photocontrol has turned off the lights. At sunset, the photocontrol will turn the lights on even though the facility is vacant.

Solving this problem requires a combination of controls. Use a timeclock to keep the lights turned off during hours of darkness when the space is normally unoccupied. In addition, install another type of automatic control, such as a motion sensor, to override the timeclock if people are present during these hours.

Types of Photocontrols

Most photocontrols are designed for exterior lighting. They are rugged and inexpensive, but they

WESINC

Fig. 3 Why are all these lights turned on? This atrium in a government building is excessively illuminated by a huge skylight. The illumination provided by the light fixtures is not noticeable during the daytime. A single inexpensive photocontrol could save a lot of money and many light bulbs in this area alone.

lack setting flexibility. They are described in [Measure 9.5.2](#). Interior photocontrol is uncommon, so the market does not offer a wide selection of photocontrols intended specifically for indoor applications, although some are entering the market. You can use exterior photocontrols for interior applications, but you may have to be creative in how you install them.

How to Install Interior Photocontrols

Interior photocontrol usually is part of a system consisting of several types of lighting control. Designing the system requires some thought, and installation details are important. Work out the following issues carefully.

■ Sensor Location and Orientation

Choosing the location of the light sensors is tricky. Remember that the purpose of the sensor is to detect how much daylighting is available within the space, not to sense the total lighting level. Therefore, aim the sensor somewhat toward the outside, so that it senses the available daylighting without being influenced too much by the electric lights inside the space.

On the other hand, if you aim the sensor too far outside the space, it will see a scene whose brightness does not correspond to the amount of sunlight entering the space. Also, this can lead to situations that trick the sensor into turning the lights off. For example, if the sensor looks toward a parking lot, reflections of the sun from the windshields of parked cars may blind the sensor. Or, reflections from the windows of adjacent buildings may do the same thing.

To minimize these difficulties, locate the sensor as close to the perimeter as possible. Ideally, you would like to install the sensor outside the window, looking

inward. If there is a soffit over the window, consider this seriously. If you choose this arrangement, be careful to install the sensor so that it cannot be fooled by reflections from the glass.

Sensors mounted on swivels are worth the small additional cost. They provide flexibility in mounting, and they make it easy to experiment to find the best orientation. Figure 6 shows a unit that has this feature.

■ Number of Sensors

Use separate sensors for each area that has a different response to exterior changes in sunlight. For example, use separate sensors for spaces that face in different directions, and for spaces that fall into the shadow of adjacent buildings at different times of day.

One sensor can control any number of fixtures, either directly or through a power relay. However, sensors are cheap in comparison with the cost of wiring labor. This makes it more economical to install a sensor in each lighting circuit, rather than extending the wiring to allow a single sensor to control a larger area.

■ Light Sensitivity Settings

Most photocontrols allow you to adjust the light levels at which the fixtures turn on and off. Most inexpensive photocontrols achieve this with a simple shutter that changes the amount of light entering the light sensor. However, even with the shutter set to admit minimum light, exterior photocontrols typically turn lights off when the illumination level rises to about 15 footcandles (150 lux). This may be adequate for corridors and other peripheral areas, but it is too dim for most work activities. For example, offices and retailing typically require about 50 footcandles (500 lux).

WESINC

Fig. 4 Area surrounding a large, brightly lighted atrium This area deserves several photocontrols. The inner and outer rows of light fixtures should have separate control. And, each side of the atrium should have separate control.

You can solve this problem by installing a simple light-absorbing filter in front of the sensor. For example, make the filter from translucent plastic diffuser material. Each sheet typically has a transparency of about 60%, so three layers reduce the light to the sensor by a factor of about five. Keep plastic diffuser material out of direct sunlight and away from light fixtures, as heat and ultraviolet light darken it.

Ordinary exterior photocontrols typically turn lights off at about three times the lighting level at which they turn lights on. In inexpensive photocontrols, this ratio is fixed. The wide ratio keeps small fluctuations in the light level from cycling the lights on and off. Clouds passing in front of the sun reduce sunlight by a factor of three to five. This is not likely to cause much cycling, unless maximum and minimum light levels happen to coincide with the upper and lower limits of the photocontrol.

The wide on-off ratio also makes the orientation of the sensor less critical. It allows the sensor to be aimed more into the space, where it senses artificial light along with daylight, without the risk of short-cycling the lights.

To save as much energy as possible, adjust the photocontrol to turn on the lights at the lowest acceptable lighting level. Unfortunately, the wide on-off ratio keeps the lights on until the light level in the space has risen considerably. How much energy saving is lost by this factor depends on the geometry of the space, the effectiveness of daylight distribution, and other factors that are covered in [Reference Note 46](#), Daylighting Design.

Explain the Controls to the Occupants

Install effective placards to inform occupants how the lighting is controlled. This will get them interested, and minimize annoyance. See [Measure 9.4.1](#) about placards.

Arrange Circuits to Maximize Daylighting Potential

Lighting control cannot exploit daylighting unless the fixtures are grouped in a way that corresponds to the availability of daylight in the space. For example, if the space has a continuous row of windows, the fixtures should be wired in rows parallel to the windows, with each row switched separately. The outer row of fixtures is turned off during most daylight hours, the next row is turned off for a lesser period of time, and so forth.

In existing buildings, you may have to rearrange the light fixture circuits to make daylighting possible. See [Measure 9.6.4](#) for details.

There are various techniques that you can use to increase the raw amount of daylight that is available to exploit. See [Reference Note 46](#) and [Subsection 8.3](#) for the full story.

Alternative Method: Dimming Controls

If switching lamps on and off is not acceptable as a method of exploiting daylight, consider automatic dimming controls. These change the output of fixtures smoothly in response to the light level in the space.

Automatic dimming has become a fairly reliable technique with fluorescent lighting. Fluorescent dimming requires special electronic dimming ballasts

WESINC

Fig. 5 Puffy clouds Cumulus clouds like this are the worst problem for daylighting control because the clouds are small and thick. Thus, the light level changes are large, abrupt, and frequent. Think of this situation when you decide whether to use photocontrol for interior lighting.

Paragon Electric Company, Inc.

Fig. 6 Photocontrol with swivel base The ability to point the sensor accurately is important. Aiming the sensor for proper response can be tricky, and it is likely to require trial-and-error.

and controls that respond to daylight. The best equipment can control the output of fluorescent lamps over a wide range. However, fluorescent dimming is much more expensive than on-off photocontrol. See [Measure 9.2.6](#) for the full story.

HID lighting can be dimmed over a limited range. It is not yet well established. See [Measure 9.3.2](#) for the details.

Automatic dimming is not commercially available for incandescent lighting. The best way to save energy with incandescent lighting is to get rid of it.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of the energy used by controlled fixtures. Lamp cost and replacement labor may be reduced by a similar percentage.

COST: Common photocontrols designed for exterior applications cost less than \$10 apiece. The cost of wiring and finish work varies widely, averaging perhaps several hundred dollars per sensor.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

PLANNING: Wherever daylight enters a building, consider using it instead of electric lighting. Make sure that occasional abrupt changes of lighting level are acceptable to occupants. Lay out the fixture wiring to exploit daylight as much as possible. Be sure to satisfy all lighting needs, including emergency and off-hours lighting.

INSTALLATION: Expect to spend some time finding the best sensor location for each space. Be sure to install informative placards.

MONITOR PERFORMANCE: This is still an experimental activity. It affects occupant comfort and productivity. Monitor it carefully, until you are sure that lighting needs are satisfied under all conditions. Expect to make adjustments. Schedule periodic checks in your maintenance calendar.

MEASURE 9.5.4 Where the need for lighting is determined by the presence of people, use personnel sensor switching.

In most spaces, lighting is needed only when people are present. Personnel sensors are devices that sense the actual presence of people. Therefore, personnel sensors can match lighting to space occupancy more accurately than any other method. They are not satisfactory for all spaces, but they are widely applicable.

Where to Use Personnel Sensors

Personnel sensors are desirable for lighting control in an exceptionally broad range of applications. For example, a lighting retrofit program for a large, diverse research hospital found personnel sensors to be the most efficient method of lighting control for a large fraction of the spaces in the hospital, including offices, laboratories, stock rooms, loading docks, etc. Figure 1 shows yet another possible application.

See Reference Note 11, Personnel Sensors, about the conditions that are required for reliable, safe lighting control using personnel sensors. Personnel sensors are not a panacea in the realm of lighting control. In many applications, personnel sensors are simply the wrong tool. Some applications have quirks that make it inadvisable to use them, for reasons that may not be obvious.

In brief, there are three conditions that must be met for a successful installation. One is that the sensor should be able to reliably detect the presence of people anywhere within the controlled area. This requires that people move continually, but only small motions are needed. The second condition is that the sensor should not be subject to an excessive amount of false triggering by things other than people. The third condition is that the lighting must be able to respond quickly enough to the presence of people. This excludes HID lighting, and it excludes some types of fluorescent lamps in some applications.

Space-by-Space Planning is Essential

You cannot successfully install personnel sensors in a broadcast manner, as you might install high-efficiency lamps or ballasts. Analyze each activity area to decide whether personnel sensors are satisfactory for that environment. In locations where they are appropriate, figure out the best places to install them. If necessary, combine personnel sensor control with other methods of control.

Expect to spend a lot of time and effort on this. For example, in a complex facility, such as a hospital or hotel, you may need three or four different types of personnel sensors to deal properly with all the conditions that exist, along with many mounting configurations.

SUMMARY

A powerful lighting control option. Applicable widely, but not everywhere. Often inexpensive. Takes thought and effort to get it right.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

You need to select the location of each sensor carefully. Installing personnel sensors carelessly or in the wrong applications can waste energy, annoy occupants, and create safety hazards.

Types of Personnel Sensors

The main types of personnel sensors are explained in Reference Note 11, Personnel Sensors. Most lighting applications favor passive infrared detectors. Many inexpensive models are available that replace existing light switches, without further wiring or installation work. These units are a major breakthrough in lower cost and ease of installation. However, these advantages tempt people to use them in locations where they cannot provide satisfactory performance. In many cases, only ceiling mounted sensors are satisfactory, and these are expensive to install.

Passive infrared sensors are now commonly built into floodlamp fixtures, intended primarily for exterior applications. Integral motion sensors are starting to appear in other types of light fixtures. Check the latest catalogs.

Avoid “On” Overrides

As a rule, do not select units that have an “on” switch to override the automatic turn-off. Occupants will eventually leave the control in the “on” option, effectively eliminating its efficiency benefit. Unfortunately, it is getting difficult to find personnel sensors that are free of this bad feature.

If activities occur in the space that require an “on” override, then a personnel sensor is not the appropriate type of lighting control.

On the other hand, all personnel sensors should have an “off” override. This allows the lights to be turned

off while people are in the space. This is useful for using slide projectors, watching television, sleeping, etc.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of the lighting energy in controlled areas, depending primarily on occupancy patterns. Lamp cost and replacement labor may be reduced by a similar percentage.

COST: \$15 to \$50 apiece for infrared sensors that replace wall switches, which can usually be installed in minutes. Ceiling mounted sensors cost \$100 to \$200 apiece, with installation costs depending on location, labor rates, etc.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

PLANNING: Expect to spend time and effort to select the best model of sensor and the best location for each space.

SELECTING THE EQUIPMENT: See [Reference Note 11](#). You can get good equipment at modest cost if you shop carefully and test samples. Cheap units may fail quickly, break easily, and create radio interference. Units should have an "off" switch but no "on" position. Try to get a lighted toggle.

INFORM THE OCCUPANTS: Don't forget the placards. They get people involved, and keep occupants from being annoyed by seemingly erratic lighting operation.

WESINC

Fig. 1 An ideal application for personnel sensor lighting control Most of the lighting in this reference library is wasted. Personnel sensors could be installed to control the lighting in each of the aisles between the shelves. Control would be certain. False triggering is easily avoided. People in adjacent areas would not be bothered. There is no safety hazard.

MEASURE 9.5.5 Where lighting can be turned off after a fixed interval, install timed-turnoff switches.

RATINGS		
New Facilities	Retrofit	O&M
B	B	

Timed-turnoff switches are the least expensive type of automatic lighting control. In some cases, their low cost and ease of installation makes it desirable to use them where more efficient controls would be too expensive.

Types and Features

The oldest and most common type of timed-turnoff switch is the “dial timer,” a spring-wound mechanical timer that is set by twisting the knob to the desired time. Typical units of this type are vulnerable to damage because the shaft is weak and the knob is not securely attached to the shaft. Some spring-wound units make an annoying ticking sound as they operate.

Newer types of timed-turnoff switches are completely electronic and silent. Electronic switches can be made much more rugged than the spring-wound dial timer. These units typically have a spring-loaded toggle switch that turns on the circuit for a preset time interval. Some electronic models provide a choice of time intervals, which you select by adjusting a knob located behind the faceplate.

Most models allow occupants to turn off the lights manually. Some models allow occupants to keep the lights on, overriding the timer.

Timed-turnoff switches are available with a wide range of time spans. The choice of time span is a compromise. Shorter time spans waste less energy but increase the probability that the lights will turn off while someone is in the space. Dial timers allow the occupant to set the time span, but this is not likely to be done with a view toward optimizing efficiency. For most applications, the best choice is an electronic unit that allows the engineering staff to set a fixed time interval behind the cover plate.

Avoid “On” Overrides

As a rule, do not select units that have an “on” switch to override the automatic turn-off. Occupants will eventually select the “on” option, effectively eliminating the efficiency benefit of the control. If activities occur in the space that require an “on” override, then a timed-turnoff switch is not the appropriate control method.

Safety Limits Applications

Time switches turn off lights without regard to whether anyone is in the space. If they are used inappropriately, they may create a safety hazard, or at least annoyance. The most dangerous situation occurs when one person turns on the lights and then leaves. A

SUMMARY

An inexpensive and reliable way to provide brief periods of lighting. Limited to spaces that cannot trap people in the dark.

SELECTION SCORECARD

Savings Potential	\$	\$		
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	
Ease of Retrofit	☺	☺	☺	

second person enters the space while the lights are still turned on, but the lights turn off unexpectedly while the second person is still in the space. For this reason, time switches are desirable primarily for spaces that are used sporadically, especially by one person or one group at a time.

Because of the hazard of unexpected darkness, do not use time switches for lighting unless:

Paragon Electric Company, Inc.

Fig. 1 Timed-turnoff switch Pressing the toggle upward starts a timer that keeps the lights turned on for a fixed period. Pressing the toggle downward turns off the lights if they are on. On this unit, the time interval is adjustable from one minute to 18 hours. This wide range makes it difficult to tune the time interval for greatest efficiency.

- **the space is so small that the exit is easily within reach.** Storage rooms and janitor closets are typical applications.
- **the space has adequate emergency lighting.** For example, you can use timer switches to provide lighting for cleaning crews who work in large office spaces late at night. The timer switch overrides a timeclock or key switch that is used to turn off the lights after hours. The emergency lighting is bright enough to provide safe access to the timer switch.
- **a minimum lighting level is provided by adjacent lighted spaces.** For example, you could safely use timed-turnoff switches for individual stacks in a library, or for individual stock shelves in a warehouse, where individual areas are used only occasionally and for short periods. Even here, timer switches would be unsatisfactory if the lighted spaces are visited frequently. Exploiting this kind of opportunity is likely to need light circuit modifications and installing the switches in unconventional locations, such as from overhead fixtures.

Timed-Turnoff Switch or Occupancy Sensor?

Personnel sensors ([Measure 9.5.4](#)) are effective in many of the same applications where time switches are appropriate. Personnel sensors can match lighting to occupancy more accurately than time switches, and they avoid the problem of unexpected loss of lighting. On the other hand, time switches are cheaper, often easier to install, and they are immune from false triggering.

Warn Occupants

Timed-turnoff switches may turn off lights unexpectedly. This makes it especially important to install conspicuous placards at the entrances to tell occupants how the lights are controlled. See [Reference Note 12](#), Placards, for details of effective placard design, materials, and installation.

ECONOMICS

SAVINGS POTENTIAL: Usually more than 50 percent of controlled lighting. Lamp cost and replacement labor may be reduced by a similar percentage.

COST: Spring-wound units cost less than \$20, electronic units less than \$30. Installation usually takes only a few minutes if replacing an existing light switch. Subdividing light circuits to provide localized control is much more expensive.

PAYBACK PERIOD: Less than one year, if replacing existing switches. Several years, typically, if rewiring is needed.

TRAPS & TRICKS

CHOICE OF METHOD: Use this type of switch only where it cannot cause safety or convenience problems.

SELECTING THE EQUIPMENT: These switches are subject to abuse, so select them for ruggedness and ease of use. Select the appropriate time interval for each location. Do not install units with an "on" override.

INSTALLATION: An effective placard is essential for this type of switch.

MEASURE 9.5.6 If a door remains open when lighting is needed, use door switches.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Janitor closets, linen rooms, small stockrooms, and similar spaces are entered by a single door that is kept open while the room is in use. In such spaces, lighting can be controlled efficiently by a door switch. The switch mounts easily on the door jamb and is connected into the fixture wiring. The switch is inexpensive. The main cost is routing the wiring from the switch to the rest of the circuit.

Unless you are sure that the door is kept closed whenever the space is vacated, install a placard that says, "The lights in this room turn off automatically when the door is closed. Please keep the door closed when you are not in the room."

Alternative Method: Timed-Turnoff Switch

An alternative to door switches is using a timed-turnoff switch. See [Measure 9.5.5](#), previous. A door switch is more convenient, but it depends on people keeping the door closed. In retrofit applications where there is an existing toggle switch, a timed-turnoff switch is less expensive to install.

SUMMARY

Simple and reliable. Usually limited to small, unoccupied spaces.

Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

ECONOMICS

SAVINGS POTENTIAL: A large fraction of the energy of the controlled lighting. The total amount of energy at stake is usually small.

COST: The hardware costs less than \$20. Labor cost varies widely, but is typically less than \$100.

PAYBACK PERIOD: Several years, typically.

Subsection 9.6

Lighting Layout

This Subsection deals with the spatial layout of fixtures and the wiring that controls them. Efficient lighting layout involves getting the light from the lamps to the task with a minimum of loss on the way, and delivering the light by paths that avoid visual problems. The light fixture controls light distribution after the light leaves the lamp. The surfaces within the space may be important to light distribution after light leaves the fixture. The first Measure deals with the surfaces of the space. The other Measures deal with fixtures and their locations in the space.

In new construction, review the Measures of this Subsection as part of the lighting design. Typically, you do not know the arrangement of activities in the spaces at the time the building or space is designed. This is a serious challenge to efficiency, which makes it especially important to design lighting that is adaptable.

In existing facilities, prioritize the Measures in the usual way. Try to combine your improvements. Most of the Measures require a detailed survey and a heavy dose of planning. Get it all done at one time.

Coordinate these Measures with the delamping, lamp improvement, and fixture improvement Measures of [Subsections 9.1 through 9.3](#). Also, coordinate fixture placement with the appropriate control methods from [Subsections 9.4 and 9.5](#). Remember that efficient lighting is accomplished one fixture at a time, matching each fixture carefully to the lighting requirements of the task.

For these activities, you need to know about the light distribution patterns of lamps and fixtures. This topic is covered in [Reference Note 57](#), Light Distribution Patterns of Fixtures.

INDEX OF MEASURES

9.6.1 Make the surfaces of spaces highly reflective.

9.6.2 Lay out lighting using the task lighting principle.

9.6.2.1 Disconnect or remove fixtures where they are not needed.

9.6.2.2 Relocate and reorient fixtures to improve energy efficiency and visual quality.

9.6.2.3 Replace fixtures and improve fixture installations that waste light.

9.6.3 Install fixtures or combinations of fixtures that provide efficient lighting for all modes of space usage.

9.6.4 Install a separate control circuit for each lighting element that operates on a distinct schedule.

9.6.4.1 Where light fixtures are needed in a predictable variety of patterns, install programmable switches.

9.6.5 Install lighting controls at visible, accessible locations.

9.6.5.1 Provide localized control of ceiling fixtures by installing pullcord switches.

RELATED MEASURES:

- [Subsection 9.1](#), for improvements to incandescent lamps and fixtures
- [Subsection 9.2](#), for improvements to fluorescent lamps and fixtures
- [Subsection 9.3](#), for improvements to HID lamps and fixtures
- [Subsections 9.4 and 9.5](#), for improved control of lamps and fixtures

MEASURE 9.6.1 Make the surfaces of spaces highly reflective.

You may be able to save a substantial amount of lighting energy in some spaces by using highly reflective surfaces for the walls and ceilings, and even for the floor. In most cases, this simply means using light colors. In some applications, mirrored surfaces are appropriate. Highly reflective surface colors are already accepted in offices and other “clean” spaces. Extend them to environments where dark or drab colors are commonplace, such as factories, hotel corridors, etc.

Using light colors and mirrored surfaces is relatively forgiving as a technique, i.e., it is unlikely to create any lighting problems. Improving surface reflection is usually simple, consisting of a new paint job or applying surface coverings.

However, make sure that the light surface treatment will continue to be acceptable in the future. Once you minimize the lighting equipment to exploit highly reflective interior surfaces, it can be expensive to increase lighting at a later date. For example, an interior decorator may get a notion to redecorate with darker colors, which would leave the space gloomy unless the lighting power is increased.

Energy Saving Potential

This Measure does not save energy by itself. Instead, it is a method of reducing lighting requirements. To save energy, you have to reduce the wattage of lamps and fixtures, and disconnect excess fixtures. Otherwise, this Measure will increase illumination levels, but it will not save energy.

Relative Light Absorption

The savings potential depends largely on the darkness of the existing color scheme. These are the light absorption percentages for some typical surfaces:

clean, bright white paint	about 10%
pastel colors of paint, stone, etc.	20% to 40%
typical “dark” colors	70% to 90%
clear mirror surfaces	about 10%
typical “smoky” mirrors	30% to 50%

The Path of Light from Fixture to Task

The savings potential depends on the fraction of light that is reflected from surfaces as it travels through the space. The reflectivity of surfaces is most important if light must reflect repeatedly before reaching the task.

For example, consider the amount of light that is lost if light is reflected three times on the way to the task. With a surface reflectance of 90%, about 72% (multiplying by 90% three times) of the light reaches

SUMMARY

A fundamental step in reducing lighting costs. Saves equipment cost in new construction and renovations. Often inexpensive to retrofit. Usually improves lighting quality.

SELECTION SCORECARD

Ease of Retrofit	😊	😊	😊	

the task. In contrast, with a surface reflectance of 50%, only about 12% (multiplying by 50% three times) of the light reaches the task. Thus, even “medium” colors can absorb a large fraction of light if the path is indirect.

Reflective surfaces are important in spaces, such as corridors, guest rooms, and function rooms, where a large fraction of the light reflects from the surfaces. Such spaces may not have specific task areas, and the surfaces may be a primary means of distributing light in the space.

High reflectivity is also important when using area illumination, indirect lighting, and shaded light fixtures. Light loss is severe with cove lighting and valance lighting, where the light must bounce off several surfaces just to get into the space. Figure 1 shows a large area that is lighted entirely by reflection from ceiling and wall surfaces.

The surfaces of the space do not affect light that travels directly from a fixture to the task. Therefore, reflective surfaces cannot save much energy if the activities are illuminated mostly by direct lighting. For example, this is typical of work in graphics studios.

Effects on Lighting Equipment and Layout

Reflective surfaces make the layout of fixtures less critical. The fact that light can survive several reflections on the way to the activity makes it less necessary to get the fixtures close to the task.

You have to get rid of some lighting capacity to reap the energy saving benefit. If you have fixtures that are less efficient, such as incandescent wall washers, exploit the opportunity to get rid of them. The reduced need for lighting equipment is an important cost saving feature in new construction and renovations.

Effects on Space Appearance and Lighting Quality

Making surfaces brighter creates a major change in the esthetics of the space. For one thing, it gives the space a more “open” feel. This is desirable in many applications, but it may be undesirable in intimate settings.

Making the surfaces of the space more reflective increases the indirect component of lighting. This usually improves visual quality. In particular, this can improve the appearance of a space that uses task lighting, which tends to create islands of light in darker surroundings. This is unpleasant psychologically, if not visually. Making the surfaces brighter also reduces the intensity of shadows at the task.

■ Can You Make Surfaces Too Bright?

Some people are concerned that making the surfaces of spaces too reflective may cause glare. Experience indicates that this is generally not a problem. The world is full of buildings that have white walls and ceilings, and they do not appear to cause discomfort. Light interior surface colors are comfortable because the surface brightness is low and it is fairly uniform over a large area. If lighting is laid out for efficiency, the task area is brighter than the surrounding surfaces, so the eyes are not overloaded by brightness from outside the task area.

Usually, the only place you need to worry about excessive surface brightness is within the “working area” of the visual field, such as the tops of desks and tables. Even in this area, highly reflective surfaces, such as white paper, do not cause comfort problems if the lighting is laid out properly. Try to make large surfaces within the task area highly diffuse. Specular surfaces

invite trouble with veiling reflections, which are explained in [Reference Note 51](#), Factors in Lighting Quality.

Not Just Walls and Ceilings

All surfaces within the space are important if they have a substantial amount of exposed surface. This includes floors, draperies, blinds, furniture, decoration, etc.

Floor color is important because a large fraction of the light emitted from typical lighting systems first strikes the floor. It is commonly believed that floors should have dark colors to hide dirt and scuff marks. This is not true in general. Many facilities maintain a satisfactory appearance with light-colored floors. Smooth-surfaced flooring, such as vinyl, can be light in color in most commercial environments.

Whether to Use Diffuse or Specular Reflection

The directional characteristics of reflecting surfaces range from “diffuse” to “specular.” “Diffuse” surfaces reflect light equally in all directions. A surface reflects diffusely if it is rough at a scale corresponding to the wavelengths of light. For example, rough masonry and flat paint are very diffuse. A diffuse surface that is reflective at all visible wavelengths looks “white.”

In contrast, “specular” surfaces reflect light at exactly the same angle as it arrives. For this reason, completely specular reflection preserves images. (The word “specular” is derived from the Latin word for mirror.) Any surface that is smooth at the microscopic level produces specular reflection. For example, plate glass and polished metal are highly specular.

WESINC

Fig. 1 Lighting power is highly dependent on surface colors here. Before light gets to any book in this library, it has to reflect from a ceiling surface at least once, and probably several times from ceiling, wall, floor and furniture surfaces. A slight reduction of surface reflectivity greatly reduces light loss.

In most cases, you want the surfaces of the space to be diffuse. If walls are painted flat white, they reflect a large fraction the light from ceiling fixtures horizontally into the space. In contrast, a mirror wall reflects the light from ceiling fixtures directly to the floor, where most of the light is lost.

Specular ceilings are about as efficient as diffuse ceilings, if they are not tinted. Specular floors are used only in discotheques, where they are appreciated by the boys.

Specular surface finishes are more expensive than diffuse finishes. Mirrors are used primarily as an item of decor, often to make a space appear larger.

Most smooth materials used for interior surfaces have a combination of specular and diffuse reflection. This is because the outer surface is both smooth and somewhat transparent. A portion of light is reflected from the smooth surface in a specular manner, but the rest of the light penetrates to a rough surface below, where it may be reflected diffusely. Examples are glossy paint, polished stone, and varnished wood.

Whether a surface is diffuse or specular is a separate issue from whether it is reflective or absorptive. For example, white wool and black wool fabrics are both diffuse, but the white wool is much more reflective. Black glass reflects in a specular manner, but it also absorbs a large fraction of the incoming light.

Unusual Color Effects

When using fluorescent or HID lighting, any color used in the surface may absorb an unexpectedly large amount of light. The light output of these types of lamps is concentrated in a few narrow bands of wavelengths. Color is created by pigments in the surface material. If any of the pigments has a high absorption at one of the major wavelengths emitted by the lamp, the surface will absorb more light than expected. For example, a pastel paint may have a reflectance of 80% in daylight, but it may reflect only 60% of the light from a particular HID lamp.

In most cases, you don't need to worry about this effect. Just avoid pigmented surfaces. A highly

reflective "white" is the most efficient color for general decor. Titanium dioxide, a common pigment for white paint, reflects all colors well. The same is true of most white surface materials. From the standpoints of esthetics and visual comfort, white has proven to be satisfactory for walls and ceilings in most applications.

Keep the Surfaces Clean

Keep the surfaces clean to maintain their high reflectivity. In most environments, using light colors does not increase the cleaning requirement. In industrial environments where surface cleaning may not be routine, initiate period cleaning. Dirtier environments also need a regular program of fixture cleaning, which is recommended by [Measure 9.7.1](#).

ECONOMICS

SAVINGS POTENTIAL: 30 to 60 percent of lighting energy, typically. Depends primarily on the original color scheme and on the amount of indirect lighting.

COST: In new construction, it usually costs nothing to make interior surfaces reflective. In retrofit, cost varies widely. Typical painting costs about \$0.15 to \$0.50 per square foot. Other types of surface finish may be much more expensive. If you do the work as part of repainting or redecoration that is needed anyway, there may be little additional cost. The total cost should include the cost of changes to the lighting fixtures.

PAYBACK PERIOD: Usually immediate, in new construction. Up to several years, in retrofit.

TRAPS & TRICKS

MAINTENANCE: Light surfaces become dirty, especially in industrial environments. To preserve the benefit, schedule cleaning of the surfaces at appropriate intervals.

EXPLAIN IT: Future managers of the facility are unlikely to realize that the color scheme was selected to maximize lighting efficiency. Leave a record that is not likely to get lost, explaining why a light color scheme should be retained.

MEASURE 9.6.2 Lay out lighting using the task lighting principle.

RATINGS

New Facilities	Retrofit	O&M
B	C	

This Measure covers the main points of task lighting in its broadest sense. It also offers some suggestions for equipment used in task lighting. Task lighting is still embryonic, so it is not yet possible to define a complete set of well proven task lighting techniques. To a greater extent than in any other aspect of lighting, it is your challenge to apply general principles to develop lighting configurations that are effective for your facilities.

The most important point in this Measure is a “standard” task lighting layout that provides illumination that is both efficient and visually pleasing. This is Figure 1.

Since task lighting has not yet come into existence as a formal method of lighting design, we cannot show rationally designed examples of it in actual installations. Instead, we will show a number of typical spaces with poor lighting efficiency, and we will discuss how these spaces could be retrofitted with task lighting in a way that would radically reduce lighting power. These spaces are shown in Figures 2 through 5.

Subsidiary Measures 9.6.2.1 through 9.6.2.3 are important lighting improvements that exploit the principles of task lighting without requiring any unconventional equipment or methods. Use this Measure and the subsidiary Measures as a checklist in your new designs and in reviewing your existing lighting.

What is Task Lighting?

Task lighting can be defined as lighting that is optimized to individual activities. Task lighting minimizes the energy waste that results from spreading light around where it is not needed.

Task lighting is partly a general concept, and partly a collection of lighting techniques. Task lighting has been discussed for years, but it has not yet been applied as a mainstream approach to lighting design. It remains a sleeping giant of lighting conservation.

Task lighting was popularized during the 1970’s, largely based on the notion of installing fixtures close to the task on furniture or equipment. That approach died on the vine, largely because the needed light fixtures were never developed. If that type of task lighting had been developed, the lighting quality probably would have been considered unacceptable, especially in comparison with the area lighting approach that has become almost universal today. To achieve good visual quality along with energy efficiency, a more general approach is needed, which we introduce here.

SUMMARY

Task lighting is the most efficient method of lighting layout. Its essence is close matching of the lighting geometry to individual activity areas. Try to exploit task lighting principles in all lighting. Appropriate fixtures, wiring methods, and other accessories are still lacking, so expect to improvise. Changes the appearance of spaces from “open” to “localized.”

Ease of Retrofit	😊	😊		

A “Standard” Task Lighting Layout

The present wasteful method of broadcast lighting is forgiving in terms of visual quality. This is because light comes from many directions. If the light coming from a particular direction causes a vision problem, such as veiling reflections, humans can still see effectively using light that is coming from the other directions.

In contrast, experience suggests that task lighting is much less forgiving of poor layout. Task lighting provides illumination from a limited range of directions, so the lighting is either mostly good or mostly bad. This makes it especially important for the layout of task lighting to avoid all the causes of lighting discomfort that are related to fixture positioning. These are the problems to be avoided, summarized from Reference Note 51:

- **source glare.** Source glare is avoided by keeping the fixture, and any localized bright spots caused by it, out of the visual field of the viewer.
- **veiling reflections.** Veiling reflections are usually caused by fixtures that are located in the direction that the viewer is facing.
- **uneven illumination.** If a single fixture is to provide reasonably uniform illumination over the task area, the distance of the fixture from the task needs to be several times greater than the width of the task area. Low ceiling heights make it impossible to satisfy this requirement. Therefore, you typically have to

Fig. 1 A “standard” layout for task lighting To make lighting energy efficient, use efficient light sources, shine the light directly on the task area, and limit light distribution to the task area. To make lighting visually pleasing, avoid glare from any light source, avoid veiling reflections, make the illumination within the task area fairly uniform, and minimize shadowing at the task. A lighting layout that satisfies all these conditions limits the fixtures to a narrow range of positions, which are illustrated by this example of office work.

The essential features are mounting the fixtures well above the viewer, pointing them steeply downward, and placing them alongside or slightly behind the viewer. In most cases, two fixtures are needed for each task area. The fixtures can be mounted on the ceiling, on furniture extensions, or on anything else. The fixtures must be able to be aimed.

At present, compact fluorescent lamps are the only type that provides the necessary combination of energy efficiency, color rendering, and small size (for focussing). With two of these lamps, the power required to illuminate each task area is about 40 watts.

To avoid “harsh” lighting, and to minimize shadowing at the task, the fixtures should have a radiating surface area much larger than shown here. A target figure is about 20% of the distance from the fixture to the task. This can be achieved with reflector fixtures.

Task lighting allows efficient localized switching. The three fixtures for the desk might be controlled by one motion sensor, and the two fixtures for the credenza by another.

Maintaining high visual quality is challenging when the viewer changes position. In this example, if the person turns to the left to work at the desk extension, the left-hand desk fixture may cause glare. Precise adjustment of the fixture position is needed to avoid this.

install two fixtures, on opposite sides of the viewer and with partially overlapping illumination patterns.

- **self shadowing.** If a fixture is located behind the viewer, the viewer's body casts a shadow on the task. If a fixture is located to the side, the viewer's hands may cast a shadow on the task. The way to avoid this shadowing is to install fixtures on both sides of the viewer.

Fixture locations that avoid all these problems are limited. In fact, acceptable locations are so limited that they become, in effect, a "standard" fixture geometry for task lighting.

This "standard" task lighting layout is shown in Figure 1. In this layout, any fixture is placed alongside the viewer, so that the beam makes an angle of about 70 degrees with the ceiling. If two fixtures are used, one on each side, both can be moved slightly to the rear of the viewer.

You have to establish this layout separately for each task area. From the standpoints of both efficiency and visual comfort, a task area can be defined as the area within a stationary person's visual field where illumination is needed. If the person moves to look in a different direction, that defines a different task area.

For example, Figure 1 is an office layout with a desk and a credenza. Each is a separate task area, and each needs its own pair of fixtures.

In principle, the "standard" layout geometry applies to any light source, whether it is an actual fixture, a reflector, a skylight, bounce light, etc. However, achieving optimum energy efficiency with electric lighting (as opposed to daylighting) generally requires fixtures that can be aimed at the task area. The "standard" layout of Figure 1 uses swiveling surface-mounted compact fluorescent aiming fixtures.

Advantages of Task Lighting

As you can see, task lighting is a big departure from conventional lighting design. To persuade yourself to try it, consider these potential advantages:

- **good visual quality.** There is no source glare, because the fixtures are entirely outside the visual field. There are no veiling reflections. It is easy to make the illumination level for each task area adjustable individually. It is easy to select lamps with different color rendering characteristics for each task area. Shadowing in the task area can be minimized by using fixtures with large surface area.
- **maximum energy efficiency.** Light is placed precisely *where* it is needed. It is easy to control the lighting of each task area to the times *when* it is needed.
- **easy maintenance.** The location and types of fixtures make lamps easy to replace. In most facilities, only a minimum variety of lamp types are required.

- **adaptability.** Because the fixtures are surface-mounted, ceiling grid patterns and equipment above the ceiling do not constrain the location of fixtures. The fixtures are much easier to relocate when the activities in the space change. (However, elegant and inexpensive electrical connections that simplify moving the fixtures are not yet available as a standard product.)
- **low initial cost.** The cost of individual fixtures is likely to be lower. Fewer fixtures are likely to be needed. Installation cost may be much lower. Far less difficulty may be encountered in retrofit.
- **independence from adjacent lighting.** Each task area has totally independent lighting, so it does not matter whether the lighting in adjacent areas is turned on or off. If necessary, glare shielding for the benefit of adjacent areas (discussed below) is easy to install.

Task Lighting Challenges

Tapping the full potential of task lighting requires innovation. Innovation involves cost, risk, and delay. Most organizations with modest resources have to wait for industry-wide improvements before they can apply task lighting in its most efficient form. On the other hand, an organization that is able to assign a talented individual to work on lighting efficiency may be able to achieve great improvements after a period of innovation and experimentation. When you set out to apply task lighting, be prepared for these differences between task lighting and conventional lighting:

- **still emerging equipment.** Until a few years ago, the right combination of fixtures and lamps for task lighting was not available. Conventional fluorescent and HID light fixtures are poorly adapted to illuminating individual task areas. Lack of ability to aim these types of fixtures is a critical weakness. Some incandescent lamps and fixtures are well adapted to aiming and localizing lighting distribution, but incandescent lighting is inefficient. However, the compact fluorescent unit is probably the breakthrough that will bring all the essential elements together. It has reasonably high efficiency, the appropriate range of wattage and light output, and fairly good color rendering. The small size of the unit makes it usable in fixtures that can be aimed. The fixtures themselves are not yet available as standard items, but they could be produced for a low price with only modest equipment and investment. The discussion below reports some successful task lighting that was set up on an experimental basis.
- **incomplete understanding of lighting comfort.** The initial failure of task lighting was caused partly by dissatisfaction with the quality of the light. In task lighting, the factors involved in visual comfort

are less forgiving than in general lighting. However, all the essentials of visual comfort are covered in [Reference Note 51](#), and it appears that task lighting can be created that will satisfy all the requirements.

- ***need for greater design effort.*** Contemporary lighting design achieves comfortable, attractive lighting with rote layout and conventional equipment. In contrast, task lighting requires a great deal of study, experimentation, innovation, and risk. These involve liability, and they add time to the design phase of the project.
- ***radically different appearance.*** Task lighting may dramatically change the appearance of the space. Task lighting does not have the regular checkerboard appearance of contemporary lighting. Light levels are not uniform throughout the space. If fixtures are ceiling-mounted, they may point in different directions and may extend different distances below the ceiling. Fixtures need large surface areas to avoid glare, but task lighting fixtures cannot be hidden in the ceiling, as in contemporary lighting. Therefore, task lighting fixtures are prominently visible as an element of the decor. Reflectors and glare shields, essential elements of task lighting, also project below the ceiling. The present stylistic prejudice toward making light sources invisible must be abandoned.

The Cost of Task Lighting

It is too early to make generalizations about the cost of task lighting. Efficient lighting in the future may require far fewer fixtures and lamps, but individual fixtures may (or may not) be more expensive. Wiring labor, which is a major component of the cost of installing lighting, will be reduced by developments that allow fixtures to be relocated more easily. In the long run, it seems likely that task lighting may reduce the initial cost of lighting. In the near term, task lighting is burdened with the high cost of innovation.

Relationship to Lighting of Surrounding Area

Task lighting can provide good illumination within the boundaries of a localized activity area. But, by definition, task lighting does not illuminate the surroundings. People do not like the sensation of being stranded in an island of light. This problem is largely subjective, as is the amount of background lighting that is considered desirable. A person who expects dark surroundings to be unpleasant is likely to want more background lighting. On the other hand, people who are interested in conserving energy may not feel a need for much background lighting. For more about background lighting, see [Reference Note 51](#).

A task-lighted area that is surrounded by other task-lighted areas may not need background or transition lighting. For example, individual desks in an open office area typically do not require additional lighting between

them. Whether background lighting is needed depends on the nature of the activities, the color scheme, the amount of light spilled out of the task lighted areas, the amount of traffic through the unlighted areas, etc. In many spaces that have windows, daylight can provide ample background lighting for daytime activities.

How to Avoid Excessive Shadowing at the Task

Light sources with small surface area create “harsh” lighting, which is primarily the result of sharp shadows cast by objects in the task area. For details, see [Reference Note 51](#). This factor is especially important in task lighting because the fixtures tend to be smaller and less widely distributed.

To avoid excessive shadowing, you need fixtures that have a large surface area. This is perhaps the most radical innovation that is needed to make task lighting suitable for general use. Specific methods of achieving this are given below.

How Important is Glare from Reflections of Light Sources?

Bright light sources may create glare by reflection from objects in the viewer’s field of vision. Most task areas include objects that can pick up reflections of light sources, for example, computer screens, the polished surfaces of machine tools, crystal paperweights, etc. Whether reflections of the light sources will cause an objectionable amount of glare depends on these factors:

- ***the surface texture of the illuminated objects.*** Smooth surfaces produce specular (mirror-like) reflections that concentrate glare. On the other hand, diffuse surfaces cannot create reflected glare. For example, reflections of the light fixtures are more troublesome for a machinist handling metal objects than for a sales clerk handling stuffed toys.
- ***the curvature of illuminated objects.*** If smooth surfaces within the visual field are highly curved, they reflect little of the light from the source into the eyes of the viewer. For example, reflections from the curved handle of a coffee cup are insignificant. On the other hand, fairly flat surfaces focus much more light into the viewer’s eyes. They can cause extreme glare, as in sheetmetal work.
- ***the orientation of illuminated surfaces.*** In order for glare to occur, the surface must be oriented to reflect the image of the fixture into the eyes of the viewer. If the surfaces are fixed, you can avoid glare by laying out the lighting geometry to avoid it. Trouble arises when the surfaces are movable, for example, when reading magazines.
- ***the steadiness of the viewer’s gaze.*** The importance of reflected glare depends on how much the viewer’s gaze is moving. For example, reflections from a computer monitor are serious because the user stares at the screen. In contrast, reflections

from the bright stainless steel surfaces in a kitchen are tolerable to the cooks because they shift their gaze continually.

- **the brightness of the light source.** Annoyance increases with the surface brightness of the light source. For a given amount of light delivered to the task, average surface brightness is inversely proportional to the surface area of the light source. A naked incandescent bulb is much more annoying than a fluorescent fixture with a diffuser.

Of these factors, the only one that you can control in the lighting design is the last one. If the task area contains objects that can reflect an image of the light sources into the eyes of the viewer, reduce the brightness of the light sources by increasing the surface area of the fixtures.

How to Achieve a Large Light Source Area

Previously, we made the point that task lighting fixtures should have a large surface area of uniform brightness. These characteristics reduce shadowing and reduce glare from reflections of the light source. Because task lighting is a pioneering area, there are no established guidelines for fixture surface area. As explained in [Reference Note 51](#), experiments suggest that there should be a ratio of at least 1:5 between the average width of the fixture's radiating surface and the distance between the fixture and the task.

There are two approaches for reducing the brightness of lamps, using diffusers and using reflectors. The two differ in light loss, control of the light distribution pattern, ability to shield the lamp from view, and ease of installation. We'll talk about diffusers first, then reflectors.

■ Lamp and Fixture Diffusers

Most general commercial lighting uses diffusers. These reduce surface brightness and disperse the light. In task lighting, the first function is useful, but the second is usually a disadvantage. Conventional diffuser material disperses light too widely for efficient task lighting, unless the task area is large or the fixtures are very close to the task.

In principle, surface brightness can be reduced to any desired level by increasing the diffuser area. The diffusers of typical fluorescent fixtures increase surface area and reduce the surface brightness by a factor of two to five, compared to the surface area of the bare tubes. This is usually adequate for most task lighting. Diffusing incandescent or HID task lighting requires some creativity. At present, there are no standard types of large-area diffusers for these sources. Custom fixtures can be fabricated using standard fixture components and diffuser materials.

Conventional diffuser materials used with fluorescent lighting absorb 30% (e.g., clear prismatic) to 50% (e.g., milky white) of the light produced by the

lamps. Some diffuser materials, such as the typical shades of table lamps, are too absorptive for efficient lighting.

■ Reflector Fixtures

A new concept for achieving large fixture surface areas in task lighting is using reflector fixtures. Reflector fixtures not only provide large surface areas, they also provide great flexibility. They can easily be aimed and they are less constrained in mounting location than light fixtures. Thus, reflector fixtures can adapt to changing conditions, which are an essential feature of efficient lighting.

Shaped specular reflectors, such as the photoflood fixtures discussed below, can provide good control of the light distribution pattern when used with incandescent lamps, compact fluorescent lamps, and HID lamps. In fact, reflector fixtures can limit the illuminated area so sharply that it may be desirable to broaden and soften the edges of their distribution patterns. For example, some photoflood fixtures allow you to modify the breadth of the pattern by adjusting the depth of the lamp within the fixture.

Diffuse reflector fixtures that use conventional fluorescent lamps, also discussed below, can provide good task lighting for larger task areas.

A problem with reflector fixtures is that they leave the bright lamp visible from the side, causing glare in adjacent areas. Even conventional fluorescent lamps may be too bright for some applications. A solution to this problem is to install a light shield around the lamp, as described below.

Reflectors generally absorb less light than diffusers. The reflectivity of most eligible reflector types is 85% to 90% when clean, whether the reflector is diffuse (e.g., white enamel) or specular (e.g., spun aluminum). As with diffusing fixtures, the total light loss is increased by multiple reflections and light trapping in the fixture.

■ Bounce Lighting

Bounce lighting achieves a large light source surface area by using a surface of the space as a diffuse reflector. A common example is using a floor-mounted torchere lamp to create a bright spot on the ceiling adjacent to a task area. Wall-mounted sconces bounce light from both walls and ceilings, which can be efficient for some task layouts.

At present, bounce lighting is used primarily for area lighting, which can be done on any scale. For example, the subway stations in Washington, D.C. are lighted by upward-aimed HID fixtures installed on the subway platforms that bounce light off the concrete ceiling. Bounce lighting has rarely been used for task lighting.

Bounce lighting has several advantages. Many common types of fixtures can be used to project light on a surface, so equipment is inexpensive and installation

is simplified. Also, you can create a virtual light source of any desired size. Bounce lighting makes it easy to keep the lamp hidden from view, eliminating light source glare.

The main disadvantage of bounce lighting is inefficient aiming. Bounce lighting provides no control of light distribution other than by proximity to the task. The “standard” task lighting layout defined previously requires the lights source to be above, alongside, and somewhat behind the viewer. If a fixture is aimed at this location on the ceiling to create bounce light, a large fraction of the light is lost outside the visual field.

You can use reflectors to reduce this light loss, as discussed below. For example, aim a directional lamp into a reflector to concentrate the reflected light toward the task. However, aiming is crude even with such arrangements. Experiments conducted by Wulfinghoff Energy Services, Inc. showed that the energy efficiency of bounce lighting cannot approach the efficiency of other methods of task lighting. Diffuse reflection simply does not provide sufficient control of the light distribution pattern.

Absorption losses for bounce lighting are about the same as for diffuser and reflector fixtures. The absorption of typical clean white and light pastel surfaces ranges from 15% to 30%.

Aiming Techniques

One of the basic elements of task lighting is careful aiming of the light at the task area. At present, there is a lack of commercially available fixtures that combine good aiming with efficient (i.e., fluorescent) lamps. Therefore, this aspect of task lighting requires innovation. The following are two general ways of aiming light toward the task area.

■ Fixtures That Can be Aimed

At present, aiming fixtures are available as standard equipment only for incandescent lamps. Compact fluorescent lamps can be used in many incandescent fixtures in a way that provides adequate illumination levels and beam control for task lighting. However, compact fluorescent lamps are too small in frontal area to avoid shadowing.

To explore task lighting with fixtures of large surface area, Wulfinghoff Energy Services, Inc. conducted experiments with a variety of fixtures. By far the best results were obtained by using two large parabolic aluminum photoflood fixtures for each task area. These reflectors have some surface etching to soften the beam. The fixtures were installed on opposite sides of the viewer, just below the ceiling, in the “standard” task lighting configuration described previously. Each

WESINC

Fig. 2 Task lighting challenge No. 1 This is a large reading room in a public library. The present light fixtures shine mostly on the carpet and on empty tables. Daylighting is not being exploited. All reading occurs at individual furniture units, which can be moved and reoriented. There are many windows, and they extend high on the wall. What would you do to make this lighting efficient and pleasing?

photoflood fixture used one 23-watt screw-in fluorescent lamp. The combination of a compact fluorescent lamp inside a deep reflector fixture works well because the lamp emits most of its light perpendicular to its axis, so there is little direct light from the small lamp in comparison with the light coming from the reflector.

In experiments conducted in a typical office, the beam of each reflector was aimed at its respective side of the desk. The beams overlapped, providing illumination that was essentially uniform within the task area. The average illumination level was about 25 footcandles (250 lux), which was more than adequate for typical office paperwork and word processing. (25 footcandles is considered a low illumination level for office work in the United States, but not in most other countries. This illustrates that illumination levels can be reduced substantially if glare and veiling reflections are eliminated.) Shadows were light and diffuse. There were no bright reflections in the computer screen or elsewhere, but the screen had a light haze from being directly illuminated by the fixtures. Visual comfort remained good over a test period of several weeks. There was no discomfort when facing either side of the desk.

In summary, this arrangement provided illumination of high quality with an energy expenditure of only 50 watts per work station.

Good results were also achieved using a pair of industrial-type skirted fluorescent fixtures for each work station. The fixtures were fitted with brackets to allow aiming, and were installed just below ceiling level. Each fixture has two 24-inch, 20-watt tubes, for a total power of about 100 watts per work station. The illumination level was somewhat lower, about 20 footcandles (200 lux), which was satisfactory for routine word processing. The fixtures spread light well outside the task area, which was a desk of normal size. This factor accounts for the lower illumination level. The illumination was uniform and pleasant.

These experiments demonstrated the feasibility of task lighting for general office work using aiming fixtures. They also showed that fluorescent task lighting fixtures can be produced at low cost. If appearance is not a major factor, task lighting fixtures can be adapted from fixtures that are readily available.

Note that fluorescent and HID lamps may have limitations in mounting position. These are explained in [Subsections 9.2](#) and [9.3](#), respectively.

WESINC

Fig. 3 Task lighting challenge No. 2 This is an office area with very tall ceilings in a public administration building. There are several desks, only one of which is being used at the moment. There is a conference table, some visitors' chairs, and a lot of empty space. It appears likely that the arrangement of the space will change repeatedly. Illumination is provided by uniformly spaced downlights that bear no relationship to the work in the space. There is a large amount of daylighting from tall windows, which is not being exploited. How would you make the lighting in this space efficient?

■ Aiming with Reflector Panels

Reflector panels are a way of improving the aiming of conventional fixtures. For example, if a reflecting panel is installed vertically alongside a fluorescent fixture that has a “batwing” distribution pattern, the distribution pattern becomes a single-lobed beam centered about an angle of 70 degrees from the ceiling, a geometry that is desirable for avoiding veiling reflections. The additional reflected light on the task may allow partial delamping of the fixture. In experiments with office task lighting, reflector panels increased the illumination of the task from 40 to 80 percent when installed with existing fluorescent ceiling fixtures.

This is primarily a retrofit technique. For example, it may be the most practical way to improve the light distribution of existing fluorescent fixtures. In new construction, consider other methods of controlling light distribution.

The surfaces of the reflector may be specular or diffuse, depending primarily on the existing fixtures. With fixtures that have broad light distribution, such as conventional fluorescent fixtures, use specular reflectors to avoid further scattering of the light.

Reflector panels can be fabricated easily from a wide variety of inexpensive materials, including paper, fabric, aluminized paper and plastic, and polished aluminum

with an anti-oxidant coating. For example, specular reflectors can be made from various types of aluminum stock used to make the fluorescent fixture “reflectors” covered by [Measure 9.2.7](#).

Panels may be flat, bent, or curved as needed to improve light distribution, to provide more effective glare shielding, and to provide rigidity. For example, a reflector may be installed around two of the four sides of a fluorescent ceiling fixture.

Coordinate reflectors with glare shielding, as described under “Glare Shielding,” below. With diffuse reflector panels, the illuminated side will appear excessively bright to persons outside the task area. On the other hand, a specular reflector will not allow a distant viewer to see an image of the bright fixture, provided that the reflector is tilted backward somewhat from the vertical. Any type of downward projecting reflector shields against glare from the rear of the panel. The rear sides of the panels can be decorated.

Fixture Mounting

Fixture mounting is another area that needs development to make task lighting practical on a large scale. The fixture mounting method should provide:

- ***ability to locate the fixtures precisely.*** The “standard” geometry for task lighting requires fairly precise fixture placement.

WESINC

Fig. 4 Task lighting challenge No. 3 This credit union office has fluorescent lighting in a tall ceiling, which is illuminating nothing at this moment. There are a few desks and work tables, some shelves, and a counter for the public. The arrangement of the space, and even its basic use, will probably keep changing. How would you provide efficient and pleasing lighting for all the activities, now and in the future?

- **ability to aim the fixtures precisely.** The mounting should allow the fixture to be aimed horizontally and vertically.
- **adaptability to changing conditions.** It should be easy, inexpensive, and safe to move fixtures from one location to another as activities are moved.

■ Distance from Fixture to Task

Contrary to intuition, the distance of a fixture from the task has no effect on task lighting efficiency, if the light distribution pattern of the fixture can be shaped properly. Light is not absorbed in the space between the fixture and the task. However, fixtures with poor control of the light distribution pattern must be mounted close to the task to minimize light loss outside the task area.

The distance between the fixture and the task matters primarily because it affects the ratio of the fixture surface area to the distance from the task. (To review, we want this ratio to be large to prevent excessive shadowing and to reduce surface brightness.) For example, if the distance of a fixture from the task is doubled, the surface area of the fixture must be increased by a factor of four to maintain the same ratio. Larger fixtures are more expensive, more difficult to install, and more difficult to make attractive. So, try to keep task lighting fixtures

reasonably close to the activities. The limitation on getting the fixture close to the task is maintaining sufficiently uniform illumination.

■ Ceiling Mounting

Expect task lighting fixtures to be surface-mounted on ceilings, rather than recessed into the ceilings. Surface mounting allows fixtures to be moved laterally by any desired amount. It also allows fixtures to be rotated, which is essential for aiming the light. Suspended ceiling systems with lay-in fixtures are not suitable for task lighting, because the grid system does not allow the fixture to be positioned properly, and it does not allow fixtures to be rotated.

■ Task Mounting

Task lighting fixtures may be installed on furniture, equipment, or partitions. Task mounting offers a number of significant advantages. It fixes the lighting geometry, it eliminates the problem of relocating the lighting when the task is relocated, and it simplifies the installation of controls.

However, task mounting produced unsatisfactory results during the 1970's wave of task lighting. The problems were basic, namely, source glare, veiling reflections, and non-uniform illumination within the visual field. The underlying cause was that the fixtures

WESINC

Fig. 5 Task lighting challenge No. 4 Lighting is a fundamental part of merchandising in this department store, and it is a major part of the store's operating cost. The present lighting is a combination of fluorescent fixtures and incandescent downlights located in a repetitive pattern, without regard to the location of the merchandise or the traffic flow. How would you save lighting energy here while improving the merchandising appeal of the lighting?

were too close to the task. A typical example was mounting a fluorescent lamp underneath a shelf in an office module.

These visual problems can be alleviated by installing the fixtures at some distance from the tasks. With task mounting, this can be done by installing outriggers on desks for holding the fixtures. This may be awkward. However, keep an open mind. There are no fixed rules in this game, yet.

■ Mounting Bounce Light Fixtures

Fixtures that bounce light off the ceiling or other surfaces can be installed in many ways. The reflecting surface usually is diffuse, so the location of the fixture does not materially affect the direction that light is reflected. You can use many types of fixtures to create bounce lighting. Torchiere lamps are handy, but they are limited to creating the lighted spot directly overhead. Pole lamps with one or more movable sockets overcome this problem. Table-mounted lamps may be suitable, but they take up space. Attractive reflector lamps can be installed on any surface or object, and they have great flexibility in aiming.

The main guideline is to install the fixtures so that the lamps and the bright surfaces of the fixtures are not visible from occupied portions of the space. One way to do this is to make the fixtures tall enough so that the bright portions of the fixtures are above eye level.

Glare Shielding

Task lighting for one task area may create serious glare at other task areas in the same space. This occurs if the fixtures are installed so that their lamps or bright surfaces are visible from adjacent areas. Glare from adjacent task lighting may be especially problematical if the fixture is aimed away from the vertical. Even though a fixture is tilted only slightly in the direction of an adjacent viewer, it will appear much brighter to a person in the distance than if the fixture were facing straight down. Furthermore, task lighting usually has to be below the ceiling level, so it intrudes more into the field of view of adjacent viewers.

The solution to this problem is to shield the fixtures from view from other occupied areas. This is another novel element of successful task lighting. Glare shielding is limited only by your creativity. Fortunately, it can be easy and inexpensive.

The shape and location of glare shields are not critical. There are only two conditions: (1) the glare shields must lie in the line of sight between the bright parts of the fixture and the eyes of persons in adjacent areas, and (2) they must lie outside the main beam of the fixtures, so that they do not become sources of glare themselves. You can use any opaque or translucent material for shielding, such as fabric, colored paper, magazine centerfolds, etc.

With aimed fixtures, glare shielding can take the form of skirts or blinders attached to the fixtures themselves. The sides of the skirts facing the lamps are flat black. This technique is commonly used with theatrical lighting fixtures and with some display lighting. To avoid wasting energy, install the skirts well outside the main part of the light beam. You can shield a group of fixtures by suspending a curtain or a series of panels around the fixtures.

If you use reflector panels for aiming, as suggested above, integrate glare shielding with the reflector panels.

Get people used to the fact that glare shielding will stand out in the decor. With a bit of imagination, you can accomplish the shielding in ways that are quite decorative. For example, one office uses marine signal pennants suspended from the ceiling alongside fixtures.

Glare in adjacent areas is generally not a problem with task lighting that is installed below the tops of furniture or partitions. However, it is difficult to achieve good visual quality with low-mounted task lighting, for the reasons given previously.

Lamp Efficiency

You want task lighting for its energy efficiency. Therefore, use efficient lamps. Until recently, there was a strong temptation to use incandescent lamps and fixtures for task lighting because these were the only kind that allowed precise aiming at short range. However, the inefficiency of incandescent lamps cancels the advantage of accurate aiming.

For most applications, only fluorescent lighting offers good lamp efficiency. Much of the bother and innovation involved in the preceding discussion stems from the need to make the light distribution of conventional fluorescent lighting more controllable.

Compact fluorescent lamps may prove to be a breakthrough. They combine most of the efficiency potential of fluorescent lighting with the aiming capability of incandescent lamps. The best compact fluorescent lamps are perhaps 70% to 80% as efficient as the best conventional fluorescent lighting, and they have all the other advantages of fluorescent lighting.

For these reasons, base your initial task lighting designs on compact fluorescent lamps. Consider installing them in large reflector fixtures, as described previously.

HID lamps are almost point sources, so you can combine them with reflector fixtures to tailor the light distribution pattern accurately. Consider HID lighting for task lighting of large areas, especially where the fixtures cannot be installed close to the tasks. Color rendering, previously a serious weakness of HID lighting, has been greatly improved in recent years.

HID lighting is not suitable for small task areas, because small HID lamps are substantially less efficient than fluorescent lamps in small wattages. Also,

remember that HID lamps cannot be turned on and off at short intervals.

Control Fixtures Efficiently

The ability to turn lights off at individual activity areas is one of the major efficiency advantages of task lighting. Be sure to exploit this advantage by using controls that minimize the duration of operation within each task area. Refer to [Subsections 9.4](#) and [9.5](#) for control devices. Also, see [Measure 9.6.4](#), in this Subsection, for efficient control circuiting.

Do Not Duplicate Lighting!

Task lighting saves energy only if it displaces other lighting. It makes no sense to add task lighting to area lighting. Doing so is likely to increase energy consumption, rather than reduce it. Eliminate area lighting when you install task lighting.

Accommodate Each Mode of Space Usage

If the activities in the space change on a predictable basis, provide lighting that is efficient for each mode of space usage, along with a separate control for each lighting function. This is covered by [Measure 9.6.3](#). Task lighting is likely to be inadequate for auxiliary functions, such as transit and cleaning. If you are retrofitting task lighting in an existing facility, it may be appropriate to leave some of the original area lighting to serve these functions.

Rehearse Before You Perform

As we said at the beginning, the methods of effective task lighting have not yet found their way into the mainstream of contemporary lighting design. You will have to be a pioneer to exploit this powerful method. Before you commit to actual installations, design task lighting for a variety of sample situations in detail. Practice dealing with all possible considerations, such as the presence of daylight and the glare from it, uncertainly in work station locations, and so forth. Because task lighting may be affected by virtually every other aspect of lighting design, review all the Measures of [Section 9](#) in terms of their potential significance to task lighting.

As a start, think how you would redesign the lighting in the spaces shown in Figures 2 through 5. Then, go

out and practice redesigning as many inefficient lighting installations as you can find. Look for an opportunity to actually test the concepts we have discussed here. Start small. Build on your successes. If you are successful, tell others how you did it.

ECONOMICS

SAVINGS POTENTIAL: 50 to 80 percent of lighting energy, compared to conventional area lighting. This Measure also provides large savings in lamp and lamp replacement costs.

COST: \$1 to \$10 per watt of task lighting capacity, in retrofit applications. Eventually, task lighting will reduce equipment cost in new construction. In the meantime, the cost for task lighting in new construction depends largely on the imagination of the lighting designer and the scale of the project. Design and development costs will be high until task lighting becomes common.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

INNOVATION: Want to become famous? Have either a major success or a major failure with task lighting. Don't tackle task lighting, in the most innovative sense, unless you have a lot of time, a modest budget for equipment, and some spaces with occupants who are willing to be test subjects. If you decide to become a pioneer in task lighting, check everything you do against the lighting quality factors explained in [Reference Note 51](#). Let your imagination roam free, but start with compact fluorescent lamps as your lamp type. If appearance matters and your facility has an interior decorator, get her involved as soon as you are ready to go beyond the prototype stage.

EQUIPMENT: Don't expect to find ideal task lighting fixtures in the standard catalogs. Specialty manufacturers will produce custom fixtures for you. But, don't place a large order until you have thoroughly tested your concepts with prototypes.

INSTALLATION: Install every fixture on a custom basis, including working out sight lines, installing glare shields, etc. If you contract for the labor, make sure that everybody knows this beforehand. Demand the time and skill required.

MEASURE 9.6.2.1 Disconnect or remove fixtures where they are not needed.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Contemporary lighting practice uses many more fixtures than required for efficient and effective illumination. Typically, a uniformly high level of lighting is installed, avoiding the need to customize lighting to the activities. This creates an opportunity to save energy by eliminating the excess fixtures. This is quick and inexpensive, but it requires thought. You need to examine the environment of each fixture individually to decide whether the fixture can be disconnected.

In the case of fluorescent lighting, consider this Measure to be an extension of [Measure 9.2.1](#), which recommends “delamping” and “deballasting” fluorescent fixtures.

Figures 1 and 2 provide two examples of fluorescent lighting where both delamping and removing excess fixtures are appropriate.

Remove the Lamps, Disconnect the Fixture, or Remove the Fixture?

You can take a fixture out of service by removing the lamps, by disconnecting the power to the fixture, or by physically removing the fixture. The last method is usually best, because the presence of an idle fixture motivates putting it back into operation. Also, it looks better to remove the fixture completely and refinish the previous mounting area.

Fig. 1 One desk does not need twelve fluorescent lamps
 This small office has three 4-lamp fixtures. The right front fixture creates serious veiling reflections at the desk. The right rear fixture cannot illuminate the desk properly because it is behind the viewer’s body. Both could be eliminated. The fixture on the left will provide ample illumination. The office has a large window, which could provide daylighting. This would require reorienting the desk and improving the window treatment.

SUMMARY

Typically saves a modest amount of lighting energy. Quick and cheap.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return, New Facilities	% % % %
Rate of Return, Retrofit	% % % %
Reliability	✓ ✓ ✓
Ease of Retrofit	☺ ☺ ☺

If you do not remove idle fixtures, at least disconnect the wiring to them. Disconnecting power at a circuit breaker panel makes it too easy to restore power. Similarly, removing the lamps is ineffective by itself because the lamps will be replaced sooner or later. Furthermore, this practice involves some safety hazard because the electrodes are left exposed.

All fluorescent and HID fixtures have ballasts. A ballast continues to draw current even if the lamp is removed. Therefore, disconnect the wiring ahead of the ballasts, rather than just removing the lamps. With fluorescent fixtures, you have the choice of leaving some of the lamps in operation. See [Measures 9.2.1 ff](#) for the details of delamping fluorescent fixtures.

Label Disconnected Fixtures

If you leave disconnected fixtures in place, label them to point out they have been disconnected for the sake of energy conservation. Otherwise, occupants and staff will be in doubt as to whether the fixture should be operating. Use the labeling techniques recommended by [Measure 9.7.3](#).

Maintaining or Improving Visual Effectiveness

At first glance, it might seem that deactivating fixtures must reduce visual effectiveness. On the contrary, careful planning can often improve visual effectiveness in facilities that have excessive lighting. Make this a primary goal. Review the lighting quality issues in [Reference Note 51](#), Factors in Lighting Quality. When eliminating fixtures, pay special attention to:

- ***maintaining appropriate illumination intensity.***
 Carry a light meter when identifying fixtures. Measure illumination levels at the task. Account for decline in light output as lamps age, and for greater light requirements by older people.

- **eliminating veiling reflections and source glare.** In many cases, deactivating fixtures can reduce veiling reflections and glare. The improvement in visual quality partially compensates for the reduced illumination level.
- **color rendering.** Consider whether the fixtures to be deactivated may be necessary for good color rendering, for example, incandescent fixtures used to highlight paintings.
- **background lighting.** All environments require some amount of background lighting, so do not disconnect fixtures to the extent that the surroundings appear excessively dark.

Conflict with Lighting Decor

The most serious resistance to deactivating lighting is likely to occur in environments where a regular pattern of fixtures is considered to be part of the decor. Disconnecting fixtures makes them appear defective. In many cases, you can avoid this problem by removing the fixture completely, leaving no evidence that a fixture was once located there. For example, remove lay-in fluorescent fixtures and replace them with ceiling tiles.

The esthetic problem tends to disappear if enough fixtures are removed to eliminate the appearance of a repetitive pattern of fixtures. In many cases, removing about a third of the fixtures accomplishes this.

Common Opportunities

The following are some common situations where fixtures can be taken out of service. Many other situations may exist.

■ Area Lighting

Almost anywhere fixtures are installed without regard to individual tasks, as in the common checkerboard pattern, there is an opportunity to deactivate a major fraction of the fixtures. Indiscriminate area lighting is sometimes justified on the grounds that it provides “background lighting.” In most cases, area lighting is much brighter than needed for this purpose.

■ Fixtures that Illuminate Dead Space

Examine where each fixture is throwing its light. If most of the light is falling on places that people cannot see, or have no need to see, disconnect the fixture. For example, disconnect fixtures installed over the tops of shelving, over walk-in freezers, etc.

■ Overlapping Fixtures

Facilities such as ballrooms and upscale restaurants often have various types of lighting fixtures that illuminate the same area. This is done to make the lighting adaptable to different types of functions. Such configurations are an invitation to use more light fixtures than are needed for any given purpose. You can often eliminate the least efficient fixtures. Retain lighting

WESINC

Fig. 2 Easy savings This government office has a high level of illumination for a few desks and work tables, some filing cabinets, and a lot of empty space. Perhaps 80% of the energy cost of lighting this space could be eliminated with easy changes. Most of the fixtures could be eliminated or delamped. Adding some inexpensive controls would adapt the space to occupancy and exploit the ample daylighting that is available. Task lighting would further reduce the remaining energy consumption.

flexibility by improving the controls ([Subsections 9.4 and 9.5](#)) and switching layout ([Subsection 9.6](#)). Using dimming with fluorescent fixtures ([Measure 9.2.6](#)) is another approach that is now practical.

■ Downlights

Installing downlights indiscriminately has become a careless habit of architects. As usually installed, downlights are very inefficient, so that other fixtures in the space do a majority of the actual lighting. In such cases, you can remove the downlights. Even in cases where downlights provide useful illumination, it may be desirable to replace them with more efficient types. See [Measure 9.6.2.3](#).

■ Wall Washers

In most cases, wall washers are a decorative extravagance. In interior spaces, they may contribute to overall illumination. As an alternative, consider making the walls more reflective. See [Measure 9.6.1](#) for the details.

■ Cove Lighting

Cove lighting is inefficient because light must be reflected many times to reach the area to be illuminated. It is so inefficient that other fixtures may be installed to

do most of the actual space lighting. In many facilities, cove lighting is primarily a decoration. See [Measure 9.6.2.3](#) for tips on eliminating cove lighting.

■ Outside Lighting

Take a walk around the facility at night. You may find some fixtures that no longer serve a useful purpose.

ECONOMICS

SAVINGS POTENTIAL: 10 to 70 percent of lighting energy. This Measure may also provide large savings in lamp and lamp replacement costs.

COST: In new construction, this activity may save money. In retrofit, the cost is usually minimal.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

PLANNING: In existing facilities, survey the facility fixture by fixture. Eliminate any that are providing only useless illumination. Eliminate any that cause veiling reflections or glare, and see whether the illumination level remains high enough. If it does not, go to [Measure 9.6.2.2](#).

MEASURE 9.6.2.2 Relocate and reorient fixtures to improve energy efficiency and visual quality.

RATINGS

New Facilities	Retrofit	O&M
A	C	

This Measure goes one step beyond [Measure 9.6.2.1](#) by relocating the fixtures to make them more effective. This Measure requires much more labor. In spaces that have more than one type of lighting, combine this Measure with [Measure 9.6.3](#).

Relocation Strategy

Your objective is to provide good illumination while saving energy. To provide good illumination, observe the principles summarized in [Reference Note 51](#), Factors in Lighting Quality. To save energy, try to achieve these objectives as you move fixtures:

- **reduce lamp wattage.** For example, moving a 4-tube fluorescent fixture to an optimum location over a work station may allow two of the four tubes to be removed.

You can reduce fixture wattage in a variety of ways. Refer to [Subsection 9.1](#) for incandescent lighting, [Subsection 9.2](#) for fluorescent lighting, and [Subsection 9.3](#) for HID lighting.

Fig. 1 Why grid-mounted light fixtures cannot be located efficiently The grid pattern limits the fixture location to increments of spacing that are too large for efficient placement. Also, duct and pipe installed above the grid may make it difficult or impossible to move the fixtures.

SUMMARY

After eliminating unnecessary fixtures, this step makes better use of the fixtures that remain. Can often improve visual quality. May be difficult in retrofit because of interference in the ceiling.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	%
Reliability	✓	✓	✓	✓
Ease of Retrofit	☺	☺		

- **eliminate fixtures.** For example, in a restaurant that uses downlights for general lighting, relocating the downlights directly over the tables may allow you to remove half of them.
- **increase the subdivision of control.** For example, in a large office area, moving the fixtures over individual desks allows them to be turned off when the individual user leaves the space. Exploiting this opportunity usually requires circuit modifications and additional controls, as explained in [Measures 9.6.4 ff.](#)

How to Relocate Fixtures

If fixtures are laid in suspended ceilings, it may be fairly easy to move the fixtures, but the available positions are limited by the dimensions of the ceiling grid. The lateral grid bars can be moved in small increments. This results in odd-sized ceiling tiles between fixtures, which may present a strange appearance.

Expect interference from ductwork, sprinkler piping, etc., above the ceiling. See [Figure 1](#). If there is sufficient space above the ceiling, it may be worth elevating these obstructions to allow fixtures to be moved.

Surface-mounted fixtures need more effort and cost to relocate because new mounting boxes need to be installed. If appearance is not a prohibitive factor, surface wiring may reduce this cost. Touch-up work is needed where the fixtures were previously located.

If the fixture is not symmetrical, its orientation matters as well as its lateral location. See [Reference Note 57](#), Light Distribution Pattern of Fixtures, about this. [Figure 2](#) shows a typical example of long, thin

fixtures that should be turned 90 degrees to provide better light distribution.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of the energy used by the affected fixtures. This Measure may also provide large savings in lamp and lamp replacement costs.

COST: In new construction, this activity typically costs nothing. In retrofit, the cost varies widely, depending on the existing mounting configurations. Most of the cost is for labor.

PAYBACK PERIOD: Immediate, in new construction. Less than one year, to several years, in retrofit.

TRAPS & TRICKS

PLANNING AND LEARNING: The key to results is effective planning. Expect to spend a lot of time on this. Build experience by doing this first in a few spaces of different types, and seeing how well the changes work. If the fixtures are installed in suspended ceilings, decide how much effort you are willing to invest to work around interferences with duct, piping, and other equipment located above the suspended ceilings.

WESINC

Fig. 2 Fixture orientation matters as well as location
This scene shows clearly that a long fixture emits light mostly perpendicular to its axis. Rotating the fixtures 90 degrees will distribute light along the corridor more uniformly. To avoid the glare that would result, it is also necessary to suspend short glare shields from the ceiling, halfway between the fixtures. The same principle applies to tunnels, walkways, etc.

MEASURE 9.6.2.3 Replace fixtures and improve fixture installations that waste light.

RATINGS

New Facilities	Retrofit	O&M
A	C	

The previous Measures eliminated unnecessary fixtures or moved fixtures to more efficient locations. In many cases, fixtures are so inefficient that they are not worth moving or salvaging. Discard such fixtures and, if necessary, replace them with more efficient fixtures.

How efficient are your fixtures? Survey your facility to find out. You may find that some are inherently inefficient. You may find that others waste energy because they are the wrong type for the lighting application. These characteristics may make a fixture too wasteful to keep:

- **the fixture creates light inefficiently.** Incandescent fixtures are the main offenders. Some HID lamps, especially mercury vapor, are much less efficient than the best HID lamps that are presently available.
- **the fixture absorbs light internally.** Fixtures with dark interior surfaces or tight baffles have this problem.
- **the fixture distributes light inefficiently.** Downlights are a common example. HID fixtures and other high-output fixtures may put much of their light in places where it is not needed. (But, note that some HID fixtures let you adjust the light distribution pattern.)
- **the fixture cannot be controlled efficiently.** HID fixtures are the worst in this regard, because they cannot be turned on and off repeatedly.

Several types of lighting are especially common energy wasters, so we will cover them in greater detail. These culprits are downlights, indirect lighting in general, and fixtures installed in ceiling plenums.

Downlights

Downlights are a fad that has created an epidemic of energy waste. Figures 1 through 4 illustrate how they are abused. Downlights waste light in several ways:

- **absorption inside the fixture.** Many downlights are designed as light traps that absorb all light from the lamp except the light that is aimed directly at the opening. Such downlights may trap from 30% to 98% of the light emitted by the lamp, depending on the type of lamp (see [Measure 9.1.3](#)). You may be able to improve the light emission of downlights by installing reflective inserts in them ([Measure 9.1.4.2](#)).
- **absorption outside the fixture.** Downlights do not illuminate activities directly, except by accident or in cases where they are deliberately installed over the activity. They typically project light on the floor,

Fig. 1 Wrong fixtures for the application The dark interiors of these deeply recessed downlights absorb most of the light of the lamps. The light that escapes from the fixtures mostly goes into the carpet. Single-tube fluorescent fixtures, mounted on the ceiling surface, would require only a few percent of the energy of these fixtures, for a given amount of illumination on the books.

which is darker than other surfaces and is too low to provide efficient lighting by reflection. As a result, most of the light emitted by a downlight is absorbed in the course of multiple reflections before it reaches the area intended for illumination.

- **inefficient lamps.** Most downlights use incandescent lamps, which are about one fourth as efficient as fluorescent or HID lighting. You can substitute screw-in fluorescent lamps for incandescent lamps in most cases ([Measure 9.1.2.1](#)), although the maximum light output presently available is not as high as with incandescent lamps.

In violation of all logic, downlights are often used for general lighting. Where this situation exists, take inventory of the areas that need to be illuminated, and select replacement fixtures that will illuminate them most efficiently. In most cases, the number of replacement fixtures required is a fraction of the original number of downlights.

Legitimate applications for downlights are rare, the most common being applications where an atmosphere of intimacy is desired, as in fine dining, or where it is necessary to eliminate all glare, as in museums. Even in such cases, the manner of installing the downlight often wastes energy.

■ Concern About Glare

The popularity of downlights appears to stem from a notion that light fixtures should not be visible. In turn,

this notion may be based on a concern about glare. However, visible fixtures do not cause visual discomfort if their surface brightness is not excessive, if they are installed outside of the viewers' usual lines of sight, and if they are not installed where they cause veiling reflections. [Reference Note 51](#), Factors in Lighting Quality, explains how to avoid glare.

■ Close Ceiling Penetrations

Downlights installed inside ceilings usually are vented to the space above the ceiling to reduce the temperature inside the fixture. If the space above the ceiling is unconditioned, such as an attic, a downlight serves as a path for wasting conditioned air. For this reason, if you deactivate a vented downlight that is installed into an unconditioned space, remove the fixture. Close and refinish the penetration. Dead downlights are not attractive, so this also improves appearance.

Indirect Lighting

Indirect lighting includes cove lighting, valance lighting, wall washers, and bounce lighting. Indirect lighting wastes energy by requiring light to be reflected repeatedly on the way from the lamp to the activity. A fraction of the light is lost at each reflection.

Even the most reflective surfaces absorb some light. For example, clean white paint has a reflectivity of about 90%. If light must reflect three times from such a surface, somewhat less than one third of the light is lost. If a the surface is dirty or has a pastel color, its reflectivity

WESINC

Fig. 2 Downlight abuse in a courthouse Downlights are used as the only source of illumination in this large courthouse lobby. Most of the light is absorbed in the carpet, making this large space gloomy. Note the dark walls, including the portraits of the learned judges. Compare the brightness of the wall in the office at left, which is illuminated with conventional fluorescent ceiling fixtures.

WESINC

Fig. 3 Downlight abuse in a military barracks Downlights are utterly inappropriate for this environment. At least the floors are polished, so some light gets into the space. These fixtures are so ineffectual that nobody notices that many of the bulbs are burned out. The remaining ones are just wasting energy, because the glass front is providing plenty of daylight. A few fluorescent fixtures and some basic controls would illuminate this space for less than ten percent of the present cost.

WESINC

Fig. 4 Downlight abuse in a university building entrance This forest of downlights is intended to provide security for the entrance to an urban classroom building. Most of the light that escapes from the highly absorbing fixtures is lost in the dark stone floor. About three small surface-mounted HID lamps would provide vastly better illumination, at a small fraction of the energy and lamp replacement cost.

is reduced to about 60% to 80%. In this case, three reflections will result in well over half of the light being lost.

Eliminating cove and valance lighting may leave the walls too dark, especially if they have decor. The solution is to install ceiling fixtures near the wall that have enough lateral distribution to highlight the walls.

Fig. 5 Ceiling plenum lighting This escalator in a department store is illuminated by fluorescent strip fixtures located in the ceiling plenum. Grilles let some of the light escape, but this arrangement is an expensive light trap. It has no advantage over conventional fluorescent fixtures.

Eliminating cove and valance lighting leaves a dark slot. You can cover this with a decorative frieze. If you want to create the appearance of illumination coming from the slot, you can create this effect with much less power by installing low-wattage lamps behind a translucent panel that covers the slot. Or, if you have budget for deco, install a neon tube along the slot.

Bounce lighting can be reasonably efficient if it involves only a single reflection. For example, you can use upward pointing HID lamps to reflect light off a white ceiling to provide area lighting. Make the surface very reflective. See [Measure 9.6.2](#) about using bounce light for task lighting.

Fixtures Installed in Ceiling Plenums

In some commercial buildings, you may find fluorescent strip fixtures installed in the ceiling plenum, illuminating the space below through grilles installed in a suspended ceiling. This arrangement is especially inefficient. It traps most of the light that does not pass directly from the lamps through the opening. Such arrangements are usually installed for appearance, but they are not particularly attractive. Figure 5 shows an example.

To eliminate the energy waste while maintaining a flush ceiling, simply install flush-mounted fluorescent fixtures that have efficient reflectors. Surface-mounted fixtures also provide greater flexibility in fixture location and light distribution.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of lighting energy in the affected spaces. Lamp and replacement labor costs may be reduced significantly.

COST: In new construction, this modification is typically inexpensive, and in some cases, it may have a lower initial cost. In retrofit, replacement lighting typically costs \$0.50 to \$3.00 per watt of capacity.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

PLANNING: Start with a survey of all your fixtures. Since you are entirely eliminating certain types of fixtures or lighting arrangements, you have a wide range of options in replacing the lighting. Make the most of this opportunity. Consider layout and fixture type together.

MEASURE 9.6.3 Install fixtures or combinations of fixtures that provide efficient lighting for all modes of space usage.

RATINGS

New Facilities	Retrofit	O&M
B	C	

In many cases, the lighting of a space is designed for one type of activity, and it is inefficient for other usage. For example, nightclubs use incandescent lighting operated by dimmers because the low intensity and warm color of incandescent lighting creates the desired mood. While, this is appropriate during evening business hours, the nightclub needs lighting at much higher intensity for many hours during the day, for activities such as cleaning, rehearsals, and serving the lunch trade. The incandescent lighting is inefficient for such activities.

The most efficient way to provide lighting for such facilities is to install the types of fixtures, or a combination of fixture types, that can accommodate each mode of space usage as efficiently as possible. How well this pays off depends on the total number of hours each year that lighting is needed for each function.

Common Opportunities

Consider all the times that lighting is required in each space, and provide appropriate lighting for each requirement. The following are common situations where different modes of lighting are needed for efficiency.

■ **Spaces that Need Incandescent Lighting for Appearance**

Facilities such as restaurants, nightclubs, theaters, and retail stores commonly use incandescent lighting for esthetic reasons during hours when they are open to the public. However, such facilities commonly operate for many hours when esthetics are not a factor. For example, cleaning and restocking require illumination that is bright and widespread, rather than subtle. Consider installing more efficient fixtures to provide illumination for these functions. Fluorescent and HID lighting is about four times as efficient as incandescent lighting, and the lamps last about ten times longer.

Incandescent fixtures often distribute light inefficiently. Downlights, commonly installed without regard to the location of activities, are the most common example. For times when incandescent lighting is needed, try to install incandescent fixtures that have efficient light distribution.

■ **Spaces with HID Lighting**

HID lighting tends to be left on in empty spaces because it cannot be restarted quickly. To eliminate this problem, install additional fluorescent fixtures for emergency lighting, transit, and activities that occur outside normal occupancy hours. An alternative is

SUMMARY

Applies to many environments where different types of activities occur on a regular basis. Needs reliable controls to produce results.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	
Ease of Retrofit	😊	😊	😊	

replacing all the existing HID lighting with fluorescent lighting, as recommended by [Measure 9.3.3](#).

■ **Emergency Lighting**

It is common practice to provide emergency lighting with some of the conventional fixtures. Often, the fixtures are much too powerful for emergency lighting, even though only a fraction of them are used. For example, the 4-tube fluorescent fixtures commonly used in office space each consume about 200 watts. This is vastly more power than needed for emergency egress.

Another disadvantage of this practice is that the lamps in the emergency fixtures burn out more often than the lamps in the other fixtures. This upsets the schedule for group relamping, if this practice is followed.

There are a number of economical solutions. The easiest, most efficient, and cheapest may be to install specialized emergency fixtures in locations that are appropriate for emergency egress. Instead of expending 200 watts per fixture, as in the previous example, each emergency fixture might have a power consumption of about 20 watts. Another improvement is to rewire some of the primary fixtures so that only a reduced number of lamps operate during unoccupied hours (see [Measure 9.6.4](#) for this). However, this solution still burns out one set of lamps at a different rate than the others.

■ **Transit Lighting**

The worst situation is turning on all the lights in a space only to pass through it. You can keep this from happening with the circuiting and control methods recommended by [Measure 9.6.4](#). If the lights in the space need to be turned on for long durations to allow transit, install appropriate fixtures for this purpose.

■ Maintenance Lighting

Industrial facilities typically have equipment that requires frequent maintenance, inspection, and cleaning outside of normal production hours. It may be practical to install specialized lighting for these functions, avoiding the need to turn on the lights in the entire plant.

Control to Prevent Duplication of Lighting

Merely installing a variety of fixtures does not make the lighting efficient. In fact, it may make the lighting even less efficient, and also annoying. Figure 1 illustrates this.

It is a big challenge to make sure that only the lighting needed for each mode of space usage is turned on. For example, if a nightclub has fluorescent lighting for cleaning, make sure that the incandescent lights are turned off when the fluorescent lights are turned on. Otherwise, the money spent on the extra fixtures is wasted and overall consumption may even increase.

An important requirement is to have efficient switching for the fixtures. To achieve this, the fixtures must be arranged properly on the power circuits, as prescribed by [Measure 9.6.4](#). In order for the switches to be used properly, they must be located where they are accessible and obvious, as prescribed by [Measure 9.6.4](#). And, the controls must be marked in a manner

that is effective for its environment, as prescribed by [Measure 9.4.1](#).

One way to keep the wrong lights from being turned on is to install a programmable light switch that turns on preset patterns of fixtures tailored to the different activities. See [Measure 9.6.4.1](#) for the details.

A foolproof method is to install a transfer switch between lighting circuits that feed different types of lighting. For example, you could put all the incandescent lighting on one circuit, and all the fluorescent lighting on the other. See [Measure 10.4.1](#) for details. The disadvantage of this method is that you can never operate both groups of fixtures at once.

See [Subsections 9.4](#) and [9.5](#) for other control techniques that customize lighting to the nature of the activity. Methods that involve manual switching are inherently unreliable. They depend on effective placards (see [Measure 9.4.1](#)) to produce a significant benefit.

While you are planning this Measure, review [Measure 9.6.4](#) about control circuits. As you install the wiring for the new fixtures, improve the control wiring of the existing lighting, if appropriate.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of lighting energy in the affected spaces. Lamp and replacement

WESINC

Fig. 1 Just installing a variety of fixtures does not make efficient lighting

This conference room has four different types of light fixtures, intended to serve a variety of functions. However, this feature alone has increased energy consumption, and it has created the potential of being extremely annoying. Note that bright reflector lamps, installed adjacent to the suspended fixtures, are shining directly into the eyes of the two persons. A dimmer for one type of fixture is hidden behind a drapery. The switches for the other fixtures are located in a different room, with no markings. The fixtures are not circuited to make it possible to darken the projection screen area without darkening the entire room.

labor costs may be reduced significantly, especially where incandescent lighting is reduced.

COST: \$0.50 to \$3.00 per watt of additional lighting capacity.

PAYBACK PERIOD: One year to several years, in new facilities. Several years or longer, in retrofit.

TRAPS & TRICKS

PLANNING AND DESIGN: Make a survey of all the ways that each space is used, along with the number of hours per year of each usage. For each usage, figure out efficient lighting methods. Attempt to minimize the different types of lighting required. Install a method of control that limits lighting to the types of equipment needed for each usage.

MEASURE 9.6.4 Install a separate control circuit for each lighting element that operates on a distinct schedule.

RATINGS		
New Facilities	Retrofit	O&M
B	C	

A common cause of lighting energy waste is controlling too many fixtures with a single circuit. For example, if one lighting circuit serves two desks, energy is wasted whenever one of the desks is vacated.

Try to provide a separate circuit for each lamp, fixture, or group of fixtures that serves a separate activity or function. This may not be economical in all cases, but it is an important general principle. In deciding whether to provide separate circuits for the lighting that serves adjacent activity areas, a key criterion is the number of hours per year that the areas are occupied on different schedules. Figure 1 shows an example where improved circuiting would pay off quickly.

Lay out the lighting circuits so that lighting can adapt efficiently to changing conditions. Planning circuit layout does not require a crystal ball to foresee all possible future layouts. In case of doubt, more partitioning of the lighting circuits is better than too little.

The final step in providing appropriate lighting circuits is installing the switches and other controls in appropriate locations. This aspect is covered in [Measures 9.6.5 ff](#), below.

The following are common situations where you should design the lighting circuits to provide flexibility in selecting fixtures and lamps.

■ **Separate Activity Areas**

Take stock of all the different lighting needs that may occur within a space. For example, in a conference room, a podium may be installed while showing slides. To accommodate this, provide separate circuits to provide bright lighting on the podium area while allowing the lighting over the projection screen to be turned off.

Do not assume that walls or partitions are the only appropriate boundaries for lighting circuits. For

SUMMARY

Electrical wiring that is needed to minimize unnecessary lighting. Applies to individual fixtures and to groups of fixtures.

SELECTION SCORECARD

Savings Potential	\$	\$	\$	\$
Rate of Return, New Facilities	%	%	%	%
Rate of Return, Retrofit	%	%	%	
Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	

example, consider whether you can provide separate lighting circuits for individual desks in a large, open office space.

Even areas that are occupied by a single person may have several areas that merit separate lighting control. For example, a large one-person office may have different fixtures that illuminate the desk, the credenza, bookshelves, file cabinets, and a supply cabinet. Separate switching may be appropriate for each of these. Provide easy access to the controls ([Measure 9.6.5](#)) or install automatic controls ([Subsection 9.5](#)) to exploit such opportunities.

■ **Movable Locations of Activities Within a Space**

In many spaces, such as hotel ballrooms and school gymnasiums, different activities occur in different parts of the space. Provide separate circuits for each area in such spaces.

■ **Separate Lighting Functions**

Provide separate circuits for separate lighting functions. For, example, put the display lighting in a

store on different circuits than the general lighting. When the store is restocking or taking inventory, the display lighting can be turned off.

Look for separate functions even where there are no separate types of lighting. For example, on an assembly line, individual machines receive maintenance outside of normal working hours. In this example, provide separate circuits to allow maintenance of each machine without turning on the lights for the entire assembly line.

■ Transit Lighting

The situation to be avoided is turning on all the lights in a space only to pass through it. A common example is turning on many lights in a large hotel conference room so that waiters can carry trays to an adjacent conference room. In such cases, connect the minimum number of lamps needed for safe transit to a separate circuit. Effective switch location and placards ([Measure 9.6.5](#)) are especially important for transit lighting.

■ Multiple Lighting Levels

If fixtures have multiple lamps, you can provide a choice of light levels by wiring separate circuits for individual lamps within the fixtures. For example, with 3-tube fluorescent fixtures, install an additional circuit to power the single-tube ballasts in each fixture. This provides three levels of illumination: a single tube on the one circuit, two tubes on the other circuit, or three tubes with both circuits.

In fluorescent fixtures where a single ballast serves two tubes, you can control individual tubes by wiring ballasts between fixtures. Refer to [Measure 9.2.1.3](#) about this arrangement.

In larger spaces, you can adjust illumination levels by circuiting the fixtures in interlaced patterns. Typical applications are banquet halls and auditoriums. To achieve sufficiently uniform illumination, make the distance between fixtures small in relation to the ceiling height.

With fluorescent lighting, dimming ([Measure 9.2.6](#)) is an alternative to switching individual lamps. Dimming incandescent lighting is undesirable because it further reduces the low efficiency of incandescent lamps.

■ Daylighted Areas

Exploit daylighting by providing separate circuits for each area of a space that is daylighted at equal intensity. For example, install one circuit for the row of fixtures closest to the windows, and another circuit for the second row of fixtures. Daylighting requires automatic controls ([Measure 9.5.3](#)) to be successful. You may also have to install window treatment (see [Subsection 8.3](#)) to exploit daylighting.

Wiring Cost and Methods

Most of the cost of this Measure is for labor, with a lesser amount for materials. Rewiring is easiest if the wiring is accessible and flexible, conditions commonly encountered in fixture wiring above suspended ceilings.

WESINC

Fig. 1 Inadequate light fixture circuiting All the lighting in this office is controlled by a single switch. The row of fixtures adjacent to the windows should have a separate circuit, to exploit daylighting. The fixtures in all three rows on the same side as the door should have separate switches. Even better, they should be removed. 36 fluorescent tubes is far too many for two desks. This room needs extensive delamping, or even better, task lighting.

In other cases, for example, where conduit is embedded in concrete, the cost of changing circuit layout may be prohibitive. Be sure to consider all your wiring options. For example, raceways may be acceptable for surface wiring if you can't rewire behind the surface.

■ Switching Fixtures from Multiple Locations

A fixture or group of fixtures can be controlled from any number of locations. The most common method is using inexpensive 3-way and 4-way switches. All the switches are connected in a chain between the power source and the fixtures. A 3-way switch is installed at each end of the chain, and 4-way switches are used in between.

Another method of switching fixtures from several locations is to use relay lighting control, which offers a number of other capabilities.

■ Relay Lighting Control

In most buildings, the power circuits for lighting also act as the control circuits, which limits control flexibility. You can overcome this limitation by adding low-voltage relay lighting control. A relay is installed at each controlled point, which may be an individual fixture, a junction box feeding a group of fixtures, or even an individual lamp within a fixture. Each relay is actuated by a separate low-voltage control wire from the switch or other control device. Consider relay lighting control for these situations:

- **to connect lighting in variable patterns.** Relay control is mandatory for switching fixtures in variable combinations. It allows a particular fixture to be controlled by more than one switch. Ordinary power switching does not allow this, because current would flow from the live circuits into the dead circuits. (If you need to be convinced of this, try sketching a variable lighting pattern using ordinary switches.) Programmable lighting controls use relay control. See [Measure 9.6.4.1](#), next, for details.
- **where the controlled lighting exceeds the amperage of individual circuits.** Individual power circuits typically are limited to 20 amperes. Using relays allows a single switch or controller to control any lighting wattage while preserving the protection of individual circuits.
- **to control fixtures from multiple locations.** It may be less expensive to run control wires from each switch location directly to the fixture than to connect the existing switches together using 3-way and 4-way switches.

- **where modifying the power wiring would be more expensive.** Low-voltage wiring may be less expensive to install than power wiring, mainly because it is smaller and easier to handle, and because code requirements for protecting low-voltage control wiring are less stringent than for power wiring. However, the cost of relays, special low-voltage switches, transformers, and their installation subtract from the saving in wiring cost.
- **where it is not practical to move the existing power wiring.** Relay control wiring can be routed independently of the power wiring, so installation is not limited by the present location of the power wiring. For example, relay control can be retrofitted even if the power wiring is buried in concrete.

Relay control involves a compromise between flexibility and installation cost. To get the most control flexibility, you need to install a relay on each light fixture, but this may be unnecessary. Use a single relay to control several fixtures if all of them are needed on the same schedule.

Alternative: Individual Control

An alternative to installing new control circuits is to provide localized control at the fixtures themselves, for example, by installing pullcord switches ([Measure 9.6.5.1](#)). This method may be much less expensive, and it may make switching more accessible to users.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of the energy of controlled lighting, depending on fixture and activity layout. Lamp and replacement labor costs may be reduced by similar amounts.

COST: \$20 to \$200 per fixture, most of which is for labor. Depends on space layout, number of fixtures, labor costs, etc.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

PLANNING: The location of activities and partitions changes throughout the life of the facility. Design the switch circuits to accommodate foreseeable changes.

LEAVE A RECORD: Don't forget to record the changes in the facility's electrical drawings. Future generations of electricians will thank you.

MEASURE 9.6.4.1 Where light fixtures are needed in a predictable variety of patterns, install programmable switches.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Programmable lighting controls allow you to change instantly from one pattern of lighting to another by selecting different groups of fixtures. A programmable lighting controller is simply a multi-pole, multi-position switch that activates relays in patterns. The controller can store a variety of patterns for instant recall. The patterns are selected by the installer or by the facility staff. Modern programmable switches are solid state devices.

Programmable switching requires relay lighting control, which is explained in [Measure 9.6.4](#), above. As with all relay-controlled lighting, the degree of control flexibility depends of the number and arrangement of lighting relays.

A typical application for programmable switching is a large multipurpose space, such as a school cafeteria. At meal times, the controller turns on all the lights except those adjacent to the windows. For evening functions, the controller turns on all the lights except those in the serving area. During meal preparation hours, only the lights in the serving area are turned on. And so forth.

Typically, an occupant will select the desired lighting pattern by pressing a button on the controller. However, you can use other control devices to change lighting patterns, provided that the controller can accept electrical input signals. In the previous example, the changeover in lighting patterns occurs at predictable times, so you could use a timeclock to tell the controller to change the lighting patterns.

Programmable lighting controllers are a convenience, rather than a necessity. You could create any lighting pattern by installing individual switches for each fixture, although this approach would be awkward to use in a space with many fixtures. Programmable controllers improve efficiency only to the extent that they increase the likelihood that users will tailor lighting to the activities.

The Achilles Heel: User Instructions

Many programmable lighting controllers have been installed. Unfortunately, these are often installed in a way that only serves to confuse occupants and waste energy. For some peculiar reason, programmable controllers never seem to be labeled with adequate instructions for those who set the lighting patterns or for space occupants who select the patterns. To be effective, the controller needs clear instructions that tell:

SUMMARY

A convenient and accurate method of matching lighting to changing requirements. Vulnerable to poor user instructions.

SELECTION SCORECARD

- what the available lighting patterns are, using diagrams if necessary
- when to use each lighting pattern
- how to press the buttons or turn the dials to make the desired selection.

If the controller does not come with clear instructions, you have to create them. Refer to [Measure 9.4.1](#) for guidance on how to do this.

ECONOMICS

SAVINGS POTENTIAL: 10 to 70 percent of the energy of controlled lighting, depending on fixture and activity layout. Lamp and replacement labor costs may be reduced by similar amounts.

COST: Several hundred to several thousand dollars, for the programmable controller itself. \$50 to \$200 per fixture to install relay lighting control.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: All programmable switches are probably reliable. Select a model that is as user-friendly as possible. Try out the models you are considering before you buy.

INSTALLATION: Install programmable switches in an obvious, easily accessible location. See [Measure 9.6.5](#), next. Invest the effort to produce clear instructions.

MONITOR PERFORMANCE: Check periodically to see whether the programmable switches are being used efficiently. If not, figure out why and make appropriate changes. Keep checking.

MEASURE 9.6.5 Install lighting controls at visible, accessible locations.

RATINGS

New Facilities	Retrofit	O&M
A	C	

It should be obvious. If lighting controls are not convenient, they will not be used efficiently. However, this important point is commonly overlooked, and a lot of energy is wasted as a result. Figure 1 shows an extreme example.

The most important point is to locate lighting controls where people would expect to find them. But, there is more. In particular, locate lighting controls so that:

- they can easily be seen and identified
- people do not have to go out of their way to use them
- the fixtures controlled by the switches can be seen from the control locations
- the occupied areas can be seen, to avoid inadvertently turning off lights needed by persons remaining within the space
- there is no risk of persons being trapped within a darkened space.

WESINC

Fig. 1 Light switch folly These are all the light switches for a large public library. It must have been expensive to bring all the lighting controls to this one point, in an obscure location from which most of the fixtures are invisible. This situation is so hopeless in terms of efficient control that nobody has bothered to label the switches. They are all on, or all off. The whole building might as well be controlled by a single switch.

SUMMARY

A basic step in making lighting controls user-friendly.

Reliability	✓	✓	✓	✓
Ease of Retrofit	😊	😊	😊	😊

These guidelines apply to automatic lighting controls as well as to manual switches, if they may require any action by occupants. For example, automatic controls often have manual override.

How to Install Lighting Controls at Exits

People expect to find light switches at exits. If the switches are presently located in some obscure or inaccessible location, relocate them to the primary exits, unless it is more effective to move them to individual activity areas, as explained below. If it is appropriate to install lighting controls at doors, install them on the latch side.

Use the same locations for manual overrides that are combined with automatic controls, such as personnel sensors.

Where there is more than one usual exit, provide switches at each exit. People will not cross a space to turn off lights at an exit that they do not intend to use. By the same token, lack of switches at each exit may require entering people to cross a darkened space in order to turn on the lights. A fixture can be controlled from any number of locations by using inexpensive 3-way and 4-way switches, or by using relay control, as explained in [Measure 9.6.4](#).

If lighting within the space is subdivided into activity areas, as discussed next, consider installing controls at both the exits and the individual activity areas.

How to Install Lighting Controls at Activity Areas

Provide a separate control circuit for each area that has distinct lighting requirements, as recommended by [Measure 9.6.4](#). Install the controls for each task area where they are most accessible to the individuals who should operate them. You may want to retain the original wall switches for collective control of the lighting. This simplifies the task of security personnel or others who

may be instructed to turn off lights after hours (see [Measure 9.4.2](#)).

You may have to use your imagination to find satisfactory mounting locations for the controls. Consider installing switches on furniture or equipment, but do not violate any safety codes. Consider installing controls on stalks suspended from the ceiling at a safe height. Anticipate changes to the space layout.

Pullcord switches are a technique for providing localized control in many environments, including offices and other activities where they are not presently used. Because of their potential, pullcord switches get separate treatment in [Measure 9.6.5.1](#), the subsidiary Measure.

How to Control Transit Lighting

If a space is used as a passage between other spaces, especially outside normal occupancy hours, people tend to turn on more light in the space than they need to pass through safely. If you can limit transit lighting to certain fixtures (as recommended in [Measure 9.6.3](#)), consider

removing all switches from the entrances except for the transit lighting switches. Install the switches for individual activity areas within those areas. If you do this, arrange the transit lighting so that regular occupants of the space can safely reach their work areas.

ECONOMICS

SAVINGS POTENTIAL: *A large fraction of excess lighting usage. Lamp and replacement labor costs may be reduced by similar amounts.*

COST: *In new construction, intelligent control layout costs little. In retrofit, modifications may cost hundreds of dollars per circuit.*

PAYBACK PERIOD: *Short, in new construction. Typically several years, in retrofit.*

TRAPS & TRICKS

INNOVATION: *This Measure is mostly about taking more initiative than the usual lighting designer in finding ways to make controls user-friendly. Let your imagination roam free.*

MEASURE 9.6.5.1 Provide localized control of ceiling fixtures by installing pullcord switches.

Installing pullcord switches may be the most practical way to provide individual control of fixtures in many applications. Consider pullcord switches for both new construction and retrofit applications. They have a lowbrow appearance, but they offer a number of potent advantages:

- they are much less expensive than switches installed remotely from the fixture
- they are easily accessible at the task location itself
- it is obvious how to use them
- they move along with the fixtures when fixtures are moved to accommodate new space layouts.

The last of these advantages is an important aspect of maintaining long-term efficiency that is not available with other types of switching.

Other methods are available for controlling individual fixtures locally. For example, some manufacturers offer switching that uses an infrared transmitter that works on the same principle as a television remote control. This method is more technically glamorous, but it is more expensive, and it requires a transmitter that can get lost. A piece of string is hard to beat for simplicity and reliability.

Where to Use Pullcord Switches

This method is appropriate in a variety of environments. In retrofit applications, it is an effective way of providing individual control of light fixtures that are connected in groups. Typical applications are individual desks in large office areas and individual work stations in factories. Figure 1 shows a typical environment where they might be used.

The pullcord switch does not have to control all the lamps in an individual fixture. You can connect pullcord switches to turn off some of the lamps in a fixture. Or, you can install more than one pullcord to control different lamps in a fixture. Going the other way, you can install a single pullcord switch to control several fixtures. (This may involve some rewiring between fixtures.) The amount of lighting that an individual switch can control is limited by its current rating, which typically is a few amperes. If necessary, you can use a relay with a pullcord switch to control any amount of wattage.

Be aware that a light fixture may provide lighting for more than one work area. Do not install pullcord switches on such fixtures if the adjacent work areas may operate on different schedules.

Perhaps the main reason that this simple, powerful technique is not popular is the concern that a jangle of

SUMMARY

An unusual, relatively inexpensive way to achieve localized lighting control. Widely applicable to environments where people are well behaved. Requires some innovation in mounting.

pullcords dangling from fixtures would look messy. Pullcords do not have to be unattractive. By using decorative tassels or other ornaments, an appearance can be created that is attractive, or at least amusing.

How to Install Pullcord Switches

Success depends on details. Work out the following aspects of the installation.

■ How to Install the Switch on the Fixture

The Achilles heel of common pullcord switches is the flimsy bead chain and string. Replace the cotton string with strong nylon cord.

Also, figure out a way to install the switch so that the chain and cord run free without binding or chafing. Common pullcord switches are designed to be installed on the sides of shop lights, which allow the chain and cord to hang freely. These switches typically extend the chain slightly more than a half inch (about 15 millimeters) beyond the side of the fixture. This is fortunate for fixtures that are installed in suspended ceilings, because it may allow the chain to clear the T-bars that support the ceiling.

Even so, the chains may not last long if they have to pass through ceiling tile. A better method is to install a small mounting plate for the switch anywhere on the ceiling tile that is convenient. A variation of this technique is to install a common junction box on the ceiling tile. You need to do this if you use one switch to control several fixtures. Do all wiring in accordance with your local electrical code.

This method of switching overcomes one of the main problems of lighting layout, namely, difficulty in adapting lighting control to changes in space

configuration. Work out the details of your switch installations to exploit this advantage. For example, mount the switches on ceiling tiles. This allows you to relocate the switch to almost any position by shifting the tile to a different point in the suspension grid and by rotating it to different positions.

■ Length of Cord

Adjust the length of the pullcord so that it is easy to reach, but not so long that it strikes the heads of occupants.

■ Tagging and Placards

Even though the operation of pullcord switches is obvious, instructions are important to provide permission and motivation. A handy method is to attach a small, durable plastic tag to the end of each pullcord that says, "Turn me off when not in use". In addition, install placards at the original wall switches, if you decide to keep them. See [Measure 9.4.1](#) for details.

■ Maintain Emergency Lighting

Do not attach switches to fixtures that are wired as emergency fixtures. It is common practice to use a fraction of the conventional fixtures for emergency lighting. You can identify emergency fixtures by turning off all the light switches and observing which fixtures keep operating.

(If you observe that a lot of wattage is being wasted by using large fixtures for emergency lighting, change the emergency lighting as recommended by [Measure 9.6.3](#).)

■ Overall Space Lighting Override

In retrofits, retain the original switches to provide a quick means of turning off all lights when the space is unoccupied. Typically, the pullcord switches are used by regular occupants for their own work areas, while the original switches are used by security personnel or others to turn off all the lights at the end of the day. Install a large placard at the original switches that explains how the lighting in the space is controlled.

In new construction, design efficient transit light to get occupants from the entrances to their activity areas.

ECONOMICS

SAVINGS POTENTIAL: *A large fraction of the lighting energy in controlled areas. Lamp and replacement labor costs may be reduced by similar amounts.*

COST: *Pullcord switches cost about \$2. Installation costs \$2 to \$20 per fixture.*

PAYBACK PERIOD: *In new construction, this method may save a large amount of money compared to other methods of switching individual fixtures. In retrofit, the payback period is typically one year to several years.*

TRAPS & TRICKS

CHOICE OF METHOD: *Consider all the ways that you can provide localized light switching. Go back to [subsections 9.4](#) and [9.5](#). This method is usually the easiest and cheapest, but it is less reliable than*

WESINC

Fig. 1 An environment for pullcord switches It takes the right kind of people to exploit pullcord switches. The main issue in installing them here is how to deal with fixtures that provide light for more than one cubicle.

automatic control. Restrict pullcords to environments where the occupants are genteel.

PLANNING AND INSTALLATION: This is an opportunity for innovation. Make the pullcords convenient for users. Install them to resist damage. Tie something attractive to the bottom of the cords, to attract attention and to make them easier to use. Don't forget to install placards at the original switches.

SELECTING THE EQUIPMENT: Search for the most rugged pullcord switches available. The cost of the switch itself is minor in comparison with the cost of installing and repairing the switch.

MAINTAIN THEM: Unless you find very rugged pullcord switches, they will break regularly. Repair them quickly, so that occupants do not revert to using the original switches.

Fixture Maintenance and Marking

The Measures in this Subsection maintain the efficiency of lighting systems over the long term. They are important for most kinds of light fixtures. Accomplish each Measure as a group activity throughout your facility.

INDEX OF MEASURES

9.7.1 Clean fixtures and lamps at appropriate intervals.

9.7.2 Replace darkened diffusers.

9.7.3 In fixtures where the type or number of lamps may vary, mark the fixtures to indicate the proper type of lamp.

MEASURE 9.7.1 Clean fixtures and lamps at appropriate intervals.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Dirt that collects on lamps and fixture surfaces may substantially reduce light output. Dirt also traps heat, and thereby reduces lamp and ballast life.

Energy Saving Potential

The amount of light that is lost from dirt depends on the cleanliness of the environment and the type of enclosure. The problem is minimal in clean environments, but it can be a major source of light loss in dirty environments. Lamps and reflectors become dirty in open fixtures, and stay much cleaner in enclosed fixtures. Diffusers collect dirt whether they enclose the lamps or not.

The amount of dirt that typically collects during the life of a lamp would absorb 10 to 50 percent of the light output, if the lamp and fixture are not cleaned.

Cleaning the lamp and fixture does not reduce the energy consumption of the lamps. Instead, it allows you to use other methods of reducing lighting power, such as using lamps of lower wattage.

What to Clean

Clean all the surfaces of lamps and fixtures that transmit or reflect light. This includes the lamps themselves, the fixture’s reflecting surfaces, and both sides of diffusers.

How Often to Clean

Fixtures in almost any environment accumulate enough dirt to substantially reduce their efficiency. The rate of dirt accumulation depends on the nature of the environment and the type of fixture. Do a “white glove inspection” to determine the need for cleaning. If enough dirt wipes off a fixture or lamp to smudge a clean cloth, dirt is absorbing a significant amount of light. Schedule fixture cleaning based on your experience with the rate of dirt accumulation.

Safety

Lamps have to be removed to clean them and the fixtures properly. This involves a potential for electric shock. If wet or electrically conductive cleaners are used, make sure to remove any residue from the electrical contact surfaces. Lock out the electrical circuits while cleaning the equipment.

SUMMARY

Routine maintenance needed to prevent energy waste and maintain lighting levels.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	✓
Ease of Initiation	😊	😊	😊

Let lamps cool before handling them. This is to protect both the lamp and the worker.

Select Appropriate Cleaning Materials

Typical glass cleaners are harmful to plastics, especially to the acrylic and polycarbonate plastics used for diffusers. Using improper cleaners on plastics crazes the surface of the plastic, which reduces its light transmission and shortens its life. When cleaning plastic components, use cleaners that are intended for the specific plastics being cleaned.

Residue of cleaning materials absorbs light. This is a problem with diffusers that are not perfectly flat. If the diffuser has a textured surface, such as a prismatic plastic sheet, remove the diffuser, clean it with a method that gets into the entire surface, and then rinse it.

Special Care for Lamps with High Surface Temperatures

Quartz lamps and some other types have very high surface temperatures. These are vulnerable to breakage caused by localized accumulations of dirt that concentrate heat. Even fingerprints can break these lamps. The problem is limited to lamps that do not have an outer glass envelope. Train the cleaning personnel to make sure that the entire transparent surface of the lamp is free of specks and smudges.

Coordinate with Group Relamping

Group relamping is a matter of economics more than a matter of efficiency. If you do group relamping, you can save some money by coordinating one of the cleaning cycles with a cycle of lamp replacement, or vice versa.

ECONOMICS

SAVINGS POTENTIAL: Up to 30 percent of lighting energy. The saving depends on how you can exploit the greater light output.

COST: Varies widely, depending on the accessibility of the lamps, the cleanliness of the environment, and lamp life. Refer to "The Cost of Lighting" in the [Section 9 Introduction](#).

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

PREPARATION: Write explicit instructions for cleaning personnel, including the materials and procedures to be used for each type of lamp and fixture. Include training of the cleaning crews as part of the cleaning schedule.

MEASURE 9.7.2 Replace darkened diffusers.

RATINGS

New Facilities	Retrofit	O&M

Plastic diffusers need to be replaced at long intervals because plastic diffuser materials lose their transparency with age. This is caused primarily by the ultraviolet light produced in fluorescent and HID lamps. Heat is also a factor, and it may cause darkening of diffusers in incandescent fixtures.

Energy Saving Potential

By the time a diffuser becomes noticeably darkened, it is probably absorbing more than 10% of the lamp's light output. Very darkened diffusers may be absorbing 50% of light output.

Replacing the diffusers does not reduce the energy consumption of the lamps. Instead, it allows other methods of reducing lighting power to be used, such as using lamps of lower wattage.

Diffuser Materials

Some types of plastic darken more slowly than others, and inhibitors can be added to plastics to slow the rate of darkening. You can't judge this from the appearance of the material. Study the manufacturers' data to determine the rate of darkening of each available material. Acrylic plastic retains its clarity best, but polycarbonate is more popular because it is cheaper and stronger. Styrene is used for diffusers because it is cheapest of all, but it darkens quickly, and is a bad bargain.

The method of diffusion has a large effect on light transmission. For example, milky white diffusers absorb considerably more light than clear prismatic diffusers. All other things being equal, use the most transparent material.

SUMMARY

Routine maintenance needed with plastic diffusers to prevent energy waste and maintain lighting levels.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return	%	%	%
Reliability	✓	✓	✓
Ease of Initiation	😊	😊	😊

Changing the Light Distribution Pattern

Your choice of diffuser material has a major effect on the light distribution pattern of the fixture. For example, the small prism patterns that are molded into clear plastic diffusers disperse light widely, but in particular directions. As another example, you can increase lateral light distribution, if this is appropriate for the activities, by replacing flat sheet diffusers with molded diffusers that are domed downward. Some manufacturers of replacement diffusers offer this as a standard feature.

You may want to replace transparent diffusers with open types, such as egg crates and parabolic cell units. These typically narrow the light distribution pattern, and the best of them provide excellent glare isolation. They may absorb more light than transparent types, especially when they get dirty. They are difficult to clean.

However, be cautious about making changes to the diffuser design. Test a few fixtures in a typical environment before changing all your fixtures. For

example, increasing lateral light distribution may cause glare problems by making fixtures appear brighter to people in adjacent areas. Broadening the light distribution pattern also reduces the light level below the fixture. See [Reference Note 57](#), Light Distribution Pattern of Fixtures, for tips.

Where to Find Replacement Diffusers

Flat sheet diffusers are widely available in standard lamp dimensions from lighting, plastics, and general hardware supply companies.

Replacement molded diffusers are offered by companies that specialize in making replacement lighting diffusers. If the fixture model number is not available, these specialty companies can replicate the diffusers using one of the original diffusers as a pattern. Compare the prices and materials offered by such companies to the prices and materials offered by the original fixture manufacturer.

Coordinate with Cleaning and Fixture Improvements

Plan to clean the fixtures when you replace the diffusers. See [Measure 9.7.1](#) about fixture cleaning.

Also, consider whether you should delamp the fixtures or make other changes as part of the same effort. Refer to the other Measures in this Section for appropriate fixture modifications.

ECONOMICS

SAVINGS POTENTIAL: *Up to 30 percent of the energy consumed by the fixtures. The saving depends on how you can exploit the greater light output.*

COST: *\$2 to \$40 per fixture, depending mostly on whether the diffusers are flat or molded, and on the accessibility of the fixtures.*

PAYBACK PERIOD: *Less than one year, to several years.*

TRAPS & TRICKS

PLANNING: *If you want to change the light distribution characteristics of the diffusers, study [Reference Note 51](#), Factors in Lighting Quality. Then, test your ideas on a few fixtures before changing them all.*

SELECTING THE MATERIALS: *Plastic is vulnerable to degradation by the ultraviolet light that leaks out of fluorescent lamps. Find out all you can about the materials that are offered. Ask vendors for references, and talk with purchasers who have used the material for several years or longer. Select the specific diffuser pattern for high transparency. Avoid milky diffusers.*

MEASURE 9.7.3 In fixtures where the type or number of lamps may vary, mark the fixtures to indicate the proper type of lamp.

Only a few styles of sockets are used for the majority of lamps in each of the major lamp categories — incandescent, HID, and fluorescent. This situation allows different types and wattages of lamps to be installed in a given fixture. This provides flexibility, but it also invites energy waste.

With incandescent lighting, it is easy to install lamps that are too big for the application. With fluorescent and HID lighting, the main problem is installing lamps that do not operate efficiently with the ballasts. This has become a major problem in recent years because of a proliferation of new lamp and ballast types.

Maintenance personnel who must replace burned-out lamps do not know the correct type of lamp to put into the socket unless you tell them. If you don't do this in an effective manner, any lamp that is on hand may find its way into the fixture. Figure 1 illustrates the problem that the maintenance staff faces.

The most convenient and foolproof way of ensuring that the lamp is matched to the fixture is to mark each fixture with the specific type of lamp required. This eliminates the need for detailed verbal instructions, and it avoids the loss of information that occurs as people change jobs and records get lost.

What Can Go Wrong If You Don't Mark the Fixtures

Putting the wrong lamps in fixtures can cause trouble in a number of ways, including these:

- **loss of delamping.** Experience shows that delamping programs tend to regress quickly. The first time a senior manager looks up at the ceiling and observes that some lamps are not operating, the maintenance staff are called to replace the lamps. Nobody tells the manager that the lamps have been removed for the sake of energy conservation, and after a number of years, nobody remembers that fact.
- **excessive lamp wattage.** It is easy to install a lamp that draws too much power, sometimes by a large margin. The wattage of incandescent lamps with medium bases can vary by a factor of 100. The wattage of HID lamps may vary by a factor of ten or more within a given socket type. The wattage of fluorescent lamps may vary by as much as 20% in a given fixture.
- **low lamp efficiency.** Lamps of lower efficiency may be installed. For example, an conventional incandescent bulb may be used to replace a halogen bulb or a compact fluorescent lamp. The efficiency of fluorescent lamps may vary by 30% for a given

SUMMARY

An innovative step needed to maintain the long-term efficiency of lighting.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

wattage. The efficiency of HID lamps varies over an even wider range.

- **poor color rendering.** HID and fluorescent lamps can have radically different color rendering within a given socket type, or wattage. Incandescent lamps all have good color rendering, but the “color temperature” (the peak wavelength of the color spectrum, roughly speaking) can vary widely.
- **inefficient light distribution pattern.** In many fixtures, the lamps play an important role in the light distribution pattern. For example, elliptical-focus lamps get light out of recessed fixtures much more efficiently than other types of incandescent bulbs.
- **incompatibility with the ballast.** Fluorescent and HID lamps should be matched to their ballasts. Mismatches reduce efficiency, light output, and equipment life.
- **inefficient or unreliable dimming.** Dimming systems for fluorescent and HID lighting may require specific lamp types. For example, the most efficient type of fluorescent dimming systems does not perform properly with some “high-efficiency” fluorescent lamps, as odd as this may seem.
- **sensitivity to ambient temperature.** Fluorescent and HID lamps vary in their minimum operating temperatures. This is why you see dim and flickering fluorescent lamps outdoors during cold weather. “High-efficiency” fluorescent lamps are even more sensitive to temperature, even to cool indoor temperatures.

Refer to the Measures and Reference Notes dealing with specific lamp types for details of these aspects. In addition to causing these performance problems, using the wrong lamps wastes money and may increase workload for more frequent lamp replacement.

What the Fixture Labels Should Say

For all types of fixtures, provide this information about the lamps:

- **the specific lamp type.** This may be a verbal description (“frosted,” “elliptical focus”), an industry standard designation (“F40/T12/CW”), or a combination of the two (“M58-250/U coated”)
- **the wattage,** if this is not included in the lamp designation.

Also, if any fixtures have been delamped, put the following information on all the fixtures of the same type, whether or not they have been delamped:

- **whether any sockets are to be left empty**
- **whether the ballasts of the delamped sockets have been disconnected or removed.**

Spell out this information. Color-coded pieces of tape or general energy conservation stickers are unsatisfactory because people will forget what they are supposed to mean.

In some cases, you may want to use external labels for motivational purposes. For example, you may do this to make delamping more acceptable to the occupants, as recommended in [Measure 9.2.1](#).

Outside or Inside the Fixture?

Marking fixtures externally is more convenient for maintenance personnel. If the markings are not visible from floor level, the maintenance person must make an extra trip up the ladder to find out what kind of lamp is

required. Furthermore, if a fixture is delamped, external marking reassures anyone who notices that the lamps are supposed to be removed. A bonus is that such markings improve general awareness of energy conservation.

In posh environments, appearance may be an objection to external labeling. You may be able to overcome this objection by making the labels attractive and/or unobtrusive.

If fixtures are partially delamped, install labels over the empty sockets that say that the lamps should not be replaced.

Make the Information Survive

Use a marking method that can survive repeated cleaning and the heat of the lamps. If you mark the fixtures internally, you can write the lamp type on the reflector with an indelible pen having a fine point.

If you really must use adhesive labels, select label materials and adhesives that can tolerate the fixture temperatures as long as possible. Install the labels on a cool, protected surface, if possible. If you must install the labels inside the fixtures, install them at the coolest part of the fixture where they are easy to read. Using a reflective color helps to keep labels cool.

Coordinate with Cleaning

Clean the fixtures before marking them. Consider reducing cost by combining the marking with one of the cleaning cycles recommended by [Measure 9.7.1](#).

WESINC

Fig. 1 Lamp stockroom This is what the maintenance staff faces. If there are several types of lamps that will fit into the same socket, the wrong lamps will eventually be installed unless you mark all fixtures with the types of lamps they use.

ECONOMICS

SAVINGS POTENTIAL: For incandescent and HID fixtures, up to 70 percent of individual fixture energy consumption. For fluorescent fixtures, up to 20 percent for individual lamps, up to 60 percent if the fixtures are delamped, and up to 50 percent if the fixtures have dimmers.

COST: \$0.05 to \$1.00 per fixture. Most of the cost is for labor to fill out the labels, clean the fixtures, and install the labels. You can purchase custom labels in large quantities for a few cents apiece.

PAYBACK PERIOD: Less than one year, typically.

TRAPS & TRICKS

METHOD AND MATERIALS: Your choice of marking method is important. A label that falls off in a year or two is useless. See [Reference Note 12](#).

STAY CURRENT: Put an entry in your long-term maintenance schedule to check the marking of fixtures every few years. Update the markings any time you change the lamp or ballast type.

Section 10. INDEPENDENT ENERGY-USING COMPONENTS

INTRODUCTION

This Section covers common energy-consuming components of buildings and plants that you can deal with in a similar manner throughout the facility. These components — motors, pumps, and fans — are responsible for a large fraction of the total energy consumption in most facilities. You can often reduce their energy consumption without needing to change the systems in which they are installed.

How to Use Section 10

To save effort and get the maximum benefit, take inventory of all the equipment in your facility that is covered by this Section. Then apply each Measure to all the applicable equipment as a group.

SUBSECTION INDEX

[10.1 A.C. INDUCTION MOTORS](#)

[10.2 CENTRIFUGAL PUMPS](#)

[10.3 FANS](#)

[10.4 STANDBY EQUIPMENT](#)

A. C. Induction Motors

Motors consume more electricity than any other type of equipment, perhaps more than half the electricity produced in the world. By far the largest portion of motor energy is consumed by large motors. Almost all of these are 3-phase induction motors.

In the industrial sector, large, replaceable motors account for a majority of total energy consumption. In the commercial sector, motors are smaller in size and they account for a smaller fraction of total energy consumption, but they are still major candidates for efficiency improvements. In the residential sector, separately replaceable motors represent only a small fraction of total energy consumption, and opportunities to upgrade them are infrequent.

This Subsection contains a single Measure that recommends installing the most efficient models of motors. It is important in new construction and in existing facilities.

Variable-frequency motor drives can have adverse effects on motor efficiency and reliability. These factors are covered in [Reference Note 36](#), Variable-Speed Motors and Drives. Refer to there before making changes to motors used in variable-speed drives. Also, see [Reference Note 36](#) about types of motors that are designed to operate at variable speed, including multi-winding motors, DC motors, and wound-rotor motors.

MEASURE 10.1.1 Install motors having the highest economical efficiency.

The efficiency of motors has increased in recent decades because of improvements in motor design and manufacturing processes. These improvements were spurred by market pressures and regulations. The percentage increase in efficiency has been modest because all motors, especially larger ones, have always been fairly efficient. However, the total amount of energy that can be saved by using more efficient motors is large.

Upgrading motor efficiency is economical because motors, except for smaller units, are relatively inexpensive in relation to the cost of the energy that they consume. Stated differently, larger electric motors in typical applications annually consume electricity that costs several times the price of the motor.

In the past, the biggest obstacle to optimizing motor efficiency was a lack of objective information about the efficiency characteristics of individual models. This is no longer a problem when selecting the most common types of 3-phase motors. These motors are now rated on the basis of efficiency. Also, efficiency standards now exist that allow you to judge the efficiency of a motor in relation to an objective baseline. A simple computer program, described below, provides comprehensive efficiency data on the most common types of 3-phase motors. This program lets you accomplish savings calculations easily.

Improving efficiency has received the most attention in the manufacture of 3-phase motors. Efficiency improvements in single-phase motors, which are smaller, are presently limited to the offering of “high-efficiency” models by some manufacturers in a limited range of sizes and types. There are presently no standards or objective guidelines for smaller motors, and little reliable efficiency data.

This Measure relates to conventional alternating-current (AC) induction motors, both 3-phase and single-phase. Other types of motors, such as DC motors and wound-rotor motors, are designed to provide variable speed. See Reference Note 36, Variable-Speed Motors and Drives, for these types. They are not presently covered by efficiency standards.

Motor Efficiency in New Construction

The best time to optimize motor efficiency is before the facility is built. Doing this is as simple as specifying the motor model or the efficiency rating that you want. Motors last a long time, so missing this opportunity condemns the facility to inefficient operation for all of its early life.

SUMMARY

This is one of the most important and most widely applicable energy conservation measures. Needs more attention in new construction. In existing facilities, replace failed motors with more efficient models. In some cases, it is economical to replace motors that are still operating.

SELECTION SCORECARD

The additional effort required is minimal. In addition to specifying the usual necessary characteristics (speed, voltage, torque, etc.), also specify the motor efficiency, using the prevailing rating method. (Rating methods are described below.) Using a readily available database, select the highest efficiency rating that is appropriate for the motor size and application. Then, write it into the drawings and specifications.

There is no excuse for neglecting this simple, powerful efficiency improvement.

When to Upgrade Motor Efficiency in Existing Facilities

If a motor fails, the cost premium to replace it with a high-efficiency motor is small in comparison with the energy cost that is saved, provided that the motor runs for a reasonably large number of hours per year. Make it a policy to replace motors in such applications with high-efficiency models, regardless of size.

What if an inefficient motor is still running well? Does it make sense to replace it with a high-efficiency model? You have to answer this question on an individual basis. For motors larger than a few horsepower, the answer depends primarily on the potential efficiency improvement, the number of operating hours, electricity costs, and the economic rate of return that is required. Under present conditions,

replacing an existing low-efficiency motor is likely to be economical if it runs continuously, or if electricity costs are higher than average.

Smaller motors generally do not warrant replacement while they are still operating. The break point in size is about one horsepower (or one kilowatt). There are two reasons for this. One is that smaller motors are more expensive in relation to the cost of the energy they consume. The other is that motor efficiency ratings presently do not apply to motors smaller than one horsepower. Both conditions may change in the future. The market for efficient small motors is still evolving.

To avoid duplicating effort, identify and analyze all your motors as a batch. Immediately replace those motors where the economics are favorable for doing so. For the rest, be sure to use the most efficient replacement model when a motor fails.

■ Be Ready at Replacement Time

If a motor fails, it usually has to be replaced quickly. The delay involved in shopping for a more efficient replacement may be unacceptable if an important piece of equipment sitting idle. Therefore, identify your sources of efficient motors before the need arises. The MotorMaster computer program, described below, provides a listing of most conventional motors of one horsepower and larger that are sold in the United States.

To avoid interruptions of equipment operation, consider keeping high-efficiency motors on hand as spares, especially if the application is critical or if the facility uses many motors of a particular type. This practice allows the motors to be ordered for best efficiency and price, rather than in haste.

■ What About Rewinding?

It is common practice to rewind larger motors when they fail. The cost of rewinding a burned-out motor is roughly half the cost of a new motor, in large sizes. Therefore, facility operators have developed the habit of rewinding large motors instead of replacing them. Nowadays, this viewpoint needs to be broadened to include the possibility of replacing the old motor with a new, higher-efficiency motor. Eliminating the cost of rewinding makes it economically attractive to replace most failed motors of lower efficiency.

Can motors be rewound in a way that increases their efficiency? Generally, no. The features of a motor that affect efficiency are explained below. Most of these features cannot be improved in the repair process. On the contrary, a rewind motor is likely to be less efficient than it was originally. The typical efficiency loss in a rewind motor, including normal deterioration of other parts of the motor, is a few percent.

If the motor has to be replaced quickly, you can usually get a new high-efficiency motor in less time than it takes to rewind a failed motor.

The MotorMaster computer program provides a quick analysis of the savings and costs of higher-efficiency motor replacement in comparison with rewinding.

Overview of Motor Efficiency Characteristics

There are substantial differences in the efficiencies of motors of a given type and size. Figure 1 depicts the range of full-load efficiencies of common types of 3-phase motors. The figure also shows the U.S. minimum efficiency standard for motors, which was enacted in 1997. These curves do not include the lower efficiencies of some special-purpose motors.

Part-load efficiency is important in applications that involve extended operation at reduced loads. Size is a major factor in part-load efficiency, as shown in Figure 2. This is usually academic, because the application dictates the size of the motor. However, there are also major differences in part-load efficiency among motors of a given size.

Fractional-horsepower motors are less efficient than larger motors for reasons that are unavoidable. Also, small motors have been less efficient for practical and economic reasons.

Small motors can tolerate greater losses because they can dissipate heat better than larger motors. This is because the ratio of surface area to volume increases as an object becomes smaller. Also, they tend to be used in applications that allow open, ventilated construction.

In addition to these physical limitations, the present lack of efficiency standards for fractional-horsepower motors causes the compromise between cost and

Reliance Electric

Fig. 1 Efficiencies of AC induction motors The "EPACT" curve is the minimum allowable for new motors under current U.S. law. The "standard" curve is typical of older motors. The "premium" curve is near the highest efficiency available.

efficiency to lean heavily toward cheapness. As a result, there is still plenty of opportunity for improving the efficiency of fractional-horsepower motors. Still, the overall savings potential is much smaller than for larger motors.

The full-load efficiencies of single-phase, fractional-horsepower motors range from 25 to 65 percent, depending mainly on size and type. Significant efficiency improvements in this size range occurred in the 1980's, so that newer "high-efficiency" motors in this category offer efficiency improvements in the range of 10 to 30 percent. The "high-efficiency" designation does not have a common definition. You can depend only on explicit efficiency ratings.

Construction Features of High-Efficiency Motors

The recent improvements in the efficiency of electric motors were not achieved by new features, but by improving the basic components that all motors have. Figure 3 shows a typical high-efficiency motor. The efficiency improvements include:

- **wire with lower resistance**, which reduces heat generation in the stator coils. Lower resistance is achieved mainly by making the wire thicker. This requires reducing the insulation thickness, which requires improved insulation materials. (There have been excessive failures of high-efficiency motors that appear to be related to this issue.) Also, the space for the stator coils may be increased by greater sophistication in the design of the steel core that holds the coils.
- **improved design of the rotor electric circuit**. The rotor current in an AC induction motor is induced by the magnetic field of the stator coils. The strength of these currents determines the power and

U.S. Department of Energy

Fig. 2 Part-load efficiency of AC induction motors In many applications, part-load efficiency is even more important than peak efficiency. This graph shows that part-load efficiency is better in larger motors. All motors retain good efficiency above half load, except for the smallest.

torque of the motor. The induced voltage is low, so the rotor conductors must have very low resistance to allow the high currents that are required. Reducing the resistance of the rotor conductors reduces heat losses and increases the power output in relation to the input energy.

- **higher permeability in the magnetic circuits of the stator and rotor**. The "permeability" of the steel cores affects the strength of the magnetic field that is induced in the steel for a given amount of excitation.
- **thinner steel laminations in the magnetic circuits**. This reduces eddy currents, which are circular electric currents induced in the steel of the magnetic circuits. These currents dissipate energy by heating the steel. They are prevented from forming by making the magnetic circuits (the "core") from steel laminations that are thinner than the diameter of the eddies.
- **improved shape of the steel stator core and rotor magnetic circuits**, to increase the force produced in relation to the losses
- **smaller gaps between stator and rotor**, to reduce magnetic flux losses
- **design of the internal fan, cooling fins, and cooling air passages to reduce the cooling power requirement**. Higher-efficiency motors produce less heat, so they need less cooling. They may also be designed to survive at higher temperatures.
- **bearings with lower friction**.

Additional Efficiency Factors in Single-Phase Motors

Improving the efficiency of single-phase motors involves the same techniques listed above. In addition, the design of starting features for single-phase motors may be improved.

The stator magnetic field of a single-phase motor does not rotate, unlike the stator field of a 3-phase motor. Therefore, any single-phase motor requires a separate method of getting it started. The names of the different types of single-phase motors are based on the starting methods.

All starting methods in single-phase motors cause some efficiency loss, but they differ significantly in this regard. In decreasing order of efficiency, the main types of single-phase motors are:

- capacitor start
- split phase
- permanent split capacitor
- shaded pole.

This same ranking also applies to starting torque, and to cost. In other words, you pay more for higher efficiency and higher torque.

"Energy-saving" versions are offered in each of these types, despite the large efficiency differences between the types. This is because economics favors

using less efficient types in certain applications. The relative price differential between the types increases in smaller sizes.

Energy and Cost Saving Potential

Better motor efficiency saves energy, both directly and indirectly. Most of the cost savings result from the energy savings, but some cost saving also results from the way electricity is priced.

■ Reduced Motor Energy Consumption

Larger electric motors annually consume electricity that costs several times the price of the motor. The energy savings from upgrading motor efficiency depend primarily on the size of the motor, its hours of operation, its load profile, its efficiency, and the efficiencies of potential replacement motors. In addition, the cost saving depends on the unit price of electricity. Most of the economic savings from improving motor efficiency typically results from a reduction in kilowatt-hour consumption.

■ Reduced Electrical Demand

In facilities where larger motors are used, billings for electricity usually include a substantial demand

charge. [Reference Note 21](#), Electricity Pricing, explains demand charges.

With the rate schedules presently used by most electric utilities, improving motor efficiency may provide significant savings in demand charges. Even so, these savings typically are small in comparison with the savings in kilowatt-hour consumption.

■ Space Heating and Cooling Load

Losses from electric motors are released into the surrounding space as heat. Whether this affects the facility's energy cost depends on whether the surrounding space is heated or cooled. If the space is unconditioned, savings are not affected.

If the space is cooled with a cooling system of typical efficiency, it requires about one additional unit of electricity to remove three units of electricity lost into the space. This increases the savings by about one third, during the period when the space is cooled.

If the space is heated, reducing motor losses increases the space heating requirement. The additional heating cost depends on the energy source used for heating, and on the efficiency of the system. The motor acts as an electric resistance heater, with respect to the

Reliance Electric

Fig. 3 Construction of AC induction motor This is a totally enclosed, fan cooled (TEFC) model. Note the internal and external fan impellers. The internal fans are needed to move heat from the rotor and windings to the motor case. The external fan is needed to blow air over the motor case. The fans are a factor in motor efficiency and insulation life.

heat that it releases into the space. If the space were continuously heated by electric resistance heat, there would be no advantage in improving the efficiency of the motor. Shorter durations of heating, and less expensive heat sources, offset efficiency savings to a lesser extent.

Cost Premium for High-Efficiency Motors

The cost premium for a motor near the maximum available efficiency averages about 15 to 30 percent above the cost of an average motor. The relationship between efficiency and price is not rigid. Careful shopping and effective price negotiation appear to affect price as much as the efficiency characteristics of the motor.

The MotorMaster Computer Program

The arithmetic of calculating the savings from upgrading motor efficiency is fairly simple. However, finding data on the efficiency of potential replacement motors used to be a major chore. Both these tasks have been made effortless by the MotorMaster computer program, which is an elegant, simple program for motor selection. It is sponsored by the U.S. Department of Energy under its Motor Challenge program. The program is updated semiannually, so you can use it to find recent additions to the motor market.

With a few keystrokes, the program prepares a list of all motors matching your input criteria, which include size, speed, enclosure type, etc. Another keystroke presents all available data on any individual motor.

The MotorMaster program covers motors sold in the United States that are within these characteristics:

- 1 to 600 horsepower
- 3-phase
- 900 to 3,600 RPM
- 200 to 4,160 volts
- all major enclosure types
- NEMA Designs A and B (motors with conventional torque characteristics)

MotorMaster provides all the usual nameplate information for each motor, including temperature ratings, service factor, etc. It includes price and warranty information. It includes all available efficiency information, including part-load efficiency. This is a significant advantage over catalog ratings, which normally indicate only full-load efficiencies.

The program quickly calculates the savings and simple payback period for three situations:

- comparing new motors of different efficiency
- replacing an existing motor with a more efficient motor
- comparing rewinding the original motor with installing a new motor.

You have to input the hours of use, the load percentage, installation cost, the local price of electricity, the demand charge, and the demand schedule. The program can accommodate dealer discounts and utility rebates, but cannot calculate based on a load profile. (You can approximate a load profile by doing a series of calculations with various percentages of load.) The program does not account for space heating or cooling load.

How to Estimate the Efficiency of Existing Motors

When you consider replacing a functioning motor with a high-efficiency motor, you need to know the efficiency of your present motor to calculate the potential savings. Unfortunately, you may not be able to get this information precisely for the present crop of installed motors. The best you can do is to estimate the efficiency of your existing motors accurately enough to make a replacement decision. Try one or more of these methods:

- **check the motor nameplate.** Older motors typically do not have efficiency information on their nameplates, but they may. It takes only a moment to check. However, be skeptical. Any efficiency ratings on motors that date prior to the present system of efficiency ratings may be nominal, or they may not be comparable to present ratings. As time goes on, a larger fraction of installed motors will carry credible efficiency ratings.
- **contact the manufacturer.** Start with the manufacturer's engineering department. Provide all the nameplate information.
- **check the original installation file.** The information submitted with the motor when it was installed may contain efficiency information. Beware of efficiency figures in promotional literature, especially if the test method is not stated. The fact that a motor efficiency may have been specified in the designer's specifications does not guarantee that the motor actually installed has this efficiency.
- **make a guess based on other characteristics.** Even if the motor efficiency is not stated explicitly, you may be able to judge the relative efficiency of the motor, compared to new motors of the same size and type. You can get clues from the nameplate or elsewhere. Consider:
 - the **age** of the motor. The maximum efficiency of motors increased substantially during the 1980's. Therefore, replacing a motor that was installed before then is likely to yield a substantial efficiency improvement.
 - the **full-load RPM**, which is shown on the nameplate, relates to efficiency. In general, a higher full-load RPM means higher efficiency. However, a comparison is valid only within a particular torque classification. High-torque

motors are designed for lower full-load RPM. Especially in older motors, the full-load RPM may be nominal.

- the **service factor** of the motor relates indirectly to its efficiency. A service factor of 1.0 suggests mediocre efficiency, but this is not always true.
- the **temperature rating** of a motor relates indirectly to its efficiency. More efficient motors usually have higher temperature ratings. Insulation technology has changed over the years, so compare the temperature rating to the temperature ratings of other motors of the same age. These ratings are explained below.
- **send the motor to a testing laboratory.** You usually cannot measure motor efficiency on site, because you typically have no accurate way of measuring output power or correcting for variations in input power. An alternative is to send out a motor to be tested. This may be an economical approach for larger motors, provided that you can remove the motor without expensive rigging, and if you can afford to have the motor missing for a week or two. In response to the growing emphasis on motor efficiency, a number of independent testing laboratories for motors have been established. You can find motor testing laboratories in the United States and Canada through the Motor Challenge program of the U.S. Department of Energy. Each laboratory has its own limitations in the types and sizes of motors that it tests.

Motor Efficiency Guidelines and Standards

Many motor manufacturers call their motors “high efficiency,” or they may have separate “high-efficiency” models. Such claims have no specific meaning. For example, one manufacturer claims that all its standard motors have efficiencies as good as the average “high-efficiency” models of other manufacturers.

Fortunately, you no longer have to select motors based on vaguely worded claims. In recent years, official ratings and standards have appeared to guide you in selecting motors for efficiency. Use the hard numbers that are now available as your primary selection tool. Here are the details.

■ NEMA Efficiency Ratings

In the United States, the National Electrical Manufacturers Association (NEMA) has established a voluntary system for stating the efficiency of the most common types and sizes of 3-phase motors.

Motor manufacturers who use this rating system now stamp the NEMA ratings on the motor nameplates, as shown in Figure 4. The ratings are usually stated in catalogs.

The NEMA system establishes a ladder of standardized efficiency levels. Each rung of the ladder has two ratings, “nominal” and “minimum.” The “minimum” rating may also be called “guaranteed.” An individual “minimum” or “guaranteed” efficiency rating may be substantially lower than the “nominal” rating. For example, if the “nominal” efficiency is 84.0%, the “minimum” efficiency is 81.5%. The differences

Fig. 4 Nameplate for high-efficiency motor This nameplate offers a rich selection of the most important information for typical motor applications. However, you have to know what all those things mean. The key efficiency ratings are on the left.

Reliance Electric

between “nominal” and “minimum” efficiencies are substantially smaller at the higher end of the efficiency range, which applies to larger motors.

Under the NEMA system, the term “energy-efficient” means that a motor has a full-load efficiency that meets or exceeds the NEMA ratings for its horsepower. The NEMA table has changed with time, so the current ratings do not apply to older “energy-efficient” motors.

Note that the similar sounding term “high efficiency” has no official meaning. This term is typically used by manufacturers to designate their own more efficient motors.

The complete listing of efficiency ratings is given in Table 10 of NEMA Publication MG1-1993. The efficiency levels differ by as little as 0.4 percent at the top of the efficiency scale, and by as much as 1.5 percent at the bottom. In order for a manufacturer to claim a particular efficiency level for a motor, a typical batch of these motors must have an average measured efficiency as high as the claimed level. The motors must be tested in accordance with the NEMA standard test method, which we examine below.

The ratings presently apply to the more common 3-phase motor designs, including NEMA Designs A and B. In 1994, NEMA published a table of efficiency guidelines for a new standard motor type, called Design E. Design E was developed primarily as a counterpart to the international (IEC) standard Design N motor. The efficiency standards for Design E motors are higher than for Designs A and B.

The ratings are updated and expanded from time to time. They have been extended progressively to larger motor sizes. They now cover the largest motors that you are likely to order.

There are presently no NEMA efficiency standards for single-phase motors of any size. Single-phase motors typically are one horsepower or less, but some are as large as 20 horsepower. Larger single-phase motors are used in applications that may be served only by single-phase electrical power. For this reason, they are common on farms.

■ Part-Load Efficiency Data

The database in the MotorMaster computer program includes part-load efficiencies as well as full-load efficiencies. The MotorMaster database covers all the motors covered by the NEMA guidelines, plus motors of larger horsepower and higher voltage. The efficiency data in MotorMaster are based on the test procedures that are used for NEMA Nominal Efficiency ratings.

■ United States Motor Efficiency Laws

In the United States, the Energy Policy Act of 1992 (EPACT) established the NEMA efficiency guidelines for Designs A and B motors as the minimum efficiency

for motors manufactured for sale in the United States. The Act went into effect in 1997.

The Act applies only to NEMA Designs A and B, 3-phase motors between 1 and 200 horsepower, driven by 60 Hertz power, that operate at 1200, 1800, or 3600 RPM. The Act does not apply to motors designed for special applications.

In addition, the Act offers the possibility of establishing standards for smaller motors, but it is not clear that any standards for small motors will actually result from the 1992 Act.

ASHRAE Standard 90, which has been revised repeatedly, is a comprehensive standard for energy efficiency in new building construction. Versions of this standard have been incorporated into building codes throughout the United States. The latest version, Standard 90.1-1989, specifies efficiency requirements for electric motors by using a table that is based on horsepower. The ASHRAE standard applies to generally the same motors as NEMA standards, and it specifies the same test method. However, the ASHRAE standard is limited to T-frame motors that are expected to operate more than 500 hours per year. The required efficiency levels are lower than those presently specified for NEMA “energy-efficient” motors.

■ Be Aware of the Efficiency Test Method

When you get efficiency data from motor manufacturers, be sure to check the test method used. There may be large differences in the results produced by different test methods.

The standard now used almost exclusively in the United States is NEMA Standard MG1-20.52. This is derived from Standard 112, Method B, of the Institute of Electrical and Electronic Engineers (IEEE).

The international (IEC) test method and test methods of other major motor manufacturing nations are also derived from IEEE Method 112-B, but these variations may produce significantly different efficiency figures.

U.S. and Canadian test methods are the most realistic. They are based on actual measured output and measured input. The standards of other nations may estimate some of the motor losses, or may ignore them.

For example, a particular 7.5 horsepower motor has a nominal efficiency of 80.3% using the U.S. and the Canadian (CSA C390-M1985) standards. The same motor has a nominal efficiency of 82.3% using the British and international (IEC 34-2) standards. It has a nominal efficiency of 85.0% using the Japanese (JEC 37) standard. In this way, the Japanese or British manufacturer may claim a much higher efficiency for a motor than an American manufacturer may claim for an identical motor.

A remaining weakness of some standards, including the U.S. and Canadian standards, is that the tests are performed by the manufacturers themselves, without

independent verification. Steps are presently being taken in the United States to certify the testing laboratories of motor manufacturers.

What to Consider When Selecting a Motor

You need to consider all the following motor characteristics to select the best motor for each application. Most of these characteristics are expressed by ratings or specifications that are available in the catalogs. The MotorMaster computer program includes related data for the motors in its database. As a point of interest, all these issues relate to efficiency directly or indirectly. For specialized applications, you may need to consider additional characteristics, such as low sound level.

■ Full-Load Efficiency

Figure 1 shows the range of efficiencies that presently exists among 3-phase motors. You can usually find an economical choice with an efficiency near the highest available. It is worth repeating that careful shopping may have a greater effect on price than the efficiency rating.

For single-phase motors, research the catalogs to find the maximum efficiencies that are presently available. Most major motor manufacturers have a “high-efficiency” line of single-phase motors, so you can narrow your search to these models. The highest efficiency is found in “capacitor start” motors, followed in declining order by “split phase,” “permanent split capacitor,” and “shaded pole” motors.

■ Part-Load Efficiency

The part-load efficiency characteristics of motors were covered previously. See Figure 2. If motors operate for long periods at reduced loads, be sure to study the part-load efficiency figures. Some manufacturers offer special models that are claimed to provide high efficiency at low loads.

Unfortunately, motor catalogs often omit part-load efficiency information. At the present time, the MotorMaster program is the only comprehensive source of information on the part-load performance of 3-phase motors. The part-load performance of single-phase motors is still a blank area.

■ Power Rating

When replacing a motor, consider whether you can substitute a motor with a lower power rating. To do this, you usually need to reduce the load. This opportunity arises commonly as a result of energy conservation measures. For example, you can trim the impeller of a pump to eliminate excess capacity, which may greatly reduce the pump’s power requirement.

Serious oversizing of the motor causes it to operate at reduced efficiency. However, it rarely pays to replace a motor simply because it is oversized. Peak motor efficiency typically occurs around 80% of full load, but

efficiency remains near maximum until the load falls well below half, except in smaller sizes. Furthermore, the larger motor is more efficient overall, and its efficiency drops less at low loads.

When operating a motor with a variable-frequency drive, it may be desirable to oversize the motor to avoid overheating. See [Reference Note 36](#), Variable-Speed Motors and Drives, for details.

To measure the present motor load accurately, use a wattmeter. A wattmeter accounts for the difference in motor power factor at different loads. If you need only a rough idea of the load, you can use an ammeter. Check the motor nameplate for the Full-Load Amps (FLA), and calculate the motor load from the ratio of the measured amperage to this value. Power factor remains fairly constant down to about 65% load, so this method is reasonably accurate at loads higher than 65%. Below this value, power factor drops rapidly. Measuring the amperage of a lightly loaded motor yields a false value of power output that is higher than actual.

■ Service Factor

“Service factor” is the highest percentage of full load at which a motor can operate continuously under standard test conditions without overheating. Service factor is related to motor temperature ratings, which are explained below. Service factor is always displayed on motor nameplates, as in Figure 4.

Service factor provides a margin for error in calculating the size of motor that is needed for an application. The lowest service factor is 1.0. High-efficiency motors usually have a service factor of at least 1.15, but this is not always true. Motors designed for high-torque applications typically have higher service factors, perhaps as high as 1.40 in smaller sizes.

A service factor higher than 1.0 is useful in applications where the motor operates for a large fraction of the time at low loads. This allows you to select the smallest possible motor, thereby achieving greater efficiency at low loads, without fear of overheating the motor during occasional periods of peak load. A higher service factor also allows operation at higher ambient temperatures.

Even if a motor has a service factor higher than 1.0, operating the motor above its rated load reduces its service life, and usually reduces its efficiency.

■ Torque Characteristics

Torque is rotational force. The torque that a motor produces changes radically with the speed. Motor applications vary widely in the torque they require at different fractions of full speed. Therefore, special names are given to the torque that develops in different parts of a motor’s speed range. Figure 5 illustrates these aspects of motor torque for a typical AC induction motor. These are the important torque characteristics:

- **full-load torque** is the torque measured at the motor's rated load. This load occurs at the motor's rated speed. This rating is especially important for loads that develop more resistance as the speed increases. Pumps and fans are the most common loads of this type.
- **locked-rotor torque** is the motor's torque when the shaft is held stationary. This is the motor's available **starting torque**. It is important when selecting a motor to drive a load that has large starting resistance, such as a loaded conveyor belt. It also indicates how rapidly a motor can accelerate a load that has high inertia, such as a centrifugal fan or a balanced elevator. Starting torque is less important with loads that move freely and have little rotational inertia, such as centrifugal pumps.
- **pull-up torque** is the minimum torque that the motor can produce. This typically occurs at a fraction of full speed. The motor will stall and burn out after starting if the load requires more torque than this amount, even if the motor is able to drive the load at normal speed. This rating is important when driving loads that quickly develop resistance when starting, such as reciprocating compressors (see Figure 6).
- **breakdown torque** is the maximum torque that the motor can produce. The motor passes through breakdown torque on the way to stalling from overload. Breakdown torque is developed at a speed slower than the rated speed, with the motor in an overloaded condition. Breakdown torque is most important in applications that have transient

U.S. Department of Energy

Fig. 5 Torque characteristics of a typical AC induction motor To select a motor's torque characteristics, start by knowing the torque requirements of the load. Then, select a motor in the appropriate NEMA Design category.

requirements for extreme torque, such as a rock crusher.

To deal with different torque requirements, motor manufacturers produce motors with several standard torque characteristics. NEMA Designs "A" and "B" are motors with conventional torque. NEMA Designs "C" and "D" produce high starting torque. Torque would have little effect on efficiency if all other factors remained the same. However, achieving higher torque requires major changes in the motor geometry, and the motor geometry affects efficiency. Torque is the product of force times moment arm, so high-torque motors typically are larger in diameter.

Some motors list the NEMA Design on the nameplate, as in Figure 4.

Among single-phase motors, the highest torque is found in "capacitor start" motors, followed in declining order by "split phase", "permanent split capacitor", and "shaded pole" motors. This sequence is the same as the ranking of single-phase motors in terms of efficiency. In other words, among single-phase motors, higher efficiency correlates to higher torque.

■ Full-Load RPM

The magnetic field of the stator in a 3-phase motor rotates at a rate that is determined by the line frequency and by the number of poles. This rate is called the "synchronous speed." With 60-Hertz power, this speed is 3,600 RPM for a 2-pole motor, 1,800 RPM for a 4-pole motor, 1,200 RPM for a 6-pole motor, etc. In single-phase motors, the synchronous speed is calculated the same way, even though the field does not actually rotate.

The actual speed of an induction (ordinary) motor at full rated load is a few percent slower than its synchronous speed. This speed differential is necessary for the operation of an induction motor. The difference in speed is called "slip." In an induction motor, the speed difference between the rotor and the magnetic field of the stator is what induces the magnetic force that turns the motor.

The actual speed of the motor when operating at full-load torque is listed on the motor nameplate, as

WESINC

Fig. 6 High-torque application This reciprocating air compressor requires full torque almost immediately after it starts. This is because the force needed to compress the air in the cylinders is almost independent of the speed.

shown in Figure 4. All other things being equal, a more efficient motor has less slip at a given load, so its speed is slightly higher.

The amount of slip has a very large effect on torque, even though it represents only a small fractional change in speed. See Figure 5.

You might think that this difference in speed is inconsequential in terms of energy consumption, but it may be significant if the motor is used to drive a pump or fan. With such loads, the power requirement rises sharply with speed. The extreme case exists where a fan or pump discharges into a system where the flow is not regulated. In this case, the energy requirement is proportional to the third power of the speed.

For example, this is true of a fan discharging into an open duct, or of a pump discharging sewage into a basin. In these examples, if the speed is increased by one percent, the power input is increased by about three percent. In such cases, the increased power requirement may cancel a large part of the efficiency advantage of the higher-efficiency motor.

This well-known third-power relationship does not occur in all applications. If the resistance facing the fan or pump is held constant, the increase in power is proportion to the first power of speed. For example, VAV air handling systems and hydronic systems with control valves tend to maintain a constant pressure. In such systems, a one percent increase in speed might increase the power requirement between one and two percent.

One way to deal with this problem is to select the replacement high-efficiency motor to have the same speed as the original motor. However, you may not be able to find such a motor without compromising efficiency or cost. In practice, you cannot adjust the power input of pumps and fans with accuracies of one percent. Instead of trying to split hairs in this manner, adjust the fan or pump to match its load requirement at the same time you upgrade motor efficiency.

With fans, you have a variety of methods to reduce output efficiently. See [Measure 10.3.1](#) for the details. With direct-drive pumps, trimming the pump impeller is the only way of reducing excessive pump output efficiently. See [Measure 10.2.1](#) for the details. These methods typically yield power reductions of 10% to 40%. With any kind of equipment that is driven by belts, you can adjust the speed by changing the size ratio of the drive pulleys.

A motor's full-load speed rating is related to its torque characteristics. Higher torque is achieved largely by designing the motor to have greater slip. For this reason, NEMA Designs A and B (conventional torque characteristics) have full-load slips well under 5%, while NEMA Designs C and D (high torque) may have full-load slips exceeding 5%. All other things remaining

equal (which never occurs), achieving high torque requires some sacrifice of efficiency.

■ Operating Temperature

The most common motor failures are insulation failure and bearing failure. Both are related to operating temperature. For a given type of insulation, the service life of a motor declines exponentially with increasing operating temperature. Experience suggests that half of all motor failures occur from the long-term effect of high temperature on the windings. It is estimated that a 10°C (18°F) increase in winding temperature reduces insulation life by about half, and bearing life by about one quarter.

In the United States, NEMA has established four classes of insulation, which are based on the operating temperature of the motor. In order of increasing temperature tolerance, these are Classes A, B, F, and H. Class B is the common class in conventional motors, and Class F is the most common in high-efficiency motors.

The temperature limitations of a motor may be indicated by stating the insulation class. Or, a specific ambient temperature may be stated. If an ambient temperature is given, the assumed service factor and the altitude may also be stated. Altitude is important because air is less dense at higher altitude, so it has less cooling ability. The nameplate in Figure 4 uses both rating methods.

In most applications, the operating temperature of a motor depends more on its load than it depends on the ambient temperature. Totally enclosed motors cannot get rid of heat by direct ventilation, so they rely on conduction through the case. Their internal temperature largely depends on the rate of heat generation inside the motor. Near full load, a motor becomes quite hot. For example, a Class F motor with a service factor of 1.15 has an allowable temperature rise of 115°C (207°F) above an ambient temperature of 40°C (104°F), for a maximum temperature of 155°C (311°F).

If a motor must operate in a high-temperature environment, there are two ways to achieve a normal life span. One is to get a motor with insulation that is rated for higher temperatures. The other is to get a motor with a larger power rating, so that the motor operates at a lower percentage of full load.

Make allowances for other factors that may raise motor temperature, including:

- **frequent starting.** The starting current of a motor is several times its running current. The heat generated by a starting cycle is dissipated slowly, so frequent starting raises temperature drastically.
- **using the motor with variable-frequency drives.** Some electronic variable-frequency drives produce a substantial amount of distorted input power that the motor converts to heat. In “constant-torque” applications, motors overheat because the current

remains high as the rotor and the cooling fan slow. Using motors with electronic drives is discussed below.

- **poor power quality.** A motor cannot efficiently use electrical power that is in the form of distortion or electrical noise. The motor converts much of this erratic power into heat. If the power supply contains a substantial amount of distortion, the motor runs hotter.
- **phase balance.** Small phase imbalances can seriously increase motor temperature. This is explained below.
- **dirty environment.** If the motor uses ambient air for internal ventilation, dirt in the environment quickly fouls the motor interior and reduces heat transfer. A coating of dirt also reduces the heat rejection from a totally-enclosed motor.
- **high altitude.** The air inside and outside a motor is what carries away most of the motor's heat. Air is thinner at higher altitudes, causing the motor to run hotter.

High-efficiency motors do not necessarily run cooler than conventional motors. Although high-efficiency motors generate less internal heat, the size of the internal cooling fan may be reduced as one way of reducing energy consumption. Base your temperature-related selection decisions on temperature ratings, not on efficiency ratings.

■ High-Voltage vs. Low-Voltage

Lower operating voltages allow higher motor efficiencies. We are talking about big differences in voltage ratings here, for example, the difference between a 460-volt motor and a 2,300-volt motor.

Lower voltage allows thinner insulation in the windings, which allows the windings to be larger in diameter. This reduces resistance losses and increases magnetic flux. The efficiency difference related to this aspect of motor design ranges from a fraction of one percent to as much as two percent.

Before you make this decision, step back and look at the bigger picture. Let's say that your facility receives power from the electric utility at 2,300 volts. For lower voltages, the facility owns a transformer that reduces the incoming voltage to 460 volts. If you select a 460-volt motor because of its higher efficiency rating, you may not save energy overall. This is because the electricity for the 460-volt motor must come through the transformer, where it suffers additional losses. In this case, you may save more energy by installing a 2,300-volt motor. In new construction, this will also reduce the cost of your transformer.

Thus, when you select your motor voltage, look at your incoming voltage, and consider who owns the transformers on site.

■ Small Voltage Differences

A motor operates at highest efficiency when it is supplied with its precise rated voltage. Lower voltage reduces efficiency, reduces starting torque, and causes the motor to run hotter. Higher voltage also reduces efficiency, and it increases starting current. If possible, adjust the taps in the power supply transformers to match the supply voltage to the motor rating.

In order to reduce inventory requirements, many motors are designed to operate at a number of standard voltages, such as 208 volts and 230 volts. Such motors tend to be less efficient than motors designed to operate at a single voltage. Select your motors for efficiency based on the actual voltage that is used.

Motors that are designed to operate at several voltages operate most efficiently at the highest rated voltage. The difference in efficiency at the different voltages may be as high as several percent. Therefore, check whether the transformer that supplies power to the motors has taps that you can reset to the higher voltage. This is often the case. However, this may not be practical if the transformer serves loads other than the motors. See whether the other equipment can operate satisfactorily at the higher voltage. Or, if possible, rearrange the power circuits to allow the motors to be operated by higher-voltage transformers.

■ Power Factor

(If you are unsure about the meaning of power factor, see [Reference Note 21](#), Electricity Pricing, for an explanation.)

Electric motors are the major cause of low power factor (along with magnetic fluorescent lighting ballasts). The power factor of motors is fairly high at high load, but drops radically at loads below about half. Larger motors have somewhat higher power factor at all percentages of load. Motor efficiency, by itself, does not have a significant effect on power factor.

Power factor may become a significant economic issue if the utility company has a large power factor penalty, and if motors operate at low loads. However, there is not much difference in the power factors of similar motors. The effective way to deal with power factor is to increase the power factor of the facility's electrical system by using power factor correction capacitors or other devices intended for this purpose.

The full-load power factor of a motor may be stated on the nameplate, as in Figure 4. This makes it easy to select power factor correction capacitors.

■ Locked-Rotor and Starting Amperage

Higher-efficiency motors may have higher starting currents than ordinary motors. This is because of the lower resistance in the windings. In retrofits, the starting current of a high-efficiency replacement motor may be too high for the existing fuses, circuit breakers, or wiring.

If this problem occurs, a fairly inexpensive solution is to use a staged (“soft”) motor starter. The starter limits the motor current until the motor is running fast enough to limit its current draw. A larger motor may already have a soft starter, except in applications requiring high starting torque.

NEMA Design B motors have the same torque characteristics as Design A motors, but they have lower starting current. However, Design B motors usually pay for this advantage with an efficiency penalty.

The starting amperage is commonly abbreviated on motor nameplates as “SLA.” This distinguishes from full-load amperage, which is commonly abbreviated “FLA.” If the nameplate lists only a single amperage, it is the starting amperage.

■ Enclosure Type

Select the type of motor casing, or enclosure, on the basis of the motor’s environment. The type of casing has little effect on efficiency.

Motor enclosures differ primarily in the degree of isolation that they provide between the inside of the motor and the outside environment. This is reflected in the names of enclosure types, such as “open,” “splash-proof,” etc.

A fully enclosed motor cannot be cooled by direct ventilation, so selecting a fully enclosed motor requires careful attention to the way that the motor is cooled. Fully enclosed motors are designated by their cooling characteristics, such as “totally enclosed nonventilated” (TENV) and “totally enclosed fan cooled” (TEFC).

The enclosure type is usually shown on the motor nameplate, as in Figure 4.

■ Frame and Face Type

High-efficiency models have become available in all the common frame and face configurations of motors larger than about one horsepower. The frame and face configuration do not strongly affect efficiency, except perhaps with some specialized motors. The frame type may be shown on the motor nameplate, as in Figure 4.

Phase Balance

A three-phase motor is served in effect by three separate power circuits, or “phases.” Voltage differences between the phases cause much more efficiency loss than fluctuations in the overall voltage. Typical phase voltage imbalances may reduce motor efficiency by several percent.

Voltage imbalance between the phases can also cause vibration and overheating. The overheating effect is significant enough that NEMA requires motors operating with an imbalance of more than 1% to be derated. Figure 7 shows the amount of derating that is required for different amounts of voltage imbalance.

If you can’t afford alarms to monitor phase balance at the motors, check it regularly with a voltmeter of good

quality. Preferably, use a digital display that makes it easy to read small differences in voltage.

Correcting phase imbalance is entirely a matter of the power supply system, rather than the motor itself. The appropriate methods of correcting phase imbalance depend on the causes, which are:

- **uneven distribution of load among phases within the facility.** The single-phase loads in a facility, such as lighting, are divided among the phases of the incoming 3-phase power supply. The load is rarely divided precisely. The differences in phase current produce differences in phase voltage, especially if the conductors are heavily loaded.

The appropriate solution may be to redistribute the single-phase loads among the phases, to increase the capacity of heavily loaded conductors, or to install separate transformers for 3-phase loads.

It is usually not a good idea to balance phase voltage by using the transformer taps. If the phase imbalance is so bad that transformer taps would make a difference, the problem is bad enough that you should correct the underlying problem.

- **power wiring phase defects.** A major current leak from a phase to ground, or less commonly, from one phase to another, can cause a voltage imbalance. A 3-phase motor may continue to run even if one of the phases is completely dead, but the motor may also fail from overheating.

The solution is to find and correct phase defects immediately. If a single phase fails, the single-phase equipment on that circuit will stop. If you see this happening, recognize the implication for the 3-phase motors and stop them immediately.

A reliable way to protect motors from phase imbalance is to install a phase monitor on each motor power circuit. This device will either sound

U.S. DOE Motor Challenge Turning Point

Fig. 7 Motor derating required to compensate for unbalanced phase voltage The message here is that very small differences in phase voltage create a serious danger to the motor.

an alarm or trip out the motors if a phase is lost or if the phases become seriously unbalanced. The device itself is inexpensive. Most of the cost is for the wiring.

- **failure of power factor correction capacitors.** Separate power factor correction capacitors are installed on each phase of a 3-phase system. Capacitors fail with age, in effect creating a ground fault. You can detect failed capacitors by testing for ground faults or by checking the power factor of each phase.
- **unbalanced power from the electric utility.** Phase imbalance in the power supplied by the electric utility occurs because the single-phase power provided to its other customers is not evenly divided among the phases. Try to solve this problem by asking the electric utility to improve its phase balance. Phase imbalance in the utility feeders may vary greatly with the season and time of day, as the utility's loads change. The phase balance of the electricity supply tends to fluctuate more when the facility is farther away from the generating plant or the substation.

Motors Used with Electronic Variable-Speed Drives

Electronic variable-speed motor drives are becoming popular for many applications. [Reference Note 36](#) describes this device in detail. In summary, a variable-frequency drive is an electronic device that changes the driving frequency of the electrical power provided to the motor. Unfortunately, electronic drives may reduce the efficiency of motors and increase their internal heating. This may make it prudent to install a special motor that is designed to operate with electronic drives.

The basis of the problem is that the simulated alternating current produced by the electronic drive is not a smooth sine wave. In fact, the output of an

electronic drive may be only a rough approximation of a sine wave. It may be a square wave, a sequence of square waves, or a series of pulses. As a result, the power delivered to the motor has a large fraction of high-frequency components. Conventional motors are designed to use pure sine waves at line frequency, so the high-frequency components are not efficiently converted to mechanical energy. The unusable high-frequency energy is converted to heat, which shortens the life of the motor. In addition, the crude waveform produced by the drive may have voltage spikes that break down the motor insulation.

Certain features of higher-efficiency motors make better use of the high-frequency components. For example, thinner core laminations reduce the eddy currents resulting from the high-frequency components. As a result, high-efficiency motors offer an even greater efficiency premium when used with variable-frequency drives than when used in other applications.

A high-efficiency motor does not necessarily deal better with all the problems created by electronic drives. In particular, a high-efficiency motor may be more vulnerable to insulation breakdown (because of its thinner insulation). For this reason, some manufacturers offer motors that are claimed to be designed specifically for use with variable-frequency drives. These models usually have a large price premium. At least one manufacturer offers different motors for different turndown ratios. A motor advertised with a 10:1 turndown ratio may cost much more than a motor advertised with a 4:1 turndown ratio. Claims of improved performance with electronic drives cannot be verified by the purchaser, because there are no standards specifically for motors used with electronic drives.

Selecting a motor for variable-frequency operation requires even more information than is needed for ordering a single-speed motor, such as the maximum allowable speed, torque limitations, etc. Figure 8 shows a typical nameplate of an “inverter duty” motor, which provides only a fraction of the information needed. See [Reference Note 36](#) for more details.

Motors advertised specifically for use with electronic drives are identified as such in the MotorMaster computer program. The program can search for such motors as a category.

Multi-Speed Motors

A multi-speed 3-phase motor is like a single-speed 3-phase motor, except that it has extra stator coils and poles. Speed is changed in steps by energizing different numbers of poles.

Multi-speed motors are fairly efficient. They are economical, and they do not require any complex controls. [Reference Note 36](#), Variable-Speed Motors and Drives, describes multi-speed motors in detail, and

What is unusual here is the information for a wide range of speeds and power frequencies. You need much more information than this to properly select a motor for your application.

compares them with other methods of driving motor loads at variable speed.

ECONOMICS

SAVINGS POTENTIAL: 2% to 15% of energy consumption, with 3-phase motors. Up to 30% of energy consumption, with small single-phase motors. Larger motors have smaller percentages of savings, but save much more energy in absolute terms.

COST: High-efficiency motors of common types cost \$50 to \$100 per horsepower in sizes larger than 10 horsepower. In sizes near one horsepower, the cost is about \$200 per horsepower. The cost premium for high-efficiency motors averages about 20%, but this varies widely.

PAYBACK PERIOD: Usually less than one year, in new construction and for replacing failed motors. Several years or much longer, for upgrading motors that are still working.

TRAPS & TRICKS

SELECTING MODELS: Get a current version of the MotorMaster computer program, and use it. It will make your life easier, save you money in buying motors, and maximize your energy savings. Go to the motor catalogs for additional information.

ADVANCE PREPARATION: For upgrading failed motors, doing your homework beforehand is the key to success. Identify vendors who can provide your selected motor models on short notice. If you have many motors of a particular size and type of service, keep at least one spare in stock.

SPELL IT OUT: To guide maintenance personnel in replacing failed motors, designate the selected models and vendors in the plant operating manual. Make sure that all maintenance personnel, including those who work the late shift, know what to do. Tell them where the spare units are stored.

Centrifugal Pumps

Centrifugal pumps are used in virtually all buildings and plants. In many, pumps are major energy consumers. This Subsection consists of two broadly applicable Measures for energy conservation in simple pump systems. Both are methods for matching the output of a pump to the system requirement. In many cases, the two Measures are alternatives to each other. The first Measure, pump impeller trimming, is much more efficient than the second Measure, pump throttling.

Also, Consider Variable-Flow Pumping

In systems with larger pumps, installing variable-flow pumping may provide large savings in pump energy. Consider variable-flow pumping for applications where the flow requirement varies widely and pump pressure can be allowed to fall along with the flow. Unlike the Measures in this Subsection, variable-flow pumping must be designed to fit the particular application. For this reason, it is covered in the Subsections dealing with specific applications. For example, refer to [Measure 2.5.2](#) for variable-flow pumping in chilled water systems.

Before Getting Started ...

These Measures require an understanding of pump performance. If you need a refresher on this topic, see [Reference Note 35](#), Centrifugal Pumps, which also explains pump construction and selection.

INDEX OF MEASURES

10.2.1 Trim pump impellers to match pump output to system pressure and/or flow requirements.

10.2.2 Throttle the discharge of pumps to match system pressure and/or flow requirements.

MEASURE 10.2.1 Trim pump impellers to match pump output to system pressure and/or flow requirements.

If a pump is producing more pressure than the application requires, it is also consuming more energy than necessary. You can eliminate the excess energy consumption in many cases by reducing the diameter of the pump impeller to the minimum needed to satisfy the pressure or flow requirement. This is a standard procedure. It is called “trimming” in the lingo of the pump business.

Trimming is a simple operation that is done on a lathe. The greatest part of the work is removing the impeller from the pump. The most complicated aspect is calculating how much to reduce the impeller diameter.

Trimming the impeller of a centrifugal pump reduces its pressure output, rather than its flow capacity. However, the resistance of the system interacts with the pump pressure to determine the actual system flow. Thus, in many applications, you can use impeller trimming to reduce excess flow as well as excess pressure.

Where to Trim Pump Impellers

In many pump installations, the pressure and/or flow delivered by the pump substantially exceeds the system requirement. This occurs because the designer who selects the pump adds a margin for uncertainties, and sometimes because the pump is not delivered in accordance with the engineer’s specifications.

If a pumping system has a partially closed valve in the discharge pipe that is acting as a “balancing” or throttling valve, this indicates that the pump should probably have its impeller trimmed. Similarly, if the pumping system has a pressure-regulating bypass valve, and the valve is always open, this indicates an opportunity to reduce pump pressure. Even if such clues are not visible, an opportunity for reducing pressure often exists.

You may be able to create opportunities for reducing pump power by modifying the system that the pump serves. An important example is converting bypass control valves on heating and cooling equipment to throttling valves.

In new construction, if you design a constant-flow pump system, write pump trimming into the construction contract as part of the system installation. Also, select pumps that will not lose efficiency badly when the impeller is trimmed.

Graphical Analysis of Impeller Trimming

As an example, we will trace the effects of impeller trimming using the typical pump curves shown in

SUMMARY

Matches pump pressure efficiently to the maximum system pressure requirement. Reduces flow capacity somewhat. Calculating the diameter reduction may be tricky.

Figure 1. (These same curves are used in the example in Measure 10.2.2, allowing you to compare the two methods.) Let’s take this step by step:

- In designing the pumping system, the engineer calculates that the system needs a flow rate of 800 GPM, and that the pump must produce a pressure of 60 feet of head at this flow rate. These pressure and flow rate requirements are marked by point “A.”
- Based on these requirements, the engineer selects a pump that has pump curve “B.”
- When the system is built, the actual system curve turns out to be “C,” so the pump actually operates at point “D.” Although the pump pressure is approximately the same as originally estimated, the flow rate is much higher than the system requires. Pump power is proportional to the third power of flow rate, so a large amount of energy is wasted.
- To eliminate this energy waste, trim the pump impeller so that the pump operates at point “E.” This produces the originally required flow rate of 800 GPM, but the pump is able to operate at a lower pressure.
- The pump curves show that the pumping power has been reduced from about 18 horsepower to about 8 horsepower. Taking into account some efficiency loss in the pump motor, the net energy input is reduced to about half.

The Effect on Pump Efficiency

Trimming the impeller usually reduces the efficiency of a pump somewhat. As long as the diameter reduction is not excessive, the efficiency loss is moderate and the reduction in pump power is substantial. In the previous

example, the pump efficiency was reduced from about 82% to about 77%, but the overall energy consumption was still reduced by half.

How much you can trim a pump impeller may depend on the application or it may depend on the pump. If the application needs only a small reduction of impeller diameter, the pump is not likely to be a limitation. However, if the application allows a large reduction of flow rate, the characteristics of your particular pump may not allow you to reduce the impeller diameter enough to eliminate all the excess pressure.

It depends on the original relationship between the impeller and the pump casing. Manufacturers make only a limited number of casing sizes. They satisfy individual customer requirements by adjusting the impeller diameter. If the impeller is originally at the small end

of the manufacturer's diameter range, reducing the diameter much more would cause a drop in efficiency that cancels part of the saving in power. For this reason, it is a good idea to call the pump manufacturer's engineering department to discuss the potential effect of trimming your pump, and to find out the maximum reduction that is advisable.

You may be wondering whether trimming the impeller of an existing pump makes it less efficient than it would have been if the manufacturer had supplied the optimum diameter. Usually, the answer is no, provided that you do not trim the impeller diameter excessively. The manufacturer trims the pump impeller in the same way that you do to satisfy an order for particular pump characteristics. In some cases, particularly with exceptionally large pumps, the manufacturer may file

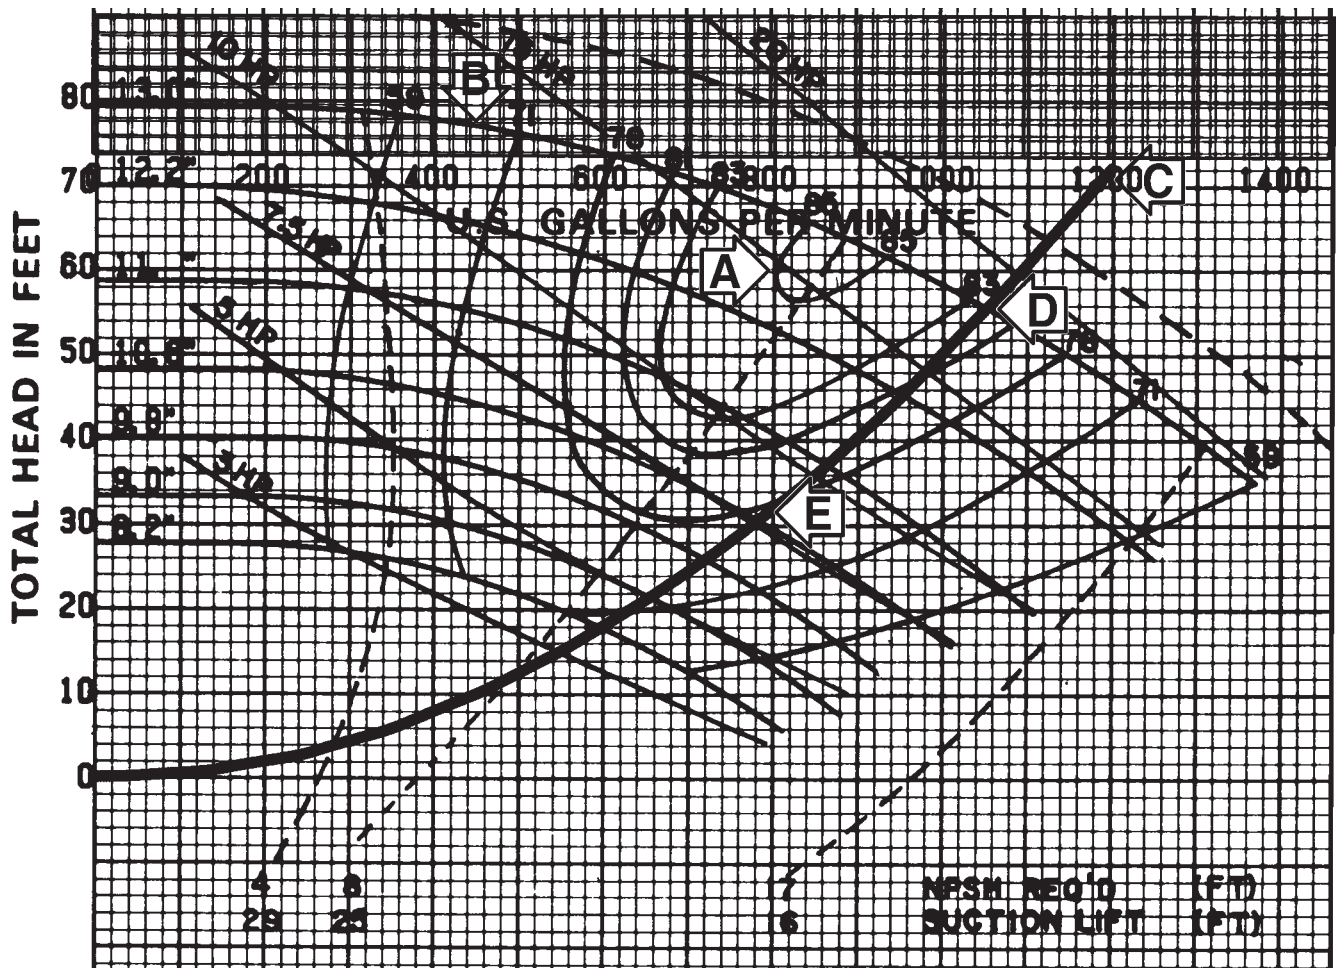

Fig. 1 Analysis of pump impeller trimming Impeller trimming may save a large fraction of pump energy because it efficiently eliminates excess pressure and flow capacity.

down the impeller vanes to adjust the pump's performance characteristics. If this refinement is appropriate, you can get it done yourself.

Pumps with higher "specific speed" suffer greater efficiency loss from impeller trimming. This may be something to consider if you are designing a large pump system that will operate at constant flow. With smaller pumps, you have little or no choice of specific speed. See [Reference Note 35](#), Centrifugal Pumps, for an explanation of specific speed.

How Much Can You Reduce Pressure and Flow?

Do not reduce either pressure or flow to an extent that harms system performance. In most cases, the optimum operating point is not clearly defined. At some point, system performance will begin to suffer. In some systems, reducing pump output will increase energy consumption elsewhere in the system. Study the system to determine what the limits are. In case of doubt, leave a modest amount of excess pressure.

Trimming the impeller reduces both the pressure and the flow rate. In some systems, pump pressure is important primarily as a means of producing flow, so the flow rate is the main issue. In other systems, the pressure itself is important. These are the pressure and flow characteristics of common devices and applications:

- **control valves.** For a control valve to provide stable control of flow into a device, the control valve itself needs to create a certain amount of flow resistance, even when it is wide open. (Without creating resistance of its own, a control valve would have nothing to change to control the flow.) A common rule of thumb is that the control valve, when fully open, should have about the same resistance as the device it is controlling. Therefore, the pump should provide sufficient pressure to overcome the control valve resistance, in addition to the resistance of the controlled device.
- **heat exchangers.** The flow rate through a heat exchanger or coil should be high enough to create turbulent flow, which is necessary for effective heat transfer. As long as the flow remains turbulent, the reduction of heat transfer is less than the reduction of flow rate. This is because a slower flow rate allows more time for heat transfer. Minimizing heat exchanger fouling requires a minimum water flow rate of about 3 feet per second (one meter per second). This velocity is needed even if the water is treated. Increasing the flow rate above this minimum does not increase the cleaning effect very much. A flow rate high enough for good heat transfer usually satisfies the requirement for tube scrubbing, since both rely on turbulence.
- **water-to-air coils.** Heating and cooling coils are heat exchangers, so they involve the same considerations in reducing flow as stated previously. These coils have narrow passages, so flow is always turbulent. Typical water-to-air coils suffer little loss of capacity with a modest reduction of water flow, because of the circuiting of the coil and the longer time that the water spends in the coil.
- **chilled water systems.** Reducing the chilled water flow rate lowers the chilled water temperature, which reduces chiller efficiency and capacity. (See [Measure 2.2.1](#) for details.) If the chilled water system serves variable-air-volume (VAV) air handling systems, higher chilled water temperature causes the air handling unit fans to operate at higher power. In addition to overcoming the resistance of the evaporator and piping, the pump must produce enough pressure for proper operation of the cooling coil control valves.
- **condenser water systems.** Reducing the condenser cooling water flow rate increases the condenser water temperature, which reduces chiller efficiency and capacity. (See [Measure 2.2.2](#) for details.) In addition to overcoming the resistance of the condenser and piping, the pump must produce pressure to lift the water from the level of the cooling tower sump to the level of the cooling water distributor pipe on top.
- **cooling towers.** Open cooling towers may require a minimum flow rate in order to avoid gaps in the water distribution pattern that would allow air to bypass the water. The minimum percentage of flow depends on the cooling tower's design, installation, and maintenance.
- **hot water space heating systems.** The pumps must provide enough pressure for satisfactory operation of the control valves, as well as delivering flow through the coils.
- **boiler feedwater pumping.** Insufficient pressure may cause a boiler to run dry under high load. This causes a sudden shutdown of the boiler by the safety controls. If the safety controls fail, the boiler is likely to explode. Don't mess with feedwater pumps unless you are really sure you know what you are doing.
- **hot and cold service water pressurization.** The pumps must provide adequate pressure for satisfactory operation of fixtures, such as shower heads and toilet flush valves. The pressure falls as water usage increases, because of the shape of the pump curve. Inadequate pressure first becomes apparent when water consumption is high in those parts of the system that need the greatest pressure.

How to Calculate the Diameter Reduction

Calculate the diameter reduction precisely, because the diameter affects the flow, pressure, and energy consumption. Pump power is especially sensitive to impeller diameter, since it is proportional to the third power of the diameter.

For example, in Figure 1, a radius cut of little more than two inches reduces the pressure from 56 feet of head to 32 feet of head, and it reduces the power requirement from 18 HP to less than 8 HP.

Use this procedure to determine the minimum acceptable pump pressure:

- If a particular flow requirement is needed to satisfy an equipment or system requirement, find out what the requirement is. For example, a cooling tower may need a certain minimum flow rate to maintain full efficiency.
- Fully open any “balancing” or throttling valves in the system, and close any bypass valves used for regulating pressure in the system.
- If system flow is variable, create the conditions for maximum flow. For example, in a heating water system, open all the control valves on heating equipment.
- Measure the flow rate. (See below for the methods.)
- Record the pressure differential across the pump, i.e., the difference in pressure between the pump suction and the pump discharge. Correct for static pressure due to differences in the height of the gauges. Call the corrected pressure difference “P1.” (See below for methods of making pressure readings accurately.)
- Use any available valve in the pump discharge to throttle the pump discharge down to the minimum acceptable system pressure or flow rate. If flow rate is the critical factor, rather than pressure, record the difference in pressure between the pump suction and the downstream side of the throttling valve. Correct for static pressure due to differences in the height of the gauges. Call the corrected pressure difference “P2.” If the system is being set to achieve a given pressure, measure the flow rate.

With this information in hand, use one of these methods to determine the new impeller diameter:

- **call the pump manufacturer’s engineering department.** In addition to the before-and-after pressures and the before-and-after flow rates, be prepared to provide all the pump identification information from the pump nameplate. Do not rely on pump information contained in engineering documents, as the actual pump may be different.
- **use the pump curves.** If the pump curves for the present pump model are available, and if they show the pump’s characteristics for different impeller diameters, use the information you collected to read

the new impeller diameter from the curves, as discussed above. Remember that performance with a trimmed impeller may be worse than performance with a new pump having an impeller of the same diameter.

- **calculate from the pressure measurements.** You can use the fact that the pressure developed by a pump is proportional to the square of the impeller diameter. Use this formula:

$$\text{Final Diameter} = \text{Initial Diameter} \times \sqrt{\frac{P2}{P1}}$$

The formula is not precise, because it fails to account for the reduction of pump efficiency that occurs with trimming. To account for this, make the final diameter somewhat greater than indicated by the formula.

- **trial-and-error.** In case of doubt, make an initial cut on the impeller that is conservative. Reinstall the impeller, and observe the changes in pressure and flow rate. Repeat as necessary.

■ How to Measure Flow Rate

To measure flow rate in a closed system, you need a flowmeter. The variety of flowmeter types has mushroomed in recent years. Externally mounted flowmeters are now available that avoid the cost and trouble of tapping into the pipe. See [Reference Note 16](#), Measurement of Liquid, Gas, and Heat Flow, for details.

With open pumping systems, such as cooling towers and service water systems, you can measure flow rate

WESINC

Fig. 2 Now you have a chance to do something useful with these gauges Supply and return pressure gauges in constant-flow systems rarely serve any purpose, except perhaps to tell whether the pumps are running. You can use them to calculate impeller trimming, but you have to do some tricks to get the information you need.

without a flowmeter. To do this, record the length of time it takes the system to fill a container of known volume. For example, you can measure the flow rate of a cooling tower water pump by recording the time required to pump water from one cooling tower sump to an adjacent sump. However, even with an open system, it is more convenient to use an external flowmeter.

■ How to Measure Pressure

You can make the necessary pressure measurements by using the existing pressure gauges that are probably installed in the pump suction and discharge lines. (See Figure 2.) You may have to install at least one new pressure gauge tap on the downstream side of the valve that you use for throttling flow.

Gauge accuracy is important in making these measurements. You can use some tricks to compensate for the fact that the pressure gauges installed in mechanical systems are typically not very accurate. First, set all gauges with the pumps turned off. With the pumps turned off, each gauge should read the static pressure at its location in the system. You can calculate the static pressure from the density of the liquid and the difference in height between the top of the system and the gauge location. (Fresh water, without antifreeze or other additives, exerts a static pressure of 0.43 PSI per foot of height.) The architectural drawings provide these heights. The pressure difference is more important than the absolute pressures. You can figure this by accurately measuring the difference in height between the gauges.

With the pumps running, read the pressure differentials. Then, swap the gauges to average out their errors. I.e., make a set of measurements, swap the gauges in pairs, repeat the measurements, and average the differences of each pair of measurements.

How to Trim the Impeller

Any competent machine shop should be able to trim the impeller using a lathe. Send the impeller to the shop on its shaft assembly, if this is practical, so that the shaft can be used to hold the impeller while it is being turned on the lathe.

Trimming is irreversible. If you reduce the impeller diameter too much, the only solution is to replace the

impeller. This can be expensive, especially if the impeller is integral with the shaft assembly.

Make System Modifications First

Before modifying pumps, accomplish any energy conservation measures that reduce the flow and pressure requirements on the pumps. For example, if there is an opportunity to convert bypass control valves to throttling valves, do this before trimming the impellers.

ECONOMICS

SAVINGS POTENTIAL: Typically 20 to 60 percent of pump power.

COST: The cost to remove, machine, and replace an impeller ranges from about one hundred dollars for a small pump to several thousand dollars for a large pump. In addition, the cost of making flow and pressure measurements may range from several hundred to several thousand dollars.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

CALCULATIONS: Calculating the diameter reduction requires a combination of theory and practical technique that may be unfamiliar. Proceed carefully.

REMOVAL, REPLACEMENT, AND HANDLING: This does not require special skill, but it does require care. Avoid damaging the shaft seals, wearing rings, and bearings. Protect the sealing surfaces on the shaft. Make a wooden cradle to carry the impeller assembly to the machine shop and back.

MACHINE WORK: Impeller trimming is routine lathe work. Even so, try to find a shop that has experience with impeller trimming.

LEAVE A RECORD: Don't forget to record the changes in the equipment records, because the pump no longer has the characteristics stated on the manufacturer's nameplate. Install a durable metal tag on the pump that indicates its new impeller diameter, and the new pressure and flow ratings.

MEASURE 10.2.2 Throttle the discharge of pumps to match system pressure and/or flow requirements.

If a pump delivers more flow than the system needs, you can usually save some energy with little effort by throttling the pump discharge. You can do this with any suitable valve in the pump discharge line, or by placing a restriction in the discharge line.

This may seem contrary to intuition. A clever individual observes that adding resistance to the system dissipates power across the throttling device. This is true. However, this loss is more than compensated by the power saving that results from throttling the pump.

A similar situation exists when a farmer reduces the speed of a tractor by applying the brakes, instead of reducing the throttle. The engine is forced to operate at lower power output, but part of this reduced power is dissipated in the brakes. Of course, it would be more efficient to reduce the throttle setting.

Likewise, it would be more efficient to reduce the pump’s output by reducing the diameter of the impeller or by reducing the impeller speed. Compared to those methods of reducing excess flow, the only advantage of this Measure is its low cost. The major disadvantage of this method is that it offers relatively little energy saving. In a given situation, impeller trimming (Measure 10.2.1) saves much more energy.

Graphical Analysis of Pump Throttling

You don’t need any fancy analysis to do pump throttling, so you can skip this part if you are not interested in the theory. However, this analysis will show you the extent to which throttling saves pump energy. It makes an interesting comparison with impeller trimming. As an example, we will trace the effects of pump throttling on the same pump curves that we used in the example in Measure 10.2.1. Let’s take it step by step:

- In designing the system, the engineer calculates that it needs a flow rate of 800 GPM, and that the pump needs to produce a pressure of 60 feet of head. These pressure and flow rate requirements are marked by point “A.”
- To meet these requirements, the engineer specifies a pump having pump curve “B.”
- When the system is built, it turns out to have system curve “C,” so the pump operates at point “D.” Although the pump pressure is approximately the same as originally estimated, the flow rate is much higher than the system requires. Pump power is proportional to the third power of flow rate, so a large amount of energy is wasted.

SUMMARY

An easy adjustment that provides a modest energy saving. Costs nothing, in most cases. Probably not economical if you have to install a throttling valve or orifice. Impeller trimming is usually a much better alternative.

SELECTION SCORECARD

Savings Potential	\$			
Rate of Return	%	%	%	%
Reliability	✓	✓	✓	
Ease of Initiation	😊	😊	😊	

- To eliminate the excess flow, a valve in the pump discharge line is partially closed to make the system flow rate equal to the original system specification. From the standpoint of the pump, this creates a new system curve “C,” causing the pump to operate at point “E.” The pressure at the pump discharge is now higher than the original specification, but the pressure in the system is lower.
- The pump curves show that the pumping power has been reduced by about one horsepower. The saving is only a small fraction of the original pump power.

This example illustrates the weakness of the throttling method, which is the waste of energy that occurs in forcing water past the throttling device. In comparison, impeller trimming would save more than half the original pump power, as we saw in Measure 10.2.1.

Do You Have a Suitable Throttling Valve?

Throttling does not save much energy, so you cannot afford to spend much money to do it. Whether it is practical depends largely on whether a valve suitable for throttling is already installed.

You need a valve somewhere on the discharge side of the pump, i.e., between the pump and the portions of the system where the liquid is being used. Throttling the suction side of the pump could result in pump cavitation, which is destructive to the pump.

You are likely to find a valve installed in a suitable part of the system, because valves are installed to isolate system components for maintenance. The question is whether the valve is satisfactory for throttling. Two types of valves are commonly used in pump systems, butterfly valves and gate valves. Butterfly valves are usually suitable for throttling, while gate valves are not.

Butterfly valves are chosen for their ease and quickness of shutoff. They require only a quarter turn to go from full open to full closed. This makes them desirable where a component may be turned on or off frequently, e.g., with individual chillers in a multi-chiller installation. You will also find them in other applications, because they are relatively inexpensive. With butterfly valves, you can control flow accurately at a relatively high percentage of maximum flow, because a large valve movement is required to achieve the relatively small reduction of flow that is typically appropriate.

If your luck is bad, your system may have gate valves instead of butterfly valves. Gate valves are used for isolation because they provide tight shutoff.

Unfortunately, gate valves are not recommended for throttling. As the name implies, gate valves have a disk that slides across the fluid stream like a gate. Tight closure requires preserving the close tolerances between the metal sealing surfaces of the disk and the seat. (Elastic seats cannot be used because of the sliding contact between disk and seat.) If the valve is left in a partially open position for extended periods, the turbulence that occurs at the sealing surfaces of the disk causes erosion that allows leakage. For this reason, gate valves should be kept either fully open or fully closed.

If a valve suitable for throttling is not presently installed, you could install a butterfly valve for this purpose. However, you might be able to trim the pump impeller for about the same amount of money, and save much more energy.

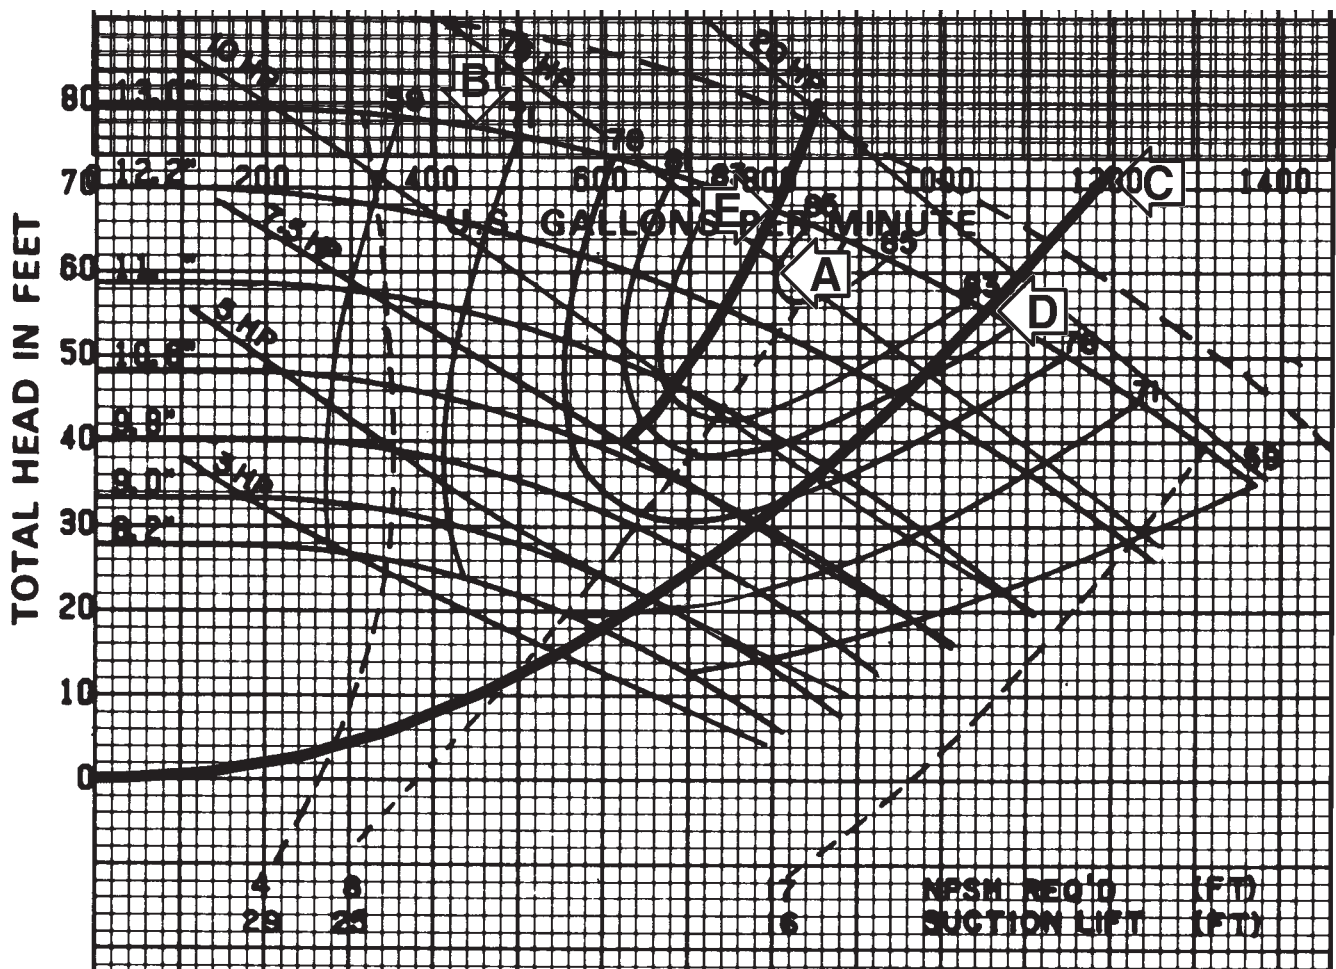

Fig. 1 Analysis of pump throttling This method of reducing excess pump capacity saves a relatively small amount of energy. The problem is that throttling forces the pump to operate at higher pressure, which largely cancels the saving from the reduced flow rate. Compare this analysis to Figure 1 in [Measure 10.2.1](#).

Another possibility is installing a simple orifice in the pump discharge line, instead of a valve. Orifice plates intended to provide a pressure differential for flow metering are available as a commercial item, and might be used for this purpose. This might be economical if there is a flanged joint where you can install the orifice plate. If you take this unusual approach, be sure to tag the flange to indicate that an orifice is installed, and state that its purpose is to optimize pump flow.

How Much Can You Reduce Pressure and Flow?

Refer to this heading in [Measure 10.2.1](#). Reducing system flow excessively degrades system performance, and may waste energy in other parts of the system.

How to Set the Throttling Valve

An advantage of this method over impeller trimming is that you can experiment until you find the optimum setting. The question is, how do you know when the setting is correct? You don't have to do any calculations. Just change the valve setting until you get the desired result.

The simplest case is when you can observe the desired flow rate directly. For example, in a service water system serving showers and toilets, observe how well the fixtures work in the highest part of the building under conditions of maximum water consumption.

If the requirement is based on flow rate, use a flowmeter while you are adjusting the valve. Strap-on, externally mounted flowmeters are available that avoid the cost and trouble of tapping into the pipe. (See [Reference Note 16](#), Measurement of Liquid, Gas, and Heat Flow.)

Another method of measuring flow in open pumping systems, such as cooling towers and service water systems, is to record the length of time it takes the system to fill a container of known volume. For example, record the time required to pump water from one cooling tower sump to an adjacent sump.

If the requirement is for a particular pressure, monitor a pressure gauge installed at the point in the system where the pressure needs to be set. If no gauge is available there, observe a gauge at a nearby location in the same run of pipe, and correct for the difference in height. The other gauge should be close enough so that

pipe friction does not create a significant pressure difference between the two locations.

How to Measure the Energy Saving

You are doing this to reduce the amount of energy going into the pump motor. So, you can determine the energy saving just by measuring the motor power before and after setting the valve. For absolute accuracy, use a wattmeter. If all you have is an ammeter, it will work reasonably well. This technique does not reduce the motor load very much, so the motor power factor will not change enough to cause a big error.

Mark and Lock the Throttling Valve

The position of the throttling valve is critical. Too little throttling wastes energy, and too much throttling may cause poor performance, inefficiency, and/or damage at the end-use equipment. Once you find the optimum throttling valve position, mark it clearly and install a lock on the valve handle.

Explain It!

The purpose of throttling the valve is not obvious. It may look wrong to anyone who does not understand the theory. Therefore, install a permanent placard at the valve that explains the valve position. See [Reference Note 12](#), Placards, for tips on effective placard design.

ECONOMICS

SAVINGS POTENTIAL: Typically, 5 to 25 percent of pump power.

COST: If a valve suitable for throttling is already installed, cost is limited to measuring and adjusting the flow, and to installing a lock and placard. If you have to install a throttling valve, the additional cost ranges from several hundred dollars in a small system to thousands of dollars in a large system.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

MAKE IT LAST: Lock the valves in position. Mark the valve position clearly and install an effective placard. Explain the valve settings in the plant operating manual.

Fans consume a substantial portion of the energy input in most commercial facilities, primarily for HVAC (heating, ventilating, and air conditioning) applications. Fans serve many purposes in industrial facilities, where their importance as energy consumers varies widely. In residential facilities, fans usually do not offer much opportunity for improvement, but consider the possibility.

This Subsection contains a single Measure that recommends eliminating excess output in constant-flow fans. This is a common opportunity for savings. Save effort by applying this Measure to all your constant-flow fan systems as a group.

In many applications, you can save much more fan energy by using the variable-air-volume (VAV) concept. This is usually a complex system feature that has to be customized to the installation. See [Section 4](#) to learn how to apply it in different types of air handling systems.

MEASURE 10.3.1 Adjust the output of constant-flow fans to the minimum needed.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Fans are often installed with hefty margins of excess capacity to account for inaccuracy in calculations and for unforeseen circumstances. This extra capacity wastes energy in a variety of ways, depending on the type of system.

You can reduce this energy waste with a simple adjustment of fan output. It is usually safe to do this on a trial basis. It costs little or nothing, and it is easily reversible.

There may be two steps in trimming fan capacity. One is adjusting the fan output to the minimum that is acceptable, using one or more of the methods suggested below. The other is eliminating any dampers or other inefficient methods that were previously used to limit fan output.

This Measure applies to fans that do not have output modulation devices. Fans with efficient modulation devices, typically found in VAV systems, do not need this action. In HVAC fan systems, this Measure is one of several that apply to the system. Refer to the Subsections covering your types of fan systems for all relevant Measures.

Energy Saving Potential

■ **Fan Energy**

The power required to drive a fan is approximately proportional to the third power of the air volume delivered. Therefore, a relatively small reduction in fan output produces a significant reduction in fan power. For example, reducing the flow rate by 20% reduces the fan power requirement by approximately one half.

There is a significant exception to the third-power relationship of fan power to air flow rate. This is variable-air-volume (VAV) systems that “ride the fan curve.” In these systems, if you reduce the fan output pressure, the terminal units open wider to keep the flow rates essentially the same as before. As a result, the energy saving is approximately proportional to the reduction in fan output pressure.

In air conditioning systems, the potential for reducing fan output is increased somewhat by the fact that a heating or cooling coil transfers more energy to the air when the air velocity through the coil is reduced. For example, a 40% reduction in air flow rate might produce only a 20% reduction in maximum coil output.

Reducing the fan output saves energy even if the fan operates in an on-off mode. This is because the reduction in fan power more than offsets the longer duration of fan operation.

SUMMARY

A simple and inexpensive adjustment that may save a significant amount of fan energy. It may also save substantial amounts of cooling, heating, and/or reheat energy in certain types of air handling systems. Overdoing it causes problems, but the adjustment is easily reversible.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓
Ease of Initiation	😊 😊 😊

■ **Heating and Cooling Energy in 100%-Outside-Air Systems**

In 100%-outside-air systems, the air handling systems must cool and/or dehumidify the air starting from outside conditions. In warm weather, this is more energy intensive than conditioning return air. Fan trimming reduces the excess energy consumption in proportion to the air volume reduction.

(To be precise, trimming the fan output reduces proportionately the amount of energy required to bring outside air to room temperature. It has no effect on the amount of energy required to raise the air from room temperature to supply temperature.)

In cool weather, reducing the amount of outside air may or may not save energy, depending on the weather and cooling load profiles. When the spaces need cooling, it sometimes requires less energy to take in outside air than to cool recirculated air. (This is the principle of the outside air economizer cycle, which is covered by [Measure 4.2.5.](#))

■ **Reheating Operation**

In a system that uses reheat, both reheat energy and the excess cooling energy required to cancel it are proportional to the air flow rate. For example, reducing the fan output by 20% reduces both the reheat energy and the excess cooling energy by 20%. Reheat operation can waste a large fraction of a system’s energy input. Consider any reheat system as a candidate for modification to VAV or some other type. See [Section 4](#) for these improvements.

Other Benefits

Trimming fan output may provide other benefits, including:

- **noise reduction.** The loudness of noise in an air handling system increases rapidly with increasing air velocity. Therefore, a small reduction in fan output substantially reduces the physical noise level. However, human hearing is relatively insensitive to sound level changes, so people may not perceive much reduction in the noise level.
- **improved control in VAV systems that “ride the fan curve.”** In this cheap type of VAV system, the fans themselves have no method of modulation, and air flow into the spaces is controlled only by the dampers in the terminal units. This causes pressure to rise in the system at low flow, which may cause control instability, increased terminal noise, and leakage of cold air into the space. Reducing the maximum fan output eases these conditions, although it is not a proper cure. (See [Subsection 4.4](#) for more effective methods.)

Limitations

The major question is, how much should you reduce the air flow? In most applications, the reduction will not be a large percentage. In HVAC applications, these factors limit the reduction that is possible, or desirable:

- **increased time to warm up or cool down** the space after a period of temperature setback. As you reduce the flow, the increased operating time of the heating and cooling equipment increasingly offsets the saving in fan energy.
- **discomfort during severe load conditions**, if the fan capacity is reduced too aggressively
- **conflict with chiller efficiency.** In cooling systems where the supply air temperature is held constant, reducing the air flow rate requires lower chilled air temperature near full load. (This applies to dual-duct and multizone systems, and to VAV systems that “ride the fan curve.”) Lower chilled air temperature requires lower evaporator temperature, which reduces chiller efficiency. Using chilled air temperature reset reduces this conflict. For details, refer to the Measures for the respective types of air handling systems.
- **other limitations** on reducing air flow are covered in [Measure 4.3.3](#), under “Factors to Consider Before Reducing Air Flow.” The limited flow reduction recommended by this Measure is usually too small to cause any of the problems covered there.

This Measure eliminates only that portion of fan power in excess of the maximum power output needed. It does not reduce fan power to follow the moment-to-moment load, which may be much less than the maximum. To follow the load, the fan must be cycled,

or it must be driven by a variable-output drive. The latter methods are recommended in [Section 4](#), in the Subsections dealing with particular types of air handling systems. You can use this Measure in combination with fan cycling, multi-speed fan motors, and damper control.

How to Adjust Belt-Driven Fans

The most efficient method of reducing the output of a centrifugal fan is to reduce fan speed. Fortunately, most larger centrifugal fans are driven by belts, as shown in Figure 1. You can easily change the fan speed by changing one or both of the sheaves. Sheaves are available in small increments of diameter, so you can adjust the speed by virtually any amount.

The fan may have an adjustable sheave. If its adjustment range is too limited to trim the fan speed as much as possible, simply change the size of the fixed sheave. Use the adjustable sheave for finer adjustment.

If the fan does not have an adjustable sheave, consider installing one. Adjusting fan output involves trial-and-error, and an adjustable sheave simplifies the process.

If the fan also has a vortex damper, inlet damper, or discharge damper, remove it or block it fully open. Reducing fan output by reducing fan speed is much more efficient than any of those methods.

Drive belts have moderate losses, typically in the range of 3% to 10% of the energy transmitted. Drive

Carrier Corporation

Fig. 1 Belt drive Changing the diameter of one or both of the sheaves allows you to reduce fan speed by any amount. This is precise, easy, cheap, and almost foolproof. Don't make either sheave too small. Installing an adjustable sheave makes it easier to find the optimum fan output.

belt losses are affected by sheave diameter in a manner that is somewhat complex. The main point is to avoid sheaves that are too small, which force the belt to make a tight turn. If the fan has a sheave that is too small, you can get rid of it by increasing the diameter of the sheaves at each end of the belt. Excessively large sheaves also waste energy.

How to Adjust Fans with Inlet Vortex Dampers

Vortex “dampers” are aerodynamic devices that alter the performance of the fan itself. The output of a centrifugal fan is proportional to the difference between the speed of air flow at the outer tips of the vanes and the speed of air flow at the inlet end of the vanes. Inlet vortex dampers provide a rotation of the inlet air flow in the direction of fan rotation. This increases the speed of the air entering the vanes, thereby reducing the speed difference between the discharge and inlet ends of the vanes.

(In contrast, conventional inlet and outlet dampers function largely by dissipating fan energy in the form of turbulence, and they force fans to operate at less efficient points on their operating curves.)

Reducing fan output by giving the air a swirl at the fan inlet is an efficient method in principle, but not as efficient as reducing the fan speed. Furthermore, most vortex dampers are aerodynamically crude. If the fan is belt-driven, use the option of slowing the fan speed, and leave the vortex damper wide open.

If the fan is coupled directly to the motor, adjusting the vortex dampers is usually the only practical method of reducing the flow rate. You would not consider any other method unless the vortex damper approaches its closed position, where it becomes inefficient. In that case, it might be worthwhile to insert a belt drive, or even to replace the fan with one that is better matched to the flow requirement.

How to Adjust Variable-Pitch Propeller Fans

Changing the blade pitch of a propeller fan is an efficient method of reducing its output. The method of changing the pitch depends on the design of the fan. Follow the manufacturer’s instructions carefully. A propeller fan with incorrectly adjusted blades may fail with catastrophic consequences.

If a variable-pitch propeller fan is belt-driven, you can reduce the flow rate by changing the propeller’s pitch or its speed. A combination of both may be most efficient. Study the manufacturer’s literature to find out how to set the fan most efficiently.

Propeller fans are especially susceptible to resonant vibrations. These may occur in the propeller itself, or the rotation of the propeller may drive resonant vibrations in the surrounding structure. Resonances can build to large amplitudes, possibly leading to catastrophic failure. Even low-amplitude resonances

can create noise problems. Resonances may be masked by the propeller noise.

Resonance depends on the speed of the fan, rather than the pitch. The speed at which resonances can occur is not predictable. In practice, you find them from observation. Set the fan speed well away from any observed resonance frequency.

Do not use variable sheaves with propeller fans. Variable sheaves allow people to set fan speeds that might inadvertently fall within a resonance band.

What to Do About Wound-Rotor Motors

Wound-rotor motors are described in [Reference Note 36](#), Variable-Speed Motors and Drives. The speed of a wound-rotor motor is usually reduced by inserting resistance into the rotor winding circuits. The current flow through these resistors wastes a considerable amount of energy. Indeed, the presence of an external resistor bank is the most obvious clue that a wound-rotor motor is installed. The resistors may be installed in the chilled air stream, compounding the energy waste. Wound-rotor motors are most likely to be found with direct-drive fans, which lack other means of adjusting speed.

Wherever possible, get rid of a wound-rotor motor and replace it with a more efficient method of speed control. For constant-speed adjustment, consider installing a conventional high-efficiency motor with a belt drive. See [Measure 10.1.1](#) about selecting conventional motors. In applications where energy can be saved by modulating the fan output, as in typical air handling systems, consider a variable-speed drive. These are expensive modifications.

Should You Install a Smaller Motor?

If you can reduce fan output substantially, it may appear desirable to substitute a smaller motor. In reality, this is rarely economical. Although motors lose efficiency at lower loads, smaller motors are less efficient than large motors. The two effects offset each other.

Installing a smaller motor may be economical in cases where the existing motor is very oversized or exceptionally inefficient. In the latter case, a large part of the saving will come from greater efficiency in the replacement motor. See [Measure 10.1.1](#) about selecting motors for efficiency.

Eliminate Inefficient Fan Throttling

As part of the fan output adjustment, eliminate any inefficient methods of fan throttling that may have been installed originally, including these:

- **discharge dampers**, which are inefficient because they require the fan to operate at a higher pressure for a given air flow. The existence of discharge dampers may not be obvious. They may be installed

in the discharge duct at some distance from the air handling unit.

- **scroll housing dampers**, which are devices that modify the discharge portion of a centrifugal fan housing. The idea is to reduce fan output by changing the fan characteristics, rather than by the brute resistance of discharge dampers. (The casing of a straight-line discharge centrifugal fan is called a scroll housing because of its shape.) Scroll dampers are somewhat more efficient than discharge dampers, but not much more.
- **inlet (not vortex) dampers**, which simply choke off the air flow at the inlet to the fan. This method is rarely used, because it may cause fan surge.

Try to physically remove these types of dampers, if the application permits. If this would require too much effort, lock the damper open by a secure method. As long as the damper remains, the possibility exists that it will work its way into a partially closed position without anyone being aware of the fact.

Before making this change, find out why the dampers were installed in the first place. In crude VAV systems, discharge dampers may be used to adjust the input pressure to the terminal units. Reducing the fan output by one of the efficient methods described previously limits pressure just as well as a damper.

Discharge dampers are sometimes installed to limit the pressure in the duct system, to keep from blowing out ductwork. If the fan discharge pressure is limited

for reasons of safety, it is prudent to install a means of limiting pressure that is independent of the fan output adjustment. For example, install a spring-loaded pressure relief door in the duct, along with an alarm that indicates when the door blows open.

Don't Overlook Any Fans

Trim the capacity of all the fans in the air handling system as appropriate. Do not overlook return fans, remote relief fans, toilet and kitchen hood exhaust fans, etc.

ECONOMICS

SAVINGS POTENTIAL: 30 to 80 percent of fan energy. In reheat systems, 10 to 30 percent of both cooling and reheat energy. In 100%-outside-air systems, 10 to 40 percent of conditioning energy.

COST: Minimal, if only adjustments of existing equipment are required. Adjustable sheaves cost from \$20 to \$200 in common sizes.

PAYBACK PERIOD: Less than one year, in most cases.

TRAPS & TRICKS

EXPLAIN IT: Explain the energy conservation purpose of the fan settings in the plant operating manual.

MONITOR PERFORMANCE: Check the performance of the fan systems at times of peak loads. Schedule this in your maintenance calendar, perhaps annually,

Subsection 10.4

Standby Equipment

This Subsection contains a single Measure that recommends simple methods of avoiding unnecessary operation of standby equipment. To save effort, apply this Measure to all your standby equipment as a group.

MEASURE 10.4.1 Install power switching that prevents unnecessary operation of standby equipment.

RATINGS

New Facilities	Retrofit	O&M
A	B	

In many systems, standby components are installed for the sake of reliability. This practice can waste energy if it allows duplicate units to be operated unnecessarily. For example, this often occurs with spare pumps because operators are not sure of how many pumps to operate.

There is a simple and reliable way to prevent this problem: connect power to the equipment so that only the proper number of units can receive power simultaneously. Where only two units of equipment are installed, a transfer switch is the simplest way of achieving this. Where more than two units are installed, a rotary switch is the simplest approach.

The only caution is to be sure that no conditions may arise that require the standby unit to operate along with the other units.

Method for Two Units: Transfer Switch

Where equipment is installed in pairs, you prevent operation of both units by providing power to the pair through a transfer switch. A transfer switch routes power to one unit or the other, but not to both.

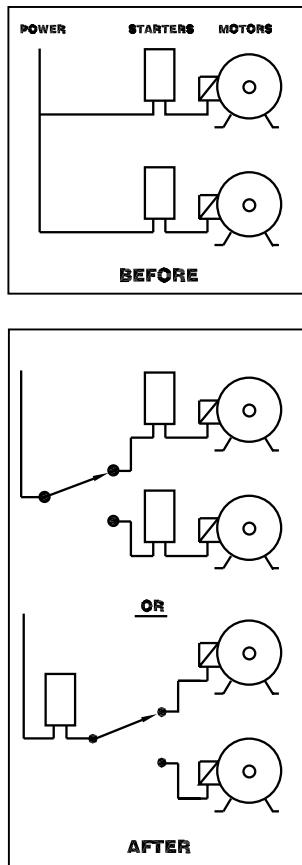

Fig. 1 How to install a transfer switch

SUMMARY

Simple, foolproof methods of preventing unnecessary operation of standby equipment.

SELECTION SCORECARD

Savings Potential	\$	\$	\$
Rate of Return, New Facilities	%	%	%
Rate of Return, Retrofit	%	%	%
Reliability	✓	✓	✓
Ease of Retrofit	☺	☺	☺

Figure 1 shows how a transfer switch is wired. Typically, an ordinary double-throw knife switch suffices for this purpose. The switch is inexpensive, and installation is routine.

In new construction, this method can save the cost of one starter and/or one set of circuit protection equipment. Only one motor can operate at a time, so you need only one set of this equipment.

Method for More Than Two Units: Rotary Switch

If more than two identical units are installed, and one is intended to be a spare, you can use a rotary switch to deny power to any one of the units. The rotary switch feeds power to all the units except one, the unpowered unit being selected by the position of the switch. Figure 2 shows how to install the rotary switch.

You can use a rotary switch even in applications where the controlled units are not operating in parallel. For example, a chiller plant has two chillers and three chilled water pumps. One of the pumps is connected to the first chiller, while another pump is connected to the second chiller. An identical third pump is connected between the first two pumps for use as a spare. The rotary switch keeps this pump from running. If one of the first two pumps fails, valve positions are changed to allow the third pump to substitute for it. Then, the rotary switch is simply turned to remove power from the defective pump.

If you cannot find an appropriate rotary switch in stock, you can order a custom switch at modest cost from a number of manufacturers. If the equipment requires too much current for an available rotary switch to handle directly, use a rotary switch to control each unit through a relay.

■ Rotary Switch Limitations

The rotary switch removes only one unit from operation. It cannot prevent waste of energy from unnecessary operation of the remaining units. For example, consider a chiller system having four chilled water pumps, one of which is a spare. The rotary switch ensures that only three of the pumps are operated. However, the system may need only one or two pumps when the cooling load is low. In this situation, you need different methods to avoid wasting pump power. Refer to the Measures dealing with the specific type of system.

Fig. 2 How to install a rotary switch

Do not install a rotary switch in addition to automatic controls that control the running of equipment. For example, a battery of pumps may be installed to provide service water pressure, and the number operating may be controlled automatically in response to the water demand. In such cases, a rotary switch would complicate the control installation without doing much to reduce the possibility of energy waste.

Automatic Switching

These switching functions do not have to be manual. They can be performed automatically if you install appropriate control devices. Automatic switching is desirable in high-reliability and unmanned installations. For switching power between two units, you can use a simple solenoid-actuated transfer switch. For switching power between more than two units, you need a more complex set of relays. Or, you can program an energy management computer for this purpose.

ECONOMICS

SAVINGS POTENTIAL: All the cost of operating standby equipment unnecessarily, including excess energy and maintenance.

COST: The switches are relatively inexpensive, costing a few dollars to several hundred dollars, depending mainly on their current capacity. In designing new facilities, this modification costs little or nothing. In retrofit, the installation cost may range from several hundred to several thousand dollars, depending on the amount of rewiring needed.

PAYBACK PERIOD: Less than one year, to many years, depending on the power consumption of the equipment and the likelihood that someone will operate the units unnecessarily.

TRAPS & TRICKS

EXPLAIN IT: Install a placard on the power switch to tell the staff how to use it. Do this for both manual and automatic switches. See [Reference Note 12, Placards](#), for tips on installing effective placards.

Section 11. REFERENCE NOTES

INTRODUCTION

The Reference Notes are self-contained explanations of specific topics. You will use them in different ways, depending on how you are using the Energy Efficiency Manual.

The Reference Notes Enhance the Measures

The Reference Notes support the Measures, which are in the first ten Sections of this Manual. As you accomplish an energy conservation program, each Measure that you select refers you to relevant Reference Notes. These give you additional in-depth information about equipment, principles of operation, installation and operating practices, calculation tools, and energy sources. Most of the Reference Notes support a number of Measures. Keeping this information separate from the Measures avoids repetition and keeps each Measure focussed on its particular applications.

A word of caution. Do not use the Reference Notes as a starting point for your energy conservation actions. Your starting point should always be the individual Measure. The Measure provides the details that are important for specific applications, along with ratings, economic analysis, and practical guidance.

Use the Reference Notes for Study

If you are using the Energy Efficiency Manual as a textbook, the Reference Notes are the place to start. As you can see from the index to the Reference Notes on the right side of this page, they are arranged in Groups. For formal study, start with any Group that is appropriate for your study plans, and read all the Notes in that Group.

As you study the Reference Notes, refer to related Measures as examples of practical applications. Find facilities, construction sites, and equipment where you can see the principles in action. Take this book with you. As its pages get dirty and full of highlighting pen, your knowledge will be growing.

This approach applies to anyone who is serious about learning energy efficiency. Use it if you are enrolled as a student, or if you are a conscientious architect or engineer seeking to improve the efficiency of your

Read the Reference Notes for General Interest

The Reference Notes are written to be clear to anyone who has a general interest in energy efficiency. If you want to browse, you can read them in any order that you find interesting. The shorter Reference Notes give you concise, simple explanations of individual efficiency concepts that you cannot find in literature that is written for specialists. The longer Reference Notes will provide you with information that is clearer, more complete, and better balanced than you will be able to find elsewhere at a practical level.

Installation Issues

The most powerful technique of energy conservation is turning off equipment when it is not needed. Timeclock controls are a primary tool for this function, because most equipment is needed on the basis of specific time schedules. This Note gives you the main points to consider when selecting and installing clock controls.

Achieving effective and long-lasting clock control involves three main steps: (1) select clock controls that have sufficient flexibility to adapt to all the predictable variations in schedule, (2) provide very clear instructions for setting and adjusting them, and (3) install overrides that allow users to easily bypass the timeclock when equipment is needed during unscheduled periods.

A programmable thermostat is a combination of a timeclock and a thermostat. It provides ease and flexibility in tailoring thermostatic control to requirements. However, you have to be as careful in selecting one as in selecting a timeclock, plus you have to select the best thermostatic features.

Upgrade to Electronic Time Controls

Until recently, lack of flexibility was a serious limitation of clock controls. For most of the modern era, time switches were mechanical devices driven by little electric motors. Figure 1 shows an example. Consider these units obsolete for most applications, even though many are still sold. These clocks are inherently limited in their ability to adapt to different schedules of operation. They lose time with every power outage. They are clumsy to set. Most cannot be set accurately. The method of override, if any, is usually obscure.

Electronic timeclocks can avoid all these shortcomings. Electronic time controls are now available that have most of the features that anyone could desire. Figure 2 shows a typical selection of models. Very capable units are available at modest cost. Even in existing facilities, it may be economical to replace old electro-mechanical timeclocks where they are presently installed.

The more sophisticated time controls approach the capabilities of the lower end of the range for energy management control systems, which are covered by [Reference Note 13](#). In fact, the boundary between the two classes of controls is not distinct. If you have a complex control application, read [Reference Note 13](#) along with this Note.

The wide variety of features available in electronic time controls makes it important to invest some study before selecting time controls for your applications. The following are the important selection considerations.

Scheduling Options

■ Number of Circuits

Some electronic timeclocks have a number of separate circuits, each of which can be controlled on a different schedule. This allows a single timeclock to

Fig. 1 Classic electro-mechanical timeclock This type is now obsolete for most applications. It is too inflexible, and it loses time with each power interruption. However, it was simple to understand and set. This unit has good instructions.

act as several separate timeclocks. In most applications, this feature does not provide a major advantage over using separate timeclocks, and it has some disadvantages.

Using separate single-circuit timeclocks for different equipment is intuitively easier for the operating staff, it makes programming the timeclock less confusing, and it simplifies troubleshooting. Furthermore, failure of a multi-circuit timeclock can disable more equipment than failure of a single-circuit unit.

Several individual timeclocks may be cheaper than a multi-circuit timeclock. Furthermore, the ability to install each single-circuit timeclock closer to the equipment it controls may save wiring cost.

As a rule, multi-circuit timeclocks offer more features than single-circuit units, simply because they are in a higher price class. You may have to buy a multi-circuit unit to get all the features you want.

■ Variety of Schedules

Electronic timeclocks generally allow “on” and “off” switching to be scheduled to the nearest minute. Models differ in the number of on and off actions that can be programmed per day, or per week. Most units provide an ample number of on/cycles per day. The cheapest timers provide only one daily sequence of on/off actions, while more sophisticated units provide a number of sequences for different day types.

Paragon Electric Company

Fig. 2 A selection of electronic timeclocks Almost any time control features you could want are available in inexpensive models. Be sure that the control you select is the best for your application.

Models differ in the way that they account for different schedules on different days. Some allow separate schedules for a few different day types, such as “weekday”, “weekend”, and “holiday.” Others allow an entire week to be scheduled, with separate settings available for each day of the week, plus a separate “holiday” schedule. All but the simplest models have sufficient flexibility for conventional applications, for example, heating and air conditioning a rental office building. Pay attention to the details of the scheduling features, especially if your schedules are more complex.

■ Daylight Saving Time and Leap Year Reset

An increasingly common feature is automatic resetting of the time when daylight saving time begins and ends. Be sure to get this.

Another feature is automatically adding February 29th on leap years. Get this feature if you plan to operate equipment on more than one daily schedule, e.g., weekday and weekend.

■ Cycling

Some timers simply repeat the same on/off switching sequence endlessly. The user can select the on and off times, and usually the duration of the cycle. For specialized cycling applications, such as control of poultry house ventilation, it is best to install a small timer that is specialized for the type of cycling required. Cycling is also included as a feature of some of the more complex models of timeclocks.

The most common energy management application for cycling is minimizing electricity demand charges (see [Reference Note 21](#), Electricity Pricing). In this application, a timeclock is used to provide power to different equipment on alternating time cycles, so that all the equipment cannot operate simultaneously. For example, a timeclock can be used to provide power alternately to two groups of air conditioners.

A single-circuit timer can be used to alternate power between two groups of equipment if it has “double-throw” output. A multi-circuit timer is needed for cycling between equipment in a non-alternating manner, or for cycling more than two groups of equipment.

■ Astronomical Settings

“Astronomical” timeclocks automatically calculate the time of sunset and sunrise each day for switching purposes. Astronomical switching is commonly used to control lighting fixtures that are installed outdoors or under skylights. It could also be used for other functions related to the position of the sun, such as air conditioning in dry climates.

Astronomical switching is provided in some specialized single-circuit timers. It is also included as a capability in some of the more expensive general-purpose models. You need to input your latitude when installing an astronomical clock.

Check for the ability to combine astronomical switching with switching at fixed times. For example, it may be desirable to turn on parking lot lights at sunset, and to turn them off at midnight.

Photoelectric switches are an alternative to astronomical time switches. Photocontrols are cheaper, and they respond to unexpected periods of darkness, such as eclipses and heavy overcasts. But, you have to install them where they can “see” daylight. You can install an astronomical timeclock anywhere. Also, the astronomical timeclock can perform both functions, turning the lights off at sunset and turning them back on at any time.

■ Advance Warning

A timeclock with an advance-warning feature has a separate circuit that is switched on at a fixed interval ahead of another circuit. Typically, the first circuit is used to activate an alarm before the second circuit takes some action, such as starting a large piece of equipment.

■ Optimum Start
